Medical Complications Associated With Hyperadrenocorticism in Dogs

Systemic hypertension
Pyelonephritis
Cystic calculi (calcium phosphate, oxalate)
Glomerulonephropathy, proteinuria
Congestive heart failure
Pancreatitis
Insulin resistant diabetes mellitus
Steroid hepatopathy
Pulmonary thromboembolism
Persistent anestrus
Pituitary macrotumor syndrome
Degenerative myopathy
Pseudomyotonia

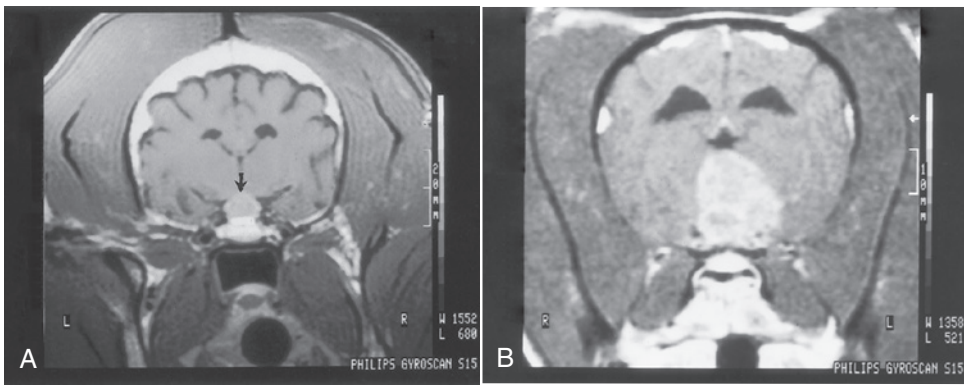

FIG 50.4
(A) Postgadolinium administration magnetic resonance imaging (MRI) scan of a 9-year-old male castrated German Shepherd dog with pituitary-dependent hyperadrenocorticism (PDH) and a pituitary mass *(arrow)*. No neurologic signs were present at the time the MRI scan was performed. **(B)** Postgadolinium administration MRI scan of an 8-year-old Boston Terrier with PDH, a large pituitary mass invading the brainstem, and signs of disorientation, ataxia, and circling. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

hypercoagulability, which is a common finding at the time hyperadrenocorticism is diagnosed, may persist despite treatment of PDH with trilostane, and may result in spontaneous thromboembolism, typically involving pulmonary vessels and causing acute respiratory distress. Pulmonary thromboembolism (PTE) occurs most often in dogs undergoing adrenalectomy for ADH. Thromboemboli may also affect the kidney, gastrointestinal tract, heart, and CNS. There is no apparent correlation between control of hyperadrenocorticism and development of thromboemboli. Factors predisposing to the development of PTE in dogs with hyperadrenocorticism include inhibition of fibrinolysis, systemic hypertension, protein-losing glomerulonephropathy, decreased serum antithrombin III concentrations, increased concentrations of several coagulation factors, and an increased hematocrit value.

Thoracic radiographs may reveal no abnormalities, or they may show hypoperfusion, alveolar pulmonary infiltrates, or a pleural effusion. Increased diameter and blunting of the pulmonary arteries may be noted, along with absence of perfusion of the obstructed pulmonary vasculature and overperfusion of the unobstructed pulmonary vasculature. Normal thoracic radiographic findings in a dyspneic dog that does not have a large airway obstruction suggest a diagnosis of PTE. Arterial blood gas analysis typically reveals a decrease in the partial pressures of arterial oxygen and carbon dioxide, as well as mild metabolic acidosis. Thrombosis may be confirmed by angiography of the lungs or by radionuclear lung scanning. Therapy consists of general supportive care, oxygen, anticoagulants, and time (see Chapter 12). The prognosis for dogs with PTE is guarded to grave. If dogs do recover, it typically takes 5 to 7 days before they can be safely removed from oxygen support.

Initial Diagnostic Evaluation

A thorough evaluation should be done in any dog suspected of having hyperadrenocorticism and should include a complete blood count (CBC); a serum biochemistry panel; urinalysis with bacterial culture; and, if available, abdominal ultrasonography and systemic blood pressure readings. Results of these tests will increase or decrease the index of suspicion for hyperadrenocorticism; will reveal common concurrent problems (e.g., urinary tract infection, systemic hypertension); and, in the case of ultrasonography, will provide valuable information for localizing the cause of the disorder (i.e., PDH versus ADH). Endocrine studies required to confirm the diagnosis and localize the cause of the disorder can then be performed.

CLINICAL PATHOLOGY

Common clinicopathologic alterations caused by hyperadrenocorticism are listed in Box 50.2. Laboratory test results must be interpreted within the context of the history and physical examination findings. None of the findings listed in Box 50.2 is diagnostic for hyperadrenocorticism; all can be seen with many other diseases. An absence of common abnormalities noted in Box 50.2 should strongly decrease the suspicion of hyperadrenocorticism. Increases in serum alkaline phosphatase (ALP) activity and cholesterol concentration are the most common abnormalities identified on the serum biochemistry panel. The major contributor to increased serum ALP is the corticosteroid-induced isoenzyme of ALP derived from the bile canalicular membrane of hepatocytes. Approximately 85% of dogs with hyperadrenocorticism have increased serum ALP activities, and values in excess of 1000 IU/L are common. No correlation has been noted between the magnitude of increase in serum ALP activity and the severity of hyperadrenocorticism, response to therapy, or prognosis, and no correlation has been observed between the magnitude of increase in serum ALP activity and hepatocellular death or hepatic failure. ALP activity can be normal in some dogs with hyperadrenocorticism, and an increase in ALP activity by itself is not diagnostic for hyperadrenocorticism. Similarly, an increase in activity of the corticosteroid-induced isoenzyme of alkaline phosphatase (SIAP) is not a finding specific to hyperadrenocorticism or exogenous glucocorticoid administration; an increase in SIAP activity occurs commonly with many disorders, including diabetes mellitus, primary hepatopathies, pancreatitis, congestive heart failure, and neoplasia, as well as in dogs receiving certain drugs (e.g., anticonvulsants). However, a finding of no SIAP in the serum may be of diagnostic value in ruling out hyperadrenocorticism.

Urine specific gravity typically is less than 1.020 and often is less than 1.006 in dogs with hyperadrenocorticism that have free access to water. Water-deprived hyperadrenal dogs maintain the ability to concentrate urine, although usually their concentrating ability remains less than normal. As

BOX 50.2

Clinicopathologic Abnormalities Commonly Identified in Dogs With Hyperadrenocorticism

Complete Blood Count

Neutrophilic leukocytosis
Lymphopenia
Eosinopenia
Thrombocytosis
Mild erythrocytosis

Serum Biochemistry Panel

Increased alkaline phosphatase activity
Increased alanine aminotransferase activity
Hypercholesterolemia
Hypertriglyceridemia
Lipemia
Hyperglycemia

Urinalysis

Urine specific gravity < 1.020
Indicators of urinary tract infection
Proteinuria
Mild increase in preprandial and postprandial bile acids

such, urine specific gravities of 1.020 to 1.025 may be identified if urine is obtained after water has been withheld from the dog.

Proteinuria is a common finding in dogs with untreated hyperadrenocorticism. Proteinuria may be caused by glucocorticoid-induced systemic and glomerular hypertension, glomerulonephritis, or glomerulosclerosis. Urine protein/creatinine ratios are usually less than 4, although values in excess of 8 have been identified. Proteinuria decreases and often resolves in response to treatment of hyperadrenocorticism.

Urinary tract infection is a common sequela of hyperadrenocorticism. Hyposthenuria and the antiinflammatory effects of glucocorticoids commonly interfere with the identification of bacteria or inflammatory cells in the urine. Whenever hyperadrenocorticism is suspected, antepubic cystocentesis with bacterial culture of the urine and antibiotic sensitivity testing is strongly recommended, regardless of urinalysis findings.

DIAGNOSTIC IMAGING

Abnormalities identified by thoracic and abdominal radiography and by abdominal ultrasonography are listed in Box 50.3. The most consistent radiographic findings in dogs with hyperadrenocorticism are enhanced abdominal contrast secondary to increased fat distribution in the abdomen; hepatomegaly caused by steroid hepatopathy; an enlarged urinary bladder secondary to the polyuric state; and calcification of soft tissues, most notably the trachea, the bronchi, and occasionally the skin and abdominal blood vessels. The most important but least common radiographic finding is a soft tissue mass or calcification in the area of an adrenal gland (Fig. 50.5); a finding suggestive of an adrenal tumor. The frequency of calcification is equally distributed between adenoma and carcinoma. Metastasis of an adrenocortical carcinoma to the pulmonary parenchyma is occasionally evident on thoracic radiographs.

Abdominal ultrasonography is used to evaluate the size and shape of the adrenals and to search for additional abnormalities in the abdomen (e.g., cystic calculi, vascular invasion, tumor thrombus; Fig. 50.6). Adrenal gland width is the most informative parameter. In healthy dogs, the maximum width of the adrenal gland ranges from approximately 0.4 to 0.75 cm. The finding of bilaterally symmetric normal-size or large adrenals (defined as having a maximum width > 0.8 cm) in a dog with hyperadrenocorticism serves as evidence of adrenal hyperplasia caused by PDH. A study by Choi et al. (2011) found that smaller dogs (<10 kg body weight) had smaller adrenal glands and recommended a cut-off of 0.6 cm as the criterion for differentiating a normal adrenal gland from adrenal hyperplasia. A subsequent study by Bento et al. (2016) involving a large population of dogs with nonadrenal gland illness concluded that, regardless of age, dogs that weighed 12 kg or less should have a maximum adrenal gland width no greater than 0.62 cm, whereas dogs that weighed greater than 12 kg should have an adrenal gland width no greater than 0.72 cm. The adrenal glands in dogs with PDH are similar but not exactly the same in size and shape; should have smooth, not irregular borders; can exceed 2 cm in maximum width; may have a bulbous cranial or caudal pole; and do not invade surrounding blood vessels or organs (see Fig. 50.6). An adrenal tumor is typically identified as an adrenal mass (Fig. 50.7). Size is variable, ranging from 1.0 to greater than 8 cm in maximum width. Small adrenal masses (i.e., <2 cm in maximum width) often maintain a smooth contour and may distort only a portion of the adrenal gland; one or both poles of the adrenal gland may still appear normal. With large adrenal masses (typically > 4 cm in maximum width), the adrenal gland usually becomes distorted and unrecognizable, the contour of the gland becomes irregular, and compression and/or invasion into adjacent blood vessels and organs, most notably the kidney, may occur (Fig. 50.8). These changes suggest adrenocortical carcinoma. Identification of calcification within

BOX 50.3

Abnormalities Identified by Abdominal and Thoracic Radiography and Abdominal Ultrasonography in Dogs With Hyperadrenocorticism

Abdominal Radiographs

Excellent abdominal detail
Hepatomegaly*
Distention of urinary bladder*
Cystic calculi
Adrenal mass
Calcified adrenal gland
Dystrophic calcification of soft tissues, calcinosis cutis
Osteoporosis of vertebrae

Thoracic Radiographs

Calcification of trachea and bronchi*
Osteoporosis of vertebrae
Pulmonary metastases from adrenocortical carcinoma
Pulmonary thromboembolism
- Hypovascular lung fields
- Alveolar infiltrates
- Enlarged right pulmonary artery
- Right-sided cardiomegaly
- Pleural effusion

Abdominal Ultrasonography

Bilateral adrenomegaly (PDH)*
Adrenal mass (ATH)*
Tumor thrombus (ATH)
Hepatomegaly*
Hyperechogenic liver*
Distention of urinary bladder*
Cystic calculi
Calcification of adrenal gland (ATH)
Dystrophic calcification of soft tissues

*Common findings.
ATH, Adrenocortical tumor causing hyperadrenocorticism; *PDH,* pituitary-dependent hyperadrenocorticism.

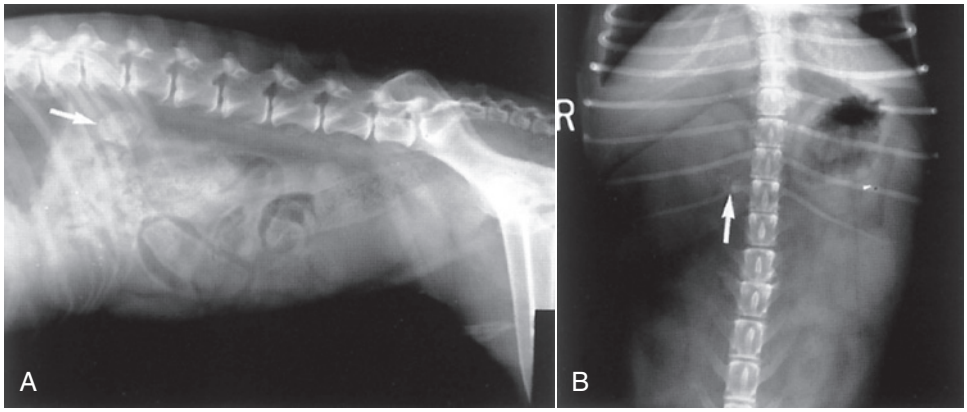

FIG 50.5
(A) Lateral radiograph from a dog with adrenal-dependent hyperadrenocorticism showing a calcified adrenal mass cranial to the kidney *(arrow)*. **(B)** Ventrodorsal radiograph from a dog with adrenal-dependent hyperadrenocorticism showing a calcified adrenal mass craniomedial to the kidney and lateral to the spine *(arrow)*. Compression of the abdomen in the region of the adrenal gland with a paddle has enhanced radiographic contrast, allowing better visualization of the adrenal mass.

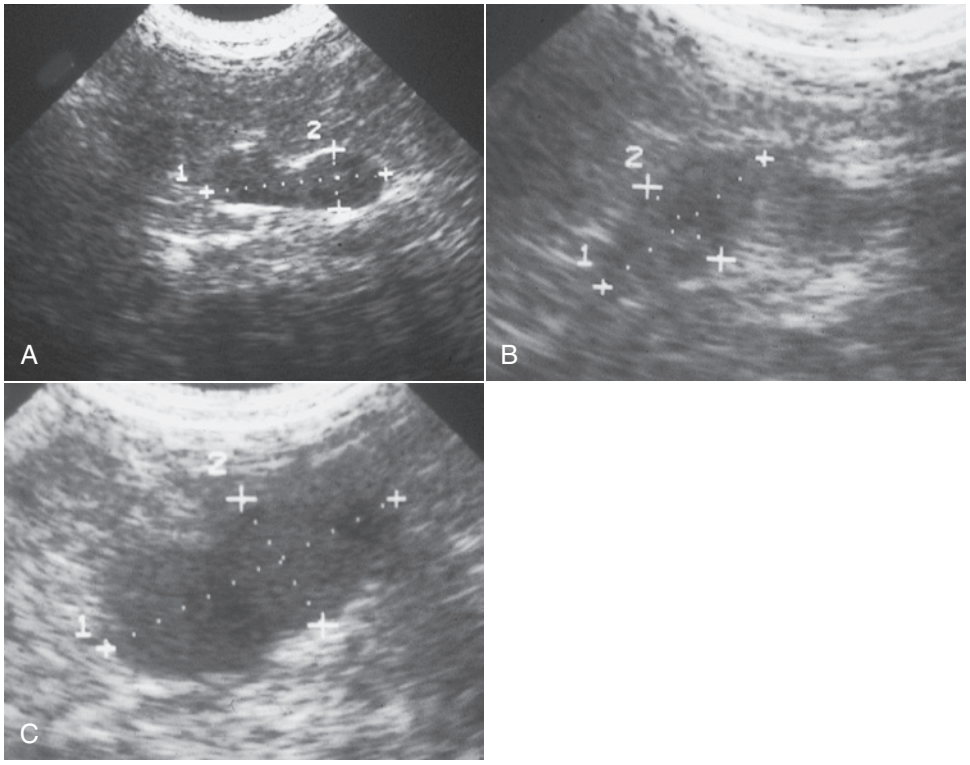

FIG 50.6
Ultrasound images of the adrenal gland in three dogs with pituitary-dependent hyperadrenocorticism (PDH), illustrating the differences in size and shape of the adrenal gland that can occur with PDH. **(A)** The adrenal gland in this dog has maintained the typical kidney-bean shape often identified in normal dogs. However, the maximum diameter of the gland was enlarged at 0.85 cm. The contralateral adrenal gland was similar in size and shape. **(B)** The adrenal gland in this dog is uniformly thickened and appears plump rather than kidney-bean shaped. The maximum diameter of the gland was 1.2 cm. The contralateral adrenal gland was similar in size and shape. **(C)** Although the adrenal gland has maintained some semblance of a kidney-bean shape in this dog, the gland has undergone marked enlargement, with a maximum diameter of 2.4 cm. The contralateral adrenal gland was similar in size and shape.

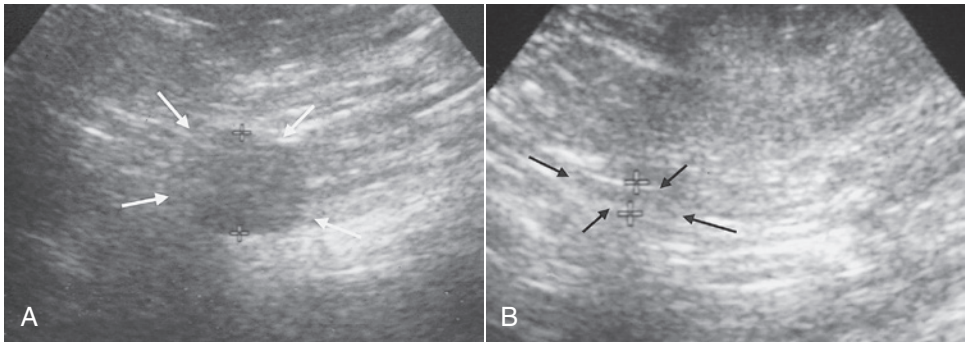

FIG 50.7
Ultrasound images of the adrenal glands in an 11-year-old male castrated Golden Retriever with adrenal-dependent hyperadrenocorticism. **(A)** Cortisol-secreting tumor affecting the right adrenal gland *(arrows)*. The maximum diameter of the adrenal mass was 1.6 cm. **(B)** The left adrenal gland has undergone marked atrophy *(arrows* and *crosses)* as a result of suppression of pituitary adrenocorticotropic hormone secretion after negative feedback inhibition caused by the adrenocortical tumor. The maximum diameter of the left adrenal gland was less than 0.2 cm.

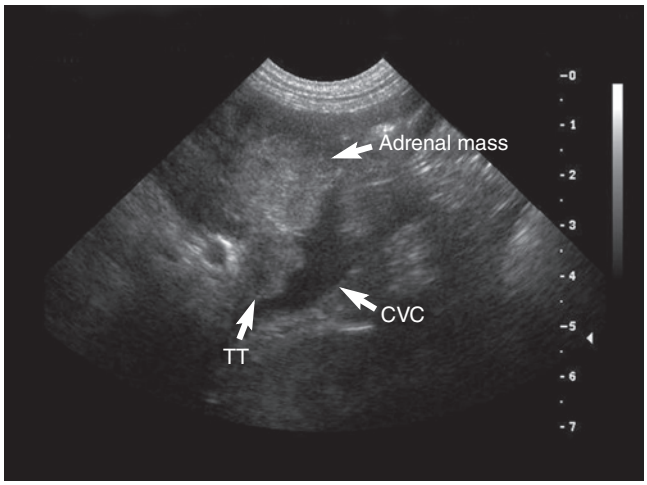

FIG 50.8
Ultrasound image of a mass affecting the left adrenal gland (adrenal mass) and extending into the lumen of the caudal vena cava *(CVC),* creating a tumor thrombus *(TT)* in a 9-year-old male Standard Poodle. The maximum width of the adrenal mass was 3.8 cm. The histopathologic diagnosis was pheochromocytoma.

the mass does not differentiate adenoma from carcinoma. Generally, the larger the mass, the more likely it is carcinoma. Asymmetry in the size of the adrenal glands is evident (see Fig. 50.2). Ideally, the contralateral unaffected adrenal should be small or undetectable (maximum width typically < 0.4-0.5 cm) as a result of ADH-induced adrenocortical atrophy (see Fig. 50.7), although a normal-size contralateral adrenal gland does not rule out ADH. Identification of an adrenal mass and a normal to large contralateral adrenal gland in a dog with clinical signs supportive of hyperadrenocorticism suggests the possibility of PDH with a concurrent adrenal mass that may be a pheochromocytoma, a functional adrenocortical tumor, or a nonfunctional adrenal tumor (Fig. 50.9). The finding of normal-size adrenal glands in a dog with confirmed hyperadrenocorticism is most consistent with a diagnosis of PDH. The finding of bilateral adrenomegaly with the appearance of multiple nodules of varying size is suggestive of macronodular hyperplasia (Fig. 50.10). Bilateral adrenal macronodular hyperplasia is believed to represent an anatomic variant of PDH. Failure to identify either adrenal is considered an inconclusive finding, and ultrasonography should be repeated at a later time.

CT and MRI can be used to evaluate the pituitary gland for a macroadenoma, to assess the size and symmetry of the adrenal glands, and to detect the presence of an adrenal tumor thrombus in the adjacent vasculature. Contrast enhancement using an iodinated contrast agent (CT) or gadolinium (MRI) given by continuous intravenous (IV) infusion during the imaging procedure aids in identification of a pituitary macroadenoma and the adrenal glands during CT and MRI examination, respectively (see Fig. 50.4). The primary indications for CT or MRI are (1) to confirm the presence of a visible pituitary tumor in a dog with clinical signs suggestive of macrotumor (see the section on pituitary macrotumor syndrome) or in a dog diagnosed with PDH for which the client is willing to consider pituitary irradiation or hypophysectomy should a pituitary mass be identified (see the sections on pituitary irradiation and hypophysectomy) and (2) to assess the size of an adrenal mass and the extent of infiltration of the mass into surrounding blood vessels, organs, and body wall before adrenalectomy. MRI is superior to CT for detecting small pituitary tumors; for revealing associated tumor features such as edema, cysts, hemorrhage, and necrosis; and for imaging the adrenal glands.

TESTS OF THE PITUITARY-ADRENOCORTICAL AXIS

Clinical signs, physical examination findings, and clinicopathologic alterations should provide strong support for

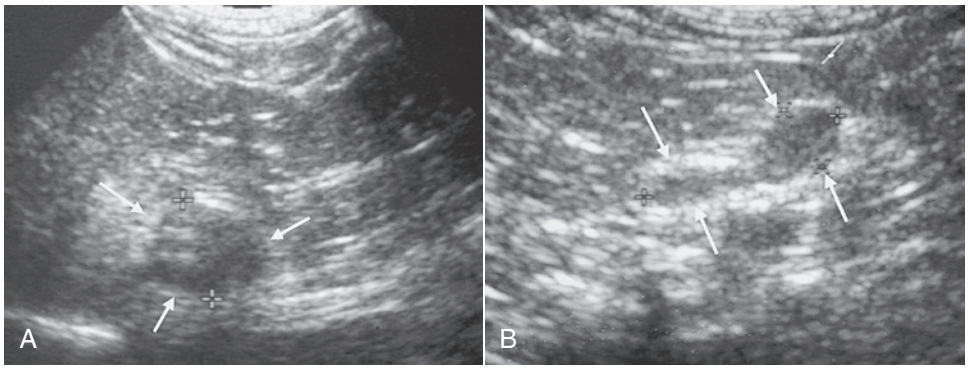

FIG 50.9
Ultrasound images of the adrenal glands in a 10-year-old female spayed Bichon Frise presented for acute onset of vomiting. **(A)** An unexpected mass involving the right adrenal gland, measuring 1.4 cm in maximum diameter, was identified *(arrows)*. **(B)** The left adrenal gland was normal in size and shape *(arrows);* the maximum diameter was 0.6 cm. The normal-size left adrenal gland suggests that the right adrenal mass is a pheochromocytoma or is nonfunctional. Results of routine blood work and of tests for hyperadrenocorticism were normal.

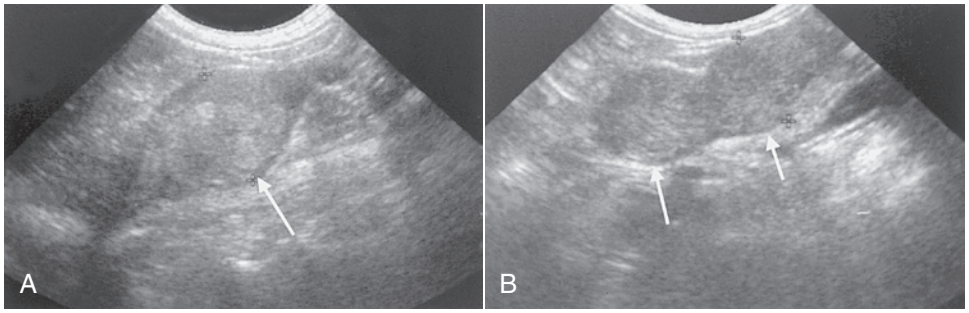

FIG 50.10
Ultrasound images of the adrenal glands *(arrows)* in an 11-year-old female spayed Shih Tzu. The right adrenal gland **(A)** measured 1.8 cm in maximum diameter and had a nodular echogenic pattern. In contrast, the left adrenal gland **(B)** had a large nodule located in each pole of the gland; each measured approximately 1.4 cm in maximum diameter. Tests of the pituitary-adrenocortical axis were diagnostic for pituitary-dependent hyperadrenocorticism; this finding, in conjunction with the findings on ultrasound, suggests macronodular hyperplasia of the adrenal glands.

diagnostic testing for hyperadrenocorticism, and results of an abdominal ultrasound may include valuable information regarding probable location of the lesion. Tests to establish the diagnosis of hyperadrenocorticism include the urine cortisol/creatinine ratio (UCCR), the ACTH stimulation test, the low-dose dexamethasone suppression (LDDS) test, and the oral dexamethasone suppression test (Table 50.2). Discriminatory tests are used to identify the cause (i.e., PDH versus ATH) in dogs with confirmed hyperadrenocorticism and include the LDDS test, the high-dose dexamethasone suppression (HDDS) test, and baseline endogenous ACTH concentration. Tests that we commonly use to establish the diagnosis of hyperadrenocorticism are UCCR in conjunction with the LDDS test, and tests that we commonly use to identify the cause (i.e., PDH versus ATH) include the LDDS test and abdominal ultrasound. The HDDS test can be used if abdominal ultrasound is not available. An endogenous ACTH concentration is evaluated when abdominal ultrasound suggests an adrenal mass but results of the LDDS test are inconclusive or suggest PDH, and when an adrenal mass is identified with contralateral adrenomegaly.

Baseline serum cortisol measurement, by itself, provides no diagnostic value in diagnosing hyperadrenocorticism. We use the ACTH stimulation test to establish the diagnosis of hypoadrenocorticism, to identify iatrogenic hyperadrenocorticism, and to monitor trilostane and mitotane treatment. We do not routinely use the ACTH stimulation test to diagnose hyperadrenocorticism because of problems with sensitivity and specificity. We never establish the diagnosis of hyperadrenocorticism solely on the basis of results of an ACTH stimulation test.

Indicators for performing diagnostic tests for hyperadrenocorticism recommended by the 2012 *American College of Veterinary Internal Medicine* (*ACVIM*) consensus statement

TABLE 50.2

Diagnostic Tests to Assess the Pituitary-Adrenocortical Axis in Dogs With Suspected Hyperadrenocorticism

TEST	PURPOSE	PROTOCOL	RESULTS		INTERPRETATION
Urine cortisol/creatinine ratio	Rule out HAC	Urine collected at home	Normal Increased		Not supportive of HAC Additional tests for HAC indicated
			4 hours post-dexamethasone:	*8 hours post-dexamethasone:*

†Suggestive of hyperadrenocorticism.

‡Inconclusive for hyperadrenocorticism.

§Baseline value is the mean of two UCCR values obtained on two consecutive mornings before dexamethasone administration.

on diagnosis of spontaneous canine hyperadrenocortisim are given in Box 50.4 (Behrend et al., 2013). Ideally, testing for hyperadrenocorticism should be avoided if serious illness exists. Many illnesses affect results of screening tests for hyperadrenocorticism. Testing for hyperadrenocorticism is not mandatory at the time suspicion arises. Postponing testing until concurrent illness is resolved or controlled is recommended, but the current illness must be considered when interpreting test results (Behrend et al., 2013).

Urine Corticoid/Creatinine Ratio

The UCCR is an excellent initial screening test for hyperadrenocorticism in dogs. The UCCR should be determined from free-catch urine samples collected on two consecutive mornings by the client in the nonstressful home environment. The stress associated with driving the dog to the veterinary hospital and having the dog undergo a physical examination before urine is collected can influence test results (Fig. 50.11). There is considerable variation in results between different urinary cortisol assays so it is important that an assay specific reference range is established by the laboratory used to determine UCCRs. A normal UCCR in one or both urine samples serves as evidence against hyperadrenocorticism. Normal UCCR test results can occur in dogs with hyperadrenocorticism but are very uncommon. Increased UCCR in both urine samples is supportive of but not definitively diagnostic for hyperadrenocorticism. The reported sensitivity and specificity of the UCCR measured on a single urine sample ranges from 75% to 100% and 20% to 25%, respectively in dogs. The UCCR is often increased in dogs with nonadrenal illness and in dogs with clinical signs consistent with hyperadrenocorticism but with a normal pituitary-adrenocortical axis (Fig. 50.12). Additional tests are indicated when the UCCR is increased or when the UCCR is normal but the clinical picture strongly suggests hyperadrenocorticism.

BOX 50.4

Indicators for Performing Diagnostic Tests for Hyperadrenocorticism in Dogs*

- Compatible history and physical examination findings; the greater the number of findings, the stronger the suspicion
- A pituitary macrotumor
- A diabetic dog with persistently poor response to high dosages of insulin not attributed to another cause including owner issues
- An adrenal mass
- Biochemical, complete blood count, urinalysis, and urine protein:creatinine ratio and blood pressure measurements, by themselves, are not indicators to test

*From: Behrend EN et al.: Diagnosis of spontaneous canine hyperadrenocorticism: 2012 ACVIM consensus statement (Small Animal), *J Vet Intern Med* 27:1292, 2013.

Low-Dose Dexamethasone Suppression Test

The LDDS test is considered the screening test of choice for hyperadrenocorticism unless iatrogenic hyperadrenocorticism is suspected (Behrend et al., 2013). In the normal dog relatively small doses of dexamethasone given intravenously can inhibit pituitary secretion of ACTH, causing a prolonged decline in the serum cortisol concentration (Fig. 50.13). Dexamethasone is used because it does not interfere with the assays used to measure cortisol. The abnormal pituitary in dogs with PDH is somewhat resistant to the negative

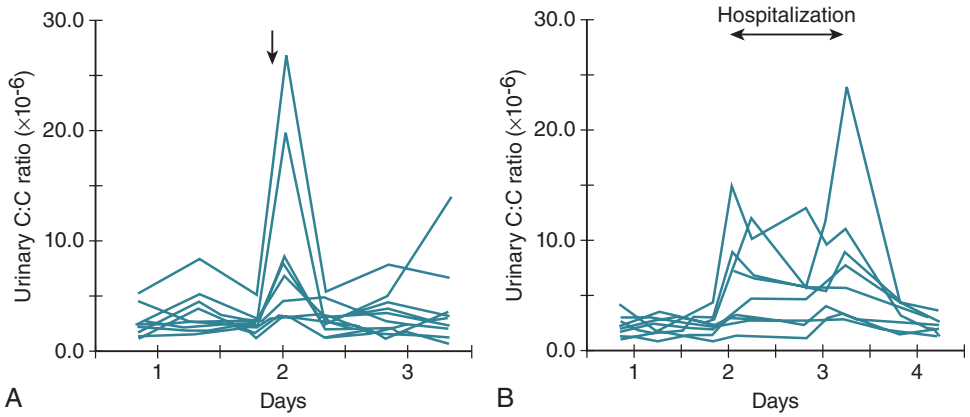

FIG 50.11
Urinary corticoid/creatinine (C:C) ratio measured in 12 pet dogs before and after a visit to a referral clinic for orthopedic examination **(A)** and in 9 healthy pet dogs before, during, and after a 1.5-day hospitalization at a referral clinic **(B).** The *arrows* indicate time of visit to the referral clinic. Note the increase in the urinary C:C ratio in a few dogs, affiliated with a visit to a veterinary practice. (From van Vonderen IK et al.: Influence of veterinary care on the urinary corticoid:creatinine ratio in dogs, *J Vet Intern Med* 12:431, 1998.)

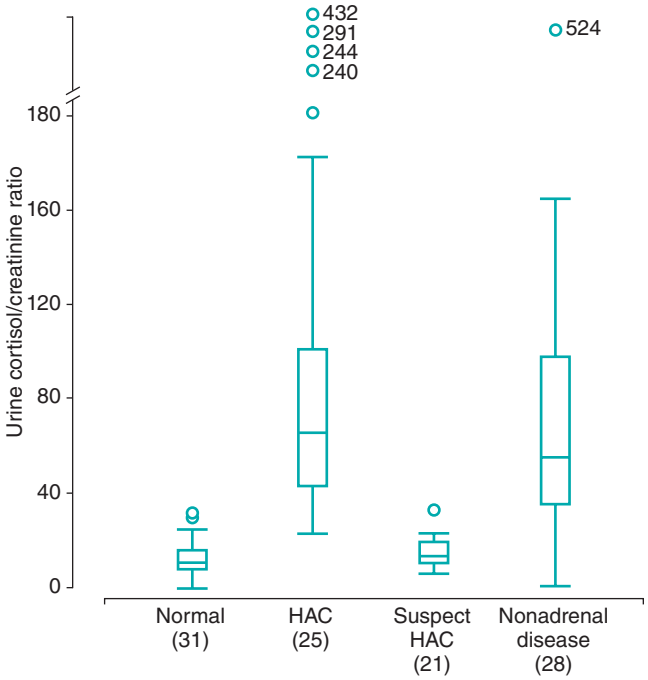

FIG 50.12
Box plots of the urine cortisol/creatinine ratios found in normal dogs, dogs with hyperadrenocorticism *(HAC)*, dogs in which hyperadrenocorticism was initially suspected but that did not have the disease (suspect HAC), and dogs with a variety of severe, nonadrenal diseases. For each box plot, T-bars represent the main body of data, which in most instances are equal to the range. Each box represents an interquartile range (twenty-fifth to seventy-fifth percentile). The horizontal bar in each box is the median. *Open circles* represent outlying data points. Numbers in parentheses indicate the numbers of dogs in each group. (From Smiley LE et al.: Evaluation of a urine cortisol/creatinine ratio as a screening test for hyperadrenocorticism in dogs, *J Vet Intern Med* 7:163, 1993.)

feedback action of dexamethasone, and the metabolic clearance of dexamethasone may be abnormally accelerated as well. Administration of a small dose of dexamethasone to a dog with PDH causes the serum cortisol concentration to be variably suppressed; however, it is no longer suppressed by 8 hours after dexamethasone administration, compared with the response seen in normal dogs. Tumors causing ADH function independently of ACTH control, and dexamethasone does not affect the serum cortisol concentration, regardless of the dose or time of blood sampling, because pituitary corticotrophs are already suppressed and blood ACTH concentration is undetectable.

The LDDS test is a reliable diagnostic test for differentiating normal dogs from those with hyperadrenocorticism and may identify PDH. Sensitivity and specificity are approximately 90% and 75%, respectively. The LDDS does not identify iatrogenic hyperadrenocorticism, nor is it used to assess a dog's response to trilostane or mitotane (lysodren) therapy. A normal or inconclusive LDDS test result does not by itself rule out hyperadrenocorticism. If hyperadrenocorticism is suspected, additional tests of the pituitary-adrenocortical axis should be performed. Similarly, an abnormal LDDS test result does not by itself confirm hyperadrenocorticism. Results of the LDDS test may be affected by concurrently administered anticonvulsant drugs, stress, excitement, exogenous glucocorticoids, and nonadrenal disease; the more severe the nonadrenal disease, the more likely it is that the LDDS test result will be falsely positive. When performing the LDDS test, the clinician must ensure that all stressors are kept to a minimum; other procedures should not be performed until the test is completed, and the effect of concurrent clinical problems should be considered when results are interpreted.

The protocol for the LDDS test and interpretation of results are described in Table 50.2. The clinician may use dexamethasone sodium phosphate or dexamethasone in polyethylene glycol. The dexamethasone sodium phosphate dosage should be calculated based on the active compound (i.e., 1.3 mg dexamethasone sodium phosphate is equivalent to 1 mg dexamethasone). The 8-hour postdexamethasone serum cortisol concentration is used to confirm hyperadrenocorticism. Normal dogs typically have serum cortisol values less than 1.0 µg/dL (28 nmol/L)—usually less than 0.5 µg/dL (14 nmol/L). Dogs with PDH and ADH typically have serum cortisol concentrations greater than 1.4 µg/dL (40 nmol/L) 8 hours after dexamethasone administration. In general, the higher the 8-hour postdexamethasone serum cortisol concentration is above 1.4 µg/dL, the more supportive the test result is for hyperadrenocorticism. Cortisol concentrations between 1.0 and 1.4 µg/dL are inconclusive. Cortisol results in this range are supportive of hyperadrenocorticism if the clinical manifestations, the results of routine blood and urine tests, and UCCRs support the disease but should not be considered diagnostic for hyperadrenocorticism if the clinical picture is questionable.

If the 8-hour postdexamethasone serum cortisol value supports a diagnosis of hyperadrenocorticism, the 4-hour serum cortisol value may be of value in identifying PDH. Low doses of dexamethasone suppress pituitary ACTH secretion and serum cortisol concentrations in approximately 60% of dogs with PDH. Suppression does not occur in dogs with ADH, nor does it occur in approximately 40% of dogs with PDH. *Suppression* is defined as a 4-hour postdexamethasone serum cortisol concentration less than 1.4 µg/dL (40 nmol/L), a 4-hour postdexamethasone serum cortisol concentration less than 50% of the baseline concentration, or an 8-hour postdexamethasone serum cortisol concentration less than 50% of the baseline concentration. Any dog with hyperadrenocorticism that meets one or more of these criteria most likely has PDH. If none of these criteria is met, then results of the LDDS test are consistent with lack of suppression but not informative in terms of whether it is pituitary or adrenal in origin. Differentiation between PDH and ADH must rely on results of abdominal ultrasound, the HDDS test, or plasma endogenous ACTH concentration.

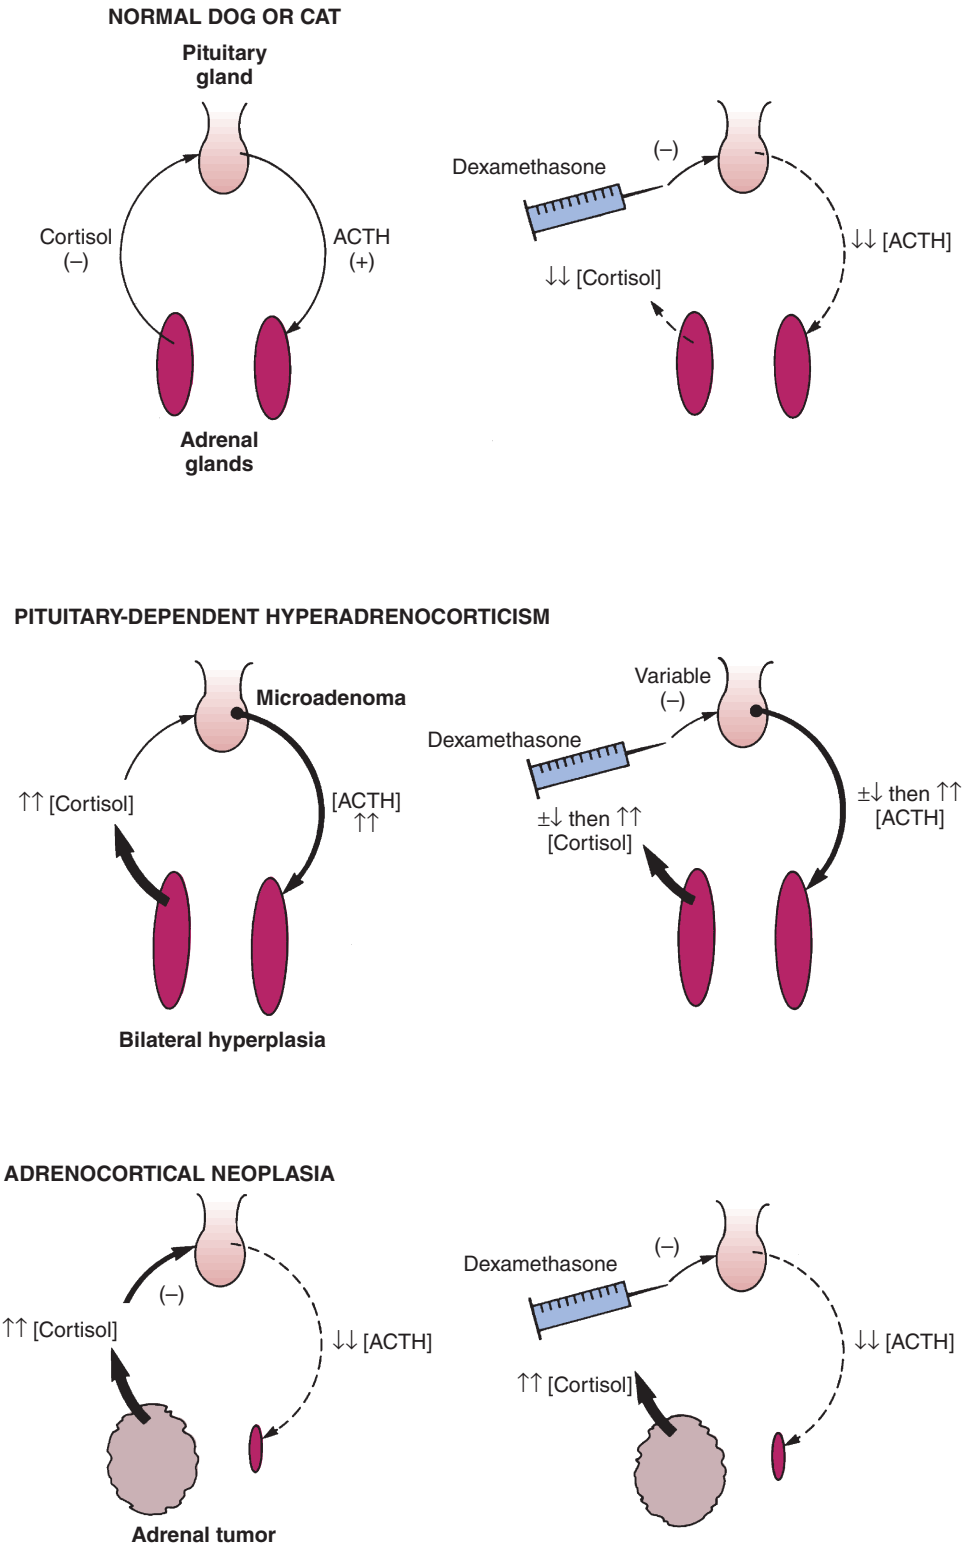

FIG 50.13
Effects of dexamethasone administration on the pituitary-adrenocortical axis in healthy dogs or cats and in dogs or cats with pituitary-dependent hyperadrenocorticism (PDH) or adrenocortical neoplasia. In PDH, dexamethasone may initially suppress pituitary adrenocorticotropic hormone *(ACTH)* secretion, but suppression is short-lived. The plasma cortisol concentrations initially decline but increase to above normal within 2 to 6 hours of dexamethasone administration. In adrenocortical neoplasia pituitary ACTH secretion is already suppressed; thus dexamethasone has no effect.

Oral Dexamethasone Suppression Test

An alternative at-home oral dexamethasone suppression test has been used for years at the University of Utrecht, The Netherlands. This test relies entirely on results of UCCRs to establish the diagnosis of hyperadrenocorticism and to identify PDH. The client is instructed to collect two urine samples from the dog on two consecutive mornings and to store them in the refrigerator. After collection of the second urine sample, the client should administer three doses of dexamethasone (0.1 mg/kg/dose) to the dog orally at 8-hour intervals. Urine is collected on the morning of the third day, and all three samples are delivered to the veterinarian for measurement of UCCRs. The first two urine samples are used as the screening test to diagnose hyperadrenocorticism. Abnormal values support hyperadrenocorticism; normal values rule out the disease. If both values are abnormal, the average of the two values is used as the baseline value and compared with the third value obtained after dexamethasone administration. The dog is described as having responded to dexamethasone (suppressed) if the UCCR result from the third urine sample is less than 50% of the baseline value. Dogs meeting this criterion have results consistent with PDH, whereas those that fail to demonstrate suppression could have either ADH or PDH.

Adrenocorticotropic Hormone Stimulation Test

The ACTH stimulation test is the gold standard for diagnosis of hypoadrenocorticism, for identification of iatrogenic hyperadrenocorticism, and for monitoring of trilostane and mitotane treatment. Because of problems with sensitivity (PDH, 80%-83%; ADH, 57%-63%) and specificity (59%-93%) and the cost of synthetic ACTH, the diagnostic usefulness of the ACTH stimulation test as a screening test for spontaneous hyperadrenocorticism is inferior to the LDDS test. We do not use the ACTH stimulation test when evaluating dogs for hyperadrenocorticism. Test results of ACTH stimulation are commonly inconclusive, and clearly abnormal test results (>30 µg/dL [800 nmol/L]) occur in dogs that do not have hyperadrenocorticism. ACTH stimulation test results do not distinguish between PDH and ADH.

The protocol for the ACTH stimulation test is given in Table 50.2. Only synthetic ACTH should be used; the lyophilized and liquid solution synthetic ACTH products can be used interchangeably. We typically administer 5 µg of synthetic ACTH/kg IV and obtain blood for serum cortisol concentration immediately before and 1 hour after ACTH administration. The unused reconstituted ACTH can be stored frozen at –20° C in plastic syringes for 6 months with no adverse effects on bioactivity of the ACTH. We use four ranges of values for interpretation of the ACTH stimulation test (Fig. 50.14). Post-ACTH serum cortisol values between 6 and 18 µg/dL (150 and 500 nmol/L) are within the normal reference range, values of 5 µg/dL (150 nmol/L) and below are suggestive of iatrogenic hyperadrenocorticism, values between 18 and 24 µg/dL (500 and 650 nmol/L) are inconclusive, and values greater than 24 µg/dL (650 nmol/L) are supportive of hyperadrenocorticism, as long as the clinical findings and clinicopathologic data are strongly consistent with the disease. An increased post-ACTH serum cortisol value does not by itself confirm a diagnosis of hyperadrenocorticism, especially if clinical features and clinicopathologic data are not consistent with the diagnosis.

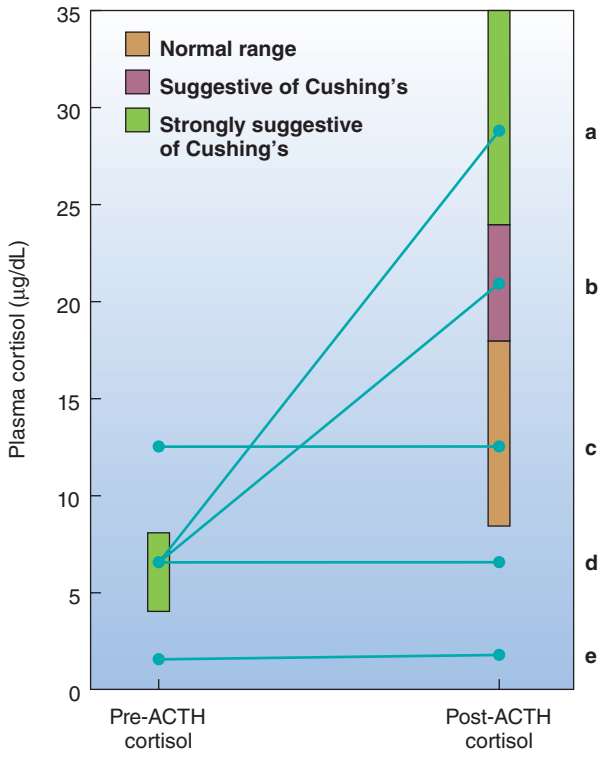

FIG 50.14
Interpretation of the adrenocorticotropic hormone *(ACTH)* stimulation test in dogs. Ideally, dogs with Cushing's syndrome have an increased post-ACTH administration cortisol concentration *(line a)*. Post-ACTH cortisol values that fall into the "gray zone" *(line b)* could be consistent with Cushing's syndrome or may result from the effects of concurrent illness or chronic stress. Post-ACTH cortisol values may also fall into the normal range in dogs with Cushing's syndrome. The absence of a response to ACTH stimulation is suggestive of adrenocortical neoplasia *(lines c* and *d)* or iatrogenic hyperadrenocorticism *(lines d* and *e)*. History and physical examination findings should differentiate between these possibilities.

Post-ACTH serum cortisol concentrations that do not increase to above the preadministration value suggest iatrogenic hyperadrenocorticism or spontaneous hypoadrenocorticism, especially if the cortisol values are below the normal baseline reference range (see Fig. 50.14). A history of recent glucocorticoid administration and the clinical presentation of the dog can help differentiate iatrogenic hyperadrenocorticism from spontaneous hypoadrenocorticism. In rare instances a dog with ADH will have a minimal cortisol response to ACTH; however, its pre-ACTH and post-ACTH administration serum cortisol concentrations should be within or above the reference range.

High-Dose Dexamethasone Suppression Test

Adrenocortical tumors causing ADH function independently of pituitary ACTH; therefore regardless of the dose, dexamethasone should never suppress the serum cortisol concentration if the source of the cortisol is an adrenocortical tumor. In contrast, dexamethasone-induced suppression of ACTH secretion from a pituitary tumor is variable and may depend on the dexamethasone dose. Administration of increased amounts of dexamethasone should eventually suppress pituitary ACTH secretion in most dogs with PDH. The protocol for the HDDS test is similar to that for the LDDS test, except that a higher dose (i.e., 0.1 mg/kg of body weight) of dexamethasone is used in an attempt to suppress pituitary ACTH secretion (see Table 50.2). Suppression is defined as a 4-hour or 8-hour postdexamethasone serum cortisol concentration less than 1.4 μg/dL (40 nmol/L) or a 4-hour or 8-hour postdexamethasone serum cortisol concentration less than 50% of the baseline concentration. Any dog with hyperadrenocorticism that meets one or more of these criteria most likely has PDH. If a dog does not meet any of these criteria, this is consistent with lack of suppression. Approximately 25% of dogs with PDH and essentially 100% of dogs with ADH do not show suppression with the HDDS test.

Endogenous Adrenocorticotropic Hormone Concentration

We do not routinely measure plasma ACTH concentrations because the LDDS test and abdominal ultrasound are very effective in differentiating between PDH and ADH. We use plasma ACTH concentrations to provide clarity in confusing cases in which test results for hyperadrenocorticism and findings on abdominal ultrasound conflict (e.g., a dog with an adrenal mass but suppression on the LDDS test, or a dog with an adrenal mass, enlargement of the contralateral adrenal gland, and lack of suppression on the LDDS test). Determination of a baseline plasma ACTH concentration is not used to diagnose hyperadrenocorticism because many of the concentrations in dogs with hyperadrenocorticism are within the reference range. However, determination of a single baseline plasma ACTH concentration may aid in distinguishing dogs with ADH from those with PDH once the diagnosis of hyperadrenocorticism has been established. Adrenocortical tumors and iatrogenic hyperadrenocorticism should suppress ACTH secretion, and PDH is the result of excessive ACTH secretion (see Fig. 50.2). Dogs with ADH should have plasma endogenous ACTH concentrations below the reference range, ideally undetectable, whereas dogs with PDH should have plasma ACTH concentrations in the upper half of the reference range or greater than the upper limit of the reference range. Plasma ACTH concentrations near the lower end of the reference range can be identified in dogs with ADH and PDH and are nondiagnostic. Timing of blood sample collection does not appear to affect results. Appropriate sample handling and appropriate analytic sensitivity and the working range of the ACTH assay are critical for ensuring accurate and interpretable results. The most common problem with the ACTH assay is poor sensitivity. The laboratory should be consulted for information on sample collection and handling; results should be interpreted on the basis of the reference range established for the laboratory being used.

Discordant Test Results

False-positive and false-negative test results occur with all of the diagnostic tests for hyperadrenocorticism. When the results are unexpected or questionable, another diagnostic test can be performed or the same diagnostic test repeated, preferably after waiting several weeks. Occasionally, results of different diagnostic tests performed in the same dog are contradictory. The decision to perform discriminatory tests or to initiate therapy should depend on the clinician's index of suspicion for the disease formulated from a review of the history, findings on physical examination, and results of diagnostic tests. If there is doubt or uncertainty about the diagnosis, therapy for hyperadrenocorticism should be withheld and the dog reevaluated several months later.

Treatment is indicated when clinical signs, findings on physical examination, and results of routine blood and urine tests and tests of the pituitary adrenocortical axis are all supportive of the diagnosis of hyperadrenocorticism. The decision to treat becomes more problematic when there is conflicting information, when the common clinical manifestations of hyperadrenocorticism are absent, when hyperadrenocorticism was not considered a differential for the tests performed (e.g., increased ALP identified during a geriatric dog evaluation), when the adrenal glands are normal in size on abdominal ultrasound, when LDDS test results are inconclusive, or when concurrent especially severe illness is present. The most important pieces of information that we rely on when deciding whether to initiate treatment are the history, findings on physical examination, and our index of suspicion for the disease after a review of all blood and urine test results. We do not initiate treatment until we are certain of the diagnosis. When in doubt, we prefer to wait and reevaluate if and when clinical manifestations of hyperadrenocorticism become more apparent. When we are contemplating a wait-and-see approach, we always try to rule out an adrenal mass with abdominal ultrasound—a finding that may warrant adrenalectomy regardless of the index of suspicion for hyperadrenocorticism.

Medical Treatment

The most viable medical treatment options for hyperadrenocorticism in dogs are trilostane and mitotane.

TRILOSTANE

Trilostane (Vetoryl, Dechra) is a competitive inhibitor of 3-β-hydroxysteroid dehydrogenase, which mediates the conversion of pregnenolone to progesterone and 17-hydroxy-pregnenolone to 17-hydroxy-progesterone in the adrenal cortex. The net effect is inhibition of cortisol, aldosterone, and progesterone production (Fig. 50.15). Trilostane is currently the preferred enzyme blocker for treating

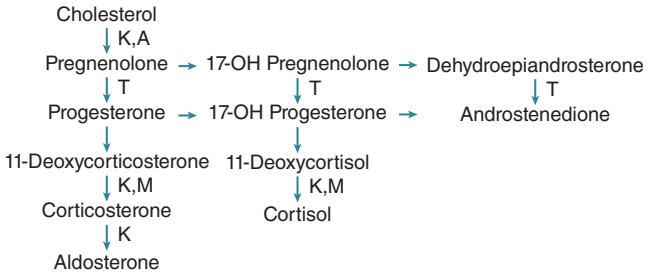

FIG 50.15
Steroid biosynthetic pathways in the adrenal cortex. The branching pathways for glucocorticoids, mineralocorticoids, and adrenal androgens are shown. The site of blockade in the steroid biosynthetic pathways by the enzyme inhibitors trilostane *(T),* ketoconazole *(K),* metyrapone *(M),* and aminoglutethimide *(A)* are also shown.

hyperadrenocorticism. Trilostane is effective in dogs with PDH and ADH, the clinical efficacy of trilostane is excellent (~90%), and trilostane can control clinical signs of hyperadrenocorticism in dogs for prolonged periods (longer than 1 year). Trilostane is used as the primary treatment modality for PDH in dogs, as an alternative in dogs in which mitotane is ineffective or not usable because of problems with drug sensitivity, as a means of reversing the metabolic derangements of hyperadrenocorticism before adrenalectomy in dogs with ADH, and as a medical option to control clinical signs in dogs with metastatic adrenocortical tumors causing ADH.

Trilostane is currently available as 5-, 10-, 30-, 60-, and 120-mg capsules. Compounded trilostane products are not recommended because of documented variation in actual trilostane content in some compounded capsules versus the prescribed strength of the compounded capsule (Cook et al., 2012)—a variation that could influence the dog's response to treatment. Some dogs have problems with short duration of cortisol suppression (<10 hours) that may result in persistence of clinical signs, subsequent administration of large doses of trilostane, and greater likelihood of adverse reactions to the drug. In our experience, twice-daily dosing using a lower dose provides better control than once-daily dosing, and the occurrence and severity of adverse reactions are less frequent. We routinely use an initial dosage of approximately 1 mg/kg twice a day administered with food to increase gastrointestinal absorption.

Dosage adjustments are based on the history, findings on physical examination, and results of serum electrolytes, ACTH stimulation test, and UCCR. Baseline serum cortisol concentrations should not be used to monitor trilostane treatment. A history and physical examination should be performed 2 weeks after trilostane treatment is initiated to ensure that problems related to hypocortisolism (e.g., lethargy, loss of appetite, vomiting) have not developed and that the dog is healthy. An ACTH stimulation test and serum electrolytes should be performed if problems have developed at 2 weeks; otherwise an ACTH stimulation test and serum electrolytes should be performed 4 weeks after initiation of treatment and approximately 4 hours after trilostane administration. Results of ACTH stimulation tests started at different times may yield significantly different results so subsequent ACTH stimulation tests should be started at or about the same time (Bonadio et al., 2014). In addition, the client should bring in a urine sample collected at home the morning of the ACTH stimulation test for a UCCR. The goals of therapy include clinical improvement without development of illness, a suppressed adrenocortical response to ACTH, and a normal UCCR. Results of the ACTH stimulation test are used to adjust the dosage of trilostane, and serum electrolytes are monitored for changes consistent with the onset of hypoaldosteronism. The goal of the ACTH stimulation test is a post-ACTH cortisol concentration between 2 and 5 μg/dL (60 and 145 nmol/L). However, it may take several weeks before maximum suppression of adrenocortical function is attained, and some dogs may need TID treatment to attain control of hyperadrenocorticism. Frequent adjustments in the trilostane dose should be avoided, especially if post-ACTH cortisol concentrations are between 5 and 8 μg/dL (145 and 225 nmol/L), the owner is reporting improvement in clinical signs, and the dog appears to be doing well. Similarly, dogs that attain a post-ACTH cortisol concentration between 2 and 5 μg/dL shortly after trilostane treatment is initiated should be watched closely for development of clinical signs of hypoadrenocorticism. Once control of the hyperadrenal state is attained, an ACTH stimulation test, serum electrolytes, and UCCR should be evaluated every 3 to 4 months—sooner if clinical signs of hypercortisolism or hypocortisolism develop.

Adverse effects of trilostane include lethargy, vomiting, and electrolyte shifts compatible with hypoadrenocorticism. Trilostane should be discontinued until adverse effects dissipate and then trilolstane should be reinitiated at a lower dose, frequency of administration, or both. Permanent hypoadrenocorticism has been reported in a small number of dogs, presumably caused by trilostane-induced adrenocortical necrosis. Acute death has been reported in a small number of dogs shortly after initiation of trilostane treatment. The reason for this is not known, but it may be affiliated with concurrent disease such as a hepatopathy.

MITOTANE

Chemotherapy using mitotane (o,p′DDD; Lysodren) is an effective treatment for PDH and should be considered in dogs that have a poor response to trilostane. Mitotane has also been used to treat ADH (i.e., cortisol secreting adrenal tumor) although our preference is to use trilostane (see section on adrenalectomy). Two treatment protocols have been used: the traditional approach, the goal of which is to control the hyperadrenal state without causing clinical signs of hypoadrenocorticism; and medical adrenalectomy, the goal of which is to destroy the adrenal cortex using mitotane to create permanent hypoadrenocorticism. We prefer the traditional approach, which involves two phases of mitotane

therapy: an initial induction phase designed to gain control of the disorder, and a lifelong maintenance phase designed to prevent recurrence of signs of the disease.

Induction Therapy

The mitotane dosage during induction therapy is approximately 50 mg/kg/day, divided into two doses. The daily dosage is reduced to 25 to 35 mg/kg in dogs without polydipsia or with concurrent diabetes mellitus. Gastrointestinal absorption of mitotane is enhanced in the presence of fat. Mitotane is more effective when each dose is ground up, mixed with a small amount of vegetable oil, and administered with food. Concurrent prednisone administration (0.25 mg/kg q24h) during induction therapy is a matter of personal preference. If prednisone is not used during induction therapy, it should always be dispensed before induction therapy is begun so that the client has prednisone on hand should adverse reactions to mitotane develop.

The induction phase of mitotane treatment is typically done with the dog in the home environment. Client awareness of the dog's activity, mental awareness, appetite, water consumption, and overall well-being is imperative for success. Clients are instructed to stop mitotane treatment and contact the veterinarian if they observe lethargy, inappetence, vomiting, weakness, decreased water intake, or any other change in the dog that does not seem right. The induction phase of therapy is usually complete once any reduction in appetite is noted or once daily water consumption decreases into the normal range (i.e., ≤80 mL/kg). Control is confirmed with the ACTH stimulation test. The first ACTH stimulation test should be performed 5 to 7 days after the start of induction therapy, even if clinical signs of hyperadrenocorticism persist.

The goal of therapy is to achieve a post-ACTH serum cortisol concentration of 2 to 5 μg/dL (60-145 nmol/L). Daily mitotane therapy and weekly ACTH stimulation tests should be continued until a post-ACTH serum cortisol concentration falls within the desired range or until clinical signs of hypocortisolism (i.e., lethargy, inappetence, vomiting) develop. In most dogs clinical signs resolve and a post-ACTH serum cortisol concentration of less than 5 μg/dL is achieved within 5 to 10 days of initiating treatment. A small number of dogs respond within 5 days, and an equally small number of dogs show minimal improvement after 20 or more consecutive days of therapy.

Reasons for a prolonged or poor response to mitotane treatment include inadequate dose, inadequate absorption from the gastrointestinal tract, concurrent administration of drugs (e.g., phenobarbital) that could accelerate the metabolism of mitotane and decrease its serum concentration, client compliance issues, and existence of ADH rather than PDH. If tests to differentiate PDH from ADH were not performed, dogs that are shown to be resistant to therapy, defined as showing little or no reduction in the post-ACTH plasma cortisol concentration after 20 or more days of therapy, should undergo further evaluation (i.e., abdominal ultrasound) to rule out ADH.

Maintenance Therapy

Mitotane must be administered periodically to prevent recurrence of clinical signs. The maintenance phase of mitotane therapy should be initiated once the post-ACTH serum cortisol concentration is less than 5 μg/dL and the dog appears healthy. The maintenance dose is defined as the weekly amount of mitotane administered, regardless of whether the weekly dose is given once per week or is divided into multiple doses and given on several days. Adverse reactions caused by sensitivity to the drug are less likely to occur when the weekly dose is divided and given on several days of the week. The typical initial weekly maintenance dosage of mitotane is 50 mg/kg administered orally, divided into two or three doses, and administered on 2 or 3 days of each week. The maintenance dose of mitotane is decreased from 50 mg/kg/wk to 25 mg/kg/wk if the post-ACTH serum cortisol concentration is less than 2 μg/dL (60 nmol/L) and the dog appears healthy. Mitotane treatment is discontinued and prednisone treatment initiated if the post-ACTH serum cortisol concentration is less than 2 μg/dL and the dog is exhibiting clinical signs of hypoadrenocorticism.

The initial dose of mitotane during maintenance therapy is arbitrary, and subsequent adjustments are made on the basis of results of ACTH stimulation tests; the first test is performed 3 to 4 weeks after the start of maintenance therapy. The goal of maintenance therapy is to maintain the post-ACTH serum cortisol concentration at between 2 and 5 μg/dL in an otherwise healthy dog. The dose and frequency of administration of mitotane are adjusted, as needed, to maintain a hypoadrenal response to ACTH administration. If the post-ACTH serum cortisol is between 2 and 5 μg/dL, a change in treatment is not indicated and the ACTH stimulation test should be repeated in 6 to 8 weeks. If the post-ACTH serum cortisol concentration is greater than 5 μg/dL, the amount of mitotane administered per week is increased. If the post-ACTH serum cortisol concentration is less than 2 μg/dL, the amount of mitotane administered per week is decreased; mitotane therapy is temporarily discontinued if clinical signs of hypoadrenocorticism are present. An ACTH stimulation test is performed 3 to 4 weeks after a change is made to the dose or frequency of administration of mitotane. Once the post-ACTH serum cortisol concentration is stable and in the range of 2 to 5 μg/dL, the frequency of performing the ACTH stimulation test can be decreased.

In most dogs an initially effective maintenance dose of mitotane becomes inadequate as the compensatory sustained increase in plasma ACTH concentration counters the adrenocorticolytic effects of mitotane. With time the dose and frequency of administration of mitotane usually increases to compensate for this effect. Periodic ACTH stimulation testing will identify when the post-ACTH serum cortisol concentration increases above 5 μg/dL, allowing the clinician to adjust the mitotane treatment protocol to maintain control of the disease. In some dogs, this can ultimately necessitate daily mitotane administration. Alternative therapy (i.e., trilostane) should be considered for dogs that become insensitive to mitotane.

Adverse Reactions to Mitotane Treatment

Adverse reactions to mitotane treatment result from sensitivity to the drug or from excessive administration and subsequent development of glucocorticoid and, if severe, mineralocorticoid deficiency (Box 50.5). The most common reactions to mitotane are gastric irritation and vomiting occurring shortly after its administration. If the gastric upset is the result of drug sensitivity and not of hypoadrenocorticism, dividing the dose further, increasing the interval between administrations, or both can help minimize vomiting.

Excessive administration of mitotane results in clinical signs of hypocortisolism, including weakness, lethargy, anorexia, vomiting, and diarrhea. Clinical improvement is usually seen within hours of administration of prednisone (0.25-0.5 mg/kg). If the dog responds, the initial dosage of glucocorticoids should be continued for 3 to 5 days and then gradually decreased and stopped over the ensuing couple of weeks. An ACTH stimulation test be performed once the dog is healthy and not receiving glucocorticoids can help determine when mitotane treatment should be started; usually when the post-ACTH serum cortisol concentration is 2 µg/dL or greater. The weekly dose of mitotane should be reduced when therapy is reinitiated.

BOX 50.5

Adverse Effects of Mitotane in Dogs

Direct Effect*

Lethargy
Inappetence
Vomiting
Neurologic signs
- Ataxia
- Circling
- Stupor
- Apparent blindness

Secondary to Overdosage*

Hypocortisolism
- Lethargy
- Anorexia
- Vomiting
- Diarrhea
- Weakness

Hypoaldosteronism (hyperkalemia, hyponatremia)
- Lethargy
- Weakness
- Cardiac conduction disturbances
- Hypovolemia
- Hypotension

PMA, Pituitary macroadenoma.
*Adrenocorticotropic hormone stimulation test, serum electrolytes, response to discontinuation of mitotane, and response to glucocorticoid therapy are used to differentiate these categories of adverse reactions.

Excessive administration of mitotane ultimately causes hypoaldosteronism. Mineralocorticoid deficiency should be considered in any dog with signs of hypocortisolism that does not respond to glucocorticoid therapy. A finding of hyponatremia and hyperkalemia supports a diagnosis of hypoaldosteronism, and mineralocorticoid therapy is indicated in such dogs (see p. 883). Hypoaldosteronism can develop within days of the start of mitotane therapy in some dogs. Hypoaldosteronism can resolve with hyperadrenocorticism recurring spontaneously, but this is unpredictable. Some dogs remain mineralocorticoid deficient for the remainder of their lives.

Medical Adrenalectomy Using Mitotane

An alternative to the traditional mitotane treatment protocol is to intentionally cause complete destruction of the adrenal cortices by administering an excessive amount of mitotane. In theory, therapy for the ensuing adrenocortical insufficiency would then be necessary for the life of the dog. The protocol consists of administering mitotane at a dosage of 75 to 100 mg/kg daily for 25 consecutive days, in three or four doses per day, with food, to minimize neurologic complications and ensure good intestinal absorption of the drug. Lifelong prednisone (0.1-0.5 mg/kg q12h initially) and mineralocorticoid therapy (see p. 888) is begun at the start of mitotane administration. The prednisone dose is tapered after completion of the 25-day protocol. Unfortunately, relapse with signs of hyperadrenocorticism occurs within the first year alone in approximately 33% of dogs so treated, indicating the need for periodic ACTH stimulation testing similar to that done in dogs treated with the traditional mode of therapy. This treatment can be considerably more expensive than long-term treatment with mitotane because of the expense of treating addisonian dogs.

Management of Concurrent Diabetes Mellitus

Hyperadrenocorticism and diabetes mellitus are common concurrent diseases in dogs. Presumably, hyperadrenocorticism develops initially and subclinical diabetes mellitus becomes clinically apparent as a result of the insulin resistance caused by the hyperadrenal state. For most of these dogs, glycemic control remains poor despite insulin therapy, and good glycemic control generally is not possible until the hyperadrenocorticism is controlled. Occasionally, diabetic dogs presumably in the early stages of hyperadrenocorticism (often identified while the cause of an increased ALP is being pursued) will be responsive to insulin and have good control of glycemia. Because the diabetes is well controlled, the decision to treat or not treat hyperadrenocorticism in these dogs should be based on other factors, such as the presence of additional clinical signs or physical examination findings and the clinician's index of suspicion for the disease. The clinician should adopt a wait-and-see approach in the absence of strong evidence for hyperadrenocorticism in these dogs. Poor control of the diabetic state will eventually occur if hyperadrenocorticism is present.

The initial focus should be on treating the hyperadrenal state in a poorly controlled diabetic dog diagnosed with hyperadrenocorticism. Concurrent insulin therapy is indicated; however, aggressive efforts to control the blood glucose concentration should not be attempted. Rather, a conservative dose (0.5-1 U/kg) of intermediate-acting insulin (i.e., lente) is administered twice a day to prevent ketoacidosis and severe hyperglycemia (blood glucose concentration > 500 mg/dL). Monitoring water consumption as a response to trilostane or mitotane treatment is not reliable when concurrent diabetes mellitus is present because both diseases cause polyuria and polydipsia, and because polyuria and polydipsia may persist if poor control of glycemia persists despite the fact that the hyperadrenocorticism is under control. As control of the hyperadrenocorticism is achieved, insulin antagonism caused by the hyperadrenocorticism resolves and tissue sensitivity to insulin improves. To help prevent hypoglycemic reactions, clients are asked to test urine for the presence of glucose, preferably two or three times each day. Any urine sample found to be negative for glucose should be followed by a 20% to 25% reduction in the insulin dose and performance of an ACTH stimulation test. Critical assessment of glycemic control and adjustments in insulin therapy, if indicated, should be initiated once hyperadrenocorticism is controlled.

KETOCONAZOLE

Ketoconazole reversibly inhibits adrenal steroidogenesis (see Fig. 50.15). The initial dosage of ketoconazole is 5 mg/kg q12h, and subsequent increases in the dosage are based on results of an ACTH stimulation test performed 10 to 14 days later, while the dog is still receiving ketoconazole. The goals of therapy are similar to those discussed for trilostane. Approximately 20% to 25% of dogs do not respond to the drug as a result of poor intestinal absorption. Adverse reactions are primarily a result of hypocortisolism and include lethargy, inappetence, vomiting, and diarrhea. Unfortunately, it is difficult to control the clinical signs of hyperadrenocorticism without creating problems with hypocortisolism. We do not recommend ketoconazole for the treatment of hyperadrenocorticism.

ADRENALECTOMY

Adrenalectomy is the treatment of choice for an adrenocortical tumor causing ADH unless metastatic lesions or invasion of surrounding organs or blood vessels is identified during the preoperative evaluation, or the dog is considered a poor anesthetic risk because it has a significant concurrent disease.

Dogs with large tumors (maximum width greater than 5 cm), dogs with extensive invasion of the caudal vena cava (especially thrombi that have extended beyond the hepatic hilus), dogs with metastatic lesions (typically in the liver and lungs) or tumors that have infiltrated the kidney or body wall, dogs with low antithrombin III concentrations, and debilitated dogs with advanced clinical manifestations of hyperadrenocorticism have a high probability of serious postoperative complications and a poor outcome. For these dogs, treatment with trilostane offers a viable alternative to adrenalectomy. Trilostane does not have antineoplastic properties but is effective in decreasing cortisol secretion by the tumor and is used to control clinical signs of hyperadrenocorticism. For dogs undergoing adrenalectomy, trilostane treatment for 3 to 4 weeks before surgery using the treatment protocol previously discussed can reverse the metabolic derangements of hyperadrenocorticism and minimize many of the complications associated with adrenalectomy.

The goals of trilostane therapy are improvement in clinical signs and a post-ACTH serum cortisol concentration between 2 and 6 µg/dL. Serum electrolytes are monitored for changes consistent with the onset of hypoaldosteronism. The dosage of trilostane is adjusted, as needed, until these goals are attained, which usually occurs within 30 days of initiating treatment. Adrenalectomy is performed once control of the hyperadrenal state is attained but generally no later than 30 days after initiating trilostane treatment, regardless of the state of control of the disease.

The reader is referred to Johnston and Tobias (2018) for more detailed information on the surgical techniques for adrenalectomy. Our current preference is laparoscopic adrenalectomy in dogs with noninvasive adrenal masses. Advantages of minimally invasive laparoscopic adrenalectomy include better visualization of abdominal organs and the adrenal mass (Videos 50.2 and 50.3), limited manipulation of other abdominal organs, decreased surgical wound complications, improved postoperative comfort, faster recovery period, and a shorter hospital stay. In our experience, recovery from the surgery is quicker, postoperative discomfort is noticeably less, most dogs are ambulatory a few hours postanesthesia, and many are discharged the next day. Problems with postoperative pancreatitis and PTE are uncommon, especially if dogs are treated with trilostane for 3 to 4 weeks before surgery.

Cortisol-secreting adrenal tumors are challenging to manage after adrenalectomy, in part because of concurrent immunosuppression, impaired wound healing, systemic hypertension and hypercoagulation, frequent infiltration of the tumor into surrounding blood vessels and soft tissues, potential development of pancreatitis postoperatively (especially with right-sided adrenal masses), and development of hypoadrenocorticism after removal of the mass. The most worrisome complication is thromboembolism, which typically develops during or within 24 hours of surgery and carries a high mortality rate (see p. 860). Prior treatment with trilostane and frequent short walks within hours of surgery to promote blood flow help minimize clot formation. Anesthetic drugs and pain medications should be administered at dosages that allow the dog to be ambulatory within 4 hours of the surgery. Glucocorticoid therapy is not indicated before adrenalectomy. Acute hypocortisolism uniformly occurs after adrenalectomy. When the surgeon begins to remove the adrenal tumor, dexamethasone (0.05-0.1 mg/kg) should be placed in the IV infusion bottle. This dose should be given over a 6-hour period. A tapering dose (e.g., decreasing the dose by 0.02 mg/kg/24 h) of dexamethasone

should continue to be administered intravenously at 12-hour intervals until the dog can safely be given oral medication without danger of vomiting (typically 24-48 hours postoperatively). At that point, the glucocorticoid supplement should be switched to oral prednisone (0.25-0.5 mg/kg q12h), and the dosage and frequency of prednisone administration should be gradually reduced during the ensuing 3 to 4 months. If a unilateral adrenalectomy has been performed, prednisone supplementation can eventually be discontinued once the contralateral normal adrenocortical tissue becomes functional. Lifelong prednisone therapy is required for dogs that undergo bilateral adrenalectomy.

Serum electrolyte concentrations should be closely monitored postoperatively. Mild hyponatremia and hyperkalemia commonly develop within 48 hours of surgery and usually resolve in a day or two as exogenous glucocorticoid doses are reduced and the dog begins to eat. Mineralocorticoid treatment is recommended if the serum sodium concentration decreases to less than 135 mEq/L or if serum potassium concentration increases to greater than 6.5 mEq/L. An injection of desoxycorticosterone pivalate (DOCP; Percorten-V) is recommended, with measurement of serum electrolytes performed 25 days after the injection (see p. 888). If the dog is healthy and serum electrolytes are normal on day 25, additional DOCP treatment usually is not needed for dogs undergoing unilateral adrenalectomy but will be needed in dogs undergoing bilateral adrenalectomy.

Reported median survival times for dogs that survived the postoperative period and were discharged from the hospital include 690 days, 492 days, 953 days, and 48 months (Schwartz et al., 2008; Lang et al., 2011; Massari et al., 2011; Helm et al., 2011). Long-term survival time was significantly shorter in dogs with adrenal carcinomas, adrenal tumors with a maximum width ≥ 5 cm, presence of metastasis, and presence of vena cava thrombosis (Massari et al., 2011).

PITUITARY IRRADIATION

Approximately 50% of dogs have a pituitary mass identified on CT or MRI at the time PDH is diagnosed. In approximately 50% of these dogs, the pituitary mass grows over the ensuing 1 to 2 years, eventually causing pituitary macrotumor syndrome (see p. 859). Pituitary macroadenoma is tentatively diagnosed by ruling out other causes of the neurologic disturbances and is confirmed by CT or MRI findings (see Fig. 50.4). Development of neurologic signs from a pituitary macrotumor is a common reason for clients to request euthanasia of dogs with PDH. Irradiation has successfully reduced the tumor size and lessened or eliminated neurologic signs in dogs with pituitary macrotumor syndrome (Fig. 50.16). Several universities and a few large referral practices in the United States offer pituitary irradiation treatment for pituitary macrotumors in dogs with PDH and cats with acromegaly. The type of irradiation (e.g., Cobalt 60, 4, 5, and 6 MV photon teletherapy using a linear accelerator, and stereotactic radiotherapy that uses a high dose of radiation delivered in a single or a few fractions) and the treatment protocol (e.g., total radiation dose, number of fractions, delivered per week, total treatment period) vary between radiation oncologists.

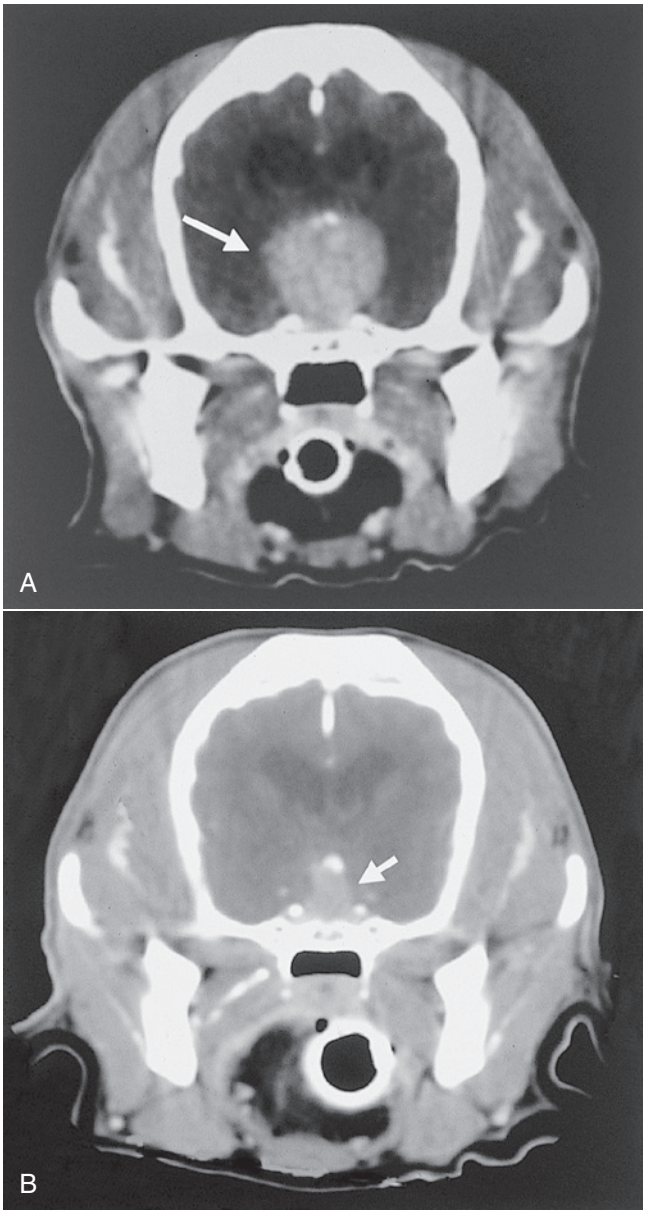

FIG 50.16
(A) Computed tomography (CT) image of the pituitary region of a 9-year-old, female, spayed Cocker Spaniel with pituitary-dependent hyperadrenocorticism (PDH). The PDH had been treated with mitotane for 2 years, at which time the dog developed lethargy, inappetence, and weight loss. A large mass measuring approximately 2.0 cm in diameter is evident in the hypothalamic-pituitary region *(arrow)*. **(B)** CT image of the pituitary region 18 months after completion of radiation therapy. The volume of the mass decreased by approximately 75%, compared with the volume before treatment. Clinical signs related to the pituitary macrotumor resolved, and mitotane treatment was discontinued after radiation treatment.

The goals of radiation therapy include shrinkage of the macrotumor, improvement or resolution of neurologic signs, improvement or resolution of clinical manifestations of

hyperadrenocorticism, and prolonged survival with a good quality of life. All studies evaluating the effect of irradiation on pituitary tumor size, to date, have documented a significant decrease in tumor size in almost all dogs treated.

Prognostic factors that affect survival time after radiation therapy include the severity of neurologic signs and the relative size of the tumor. Generally, dogs with subtle or mild neurologic clinical signs and the smallest tumors show the best response to treatment. Theon et al. (1998) found a mean survival time after radiation of 25 months in dogs with mild neurologic signs, 17 months in dogs with severe neurologic signs, and only 5 months in untreated dogs with neurologic signs. In a study by Kent et al. (2007), mean survival time in 19 dogs with pituitary masses treated with radiation therapy was 1405 days, and 1-, 2-, and 3-year estimated survival was 93%, 87%, and 55%, respectively. In contrast, mean survival time in 27 untreated dogs with pituitary masses was 551 days, and 1-, 2-, and 3-year estimated survival was 45%, 32%, and 25%, respectively.

Because of the high prevalence of a pituitary mass at the time PDH is diagnosed and the potential for future growth and development of neurologic signs, we routinely discuss CT imaging of the pituitary gland as part of the evaluation of a dog with newly diagnosed PDH even if there is no clinical evidence of a large pituitary mass, especially if the client is willing to consider irradiation therapy if a large pituitary mass is identified. Our preference is to perform CT imaging once clinical signs of hyperadrenocorticism are controlled with medical treatment. We understand that CT imaging is expensive but many of our clients are interested and want to know the status of the pituitary mass. No further evaluation of the pituitary is indicated if a pituitary mass is not identified on the initial CT scan. If a pituitary mass is identified and measures 3 to 7 mm in greatest vertical height, a repeat pituitary scan is recommended 12 months later. If a pituitary mass is identified equal to or greater than 8 mm in greatest vertical height, pituitary irradiation is recommended. The goal of pituitary irradiation is to shrink the mass and prevent development of macrotumor syndrome; trilostane or mitotane therapy may still be needed to control clinical signs of hyperadrenocorticism.

HYPOPHYSECTOMY

For several decades, selective pituitary microsurgery using the transsphenoidal approach has been considered the treatment of choice for pituitary tumors causing hyperadrenocorticism in humans. Initial studies in veterinary medicine developing the microsurgical technique, identifying postoperative complications and assessing postoperative pituitary function, or lack thereof, were done in healthy dogs approximately 25 years ago. Since then, Meij and co-investigators at Utrecht University, the Netherlands, have published several articles detailing their experiences with transsphenoidal hypophysectomy in dogs with PDH. In 2005, the Utrecht group reported on the long-term results of transsphenoidal hypophysectomy in 150 dogs with PDH (Hanson et al., 2005). Postoperative complications included transient and, less commonly, permanent central diabetes insipidus (CDI), hypernatremia, keratoconjunctivitis sicca (KCS), and secondary hypothyroidism (Hanson et al., 2005). Postoperative hormonal replacement therapy included synthetic vasopressin (DDAVP), glucocorticoids, and levothyroxine. CDI was present until death or until latest follow-up in 22% of the dogs. In another study, the incidence of postoperative permanent CDI in dogs undergoing transsphenoidal surgery for PDH was strongly influenced by the size of the pituitary tumor; the larger the tumor, the more likely for postoperative CDI to be permanent (Teshima et al., 2011). Twelve of the 150 dogs died within 4 weeks of surgery. One-hundred twenty-seven (92%) of 138 dogs that were alive after 4 weeks experienced remission within 8 weeks of surgery; remission was defined as resolution of clinical signs of hyperadrenocorticism and UCCR values in the reference range. Hyperadrenocorticism remained in remission in 95 of 127 dogs (75%). In 32 of 127 dogs (25%), signs of hyperadrenocorticism and increased UCCR values recurred at 6 weeks to 56 months (median, 18 months) after surgery. The 1-year, 2-year, 3-year, and 4-year estimated survival rate was approximately 84%, 76%, 72%, and 68%, respectively. The 1-year, 2-year, 3-year, and 4-year estimated relapse-free fraction was approximately 88%, 75%, 66%, and 59%, respectively. Survival and disease-free fractions of dogs with enlarged pituitaries were significantly lower than in dogs with nonenlarged pituitaries.

Based on the experiences at Utrecht University, microsurgical transsphenoidal hypophysectomy is an effective long-term treatment of PDH in dogs. Early diagnosis of a corticotroph adenoma is important. Transsphenoidal hypophysectomy is most effective in dogs with nonenlarged or moderately enlarged pituitaries. Size of the pituitary tumor has a direct impact on survival, disease-free fractions, and incidence of permanent CDI in dogs. Unfortunately, the number of sites currently offering hypophysectomy as a treatment option for PDH is limited in the United States.

Prognosis

Reported median survival times for dogs with ADH that survive the initial postadrenalectomy month range from 492 to 953 days, with some dogs living 4 to 5 years after surgery (Schwartz et al., 2008; Lang et al., 2011; Massari et al., 2011). In one study by Helm et al. (2011), median survival times for dogs with ADH treated with trilostane and mitotane were 353 days (95% confidence interval [CI], 95-528 days) and 102 days (95% CI, 43-277 days), respectively. Dogs with adrenocortical adenoma or adrenocortical carcinoma that has not metastasized (uncommon) have a good prognosis, whereas dogs with metastatic adrenocortical carcinoma or carcinoma with vein invasion (common) have a poorer prognosis, and these dogs typically succumb to the disease within 1 to 2 years of diagnosis. Although clinical signs can be controlled with trilostane and mitotane, death ultimately results from the debilitating effects of the tumor, complications of vein thrombosis (e.g., ascites) or metastatic growth, or other geriatric disorders (e.g., chronic kidney disease, congestive heart failure).

The prognosis for dogs with PDH depends in part on the age and overall health of the dog and on the client's commitment to therapy. The mean life span of affected dogs after diagnosis of PDH is approximately 30 months. Younger dogs may live considerably longer (i.e., 5 years or longer). Many dogs ultimately die or are euthanized because of complications related to hyperadrenocorticism (e.g., pituitary macrotumor syndrome) or other geriatric disorders.

OCCULT (ATYPICAL) HYPERADRENOCORTICISM IN DOGS

Occult hyperadrenocorticism is defined as a syndrome in which a dog appears to have hyperadrenocorticism based on history, physical examination and clinicopathologic findings, but results of the ACTH stimulation test, LDDS test, and UCCR are within reference ranges. Possible explanations for occult hyperadrenocorticism include dogs early in the course of hyperadrenocorticism, dogs that have a disease that mimics some of the clinical manifestations of hyperadrenocorticism (e.g., Alopecia X), and dogs that have increased of adrenocortical precursor hormones such as progesterone and 17-hydroxyprogesterone (see Fig. 50.15). Adrenal tumors that secrete progesterone may cause a clinical syndrome that mimics hyperadrenocorticism in dogs and cats. Clinical signs presumably result from intrinsic glucocorticoid activity of progestins, progestin-induced displacement of cortisol from cortisol-binding protein in the circulation, or both. Cortisol concentrations are inappropriately low on hyperadrenocorticism screening tests in dogs and cats with progesterone secreting tumors.

Abnormal secretion of adrenocortical precursor hormones has been proposed as a cause of occult hyperadrenocorticism but this proposal is controversial, in part, because adrenocortical precursor hormones have not been proven to cause occult hyperadrenocorticism. Results of studies aimed at documenting a relationship between adrenocortical precursor hormones and generation of the clinical abnormalities affiliated with this syndrome are conflicting and improvement of clinical signs after mitotane and trilostane treatment unpredictable.

Alterations in concentrations of adrenocortical precursor hormones before and after ACTH stimulation has been used to establish the diagnosis. Because these precursor hormones precede cortisol in the production pathway, dogs with hyperadrenocorticism also have increased concentrations of precursor hormones, as can dogs with nonadrenal illness, and healthy female dogs during estrus, diestrus, and pregnancy. A recent study by Frank et al. (2015) documented higher serum cortisol concentrations during a 9-hour blood sampling period in dogs with occult hyperadrenocorticism compared with control dogs but lower cortisol concentrations compared with dogs with pituitary-dependent hyperadrenocorticism. In addition, average transverse adrenal gland diameter determined by abdominal ultrasound was less in control dogs compared with dogs with PDH and occult hyperadrenocorticism, but transverse diameter did not differ between PDH and occult hyperadrenocorticism dogs. The authors speculated that occult hyperadrenocorticism not caused by an adrenal tumor may be due to increased 24-hour cortisol secretion, an increase that may not be detected using routine screening tests.

Currently, an ACTH stimulation test with measurement of serum and plasma adrenocortical steroid precursor hormones is used to identify occult hyperadrenocorticism in dogs. The most common finding is an increase in pre- and post ACTH stimulation serum 17-hydroxyprogesterone concentrations. Currently, the only laboratory with established reference ranges for precursor and sex steroids is the Endocrinology Laboratory at the University of Tennessee, College of Veterinary Medicine, in Knoxville, Tennessee. Treatment recommendations have included low dosages of mitotane and trilostane, although Sieber-Ruckstuhl et al. (2006) failed to document a decrease in 17-hydroxyprogesterone concentration in dogs with PDH treated with trilostane.

We do not routinely measure serum adrenocortical precursor hormones when evaluating dogs for hyperadrenocorticism. If results of the LDDS test and UCCR are normal or equivocal, we look for another cause for the clinical signs. If another cause is not identified and clinical signs are mild, we recommend waiting and testing for hyperadrenocorticism if progression is noted. Readers are referred to Behrend et al. (2013) in the suggested reading section for more information on occult hyperadrenocorticism.

HYPERADRENOCORTICISM IN CATS

Hyperadrenocorticism is uncommon in cats. Although many of the clinical characteristics of feline hyperadrenocorticism are similar to those seen in dogs, some important differences should be emphasized. Most notable is the very strong association with diabetes mellitus; the progressive, relentless weight loss leading to cachexia; and dermal and epidermal atrophy leading to extremely fragile, thin, and easily torn and ulcerated skin (i.e., feline fragile skin syndrome) in cats with hyperadrenocorticism. Establishing the diagnosis can be difficult, abnormalities on routine blood and urine tests that are suggestive of hyperadrenocorticism in dogs are usually absent in cats, and medical treatment for hyperadrenocorticism in cats is not consistently effective.

Etiology

Hyperadrenocorticism in cats may be classified as pituitary dependent (PDH) or adrenocortical tumor dependent (ADH). Approximately 80% of cats with hyperadrenocorticism have PDH and 20% have ADH, with 50% of adrenal tumors being adenomas and 50% carcinomas. Cats with PDH have a pituitary microadenoma, macroadenoma, or carcinoma identified at necropsy. Iatrogenic hyperadrenocorticism is uncommon in cats; typically prednisone or prednisolone administration for months is required before clinical signs occur.

Clinical Features

CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

Hyperadrenocorticism is a disease of older (average age, 11 years; range, 5-7 years) mixed-breed cats. A strong correlation has been noted between hyperadrenocorticism and diabetes mellitus and almost all cats are diabetic or prediabetic at the time hyperadrenocorticism is diagnosed. The most common initial clinical signs of feline hyperadrenocorticism (i.e., polyuria, polydipsia, polyphagia) are more likely caused by diabetes than by hyperadrenocorticism. Other clinical signs and physical examination findings are not as frequently observed in cats as in dogs and tend to be very subtle in the early stages of the disease (Box 50.6 and Fig. 50.17).

A frequent clue to the existence of hyperadrenocorticism in cats is the presence of diabetes mellitus that is difficult to control and ultimately progresses to severe insulin resistance. Initially, clinical signs of hyperadrenocorticism are mild, and tests of the pituitary-adrenocortical axis are often inconclusive and difficult to interpret in the

Note the relatively normal physical appearance of the cat in its normal posture **(A).** Abdominal enlargement and inguinal alopecia are evident on physical examination **(B). (C)** and **(D)** A 16-year-old cat with PDH and insulin-resistant diabetes mellitus. Note the relatively normal appearance of the cat and the alopecia and ulceration in the dorsal cervical and anterior thoracic regions in the area of a collar worn by the cat. Alopecia was also present in the ventral region of the neck.

presence of poorly controlled diabetes. With time, hyperadrenocorticism becomes more apparent as affected cats become progressively more debilitated despite aggressive insulin therapy; weight loss leads to cachexia; and dermal and epidermal atrophy results in extremely fragile, thin, and easily torn and ulcerated skin (Fig. 50.18). Dermal and epidermal lesions often occur when the cat is groomed or when the cat is handled during the physical examination. Insulin resistance is usually severe by the time cachexia and skin fragility develop. The primary differential diagnosis for insulin resistance, cachexia, and feline fragile skin syndrome is excess progestins, as occur with progesterone-secreting adrenal tumors (see p. 894 and Table 50.6).

CLINICAL PATHOLOGY

The classic clinicopathologic alterations seen in dogs with hyperadrenocorticism are infrequently found in cats. The most frequently observed abnormalities in cats are hyperglycemia, glycosuria, hypercholesterolemia, and a mild increase in alanine aminotransferase activity. These alterations can be explained by concurrent, poorly regulated diabetes mellitus. A stress leukogram, an increase in ALP activity, and isosthenuric-hyposthenuric urine are not common findings in hyperadrenal cats. An inability to document histologic changes in the liver consistent with steroid-induced hepatopathy, an absence of the steroid-induced ALP isoenzyme activity, and the relatively short half-life of ALP activity in cats may account for the absence of an observed increase in

FIG 50.18
(A) A 15-year-old cat with pituitary-dependent hyperadrenocorticism (PDH), insulin-resistant diabetes mellitus, and feline fragile skin syndrome. Note the torn skin over the back of the neck, which occurred while the cat was being restrained during a physical examination. **(A)** A 12-year-old cat with hyperadrenocorticism and severe insulin-resistant diabetes mellitus. This cat weighed 2.2 kg and was receiving 25 units of regular insulin three times a day with no glucose-lowering effect. Note the emaciated appearance, presumably resulting from protracted poor glycemic control, alopecia, severe dermal and epidermal atrophy, and lesions resulting from easily torn skin *(arrow)*. **(C)** A 17-year-old cat with PDH and insulin-resistant diabetes mellitus. Note the emaciated appearance of the cat, the enlarged abdomen (pot-bellied appearance), and absence of hair growth on the ventral abdomen, which had been shaved for an abdominal ultrasound 10 months before presentation.

ALP activity. Urine abnormalities frequently identified in dogs with hyperadrenocorticism are not common in cats.

DIAGNOSTIC IMAGING

Abdominal ultrasonography is used to identify adrenal masses and to clarify the clinician's index of suspicion for PDH. Interpretation of results of adrenal imaging in cats is similar to that in dogs (see p. 862). The maximum width of the adrenal gland in healthy cats is typically less than 0.5 cm. Adrenomegaly should be suspected when the maximum width is greater than 0.5 cm; a maximum width greater than 0.8 cm is strongly suggestive of adrenomegaly. The finding of easily visualized, bilaterally large adrenals in a cat with appropriate clinical signs and physical examination findings and abnormal test results of the pituitary-adrenocortical axis is strong evidence for PDH. CT and MRI can be used to look for pituitary macroadenoma and to determine the size of an adrenal mass and the extent of infiltration of the mass into surrounding blood vessels and organs before adrenalectomy.

TESTS OF THE PITUITARY-ADRENOCORTICAL AXIS

Although the tests used to diagnose hyperadrenocorticism in cats and dogs are similar (see p. 864), some important differences have been noted in the testing protocol and in interpretation of results (Table 50.3). We rely most heavily on the UCCR, the dexamethasone suppression test (sensitivity ≈90%), and abdominal ultrasonography to establish the diagnosis of hyperadrenocorticism in cats. The ACTH stimulation test lacks sensitivity (≈40%) in the cat and is not recommended. We also rely on abdominal ultrasound rather than endogenous plasma ACTH concentration to differentiate PDH from ADH.

Urine Cortisol/Creatinine Ratio

The theory behind and the specifics regarding the UCCR are similar for dogs and cats and are discussed on page 867. The UCCR test is a sensitive diagnostic test for identifying hyperadrenocorticism in cats, but similar to dogs, specificity of the test is low in cats. We use the UCCR as the initial screening test for hyperadrenocorticism in cats. Urine should be collected at home, preferably on two consecutive days. A normal UCCR in one or both urine samples is strong evidence against hyperadrenocorticism. An increase in UCCR in both urine samples does not establish the diagnosis by itself but supports performing the dexamethasone suppression test.

Dexamethasone Suppression Test

The duration of the suppressive effects of intravenously administered dexamethasone on serum cortisol concentrations is

TABLE 50.3

Diagnostic Tests to Assess the Pituitary-Adrenocortical Axis in Cats With Suspected Hyperadrenocorticism

TEST	PURPOSE	PROTOCOL	RESULTS	INTERPRETATION
Urine cortisol/creatinine ratio	Rule out HAC	Urine collected at home	Normal Increased	Not supportive of HAC Additional tests for HAC indicated
			8 hours post-dexamethasone:	
Dexamethasone suppression test	Diagnose HAC	0.1 mg dexamethasone/kg IV; serum pre- and 4 and 8 hours post-dexamethasone	<1.0 µg/dL 1.0-1.4 µg/dL >1.5 µg/dL and 4 hours <1.5 µg/dL >1.5 µg/dL and 4 hours >1.5 µg/dL	Normal Nondiagnostic Suggestive[†] Strongly suggestive[‡]
			Post-ACTH cortisol concentration:	
ACTH stimulation	Diagnose HAC	125 µg of synthetic ACTH*/cat IV; serum pre- and 30 and 60 minutes post-ACTH	>20 µg/dL 15-20 µg/dL 5-15 µg/dL <5 µg/dL	Strongly suggestive Suggestive Normal Iatrogenic HAC
Endogenous ACTH	Differentiate PDH from ATH	Specific sample handling required	Below reference range Upper half of reference range or increased Lower half of reference range	ATH PDH Nondiagnostic

*Synthetic ACTH: Cortrosyn, Cosyntropin, Synacthen.
[†]Suggestive of hyperadrenocorticism.
[‡]Strongly suggestive of hyperadrenocorticism.

more variable in cats than in dogs. Approximately 20% of healthy cats do not experience the suppressive effects of dexamethasone, and their serum cortisol concentrations are greater than 1.4 µg/dL (40 nmol/L) 8 hours after dexamethasone administration. This "escape phenomenon" is more likely to occur in cats receiving lower doses of dexamethasone. Because of potential misinterpretation caused by the escape phenomenon and the fragile state of many diabetic hyperadrenal cats, we typically use only one dexamethasone suppression test protocol (0.1 mg/kg dexamethasone administered intravenously; blood obtained before and 4 and 8 hours after dexamethasone administration) when evaluating the pituitary-adrenocortical axis in cats. An 8-hour postdexamethasone serum cortisol concentration less than 0.8 µg/dL (22 nmol/L) is suggestive of a normal pituitary-adrenocortical axis, values between 0.8 and 1.4 µg/dL are inconclusive, and values greater than 1.4 µg/dL are supportive of the diagnosis of hyperadrenocorticism. The higher the 8-hour postdexamethasone serum cortisol concentration is above 1.4 µg/dL, the more supportive the test is for the diagnosis of hyperadrenocorticism. A serum cortisol concentration greater than 1.4 µg/dL at the 4-hour postdexamethasone blood sampling time adds further support for the diagnosis of hyperadrenocorticism (Fig. 50.19). Whenever the 4-hour postdexamethasone cortisol value is less than 1.4 µg/dL (especially < 0.8 µg/dL) and the 8-hour postdexamethasone cortisol value is greater than 1.4 µg/dL, test results should be considered consistent with, but not definitively diagnostic of, hyperadrenocorticism, and the clinician must rely on clinical signs, physical examination findings, and results of other diagnostic tests to help establish the diagnosis. The 0.1 mg/kg dexamethasone suppression test is an excellent and extremely sensitive screening test for hyperadrenocorticism in cats, however, results of the dexamethasone suppression test should never constitute the sole evidence for hyperadrenocorticism in cats.

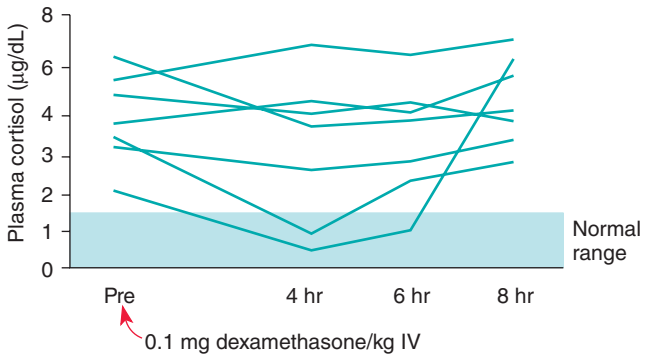

FIG 50.19
Dexamethasone suppression test results in seven cats with histologically confirmed hyperadrenocorticism. Blood for the cortisol determination was drawn before and 4, 6, and 8 hours after intravenous administration of 0.1 mg of dexamethasone/kg body weight. In most cats the plasma cortisol concentration remained greater than 1.4 µg/dL throughout the test—results that are very consistent with a diagnosis of hyperadrenocorticism.

Adrenocorticotropic Hormone Stimulation Test

The ACTH stimulation test is brief to perform and relatively easy to interpret. The peak increase in the post-ACTH serum cortisol concentration occurs earlier in cats than in dogs, and serum cortisol concentrations can approach baseline values by 1 hour after administration of synthetic ACTH. For this reason, blood samples should be obtained 30 minutes and 1 hour after administration of synthetic ACTH in cats. Unfortunately, the sensitivity of the ACTH stimulation test in identifying hyperadrenocorticism is low in cats. In one study, results of the dexamethasone suppression test were consistent with hyperadrenocorticism in 27 of 28 cats whereas ACTH stimulation testing was suggestive of hyperadrenocorticism in only 9 of 16 cats (Valentin et al., 2014). Because of low sensitivity, we do not rely on the ACTH stimulation test for diagnosing hyperadrenocorticism in cats.

Endogenous Plasma ACTH Concentration

The endogenous plasma ACTH concentration test is discussed on page 871. Plasma ACTH concentrations below the reference range, especially undetectable results, are consistent with ADH, and plasma ACTH concentrations in the upper half of the reference range or increased are consistent with PDH in cats. Plasma ACTH concentrations in the lower half of the reference range can occur with PDH and ADH and are nondiagnostic.

Diagnosis

Hyperadrenocorticism is diagnosed on the basis of history; findings on physical examination; results of routine blood and urine tests, abdominal ultrasonography, and tests of the pituitary-adrenocortical axis; and the clinician's index of suspicion for the disease. Ideally, all diagnostic tests performed in the assessment of a cat with suspected hyperadrenocorticism should be abnormal. Discordant test results raise doubt regarding the diagnosis. False-positive and false-negative results occur with all of the diagnostic tests used to assess the pituitary-adrenocortical axis. Although normal UCCR and dexamethasone suppression test results do not support the diagnosis of hyperadrenocorticism, abnormal results of these tests do not by themselves confirm the diagnosis. If there is doubt or uncertainty about the diagnosis, therapy for hyperadrenocorticism should be withheld and the cat reevaluated 1 to 2 months later.

Treatment

Trilostane is the current medical treatment of choice for PDH in cats. Trilostane is effective in controlling clinical signs of PDH, is generally well tolerated, and is effective in improving insulin resistance in those cats with concurrent diabetes. Trilostane treatment and monitoring protocols are similar for dogs and cats (see p. 871). Recommendations for the starting dose and frequency of administration vary among clinicians. Our initial starting dose is 30 mg/cat administered once a day. Adjustments in dose and frequency of administration are based on clinical response and on

results of the ACTH stimulation test, UCCR, and serum electrolyte concentrations, initially performed 4 weeks after initiation of trilostane treatment—earlier if clinical signs suggestive of hypoadrenocorticism or clinical signs suggestive of hypoglycemia in cats with insulin-resistant diabetes develop. The dosing schedule should be continued if improvement in clinical signs and test results are noted by 4 weeks, even if the goals of therapy have not yet been attained. The dosing schedule should be changed if no improvement or worsening of clinical signs and test results are observed at 4 weeks. In general, twice-daily dosing provides better control than once-daily dosing and should be the initial adjustment in cats that remain symptomatic at the starting dose given once daily. Subsequent adjustments in the dose of trilostane should be based on findings at the 4-week rechecks. A decrease in insulin requirements will usually occur as control of PDH is attained. Mellett et al. (2013) reported a median survival of 617 days in 15 cats treated with trilostane.

Adrenalectomy is the treatment of choice for ADH; bilateral adrenalectomy is also an effective treatment for PDH. Medical treatment with trilostane is usually necessary for 4 to 6 weeks before adrenalectomy to reverse the catabolic state of the cat, improve skin fragility and wound healing, and decrease the potential for perioperative complications. The surgical approach and medical management during and after surgery are similar to those used in dogs (see p. 875). Treatment for hypoadrenocorticism should begin immediately after bilateral adrenalectomy and should include injectable DOCP (2.2 mg/kg administered subcutaneously every 25 days initially; Percoten-V) or fludrocortisone acetate (0.05 mg/cat administered orally q12h initially; Florinef), as well as prednisolone (1-2.5 mg once daily). Subsequent adjustments in the dose of DOCP or fludrocortisone acetate should be based on periodic measurement of serum electrolyte concentrations (see p. 888). Insulin therapy can be discontinued in approximately 50% of cats once hyperadrenocorticism is eliminated, and diabetes is easier to control with the use of less insulin in the remaining cats.

Prognosis

The prognosis is guarded to poor. Untreated hyperadrenal cats die within months after the diagnosis has been established because of the deleterious effects of chronic hypercortisolism and insulin-resistant diabetes mellitus on skin integrity and immune function, and as a result of progressive weight loss leading to severe cachexia. The effectiveness of trilostane remains to be evaluated in a large group of hyperadrenal cats. Unilateral (ADH) or bilateral (PDH) adrenalectomy has the potential for excellent success; however, success depends, in part, on correction of the debilitated state and skin fragility with medical treatment before surgery, involvement of a surgeon with expertise in adrenal surgery, avoidance of perioperative complications, and the client's commitment to managing iatrogenic adrenal insufficiency after bilateral adrenalectomy. Periodic evaluation of serum electrolytes and review of the treatment protocol are important to avoid an addisonian crisis in cats undergoing bilateral adrenomegaly.

HYPOADRENOCORTICISM

Etiology

Hypoadrenocorticism is a deficiency of mineralocorticoids (i.e., aldosterone), glucocorticoids (i.e., cortisol), or both. Primary adrenocortical insufficiency (Addison's disease) with a deficiency of mineralocorticoid and glucocorticoid secretion is the most common. Primary hypoadrenocorticism is usually classified as idiopathic because the cause of the disease is not obvious, and necropsies are usually done years after the diagnosis is established, at which time idiopathic atrophy of all layers of the adrenal cortex is the most frequent histopathologic finding. Immune-mediated destruction of the adrenal cortices is believed to occur in most dogs with idiopathic adrenal insufficiency; lymphoplasmacytic inflammation and fibrosis are common findings in animals that undergo necropsy near the time of diagnosis. Bilateral destruction of the adrenal cortex by neoplasia (e.g., lymphoma), granulomatous disease, hemorrhagic infarction, arterial thrombosis, or drugs such as mitotane and trilostane can also cause primary adrenocortical insufficiency. For clinical signs to develop, it is believed that at least 90% of the adrenal cortices must be destroyed. The zones of the adrenal cortices are usually damaged at about the same rate, with aldosterone and cortisol deficiencies typically occurring in tandem. Destruction is progressive, ultimately leading to complete loss of adrenocortical function. Dogs and cats typically have complete loss of adrenocortical function at the time hypoadrenocorticism is diagnosed. A partial deficiency syndrome characterized by inadequate adrenal reserve may occur initially, with clinical signs manifested only during times of stress such as boarding, travel, and surgery. As destruction of the adrenal cortex progresses, hormone secretion becomes inadequate even under nonstressful conditions, and a true metabolic crisis occurs with no obvious inciting event.

Mineralocorticoids (i.e., aldosterone) control sodium, potassium, and water homeostasis. In the setting of primary adrenocortical insufficiency, loss of aldosterone secretion results in impaired renal conservation of sodium and chloride and excretion of potassium, leading to the development of hyponatremia, hypochloremia, and hyperkalemia. The inability to retain sodium and chloride reduces extracellular fluid volume, leading to progressive development of hypovolemia, hypotension, reduced cardiac output, and decreased perfusion of the kidneys and other tissues. Hyperkalemia has a deleterious effect on cardiac function, causing decreased myocardial excitability, an increased myocardial refractory period, and slowed conduction. A concurrent glucocorticoid deficiency typically results in gastrointestinal tract signs (e.g., anorexia, vomiting, diarrhea, weight loss) and changes in mental status (e.g., lethargy). One of the hallmark signs of hypocortisolism is impaired tolerance to stress, and

clinical signs often become more pronounced when the animal is placed in stressful situations.

Some dogs and cats with hypoadrenocorticism present to the veterinarian with clinical signs of glucocorticoid deficiency but serum electrolyte concentrations that are within the reference range at initial presentation. A deficiency in glucocorticoid but not mineralocorticoid secretion is referred to as *atypical hypoadrenocorticism* and is discussed on page 889. Glucocorticoid deficiency resulting from pituitary dysfunction causing a deficiency in ACTH is called *secondary hypoadrenocorticism*. Destructive lesions in the pituitary gland or hypothalamus, long-term administration of exogenous glucocorticoids, and idiopathic loss of function are the most common causes of secondary adrenal insufficiency. Naturally occurring, isolated hypoaldosteronism is rare in dogs and cats.

Clinical Features

SIGNALMENT

Hypoadrenocorticism is typically a disease of young to middle-aged female dogs with a median age of onset for all breeds of 4 years (range, 2 months to 14 years). Dogs with glucocorticoid-deficient hypoadrenocorticism tend to be older at the time of diagnosis than dogs with mineralocorticoid and glucocorticoid–deficient hypoadrenocorticism. Breeds reported to be at increased risk for hypoadrenocorticism are listed in Box 50.7. The disease is inherited as an autosomal recessive trait in Portuguese Water Spaniels, Nova Scotia Duck Tolling Retrievers, Standard Poodles, and Bearded Collies. Hypoadrenocorticism is rare in cats. There is no apparent sex-related predisposition in cats, although the disease tends to occur in young to middle-aged cats (average age, 6 years). Hypoadrenocorticism can, however, occur in aged dogs and cats as well.

CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

Clinical signs and physical examination findings are listed in Box 50.8. The most common clinical manifestations are related to alterations in the gastrointestinal tract and mental status and include lethargy, anorexia, vomiting, and weight loss. Weakness is a common client complaint. Additional physical examination findings may include dehydration, bradycardia, weak femoral pulses, and abdominal pain. Hyperkalemia and hypoadrenocorticism should be suspected in an animal with bradycardia and signs consistent with hypovolemia. Bradycardia by itself, however, is not pathognomonic for hypoadrenocorticism, especially in an otherwise healthy dog. Similarly, dogs with hypoadrenocorticism can have normal heart rates. Polyuria and polydipsia are not common presenting signs, although they may surface during the taking of a complete history.

Clinical signs are often vague and easily ascribed to more common disorders involving the gastrointestinal and urinary tracts. Observant clients may occasionally describe an illness with a waxing-waning or episodic course; however, this bit of historic information is the exception rather than the rule. Most dogs with hypoadrenocorticism are first seen because of progressive problems that vary in severity, depending on the degree of stress and the adrenocortical reserve.

If hyponatremia and hyperkalemia become severe, the resultant hypovolemia, prerenal azotemia, and cardiac arrhythmias may result in an addisonian crisis. Clinical manifestations are the same as those previously described; the only difference is noted in the severity of signs. In severe cases the animal may be presented in shock and may be moribund. An addisonian crisis must be differentiated from other life-threatening disorders, such as diabetic ketoacidosis, necrotizing pancreatitis, acute hepatitis, septic peritonitis, and acute renal failure.

CLINICAL PATHOLOGY

Several abnormalities may be identified on CBC, serum biochemistry panel, and urinalysis (Box 50.9). Hyperkalemia, hyponatremia, and hypochloremia are the classic electrolyte alterations in animals with adrenal insufficiency and provide perhaps the most important evidence ultimately used to

Urine specific gravity < 1.030

establish a diagnosis of hypoadrenocorticism. Serum sodium concentrations vary from normal to as low as 105 mEq/L (mean, 128 mEq/L), and serum potassium concentrations vary from normal to greater than 10 mEq/L (mean, 7.2 mEq/L). The sodium/potassium ratio reflects changes in these electrolyte concentrations in serum and frequently has been used as a diagnostic tool to identify adrenal insufficiency. The normal ratio varies between 27:1 and 40:1. Values are often less than 27 and may be less than 20 in animals with primary adrenal insufficiency.

Electrolyte alterations by themselves can be misleading. Normal serum electrolyte concentrations do not rule out adrenal insufficiency. Electrolyte abnormalities may not be evident in early stages of the disorder, when clinical signs result from glucocorticoid deficiency, and do not develop with secondary adrenal insufficiency caused by pituitary failure. Alternatively, other disorders can cause alterations in serum electrolyte concentrations that mimic adrenal insufficiency, most notably disorders involving the hepatic, gastrointestinal, and urinary systems (see Boxes 53.2 and 53.3). For most disorders, a thorough history and physical examination, together with a critical evaluation of results of the CBC, serum biochemistry panel, and urinalysis, allow the clinician to prioritize the potential differential diagnoses. Important clues for hypoadrenocorticism include lack of a stress leukogram in a sick dog or cat and identification of hypoalbuminemia, hypocholesterolemia, hypoglycemia, or a combination of these on the serum biochemistry panel.

The most challenging aspect of diagnosis is the differentiation between acute renal failure and primary adrenal insufficiency. The azotemia of adrenal insufficiency occurs secondary to reduced renal perfusion and an associated decrease in glomerular filtration rate after the onset of hypovolemia and hypotension. A compensatory increase in urine specific gravity to greater than 1.030 allows prerenal azotemia to be differentiated from primary renal azotemia and therefore adrenal insufficiency to be differentiated from acute renal failure, respectively.

Unfortunately, many hypoadrenal dogs and cats have an impaired ability to concentrate urine caused by chronic urinary sodium loss, depletion of the renal medullary sodium content, loss of the normal medullary concentration gradient, and impaired water resorption by the renal collecting tubules. As a result, some hypoadrenal dogs and cats with prerenal azotemia have urine specific gravities in the isosthenuric range (i.e., 1.007-1.015). Fortunately, the initial therapy for acute renal failure is similar to that used for adrenal insufficiency. Ultimately, the differentiation between these two disorders must rely on testing of the pituitary-adrenocortical axis and the animal's response to initial fluid and other supportive therapy.

ELECTROCARDIOGRAPHY

Hyperkalemia depresses cardiac conduction and causes characteristic alterations on an electrocardiogram (ECG; see Box 53.4). The severity of the ECG abnormalities correlates with the severity of hyperkalemia. The ECG can be used as a diagnostic tool to identify and estimate the severity of hyperkalemia and as a therapeutic tool to monitor changes in the blood potassium concentration during therapy.

DIAGNOSTIC IMAGING

Hypoadrenal dogs and cats with severe hypovolemia often have microcardia, a descending aortic arch that is flattened and has a decreased diameter, and a narrow caudal vena cava, as seen on lateral thoracic radiographs. These findings serve as a crude means of evaluating the degree of hypovolemia and hypotension. Concurrent generalized megaesophagus may be evident and may resolve in response to treatment for hypoadrenocorticism. Abdominal ultrasonography may reveal small adrenal glands (i.e., maximum width of 0.3 cm or less)—a finding strongly suggestive of adrenocortical atrophy. A finding of normal-size adrenal glands, especially glands with a maximum width less than 0.5 cm, does not rule out hypoadrenocorticism.

Diagnosis

Hypoadrenocorticism is often tentatively diagnosed on the basis of the history; physical examination findings; clinicopathologic findings; and, in the case of primary adrenal insufficiency, identification of appropriate electrolyte abnormalities. Results of an ACTH stimulation test confirm the diagnosis (see Table 50.2). The post-ACTH serum cortisol concentration is less than 2 µg/dL (55 nmol/L) (see Fig. 50.14). A baseline serum cortisol concentration can be used

as an initial screening test to rule out hypoadrenocorticism, as long as glucocorticoids (e.g., hydrocortisone, prednisone, prednisolone) that may be measured by the cortisol assay have not been recently administered to the dog or cat. Baseline serum cortisol concentrations greater than 2 µg/dL do not support the diagnosis of hypoadrenocorticism. Baseline serum cortisol concentrations of 2 µg/dL or less are suggestive of but not definitively diagnostic for hypoadrenocorticism. An ACTH stimulation test should be done on these dogs to confirm the diagnosis. UCCRs are not reliable for confirming the diagnosis. Post-ACTH serum cortisol values between 2 and 4 µg/dL (55 and 110 nmol/L) may occur with secondary hypoadrenocorticism and with critical illness-induced corticosteroid insufficiency (CIRCI; also called relative adrenal insufficiency)—a syndrome defined as inadequate production of cortisol in relation to increased demand during periods of critical illness such as sepsis. Prolonged or excessive inflammatory cytokine activity suppresses pituitary and adrenal function in humans and possibly in dogs as well. In a study by Burkitt et al. (2007), dogs with severe sepsis had suppressed response of the adrenal cortex to exogenously administered ACTH, an increase in serum cortisol concentration of less than 3 µg/dL (82 nmol/L) after ACTH administration, and resolution of the relative adrenal insufficiency after resolution of the illness. Fortunately, baseline cortisol concentrations are usually within the reference range in dogs with CIRCI.

Results of the ACTH stimulation test do not distinguish dogs and cats with naturally occurring primary adrenal insufficiency from those with secondary insufficiency resulting from pituitary failure, dogs and cats with secondary insufficiency resulting from prolonged iatrogenic glucocorticoid administration, or dogs with primary adrenocortical destruction caused by mitotane or trilostane overdosing. Concurrent abnormal serum electrolyte concentrations imply the existence of primary adrenal insufficiency and the need for mineralocorticoid and glucocorticoid replacement therapy. Normal serum electrolyte concentrations do not differentiate between primary hypoadrenocorticism that progresses and primary hypoadrenocorticism that does not progress to mineralocorticoid deficiency, or between primary hypoadrenocorticism and secondary hypoadrenocorticism (see the section on atypical hypoadrenocorticism). If secondary hypoadrenocorticism can be documented, only glucocorticoid replacement therapy is indicated. Primary and atypical or secondary hypoadrenocorticism can be differentiated prospectively by periodic measurement of serum electrolyte concentrations, by measurement of baseline endogenous ACTH concentration, or by measurement of plasma aldosterone concentrations during the ACTH stimulation test (Table 50.4). In theory, measurement of plasma aldosterone concentration should be helpful in distinguishing between the various forms of adrenal insufficiency. Unfortunately, there is no clear demarcation in plasma aldosterone concentrations between these groups of dogs.

Treatment

The aggressiveness of therapy depends on the clinical status of the animal and the nature of the insufficiency (i.e., glucocorticoid, mineralocorticoid, or both). Many dogs and cats with primary adrenal insufficiency are presented at varying stages of an acute addisonian crisis, requiring immediate, aggressive therapy. In contrast, dogs and cats with isolated glucocorticoid deficiency often have a chronic course that poses more of a diagnostic than a therapeutic challenge.

THERAPY FOR ACUTE ADDISONIAN CRISIS

An acute addisonian crisis involves both a mineralocorticoid and a glucocorticoid deficiency. Treatment of acute primary adrenal insufficiency is directed toward correcting hypotension, hypovolemia, electrolyte imbalances, and metabolic acidosis; improving vascular integrity; and providing an immediate source of glucocorticoids (Box 50.10). Because death resulting from hypoadrenocorticism is often attributed to vascular collapse and shock, correction of hypovolemia is the first and most important therapeutic priority. The type of fluid used depends somewhat on the severity of the hyponatremia (see Table 53.2). Ringer's or Ringer's lactate solution can be used for mild hyponatremia (serum sodium concentration > 130 mEq/L) and physiologic saline solution for more severe hyponatremia (serum sodium concentration

TABLE 50.4

Differentiation of Primary Versus Secondary Hypoadrenocorticism

BOX 50.10

Initial Treatment for Acute Addisonian Crisis

Fluid Therapy

Type: 0.9% saline solution if serum sodium concentration less than 130 mEq/L; isotonic crystalloid solution (e.g., Ringer's, Ringer's lactate) if serum sodium is 130 mEq/L or higher
Rate: 40 to 80 mL/kg/24 h IV initially
Potassium supplementation: not indicated
Dextrose: 5% dextrose infusion (100 mL of 50% dextrose per liter of fluids) if hypoglycemic

Glucocorticoid Therapy

Dexamethasone or dexamethasone sodium phosphate, 0.5 to 1 mg/kg IV, repeat q12h at dosage of 0.05 to 0.1 mg/kg in IV fluids until oral prednisone can be administered*

Mineralocorticoid Therapy

Desoxycorticosterone pivalate (DOCP; Novartis), 2.2 mg/kg IM

Bicarbonate Therapy

Indicated if HCO_3 < 12 mEq/L or total venous CO_2 < 12 mmol/L or animal is severely ill
mEq HCO_3 = body weight (kg) × 0.5 × base deficit (mEq/L); if base deficit unknown, use 10 mEq/L. Add one quarter of calculated HCO_3 dose to IV fluids and administer over 6 hours. Repeat only if plasma HCO_3 remains < 12 mEq/L.

IM, Intramuscular; *IV,* intravenous.
*Higher doses of glucocorticoids may be required if the dog or the cat is in shock.

< 130 mEq/L). Hyperkalemia is reduced by simple dilution and by improved renal perfusion even when potassium-containing fluids are used. The more acute and severe the hyponatremia, the more slowly the serum sodium concentration should be corrected. A rapid increase in the serum sodium concentration should be avoided in animals with severe hyponatremia (serum sodium concentration < 120 mEq/L), especially if severe hyponatremia has been present for 24 hours or longer. For these animals, the serum sodium concentration should be gradually increased by 10 to 12 mEq/L per day. If hypoglycemia is present, 50% dextrose should be added to the IV fluids to produce a 5% dextrose solution (i.e., 100 mL of 50% dextrose per liter of fluids). Dextrose added to isotonic solutions produces a hypertonic solution that ideally should be administered through a central vein to minimize phlebitis.

Dogs and cats with acute adrenal insufficiency usually have a mild metabolic acidosis that does not require therapy. Fluid therapy alone corrects the mild acidosis as hypovolemia lessens and tissue perfusion and glomerular filtration rate improve. If the total venous carbon dioxide or serum bicarbonate concentration is less than 12 mmol/L or 12 mEq/L, respectively, conservative bicarbonate therapy is indicated. In a severely ill animal for which laboratory results are not yet known, a base deficit of 10 mEq/L can be assumed to be present. The milliequivalents of bicarbonate needed to correct the acidosis can be determined from the following equation:

$$\text{Bicarbonate deficit}\left(\frac{\text{mEq}}{\text{L}}\right) = \text{Bodyweight (kg)} \times 0.5 \times \text{Base deficit (mEq/L)}$$

One fourth of the calculated bicarbonate dose should be administered in IV fluids during the initial 6 to 8 hours of therapy. The acid-base status of the animal should be reassessed at the end of this time. Rarely, a dog or cat may require additional parenterally administered sodium bicarbonate.

Sodium bicarbonate therapy helps correct the metabolic acidosis and decreases the serum potassium concentration. Intracellular translocation of potassium ions after bicarbonate administration, in conjunction with the dilutional effects of fluid therapy and improved renal perfusion, is usually effective in lowering the serum potassium concentration and returning any ECG abnormalities toward normal. Additional therapy to rapidly correct life-threatening hyperkalemia is rarely needed (see Table 53.3).

Glucocorticoid and mineralocorticoid therapy is also indicated in the initial management of an acute addisonian crisis. Ideally, glucocorticoids should not be given until after completion of the ACTH stimulation test. IV fluids are usually sufficient therapy during the initial 1 or 2 hours while the ACTH stimulation test is being completed. Point-of-care cortisol assays (e.g., SNAP Cortisol, IDEXX Laboratories) may be useful for an initial confirmation of hypoadrenocorticism, but the diagnosis should always be confirmed using a reference laboratory. Dexamethasone does not interfere with the cortisol assay and can be used if glucocorticoid therapy cannot be delayed. The glucocorticoid of choice for treating an acute addisonian crisis is dexamethasone sodium phosphate, given intravenously at an initial dosage of 0.5 to 1 mg/kg and repeated q12h at a dose of 0.05 to 0.1 mg/kg in the IV solution until oral medication can be safely given. Rapid-acting, water-soluble glucocorticoids such as hydrocortisone sodium succinate, hydrocortisone hemisuccinate, hydrocortisone phosphate, and prednisolone sodium succinate may be measured by the cortisol assay, causing falsely increased cortisol results, and should not be administered until after the ACTH stimulation test is completed. We do not routinely use these glucocorticoids for treating acute adrenal insufficiency.

Currently available mineralocorticoid supplements include DOCP (Percorten-V) and fludrocortisone acetate (Florinef). Both are intended as long-term maintenance therapy for primary adrenal insufficiency. Injectable DOCP is the preferred mineralocorticoid for the treatment of a sick dog or cat suspected of having adrenal insufficiency. The drug is initially administered at a dose of 2.2 mg/kg intramuscularly or subcutaneously. IV administration of fluids

and intramuscular administration of DOCP correct electrolyte abnormalities in most hypoadrenal animals within 24 hours. No adverse reactions have been noted to a single injection of DOCP administered to dogs subsequently shown to have normal adrenocortical function. Atrial natriuretic peptide provides natural protection against hypernatremia. Fludrocortisone acetate is also an effective treatment. However, it is available only in tablet form, and most dogs and cats are too ill to receive oral therapy initially.

Most dogs and cats with acute adrenal insufficiency show dramatic clinical and biochemical improvement within 24 to 48 hours. Over the ensuing 2 to 4 days, the animal should be gradually switched from IV fluids to oral water and food. Maintenance mineralocorticoid and glucocorticoid therapy should be initiated. If the animal fails to make this transition smoothly, persistent electrolyte imbalance, insufficient glucocorticoid supplementation, concurrent endocrinopathy (e.g., hypothyroidism), or concurrent illness (most notably renal damage, pancreatitis, or hemorrhagic gastroenteritis resulting from poor perfusion and hypoxia caused by adrenal insufficiency) should be suspected.

MAINTENANCE THERAPY FOR PRIMARY ADRENAL INSUFFICIENCY

Mineralocorticoids and usually glucocorticoids are required for maintenance of the dog or cat with primary adrenal insufficiency. The preferred mineralocorticoid supplementation is injectable DOCP (Percorten-V), which slowly releases the hormone at a rate of 1 mg/day/25 mg suspension. The initial dosage is 2.2 mg/kg body weight, given intramuscularly or subcutaneously every 25 days. Subsequent adjustments are based on results of serum electrolyte concentrations, which are initially measured 12 and 25 days after each of the first two or three DOCP injections. If the dog or cat has hyponatremia or hyperkalemia (or both) on day 12, the next dose should be increased by approximately 10%. If the day 12 electrolyte profile is normal but the day 25 profile is abnormal, the interval between injections should be decreased by 48 hours. DOCP is very effective in normalizing serum electrolyte concentrations. The only adverse reaction is polyuria and polydipsia that improve after reduction of the DOCP dose or frequency of administration. Most dogs (and presumably cats) receiving DOCP also require a low dose of glucocorticoids (prednisone, 0.25 mg/kg q12h initially).

Drawbacks to DOCP include problems with availability and the inconvenience and expense associated with the need to make frequent visits to the veterinarian for the injection. To minimize inconvenience and expense, the client can be taught to give the injection subcutaneously at home. Every third or fourth treatment, the client should bring the dog or cat into the clinic for a complete physical examination, measurement of serum electrolyte concentrations, and administration of DOCP to ensure that problems with administration of DOCP have not developed. Many dogs require much lower doses than the recommended starting dose to achieve normal electrolyte concentrations. Once the dog or cat is healthy and serum electrolyte concentrations are stable, the amount of DOCP administered can be decreased by 10% increments initially, and the frequency of DOCP administration can be shortened to every 21 days to allow lower doses of DOCP to be administered (typically ≈1.5 mg/kg/injection), thereby decreasing the expense of treatment. The goal is to identify the lowest dosage of DOCP that maintains the health of the dog or cat and keeps serum electrolyte concentrations in the reference range.

Fludrocortisone acetate (Florinef) is another commonly used mineralocorticoid supplement. The initial dose is 0.02 mg/kg/day, divided into two doses and administered orally. Subsequent adjustments in the dose are based on serum electrolyte concentrations, which initially are assessed every 1 to 2 weeks. The goal is to reestablish normal serum sodium and potassium concentrations. The dose of fludrocortisone acetate typically must be increased during the first 6 to 18 months of therapy. This increasing need may reflect the continuing destruction of the adrenal cortices. After this time the dose usually plateaus and remains relatively stable.

Major drawbacks to oral therapy with fludrocortisone acetate include the wide range in the doses required to control serum electrolyte concentrations; the development of polyuria, polydipsia, and incontinence in some dogs (presumably caused by the glucocorticoid activity of this drug); resistance to the effects of the drug, which has been observed in some animals; and persistent mild hyperkalemia and hyponatremia in some animals. Ineffectiveness of fludrocortisone acetate should be suspected when clients report that their pet is "just not right" and hyponatremia and hyperkalemia persist despite high dosages of the mineralocorticoid supplement. The concurrent administration of oral salt may help alleviate the electrolyte derangements in dogs and cats in which fludrocortisone acetate by itself is not completely effective. Alternatively, switching to DOCP should be considered.

Glucocorticoid supplementation is initially indicated for all dogs and cats with primary adrenal insufficiency. Prednisone (dogs) and prednisolone (cats) is given at an initial dose of 0.25 mg/kg twice a day orally. Over the ensuing 1 to 2 months the dose and frequency of administration of prednisone or prednisolone should gradually be reduced to the lowest amount given once a day that still prevents signs of hypocortisolism. Approximately 50% and less than 10% of dogs receiving fludrocortisone and DOCP, respectively, ultimately do not require glucocorticoid medication, except during times of stress. All clients should have glucocorticoids available to administer to their dogs and cats in times of stress. Veterinarians should be aware of the increased glucocorticoid requirements of hypoadrenal dogs and cats undergoing surgery or during times of illness with a non–adrenal-related disease. The glucocorticoid dose being administered should be doubled on days when increased stress is anticipated.

The most common reason for persistence of clinical signs despite appropriate treatment is inadequate glucocorticoid supplementation. When healthy and in a nonstressed environment, dogs and cats with adrenal insufficiency typically

require small amounts of prednisone or prednisolone, if any. However, when stressed or ill, these same animals may require large amounts of prednisone or prednisolone (i.e., 0.25-0.5 mg/kg) given twice a day. Failure to provide adequate quantities of glucocorticoids can lead to persistent and worsening lethargy, inappetence, and vomiting. The amount of prednisone or prednisolone required to offset the deleterious effects of stress and illness is variable and unpredictable. Therefore it is always better to err on the high end of the dosage range and then gradually decrease the dosage over the ensuing weeks.

Prognosis

The prognosis in dogs and cats with adrenal insufficiency is usually excellent. The most important factors in determining an animal's long-term response to therapy are client education about the disease and client dedication to treatment. If client–veterinarian communication is good, if frequent rechecks are performed, and if clients are conscientious about carrying out therapy, dogs and cats with adrenal insufficiency can have a normal life expectancy.

ATYPICAL HYPOADRENOCORTICISM

Some dogs with hypoadrenocorticism present to the veterinarian with clinical signs of glucocorticoid deficiency but with serum electrolyte concentrations within the reference range at initial presentation. A deficiency in glucocorticoid but not mineralocorticoid secretion is referred to as *atypical hypoadrenocorticism,* a syndrome identified in up to 30% of dogs with hypothyroidism. Glucocorticoid deficiency may be adrenocortical in origin (primary atypical hypoadrenocorticism; most common) or may result from impaired secretion of ACTH by the pituitary gland (secondary hypoadrenocorticism). Baseline endogenous plasma ACTH concentrations are normal or increased when the primary problem is adrenal in origin and are decreased when the primary problem is pituitary in origin (see Table 50.6). Glucocorticoid but not mineralocorticoid deficiency of adrenal origin may be seen in a dog in the early stages of development of typical primary hypoadrenocorticism with destruction of the zona fasciculata more advanced than destruction of the zona glomerulosa. Mineralocorticoid deficiency and abnormal serum electrolyte concentrations develop weeks to months later. In some dogs and cats glucocorticoid deficiency does not progress to mineralocorticoid deficiency. The cause of this form of hypoadrenocorticism is not known, although drugs such as mitotane, trilostane, and megestrol acetate (cats) are known to play a part.

Glucocorticoid deficiency resulting from pituitary dysfunction is called *secondary hypoadrenocorticism.* Destructive lesions (e.g., neoplasia, inflammation) involving the pituitary gland or hypothalamus and long-term administration of exogenous glucocorticoids are the most common recognized causes of secondary adrenal insufficiency. Adrenocortical atrophy may develop after the injectable, oral, or topical administration of glucocorticoids. Adrenal function usually returns within 2 to 4 weeks after the medication is discontinued, unless long-acting depot forms of glucocorticoids are used.

Glucocorticoid-deficient hypoadrenocorticism is usually identified during the diagnostic evaluation of dogs and cats with chronic, vague gastrointestinal clinical signs such as lethargy, anorexia, vomiting, diarrhea, and weight loss. Results of routine blood and urine tests are typically normal. Diagnosis requires an ACTH stimulation test (see p. 870). Therapy involves the administration of glucocorticoids, as previously described for the treatment of primary hypoadrenocorticism. The exception is secondary adrenal insufficiency induced by the overzealous administration of glucocorticoids, in which case treatment revolves around a gradual reduction in the dose and frequency of administration, with eventual discontinuation of the medication. Dogs and cats with secondary adrenal insufficiency should not have mineralocorticoid deficiency. Periodic measurement of serum electrolytes is advisable because primary glucocorticoid-deficient adrenal insufficiency may progress to mineralocorticoid deficiency weeks to months after glucocorticoid-deficient hypoadrenocorticism is diagnosed.

PHEOCHROMOCYTOMA

Etiology

Pheochromocytoma is a catecholamine-producing tumor derived from the chromaffin cells of the adrenal medulla. Pheochromocytomas are uncommon in dogs and rare in cats. Pheochromocytomas are usually solitary tumors ranging in size from nodules of less than 0.5 cm in diameter to masses greater than 10 cm in diameter. Pheochromocytoma involving both adrenal glands, pheochromocytoma involving one adrenal gland with a functional adrenocortical tumor in the contralateral gland, and pheochromocytoma with concurrent PDH have also been identified in dogs. Pheochromocytomas have an unpredictable growth pattern, ranging from slow to rapid, and infiltration of the phrenicoabdominal vein, caudal vena cava, and surrounding soft tissue structures can occur when the tumor is relatively small (<2.5 cm in maximum width; see Fig. 50.8). In one report, 87% of pheochromocytomas in 38 dogs were greater than 2.5 cm in width, 45% were greater than 5 cm in width, and most (62%) involved the right adrenal gland. Pheochromocytoma should always be considered a malignant tumor in dogs and cats. Distant sites of metastasis include the liver, lung, regional lymph nodes, bone, and CNS. Paragangliomas are tumors arising from chromaffin cells located outside the adrenal medulla, most commonly near the sympathetic ganglia; they are rare in dogs and cats.

Clinical Features

Pheochromocytomas occur most commonly in older dogs and cats, with a median age of 11 years at the time of diagnosis in dogs. There is no apparent sex- or breed-related predisposition.

TABLE 50.5

Clinical Signs and Physical Examination Findings Associated With Pheochromocytoma in Dogs

CLINICAL SIGNS	PHYSICAL EXAMINATION FINDINGS
Intermittent weakness*	No identifiable abnormalities*
Intermittent collapsing episodes*	Panting, tachypnea*
Intermittent panting*	Weakness*
Intermittent tachypnea*	Tachycardia*
Intermittent anxious behavior*	Cardiac arrhythmias
Polyuria, polydipsia	Weak pulses
Lethargy	Pale mucous membranes
Inappetence	Muscle wasting*
Vomiting	Findings from systemic hypertension:
Diarrhea	Nasal hemorrhage
Weight loss	Oral hemorrhage
Abdominal distention	Retinal hemorrhage
Rear limb edema	Retinal detachment
	Lethargy
	Abdominal pain
	Palpable abdominal mass
	Ascites
	Rear limb edema

*Common signs and physical examination findings.

Clinical signs and physical examination findings develop as a result of the space-occupying nature of the tumor and its metastatic lesions, as a result of excessive secretion of catecholamines, or as a result of spontaneous hemorrhage from the tumor into the retroperitoneal cavity (Table 50.5). The most common clinical signs and physical examination abnormalities involve the respiratory, cardiovascular, and musculoskeletal systems and include generalized weakness, anorexia, weight loss, episodic collapse, agitation, nervous behavior, excessive panting, tachypnea, and tachycardia. Excess catecholamine secretion may also cause severe systemic hypertension, resulting in nasal and retinal hemorrhage, retinal detachment, acute blindness and epistaxis. Catecholamine secretion by a pheochromocytoma typically is episodic and random, not sustained. Therefore clinical signs tend to be paroxysmal and usually are not evident at the time the dog is examined; the physical examination often does not provide clues to the presence of a pheochromocytoma because a catecholamine surge usually is not happening at the time the dog is examined. Because clinical signs and physical examination findings are often vague, nonspecific, and easily associated with other disorders, pheochromocytoma often is not considered a possible differential diagnosis until an adrenal mass is identified on abdominal ultrasound.

Diagnosis

Pheochromocytoma should be on the list of differential diagnoses for dogs presenting with clinical signs suggestive of catecholamine excess, dogs with an unexpected adrenal mass identified by abdominal ultrasound, and dogs that develop unexpected problems with systemic hypertension, nasal or retinal hemorrhage, or cardiac arrhythmia during anesthesia. Pheochromocytoma may also be an unexpected or incidental finding at necropsy or may cause sudden collapse and death from a sudden, massive, and sustained release of catecholamines by the tumor.

No consistent abnormalities are identified in the CBC, serum biochemistry panel, or urinalysis that would raise suspicion for pheochromocytoma. Many abnormalities identified in results of routine blood and urine tests are caused by concurrent disorders that are commonly present in dogs with pheochromocytoma or are nonspecific findings affiliated with hypertension. A history of acute or episodic collapse, identification of appropriate respiratory and cardiac abnormalities during physical examination, documentation of systemic hypertension, and identification of an adrenal mass by abdominal ultrasonography are most helpful in establishing a tentative diagnosis of pheochromocytoma. Systemic hypertension may be sustained or episodic. Failure to document systemic hypertension in a dog with appropriate clinical signs does not rule out a diagnosis of pheochromocytoma.

Ultrasound identification of an adrenal mass with a normal-size contralateral adrenal gland is perhaps the most important clue for pheochromocytoma. Pheochromocytoma is one of several differentials for an adrenal mass (Table 50.6; see also the discussion of incidental adrenal mass). Pheochromocytomas cannot be distinguished from other tumors in the adrenal gland on the basis of sonographic appearance, although identification of hypoechoic foci within the tumor is suggestive of pheochromocytoma. Regardless, the primary differential diagnosis for an adrenal mass is ADH. Many of the clinical signs (e.g., panting, weakness) and blood pressure alterations seen in dogs with hyperadrenocorticism (common) are similar to those observed in dogs with pheochromocytoma (uncommon). In addition, both pheochromocytoma and adrenocortical carcinoma invade adjacent structures and cause tumor thrombi in the phrenicoabdominal vein and caudal vena cava. It is important to rule out ADH before focusing on pheochromocytoma in a dog with an adrenal mass.

Measurement of urinary catecholamine concentrations is being used with increased frequency to aid in the diagnosis of pheochromocytomas. Urine normetanephrine-to-creatinine ratios and plasma-free normetanephrine can strengthen the tentative diagnosis of pheochromocytoma, but do not provide a definitive diagnosis. Urine normetanephrine ratio or plasma free-normetanephrine concentrations greater than or equal to four times the upper limit of the reference range increase the probability of a pheochromocytoma to nearly 100%; with smaller increases a pheochromocytoma may or may not be present. Proper sample handling and species specific reference ranges are critical for accurate results and interpretation. The antemortem definitive diagnosis of a pheochromocytoma ultimately

relies on histologic evaluation of the surgically excised adrenal mass.

Treatment

A period of medical therapy intended to reverse the effects of excessive adrenergic stimulation, followed by surgical removal of the tumor, is the treatment of choice for pheochromocytoma. The success of chemotherapy and radiation therapy in humans with pheochromocytoma has been limited, and results of chemotherapy or radiation therapy for the treatment of pheochromocytoma in dogs or cats have not been reported. Mitotane and trilostane are ineffective for tumors arising from the adrenal medulla and are not recommended. Long-term medical therapy is primarily designed to control excessive catecholamine secretion.

Potentially life-threatening complications are common during the perioperative period, especially during induction of anesthesia and manipulation of the tumor during surgery. The most worrisome complications include episodes of acute, severe hypertension (systolic arterial blood pressure > 300 mm Hg), episodes of severe tachycardia (heart rate > 250 beats/min) and arrhythmias, and hemorrhage. Preoperative α-adrenergic blockade using phenoxybenzamine helps control potentially life-threatening fluctuations of blood pressure and heart rate during anesthesia and surgery. The dose and frequency of phenoxybenzamine administration and the duration of therapy required to adequately achieve desired effects have not been defined for dogs. Our current protocol for the management of hypertension in dogs with pheochromocytoma includes preoperative phenoxybenzamine and intraoperative phentolamine. The initial dosage of phenoxybenzamine is 0.5 mg/kg q12h. Unfortunately, many dogs with pheochromocytoma have episodic clinical signs and hypertension, making it difficult to adjust dosage on the basis of improvement in clinical signs and blood pressure. In addition, this dosage is often ineffective in preventing severe hypertension during surgery. Therefore we gradually increase the phenoxybenzamine dosage every 3 to 4 days until clinical signs of hypotension (e.g., lethargy, weakness, syncope), adverse drug reactions (e.g., vomiting), or a maximum dosage of 2 mg/kg q12h is attained. Surgery is recommended 1 to 2 weeks later either by laparotomy or laparoscopic adrenalectomy. The drug should be continued until the time of surgery. Complications may occur despite prior treatment with α-adrenergic blocking drugs; close monitoring of the dog during the perioperative period is critical for a successful outcome after adrenalectomy. (See Suggested Readings for more information on the perioperative and surgical management of dogs with a pheochromocytoma.) In a study by Herrera et al. (2008), the significant prognostic indicators for survival after adrenalectomy for pheochromocytoma included lack of intraoperative arrhythmias, decreased surgical time, younger age, and pretreatment with phenoxybenzamine.

Medical management with α-adrenergic blockade is recommended whenever pheochromocytoma is suspected and

adrenalectomy is not performed. Long-term medical management is designed to control excessive catecholamine secretion, not to lessen the risk of local invasion or metastasis of the tumor. Phenoxybenzamine at an initial dosage of 0.50 mg/kg q12h is recommended. The dose is gradually titrated upward until clinical signs are controlled or clinical signs suggestive of hypotension occur.

Prognosis

The prognosis depends in part on the size of the adrenal mass, the presence of metastasis or local invasion of the tumor into adjacent blood vessels or organs (e.g., kidney), avoidance of perioperative complications if adrenalectomy is performed (i.e., hypertension, cardiac arrhythmias, respiratory distress, and hemorrhage), and the presence and nature of concurrent disease. Surgically excisable tumors carry a guarded to good prognosis. Survival time in our dogs that underwent adrenalectomy and survived the immediate postoperative period ranged from 2 months to longer than 3 years. If metastatic disease is not present, perioperative complications are prevented, and serious concurrent disease is not present, the dog has the potential to live a significantly longer time (i.e., longer than a year). Treatment with an α-adrenergic blocking drug before surgery and the involvement of an experienced anesthesiologist and surgeon with expertise in adrenal surgery help to minimize potentially serious perioperative complications associated with anesthesia and digital manipulation of the tumor. Medically treated dogs can live longer than 1 year from the time of diagnosis if the tumor is relatively small (<3 cm maximum width), vascular invasion is not present, and treatment with an α-adrenergic blocking drug is effective in minimizing the deleterious effects of episodic excessive catecholamine secretion by the tumor. Most dogs die or are euthanized because of complications caused by excessive catecholamine secretion, complications caused by tumor-induced venous thrombosis, or complications caused by invasion of the tumor or its metastases into surrounding organs.

INCIDENTAL ADRENAL MASS

Ultrasonography has become a routine diagnostic tool for the evaluation of soft tissue structures in the abdominal cavity. One consequence of abdominal ultrasonography is the unexpected finding of a seemingly incidental adrenal mass. Recent retrospective studies identified an unexpected adrenal lesion in 4% of 3478 dogs undergoing abdominal ultrasound (Cook et al., 2014) and 9% of 270 dogs undergoing abdominal CT (Baum et al., 2016). Several factors determine the aggressiveness of the diagnostic and therapeutic approach to an adrenal mass, including the severity of concurrent problems, the original reason for performing abdominal ultrasound, the age of the dog or cat, the likelihood that the mass is hormonally active, the likelihood that the mass is a malignant tumor, the size and invasiveness of the mass, and the client's desires and willingness to pursue the problem. The first consideration is to verify an adrenal mass exists by repeating the abdominal ultrasound. An adrenal tumor should be suspected when there is loss of the typical shape of the gland (i.e., the gland looks like a mass) regardless of size, there is asymmetry in shape and size between the affected adrenal gland and the contralateral adrenal gland, or there is infiltration of the mass into the phrenicoabdominal vena, vena cava, or surrounding soft tissues.

A bulbous enlargement or "nodule" of the cranial or caudal pole of an otherwise recognizable adrenal gland is a common finding in older dogs and is often misinterpreted as an adrenal mass or tumor (Fig. 50.20). Bulbous enlargements are typically less than 1.5 cm in maximum width and the contralateral adrenal gland is usually normal in size and shape. A bulbous enlargement is usually not neoplastic or functional (i.e., autonomously secreting a hormone). Histologic examination usually reveals normal tissue, inflammation, granuloma or clinically irrelevant benign tumor (e.g., myelolipoma). Less commonly, cortical tumors and pheochromocytomas in the early stages of development have been identified. If there are no clinical signs or findings on physical examination and routine blood and urine tests do not support a functional adrenal tumor, a conservative approach centered around periodic monitoring with ultrasound, initially at monthly intervals, for changes in size of the nodule and appearance of the adrenal gland is recommended. If the adrenal mass has not changed in size after 3 months, the clinician can increase the time interval between ultrasound evaluations recommended. However, if the adrenal nodule is increasing in size, changing in appearance, compressing or infiltrating surrounding blood vessels or soft tissues, or clinical signs affiliated with an excess of cortisol, catecholamines, or aldosterone develop, adrenalectomy may be warranted.

Adrenalectomy is the treatment of choice if the mass is suspected to be malignant. Unfortunately, it is not easy to determine whether an adrenal mass is neoplastic and malignant or benign before surgical removal and histopathologic evaluation. Guidelines to suggest malignancy include size of the mass, infiltration of the mass into surrounding organs and blood vessels, and identification of additional mass lesions with abdominal ultrasound and thoracic radiographs. The bigger the mass, the more likely it is malignant and the more likely metastasis has occurred, regardless of findings on abdominal ultrasound and thoracic radiographs. Cytologic evaluation of specimens obtained by ultrasound-guided fine-needle aspiration of the adrenal mass may provide guidance regarding malignancy and origin of the mass (i.e., adrenal cortex versus medulla).

An adrenal tumor may secrete a hormone or be nonfunctional. Excessive secretion of cortisol, catecholamines, aldosterone, progesterone, and steroid hormone precursors has been documented in dogs and cats (see Table 50.6). The most common functional adrenal tumors secrete cortisol

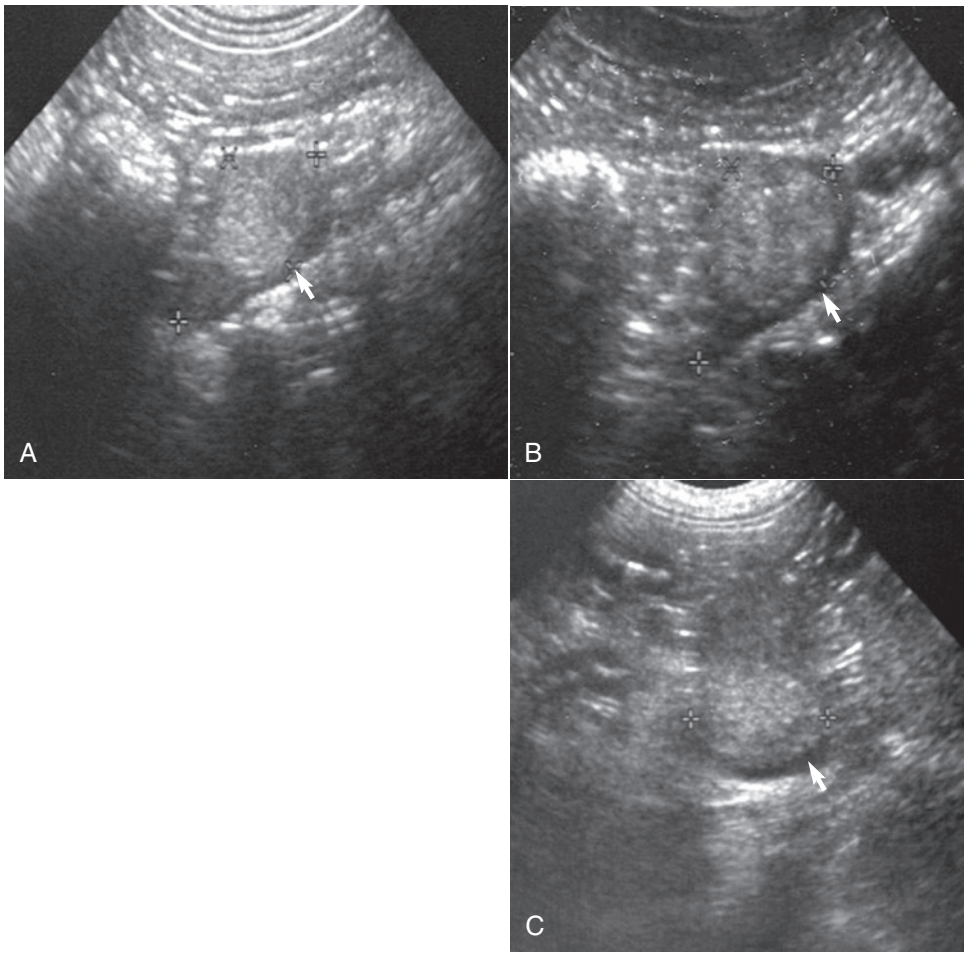

FIG 50.20
(A) An 11-year-old male castrated Doberman Pinscher mix presented for clinical signs consistent with acute gastroenteritis. Abdominal ultrasound identified a 1.4-cm-diameter adrenal mass *(arrow)* and a normal-size contralateral adrenal gland. The history, physical examination findings, and results of routine blood and urine tests were not supportive of adrenal disease, and the dog responded to symptomatic therapy for acute gastroenteritis. The adrenal mass was periodically evaluated with ultrasound. Over the ensuing 2 years, the dog remained healthy, and minimal growth or change was noted in the echogenicity of the adrenal mass. **(B)** The adrenal mass 1 year after presentation; maximum diameter was 1.8 cm. **(C)** The adrenal mass 2 years after presentation; maximum diameter was 2.0 cm.

or catecholamines. Aldosterone-secreting tumors causing primary hyperaldosternism (Conn's syndrome) are more common in cats than dogs. Excessive secretion of aldosterone causes sodium retention and potassium depletion which manifests as increased serum sodium (>155 mEq/L) and decreased serum potassium (<3.0 mEq/L) concentrations. Hypokalemia causes lethargy and weakness which are the most common clinical signs of primary hyperaldosteronism. Hypernatremia causes systemic hypertension. An adrenal mass should be identified on abdominal ultrasound, and the contralateral adrenal gland should be normal in size and shape. An increased baseline plasma aldosterone concentration is documented and used to establish the diagnosis.

Progesterone-secreting adrenal tumors are identified most commonly in cats. Excessive progesterone secretion in affected cats causes diabetes mellitus and feline fragile skin syndrome (Fig. 50.21). Clinical features mimic feline hyperadrenocorticism. Results of tests of the pituitary adrenocortical axis are normal to suppressed in cats with a progesterone-secreting adrenal tumor. Diagnosis requires documentation of an increased plasma progesterone concentration.

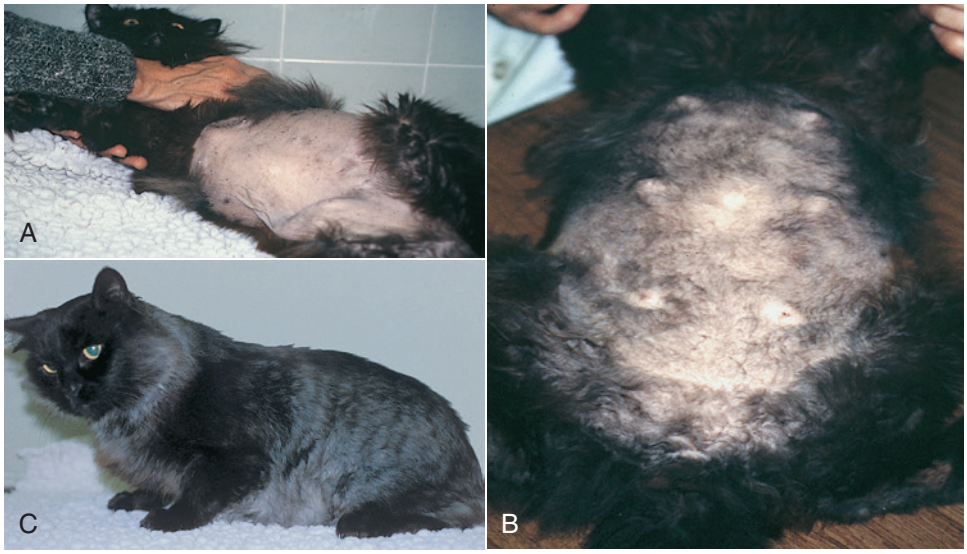

FIG 50.21
(A) A 9-year-old male castrated domestic long-haired cat with a 2-year history of poorly controlled diabetes mellitus, failure of hair to regrow after clipping 1 year before presentation, and recent development of feline fragile skin syndrome. Diagnostic evaluation revealed an adrenocortical tumor, increased serum progesterone concentration, and suppression of the pituitary-adrenocortical axis on adrenocorticotropic hormone stimulation and dexamethasone suppression testing. A progesterone-secreting adrenocortical tumor was suspected. **(B)** Five weeks after initiation of treatment with aminoglutethimide. Feline fragile skin syndrome was resolving, hair was growing, and gynecomastia had developed. The serum progesterone concentration had decreased from a pretreatment value of 4.7 ng/mL to less than 1 ng/mL. **(C)** Four months after adrenalectomy. Insulin-requiring diabetes mellitus had resolved.

Drugs Used in Endocrine Disorders

GENERIC NAME (TRADE NAME)	PURPOSE	RECOMMENDED DOSAGE	
		DOG	CAT
Calcium—injectable and oral preps	Treat hypocalcemia, Treat hypoparathyroidism	See Box 53.7	See Box 53.7
Carbimazole (Neo-Mercazole)	Treat feline hyperthyroidism	NA	2.5-5 mg PO q12h initially; increase q2wk to effect
Chlorpropamide (Diabinase)	Treat partial central diabetes insipidus	5-20 mg/kg PO q12h	Unknown
Chlorothiazide (Diuril)	Treat central/renal diabetes insipidus	20-40 mg/kg PO q12h	20-40 mg/kg PO q12h
Desmopressin (DDAVP)	Treat central diabetes insipidus	1-4 drops of nasal spray in conjunctival sac q12-24h; tablets: 0.05-0.2 mg/dog PO q8-12h	1-4 drops of nasal spray in conjunctival sac q12-24h; tablets: 0.05 mg/cat PO q8-12h
Desoxycorticosterone pivalate (DOCP)	Treat hypoadrenocorticism	2.2 mg/kg, IM or SC, q25d initially	2.2 mg/kg, IM or SC, q25d initially
Dexamethasone sodium phosphate	Treat acute addisonian crisis	0.5-1 mg/kg IV, repeat q12h at 0.05-0.1 mg/kg in IV fluids	0.5-1 mg/kg IV, repeat q12h at 0.05-0.1 mg/kg in IV fluids
Diazoxide (Proglycem)	Treat hypoglycemia caused by β-cell neoplasia	5 mg/kg PO q12h initially	Unknown
Fludrocortisone acetate (Florinef)	Treat hypoadrenocorticism	0.01 mg/kg PO q12h initially	0.05-0.1 mg/cat PO
Glucagon USP	Treat hypoglycemia caused by a β-cell neoplasia	5-10 ng/kg/min as continuous IV infusion; adjust dose to effect	Unknown
Growth hormone—porcine origin	Treat pituitary dwarfism	0.1 IU/kg SC 3 times/wk for 4-6 weeks	Unknown
Insulin	Treat diabetic ketoacidosis Treat diabetes mellitus Provide supportive treatment for hyperkalemia	See Box 49.11 See Table 49.3 See Table 53.3	See Box 49.11 See Table 49.3 See Table 53.3
Ketoconazole (Nizoral	Treat hyperadrenocorticism	5 mg/kg PO q12h initially, increase to effect q2wk	Not recommended
Melatonin	Treat alopecia X syndrome	3 mg (dogs ≤ 15 kg) or 6 mg (dogs >15 kg) PO q12h for 6-8 weeks initially	NA
Methimazole (Felimazole)	Treat hyperthyroidism	2.5 mg/dog PO q12h initially; increase q2wk to effect	2.5 mg/cat PO q12h initially; increase q2wk to effect
o,p'DDD (Mitotane, Lysodren)	Treat canine hyperadrenocorticism Long-term treatment of hypoadrenocorticism	Induction: 25 mg/kg PO q12h until controlled Maintenance: 25-50 mg/kg PO per week initially divided into 2 or 3 doses	Not recommended
Phenoxybenzamine (Dibenzyline)	Supportive treatment forpheochromocytoma	0.5 mg/kg PO q12h initially, gradually increase to effect	Unknown

CHAPTER 51

Weight Loss and Obesity

POLYPHAGIA WITH WEIGHT LOSS

In some dogs and cats, polyphagia with concurrent weight loss is the presenting complaint. The most common cause of polyphagia with concurrent weight loss is inadequate caloric intake (Table 51.1). Although this seems obvious, some owners are surprisingly unaware of appropriate feeding amounts and unintentionally underfeed their pets. Daily caloric needs may not be met if inadequate quantities of food are being fed, if the diet is not complete and balanced, or if the diet is of poor quality. Alternatively, the client may not recognize changes in nutritional needs (e.g., during late pregnancy and lactation, and at times of strenuous exercise, such as during hunting season) and may continue to feed the animal at previously adequate caloric levels. Likewise, the owner may switch diets and continue to feed the same volumes despite a lower energy density in the new food.

Endocrinopathies and gastrointestinal tract disorders also cause polyphagia and weight loss in some dogs and cats (see Table 51.1) as a result of an increase in basal metabolic rate (hyperthyroidism), inadequate assimilation of dietary nutrients (gastrointestinal tract disorders), or inappropriate use of nutrients (diabetes mellitus). Gastrointestinal tract disorders include parasitism, pancreatic exocrine insufficiency, infiltrative bowel disorders, lymphangiectasia, and neoplasia (most notably gastrointestinal lymphoma). In most cases the history and physical findings usually provide valuable clues to the diagnosis. For example, polyuria and polydipsia are common signs of diabetes mellitus. A thyroid nodule is usually palpable in dogs and cats with hyperthyroidism. Fatty, voluminous stools are noted in animals with pancreatic exocrine insufficiency. Diarrhea and vomiting may occur in animals with various gastrointestinal tract disorders, and palpation of the abdomen may reveal abnormal loops of intestine and mesenteric lymphadenopathy. The last condition may be discernible in animals with any of the infiltrative diseases, but it is especially noticeable in those with gastrointestinal tract lymphoma, eosinophilic enteritis, or histoplasmosis.

In addition to routine medical history and status questions posed to the client, the clinician should perform a nutritional assessment including a diet history (types and amounts of foods offered; total daily caloric intake from foods, treats, and supplements; feeding routines; and competition for food from other dogs or cats). Daily caloric requirements in individual cats and dogs are quite variable and depend on numerous factors, such as signalment, climate, and the amount of daily physical activity. The average daily caloric requirement can be calculated using the equation for the resting energy requirement (RER): 70 × body weight in kilograms$^{0.75}$. Although most people have ready access to computers and smart phones, this can also be calculated on a simple calculator with a square root button. To determine RER, the current body weight in kilograms is multiplied by itself three times, and the square root of the result is taken twice before multiplying by 70. This value for RER has a unit of kcal per day and is multiplied by a factor to derive the maintenance energy requirement (MER). The factor for a neutered cat is 1.2, an intact cat's factor is 1.4, a neutered dog's factor is 1.6, and an intact dog's is 1.8. The daily caloric requirements in any individual dog or cat may vary by as much as 50% more or less than this estimated value. Although this represents a large range for normal caloric intake, the clinician may have a greater suspicion that an inadequate amount of calories is being fed if a confident estimate of intake can be determined from the diet history, and if this amount is closer to 50% of MER. Similarly, consumption of calories closer to 150% of MER may increase the suspicion that adequate calories are being fed but that an endocrinopathy and/or gastrointestinal tract disorder may be leading to polyphagia with concurrent weight loss. It is important to note that adjustment and monitoring is the most valuable procedure for determining an individual's true calorie needs. If comparison of the actual caloric intake with

TABLE 51.1

Differential Diagnosis for Polyphagia and Weight Loss

ETIOLOGY	DEFINITIVE DIAGNOSTIC TESTS
Inadequate nutrition	Response to diet change and/or increased amounts
Hyperthyroidism	Serum T_4 and free T_4 concentrations
Diabetes mellitus	Blood glucose concentration and urinalysis
Gastrointestinal Disease	
Parasitism	Fecal examination, trial therapy
Infiltrative bowel disease: plasmacytic, lymphocytic, eosinophilic, lymphoma	Intestinal biopsy
Histoplasmosis	Intestinal biopsy, serology
Lymphangiectasia	Intestinal biopsy
Pancreatic exocrine insufficiency	Serum trypsin-like immunoreactivity, response to therapy
Protein-losing nephropathy	Urinalysis, urine protein/creatinine ratio
Hypothalamic mass	Computed tomography, magnetic resonance imaging

the calculated MER prove equivocal or cannot be attained, simply feeding more food or calories and reassessing the patient's weight may be illuminative.

A complete blood count, serum biochemistry panel, measurement of baseline thyroxine concentration, urinalysis, and fecal examination for parasites should be done if the history and physical findings are unremarkable. Results of these tests usually help identify additional specific diagnostic tests that may be required to establish a definitive diagnosis. Inadequate nutrition should be suspected if the diagnostic testing is unremarkable and especially in the face of adequate or increased appetite. Changes in the types of foods provided, daily caloric intake, and feeding routine should be made to ensure that the animal has an adequate caloric intake of a palatable and nutritionally complete and balanced food. Carefully questioning the owner regarding the feeding environment can also be important, as often subtle food guarding behaviors can be exhibited by both dogs and cats. The animal's body weight should be determined 2 and 4 weeks after the start of an appropriate diet. Resolution of signs and weight gain confirm the diagnosis. Failure to gain weight indicates problems with client compliance or the presence of occult disease, most likely disease involving the gastrointestinal tract.

BOX 51.1

Documented Potential Adverse Effects of Obesity

Decreased life span
Exacerbation of orthopedic disease, including osteoarthritis and intervertebral disk disease
Cardiopulmonary dysfunction—impaired lung compliance, Pickwickian syndrome
Exercise intolerance, heat intolerance
Insulin resistance and predisposition for diabetes mellitus
Hyperlipidemia
Hepatic lipidosis
Predisposition for pancreatitis
Problems with constipation
Predisposition for feline lower urinary tract disease
Predisposition for urinary incontinence in spayed female dogs
Predisposition for reproductive problems—dystocia
Predisposition for dermatologic problems—seborrhea, pyoderma
Increased surgical and anesthetic risk

OBESITY

Obesity is a clinical syndrome defined by the excess accumulation of body fat and its consequences. It is defined, as in people, as a body weight approximately 25% over ideal. Obesity is considered the most common form of malnutrition in small animal practice. Indeed, studies have shown that up to 59% of dogs and 63% of cats in various populations are diagnosed with overweight or obesity. The significance of obesity pertains to its role in the pathogenesis of a variety of diseases and its ability to exacerbate preexisting disease and decrease life span. Obesity has been associated with an increased incidence of osteoarthritis and other orthopedic disease, diabetes mellitus, hyperlipidemia, hepatic lipidosis, feline lower urinary tract disease (FLUTD), urine incontinence in spayed bitches, constipation, non-allergic dermatitis, cardiopulmonary dysfunction, respiratory problems, and increased anesthetic and surgical risks (Box 51.1). In addition, Scarlett et al. (1998) found a threefold increase in risk of death in obese middle-aged cats compared with the risk in lean middle-aged cats. Kealy et al. (2002) found that dogs that were kept lean throughout their life lived almost 2 years longer than control-group litter mates that were overweight. The lean dogs also did not need treatment for co-morbidities such as osteoarthritis until later in life.

Etiology

Obesity develops when daily energy intake consistently exceeds daily energy expenditure. Numerous animal and

owner factors contribute to the development of obesity (Box 51.2). These include decreased daily exercise as a result of confinement to the house and overfeeding of the pet. Clients may overfeed their pet because a good appetite is perceived as a sign of good health, they may use food as a palliative agent when they leave the pet on its own, they may replace exercise with food, and they often indulge begging behavior because they find it endearing. Clients also tend to feed the same volume of food each day despite changes in energy requirements and the energy density of foods provided. Daily energy requirements vary according to environmental temperature, the life stage of the pet (i.e., growth, pregnancy, lactation, adult maintenance, old age), neuter status, and the activity level of the pet. Therefore it is necessary to adjust the amount of food according to these factors. Feeding errors also arise when a client purchases a different type of food with a higher energy density but does not reduce the amount accordingly. It is worth noting that dry extruded foods (kibble) can range widely from approximately 200 kcal to more than 600 kcal per cup per 8-fluid ounce cup. Overfeeding may also occur if the feeding guidelines provided by pet food manufacturers are incorrect or not accurate for the individual pet. In some situations, clients are simply not aware that they are overfeeding their pet and actually perceive their overweight pet as picky or as not eating much food. Ad libitum feeding may also predispose to overeating, particularly if the pet is bored and inactive, or if there is inter-pet competition in the household. Likewise, highly palatable foods encourage overconsumption. Snacks and treats are a significant but often unappreciated contributor to excess daily caloric intake as well. It takes only about 11 extra kcal a day for a pet to gain 1 pound over the course of a year; many common treats provide between 50 and 100 extra kcal apiece.

Obese or older clients may be more likely to have obese dogs; similar findings have not been documented in cats. The client's sedentary lifestyle may contribute to lack of exercise by the pet, and the consumption of high-fat foods by the client may increase the likelihood that these energy-dense scraps are fed to the pet. In addition, it is possible that obese clients do not believe (or recognize) that obesity is a major problem for their pet. Underestimation of the pet's body condition score (BCS) is also associated with overweight and obesity in both dogs and cats; owner education of appropriate body composition may be important in prevention of obesity.

Because of genetic differences, some animals have significantly lower energy requirements and therefore require fewer calories per day to maintain their ideal body weight. Likewise, many working or sporting breeds have higher requirements for exercise, which is often not satisfied in most urban and suburban environments. In addition, some breeds tend to be more interested in food as a primary motivator for various food-seeking and consumptive behaviors. These genetic differences may be reflected by the increased propensity of certain breeds to gain excessive weight (Box 51.3).

Neutering is an important risk factor for obesity in both dogs and cats. It has been suggested that hormonal alterations secondary to neutering may alter energy expenditure,

BOX 51.2

Factors Associated with Obesity in Cats and Dogs

Primary Obesity

Excess caloric intake
- Energy-dense food
- Inappropriate feeding practices
- Inadequate feeding guidelines
- Ad libitum feeding

Reduced energy expenditure (exercise, activity)
Growth rate
Age
Neuter status
Owner income, age, and body composition
Underestimation of pet's body composition
Genetic predisposition (breed)

Secondary Obesity

Hypothyroidism
Hyperadrenocorticism
Hyperinsulinism
Acromegaly
Hypopituitarism
Hypothalamic dysfunction
Medications
- Glucocorticoids
- Progestagens
- Phenobarbital
- Primidone

but disruptions in the regulation of food intake appears to be the most important effect. This apparently occurs rapidly, and increased food intake occurs almost immediately after neutering. Obesity has been reported to be more common in female neutered dogs and male neutered cats, and greater gains are seen with free-feeding. As such, portion control is critically important to avoid weight gain after neutering.

Obesity is less likely to result from a disease process or drug. Indeed, it has been suggested that less than 5% of obesity is due to a disease or drug. Endocrine abnormalities associated with obesity include hypothyroidism, hyperadrenocorticism, hyperinsulinism, and acromegaly. Drugs such as progestagens and corticosteroids have been associated with the development of obesity.

Diagnosis

Obesity is defined as a "pathological condition characterized by an accumulation of fat much in excess of that required for optimal body function" (Mayer, 1973). However, what is an excess amount of body fat, and what is an acceptable amount? To answer these questions, the clinician must accurately determine the amount of body fat. Body fat can be assessed by techniques such as morphometric measurements, dilutional methods, bioelectrical impedance analysis, dual energy X-ray absorptiometry (DEXA), densitometry, computed tomography, magnetic resonance imaging, determination of total body electrical conductivity, determination of total body potassium, neutron activation analysis, and morphometric measurements. Although numerous methods may be used to determine body fat, the most clinically useful techniques in small animal practice include measurement of body weight and determination of a BCS.

Measurement of body weight is a standardized, simple technique and should be included in the examination of every animal. However, body weight does not provide information regarding body composition, so additional assessments are necessary. Consideration of the potential contribution to absolute body weight of excessive adipose, decreased muscle mass, and fluid accumulation may be warranted in many cases.

Body condition scoring provides a quick and simple subjective assessment of the animal's body condition based on estimates of stored body fat (adipose tissue). It does not include assessment of lean body mass, and muscle condition scoring systems are distinct from BCS systems. The two most commonly used BCS systems in small animal practice include a 5-point system in which a score of 3 is considered ideal, and a 9-point system in which a score of 5 is considered ideal for cats and 4 or 5 is considered ideal for dogs (Figs. 51.1 and 51.2). Larger numbers are used for patients with greater adiposity. Each point above ideal on the 9-point system approximates a body weight 10% to 15% over ideal. Thus a feline patient that has a BCS of 7 out of 9 is 20% to 30% overweight as a result of the accumulation of adipose tissue. The BCS technique is subjective as it depends on operator interpretation and does not provide any precise quantitative information concerning alteration in fat-free or lean body mass relative to fat mass.

Height and circumferential measurements of the abdomen, hip, thigh, and upper arm are commonly used to estimate the percentage of body fat in humans. Body (morphometric) measurements have also been developed to estimate the percentage of body fat in dogs and cats. These tools have been promoted as one way to estimate ideal body weight to provide guidance for determining the amount to feed for weight loss plans. However, successful weight loss plans utilizing morphometric measurements to estimate ideal body weight have not been reported in the literature. Studies have demonstrated that proportion of body fat as estimated using BCS systems correlates well with that determined by DEXA measurements in both dogs and cats. However, marked individual variability was reported when using a 5-point BCS system to estimate ideal body weight in dogs (German et al., 2009). Very few clinical settings can access more precise and validated measures of body composition to more accurately estimate ideal body weight (such as DEXA). Regardless, providing an approximate quantitative assessment of a patient's degree of adiposity can be helpful in diagnosing obesity even if not exact (using either morphometric measurements or BCS or both). Ultimately, focusing the owner on the process rather than the end goal may be warranted, given that measurable benefits are seen with weight loss even before the target ideal body weight is achieved.

Treatment

After diagnosing a patient as overweight or obese, the clinician should obtain a thorough dietary history to calculate the patient's daily caloric intake. The clinician should gather the following information:

- Name, manufacturer, and type (i.e., wet versus dry, etc.) of the current food(s)
- Amount of food that is fed each day (pouches, cans, cups, or grams of food)
- Method of feeding (ad libitum versus meal fed)
- Person responsible for feeding the pet
- Additional persons who may feed the patient (children, elderly parents, or neighbors)
- Number and types of snacks, treats, or human foods given each day
- Type and amount of any supplements given each day
- Potential access to other foods (for other pets, from the garden, etc.)

The patient's current body weight should be recorded and a BCS assigned. Body weight trends should be considered as well (is the patient gaining, stable, or losing). The BCS can be used to determine the percentage of body weight that must be lost. Because each point above ideal on a 9-point scale represents an additional 10% to 15% of weight over ideal, the clinician can calculate the percentage of weight that should be lost. For example, an otherwise healthy feline

FIG 51.1

patient that has a BCS of 8 out of 9 is 30% to 45% overweight given an ideal BCS of 5. Likewise, a dog with orthopedic disease and a BCS of 7 is also 30% to 45% overweight because ideal BCS is 4 in that case. The goal rate of loss is 1% to 2% of their body weight per week. Therefore it should be expected that most overweight and obese patients will take at least several months to lose enough adipose tissue to attain their ideal body weight. Given the necessary length of time and the importance of owner persistence and compliance, it is imperative to emphasize the process goals rather than the ultimate goal of an ideal body weight. These shorter-term goals (1%-2% body weight loss per week) are typically more manageable and more motivating, and they provide additional opportunities for adjustment of the weight loss plan if needed.

The rate of weight loss of 1% to 2% of current body weight per week is typically recommended for several reasons. First, greater rates of weight loss will require that the patient receive a very small allowance of food, which is more likely to encourage begging behavior and garbage scavenging. These undesirable behaviors, along with the small volume of food to be provided, can jeopardize client compliance. Second, weight loss greater than 2% of body weight per week has been associated with greater losses of lean body mass. Third, rapid weight loss is most likely to result in a rebound weight gain effect after cessation of the program.

Given the large variation in energy requirements that can be seen in cats and dogs, the best method to determine the number of calories that one should feed a patient to induce weight loss is the use of an accurate diet history. Typically, the weight of overweight and obese patients is relatively stable at presentation; therefore feeding 80% of the patient's current caloric intake based on an accurate diet history results in weight loss at an appropriate rate. In patients in which an accurate diet history cannot be determined or that are roughly weight-stable or losing, the client may start with feeding 80% of RER for cats and RER for dogs; if the pet is gaining weight, more severe restriction is warranted. Regardless of the method used to determine the number of calories that should be fed to initiate weight loss, clients should be

FIG 51.2

told to expect to adjust the amount of food on the basis of frequent weigh-ins. Initially, some patients gain weight on the new weight loss plan, some stay weight-stable, some lose the desired amount, and some may even lose weight too quickly.

After determining the daily number of calories to feed the patient, the clinician should consider the most suitable type of food. There are essentially two main dietary options: (1) feed a reduced amount of the current diet (typically a regular maintenance food), or (2) feed a food that has been specifically formulated for weight reduction. It is not advisable to feed less of the current diet because this most likely was the food that resulted in the problem in the first place, and compliance over the long term is less likely due to habit as well as reluctance to feed low food volumes. More important, feeding a maintenance food may increase the risk of nutrient deficiency, because these are formulated for animals with normal body composition and average calorie needs. This means that if a normal dog or cat eats its daily energy requirement, it will also consume the required quantities of additional essential nutrients, such as amino acids, fatty acids, minerals, and vitamins. By feeding less of the maintenance food to induce weight loss in an obese pet, not only is the amount of energy being reduced below requirements but also the quantities of amino acids, fatty acids, minerals, and vitamins, thereby risking malnutrition, especially given the length of time often needed to achieve an ideal body condition. Conversely, diets that have been specifically formulated for weight reduction contain more essential nutrients relative to the energy content. This means that the patient is more likely to ingest the required quantities of essential nutrients even in fewer calories.

Most foods designed for weight reduction are one half to two thirds less energy-dense than typical maintenance foods. Therefore clients will not visually perceive as much of a decrease in volume when a food designed for weight reduction is used. Decreased energy density on a volume basis is achieved by decreasing the fat content of food, modifying kibble size and shape to reduce "packing" together in a cup or bowl, increasing the moisture content of wet foods, and/or increasing fiber concentration. Some of these strategies are directed at owner perceptions of volume, but others aim

to achieve a filling effect for the pet (fiber, moisture); surprisingly, even air-puffed kibble showed a satiety effect in one study of dogs, possibly by slowing food intake.

Veterinary therapeutic diets formulated specifically for weight reduction in dogs and cats typically vary according to energy density and caloric distribution (Tables 51.2 and 51.3); however, most are less energy-dense than maintenance foods. This enables greater filling of both the bowl and the bowel, which is a strategy targeted to increased compliance and satiety. Most weight reduction diets are high in fiber, as fiber is used as a bulking agent to dilute the calories as well as to provide a satiating effect. However, conflicting research findings have led to uncertainty about whether fiber reliably increases satiety. Because some patients may not respond well to higher-fiber foods, a few diets do not use this nutritional strategy, especially those formulated for cats.

Higher-protein diets not only ensure adequate amino acid intake despite caloric restriction but also help increase the proportion of fat loss while preserving or, indeed, increasing lean body mass during weight reduction. The lean body mass is the most metabolically active portion of the body and includes skeletal muscle tissues. Preservation of lean body mass in humans has been shown to facilitate successful long-term maintenance of ideal body weight after successful weight loss. Lower fat diets that provide a reduced percentage of calories from fat help reduce the energy density of the food because fat provides almost 2.5 times the calories per gram as provided by protein or carbohydrate. This is one drawback of the lower-carbohydrate diet options designed for weight reduction in cats, as they are often higher in fat; their increased energy density means that a small volume is needed to achieve the required degree of restriction, which may not be acceptable to the owner or the pet.

Once the daily caloric intake has been determined and appropriate weight reduction diet chosen, the method of feeding should be decided. Ideally, the patient should receive portion-controlled meals rather than be fed ad libitum. The number of feedings per day can be selected to suit the client's schedule, but two to four meals per day is adequate. One member of the household should be selected to feed the pet. This will reduce inadvertent overfeeding by additional family members. If treats are typically fed or are desired, the client

should be instructed to limit the number of treats to less than 10% of the daily caloric intake. Ideally, low-calorie treats should be selected. Commercial treats are available, but high-moisture, low-energy-density fruits (excluding grapes or raisins) and/or vegetables (no garlic or onions) can be good alternatives for dogs and even some cats. Baby carrots are an especially good vegetable treat for most dogs and provide only 4 kcal each. A small amount of lean meat, such as skinless, boneless chicken breast, can be a good alternative treat for cats. It is also important to modify the behavior of the client in such a way that the pet should not be allowed in the kitchen or dining room during meal preparation or eating, if this is typically a tempting time to respond to begging. In addition, the client should inform and enlist the support of all family members and neighbors so that they do not unknowingly give the pet additional calories. In some cases it may be useful for the client to use a food diary to record the amount of food and snacks fed each day.

Multicat households in which one cat is obese and the remainder are of normal body weight or are lean can present some management challenges. Ideally, cats should be fed in separate rooms, but this is not always possible. If this works for the family, most cats can consume their caloric needs if given at least 4 hours of access to their food daily. Thus the time that cats are separated can be minimized. Moreover, fat cats usually cannot jump very high, and it may be a useful strategy to place the food for the lean, healthy cats on an elevated bench or counter that the healthy cats can reach but the obese cat cannot. Alternatively, a hole can be cut into a cardboard box that is large enough to allow the lean cats to enter but small enough to restrict the entry of the overweight or obese cat. The lean cats are then fed in the box. Other options include boxes or pet doors controlled by collars that allow access to only one cat.

In addition to reducing daily caloric intake, every effort should be made to increase the pet's daily energy expenditure by encouraging exercise. Toys that the cat or dog can chase and play with should be encouraged. Laser pointers are particularly useful for encouraging cats to play. Ideally, dogs should receive at least two 20-minute walks per day, which include adequate sniffing opportunities; this is an important and enriching activity for dogs. Swimming is an equally effective exercise, particularly for dogs with osteoarthritis. Providing the client with written instructions for weight loss as well as scheduled rechecks will typically improve both compliance and success. Photographing the patient before institution of the weight reduction program will help clients see the effect of the weight loss on their pet. Institution of reward boards or incentive programs will also increase compliance with the weight reduction program and will help to recruit additional patients in need of weight reduction.

Patients on weight reduction programs should be reevaluated every 2 weeks initially. Body weight and BCS should be recorded. The dietary history should be reviewed to ensure compliance. Cats especially should achieve no more than a 2% body weight loss per week due to the risk of hepatic lipidosis. Dogs should achieve a weight loss rate of approximately 1% body weight loss per week (a range of 0.5%-2% is acceptable). If the rate of weight loss exceeds a 2% body weight loss per week, then the quantity of calories fed to the patient should be increased by 10% to 20%, depending on how rapidly they have lost weight. If the patient has not lost any weight, the dietary history should be reevaluated for a source of additional calories and compliance with the weight loss plan confirmed. If no such reasons are found, the daily caloric intake should be further reduced by 20%. If weight loss is being maintained at the current rate, weight checks can be performed monthly.

Once the ideal body condition has been achieved, the daily caloric intake can be adjusted to maintain an ideal body condition. The patient's weight loss diet can be maintained, or a diet with lower energy density than initially fed can be tried. Maintenance diets that are intended for weight control are widely available. Continued guidance on appropriate amounts to feed as well as types and amounts of treats should be provided. The patient should be reevaluated initially after 2 to 3 weeks, then at least every 2 to 3 months after weight loss to ensure that weight stability is maintained and that the patient is not gaining weight on its new diet regimen. Currently, medications or effective nutraceuticals for facilitating weight loss in dogs and cats are not available. Chronic energy restriction together with appropriate owner education and ideally increased activity and exercise to increase energy expenditure remain the standard strategies for achieving successful weight loss.

Prevention

Ideally, clinicians should focus more on obesity prevention than on treatment because treatment can be very challenging. Because increased food intake and overconsumption of energy resulting in the development of obesity occurs soon after gonadectomy, prevention should begin at the time that the pet is neutered. Clients should be counseled about the risk factors of obesity (e.g., male neutered cats, female neutered dogs, inactive and indoor lifestyle, free-feeding, energy-dense foods) and the consequences of obesity (e.g., increased incidence of lower urinary tract disease, diabetes mellitus, arthritis, decreased life span). It is important that clients be instructed how to properly feed their pet and how to regularly determine the pet's body condition such that they can maintain the ideal body condition of their pet. Weight education should be reinforced at least annually during the health examination.

CHAPTER 52

Hyperlipidemia

HYPERLIPIDEMIA

Hyperlipidemia is defined as increased blood concentrations of triglycerides (hypertriglyceridemia), cholesterol (hypercholesterolemia), or both. In the fasted state (>10 hours without food), hyperlipidemia is an abnormal finding that represents accelerated production or delayed degradation of circulating lipoproteins. The lipoproteins function as a carrier system to transport water-insoluble triglycerides and cholesterol through the aqueous environment of the blood. Lipoproteins consist of a core of triglycerides and cholesterol esters surrounded by a surface layer of cholesterol, phospholipid, and apolipoproteins. The apolipoproteins (A, B, C, and E) are responsible for the structure of the lipoprotein particle, binding of the particle to cell surface receptors, and activation of enzymes. There are four major classes of lipoproteins, each differing in lipid and apoprotein content as well as physicochemical characteristics such as size, buoyant density on ultracentrifugation, and electrophoretic mobility. In order of increasing density, lipoproteins are categorized as chylomicrons, very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), or high-density lipoproteins (HDLs). The density is inversely proportional to the triglyceride content such that chylomicrons are composed largely of triglyceride, whereas HDLs have virtually no triglyceride content. It should be understood that other significant structural and functional heterogeneity exists within the classes. In addition, the system is a dynamic and progressive one, with one class becoming another during its metabolism. Chylomicrons and VLDLs are primarily involved in triglyceride metabolism, whereas HDLs and LDLs are primarily involved in cholesterol metabolism. Dogs and cats are more resistant to the development of atherosclerosis than humans because HDLs predominate in dogs and cats, as opposed to the LDLs that predominate in humans. There may also be effects related to typical life span because although atherosclerosis is slowly progressive and may begin in childhood, it typically only becomes of concern in humans when they are much older than the longest-lived dogs and cats.

Pathophysiology

After digestion and absorption occur, dietary cholesterol and triglyceride are packaged by the enterocyte into chylomicron particles. The chylomicron particles are secreted into the mesenteric lymph, through which they ultimately reach the systemic circulation via the thoracic duct. As the chylomicrons pass through adipose and muscle tissue, they are exposed to lipoprotein lipase, an enzyme that is present on the surface of capillary endothelial cells. After activation by apoprotein C-II, lipoprotein lipase hydrolyzes the triglyceride from the core of the lipoprotein to free fatty acids and glycerol. The activity of lipoprotein lipase is influenced by several factors including heparin, insulin, glucagon, and thyroid hormone. The liberated free fatty acids diffuse into adjacent tissue and may be resynthesized into triglycerides and stored (in adipocytes) or used for energy by the cell (by myocytes and other cells). Depletion of the triglyceride component of the chylomicron alters the surface such that the chylomicron is converted into a chylomicron remnant. The remnant particle is rapidly recognized by specific hepatic receptors and removed from the circulation. Within the hepatocyte the contents of the chylomicron remnant are degraded. Chylomicrons are present in plasma 30 minutes to 2 hours after consumption of a fat-containing meal, and hydrolysis is normally complete within 6 to 10 hours.

Excess free fatty acids that are not directly oxidized for energy are transformed into triglycerides by the liver. These free fatty acids may originate from residual dietary triglyceride present in chylomicron remnants, from endogenous production secondary to surplus dietary carbohydrate, and from excessive endogenous mobilization of free fatty acids. Free fatty acids can be mobilized from adipose tissue by activation of the intracellular enzyme hormone-sensitive lipase (HSL). HSL hydrolyzes stored triglycerides into free fatty acids and glycerol. Activation of HSL is a normal physiologic response that provides the body with energy during periods of fasting. Stimulators of HSL include epinephrine, norepinephrine, adrenocorticotropic hormone (ACTH), corticosteroids, growth hormone, and thyroid hormone. Of course, HSL is also activated by insulin deficiency during

normal fasting or in diabetes mellitus. In addition, HSL can be inappropriately activated in several pathologic conditions associated with an altered metabolic state.

The triglycerides produced by the hepatocyte are packaged into VLDL particles and subsequently secreted into the bloodstream. VLDL particles are produced continuously by the liver and, in the fasting state, are the main carriers of triglycerides. In addition, VLDL particles are used to export cholesterol from the liver and therefore contain a significant proportion of cholesterol. Analogous to chylomicron metabolism, endothelial lipoprotein lipase hydrolyzes the triglyceride portion of the VLDL particle into free fatty acids and glycerol. The free fatty acids can be oxidized for energy or reconstituted into triglycerides and stored. Removal of the triglyceride core converts the VLDL particle into a remnant particle, which may be removed and catabolized by the liver. Alternatively, a second endothelial lipase, hepatic lipase, can further remove any residual triglyceride and convert the VLDL remnant particle to an LDL particle.

The LDL particle is a cholesterol and phospholipid–rich entity that functions to transport cholesterol to tissues, where it may be used for membrane synthesis or steroid hormone production. Ultimately, the LDL particle can bind to LDL receptors and is removed by the liver. In addition to VLDL particles, the liver secretes nascent HDL particles into the circulation. HDL particles act to scavenge excess unesterified cholesterol from the cells and other lipoproteins and return it to the liver for excretion into bile. This process is often referred to as *reverse cholesterol transport*.

Hypertriglyceridemia can develop secondary to increased chylomicron production (excessive dietary intake of lipid), ineffective clearance of the chylomicron particle, increased VLDL production (excessive dietary intake of lipid and/or carbohydrate, excessive endogenous production or mobilization of lipids), and ineffective clearance of the VLDL particle. Hypercholesterolemia can arise from increased production of the LDL precursor particle (VLDL) or as a result of reduced clearance of the LDL or HDL particle.

Classification

Postprandial hyperchylomicronemia is the most common cause of hyperlipidemia in dogs and cats. It is a normal physiologic manifestation that is caused by the production of triglyceride-rich chylomicrons and usually resolves within 2 to 10 hours. As such, assessments of blood lipid concentrations should be done after at least a 12-hour fast. In contrast, pathologic abnormalities in plasma lipids and lipoproteins may be of genetic or familial origin (primary) or may arise as a consequence of disease (Box 52.1).

Primary hypertriglyceridemia disorders include the idiopathic hyperlipidemia of Miniature Schnauzers and the hyperchylomicronemia of cats. Idiopathic hyperlipidemia of Miniature Schnauzers is characterized by severe hypertriglyceridemia resulting from excessive VLDL particles with or without concurrent hyperchylomicronemia and hypercholesterolemia. Although the exact mechanism and genetics have not been fully elucidated, the problem progresses with age, and affected dogs have reduced activity of lipoprotein lipase but not hepatic lipase. Proteinuria is a common finding in these cases and may be due to lipid-induced injury to the glomerulus.

BOX 52.1

Causes of Hyperlipidemia in Dogs and Cats

Postprandial Hyperchylomicronemia

Primary hyperlipidemia

- Megestrol acetate (cat)

Feline familial hyperlipidemia is characterized as a fasting hyperchylomicronemia with a slight increase in VLDL particles. The defect is due to the production of an inactive form of lipoprotein lipase resulting from a mutation in the genetic sequence such that a single amino acid is miscoded (Gly412Arg); inheritance is autosomal recessive. Idiopathic hyperchylomicronemia has also been observed in dogs. Similar to the situation with the cat, the disease in the dog is characterized by hypertriglyceridemia, hyperchylomicronemia, and normal serum cholesterol concentrations. Idiopathic hypercholesterolemia has been reported in Shetland Sheepdogs, Doberman Pinschers, and Rottweilers. Lipid derangements consist of hypercholesterolemia caused by an increased serum LDL concentration. The cause of this disorder is unknown.

Diseases commonly associated with secondary hyperlipidemia include endocrine disorders (hypothyroidism, diabetes mellitus, hyperadrenocorticism), nephrotic syndrome, and pancreatitis as well as obesity and some hepatic diseases. Some medications such as phenobarbital and glucocorticoids are also associated with hyperlipidemia. Hypothyroidism is the most common cause of hypercholesterolemia in the dog. Hyperlipidemia secondary to hypothyroidism can be attributed to both a decrease in lipid synthesis and degradation (lipid degradation is more severely affected). Decreased lipoprotein lipase activity contributes to impaired removal of triglyceride-rich lipoproteins. In addition, thyroid hormone deficiency reduces the biliary excretion of cholesterol. The resultant increase in intrahepatic cholesterol concentration

downregulates the hepatic LDL receptor, which increases the concentration of circulating LDL and HDL cholesterol–rich particles.

Insulin deficiency (diabetes mellitus) reduces the production of lipoprotein lipase, which contributes to decreased clearance of triglyceride-rich lipoproteins. Furthermore, insulin deficiency activates HSL, causing the release of large quantities of free fatty acids into the blood. These free fatty acids are ultimately converted by the liver into triglycerides, packaged into VLDL particles, and secreted back into the circulation. Therefore the hypertriglyceridemia seen with diabetes mellitus is attributed to both reduction of lipoprotein lipase and increased production and decreased clearance of VLDL particles. Insulin deficiency increases the synthesis of cholesterol in the liver. The increased intrahepatic cholesterol concentration downregulates the hepatocyte LDL receptor, consequently reducing the clearance of circulating LDL and HDL particles, which in turn causes hypercholesterolemia.

The mechanism of hypertriglyceridemia associated with hyperadrenocorticism is probably due to stimulation of HSL with release of free fatty acids into the circulation. Similar to the situation with diabetes mellitus, excess free fatty acids are converted into VLDL particles. In addition, glucocorticoids inhibit lipoprotein lipase activity, thereby reducing the clearance of triglyceride-rich lipoproteins.

Clinical Features

Waxing-and-waning vomiting, diarrhea, and abdominal discomfort are the most common clinical presentations associated with hypertriglyceridemia (Table 52.1). Severe hypertriglyceridemia (levels exceeding 1000 mg/dL) has been associated with insulin resistance, pancreatitis, lipemia retinalis, seizures, cutaneous xanthomas, peripheral nerve paralysis, and behavioral changes. Cutaneous xanthomas, which represent lipid-laden macrophages and foam cells, are the most common manifestation of hypertriglyceridemia in the cat. Severe hypercholesterolemia has been associated with arcus lipoides corneae, lipemia retinalis, and atherosclerosis (not severe enough to cause myocardial infarction).

In addition to the clinical manifestations, hypertriglyceridemia may interfere with the results of several routine biochemical tests (Table 52.2). The degree of interference depends on the specific assay used by the laboratory, the species (canine versus feline), and the severity of the hypertriglyceridemia. In addition, hyperlipidemia may cause hemolysis, which in turn can interfere with the results of some biochemical assays. Alternatively, hyperbilirubinemia may cause the cholesterol concentration to be falsely lower. These potential alterations in biochemical data must be considered when results of testing in animals with hyperlipidemia are interpreted. Fortunately, many laboratories will attempt to clear the hypertriglyceridemia by ultracentrifugation before performing biochemical assays.

HYPERCHOLESTEROLEMIA CLINICAL SIGNS	**HYPERCHOLESTEROLEMIA CONSEQUENCES**
Xanthoma formation	Corneal arcus lipoides
Peripheral neuropathy	Lipemia retinalis
Horner's syndrome	Atherosclerosis (not severe enough to cause fatal myocardial infarction)
Tibial nerve paralysis	
Radial nerve paralysis	

Diagnosis

The presence of grossly lipemic serum suggests that the animal is hypertriglyceridemic. *Lactescence* refers to the opaque, milk-like appearance of serum samples that occurs with sufficiently severe elevation of the triglyceride concentration. Animals with lactescent serum typically have triglyceride concentrations that exceed 1000 mg/dL; samples with a less opaque character than that of nonfat milk may correspond to elevated lipid content but visual inspection is not a reliable indicator of severity. Conversely, animals that are purely hypercholesterolemic do not exhibit lipemic or lactescent serum because the cholesterol-rich LDL and HDL particles are too small to refract light. Blood samples to confirm hyperlipidemia should be obtained after a fast of at least 12 hours. A serum sample rather than whole blood or plasma should be submitted for assessment. The sample can be refrigerated or frozen for several days with no effect on the assays. When assessing the sample for hypertriglyceridemia, the technician should not clear the sample before determining the triglyceride concentration. Clearing lipemic samples by centrifugation removes chylomicrons, and this will artificially lower the triglyceride result. Reference intervals for serum triglyceride concentration are typically 50 to 150 mg/dL for the adult dog and 20 to 110 mg/dL for the adult cat. Reference intervals for serum cholesterol concentration are typically 125 to 300 mg/dL for the adult dog and 95 to 130 mg/dL for the adult cat.

The chylomicron test can be helpful in delineating whether lipemia is predominantly a chylomicron or a VLDL defect. The test is performed by refrigerating a serum sample for 12 hours. Chylomicrons are less dense than the other particles and hence will float to the top of the sample to form an

opaque cream layer over a clear infranatant of serum. If hypertriglyceridemia is due to excess VLDL particles, the serum sample will remain turbid. Formation of a cream layer over a cloudy serum layer suggests excess chylomicrons and VLDL particles.

Lipoprotein electrophoresis can be used to distinguish the lipoproteins, and density gradient ultracentrifugation can provide a quantitative measurement of each of the lipoprotein classes. However, both of these procedures are time-consuming and are not routinely available for clinical application. The activity of lipoprotein lipase can be assessed by the heparin release test. Serum samples for determination of triglyceride concentrations (and, if possible, lipoprotein concentrations) are obtained before and 15 minutes after intravenous administration of heparin (100 IU/kg body weight in dogs and cats). Heparin causes the release of lipoprotein lipase from the endothelium and stimulates the hydrolysis of triglycerides. A defect in lipoprotein lipase is suspected if there is no difference between serum triglyceride concentrations before and after administration of heparin.

Treatment

Before therapy is recommended, every attempt should be made to determine whether the hyperlipidemia is primary or secondary to an underlying disease process or medication. Hyperlipidemia secondary to an underlying disorder will typically resolve or improve with correction of the metabolic disturbance. Therefore in addition to confirming fasting, each animal requires a full history, physical examination, complete blood count, serum biochemistry panel with thyroxine concentration, and urinalysis. Results of the initial diagnostic evaluation may indicate the need for additional diagnostic tests such as abdominal ultrasound, pancreatic lipase immunoreactivity assay, and low-dose dexamethasone suppression test. A recommendation to treat hyperlipidemia involves a lifelong commitment by the client and therefore must not be undertaken lightly. In general, severe hypertriglyceridemia (concentrations > 1000 mg/dL) mandates treatment. In this circumstance catabolic mechanisms can be assumed to be overwhelmed, and the triglyceride concentration is very sensitive to a small increase from the intestine or the liver. Triglyceride concentrations must be decreased to prevent possible complications, including pancreatitis. In other situations, recommendations will be influenced by additional variables, including the underlying disease process. A realistic goal of therapy is to reduce the triglyceride concentration to less than 400 mg/dL, even though such a level will still be above the reference interval.

Chylomicrons are produced from dietary fat. Therefore restriction of dietary fat relative to the current intake is the cornerstone of therapy for hypertriglyceridemia. A thorough dietary history should be reviewed, and the diet altered to one that accomplishes at least a 50% reduction in fat on a metabolizable energy (ME) basis. For dogs with moderate to severe hypertriglyceridemia, the goal is often a diet with less than 20% fat on a ME basis (Table 52.3) or lower if the patient is already on a lower-fat diet. Nutritional management of hypertriglyceridemia in cats is more difficult because of the limited availability of diets with less than 25% fat on an ME basis (Table 52.4). Care should be taken assessing fat content of pet foods. Because the guaranteed analysis reported on pet food labels requires only a minimum, rather than an average, crude fat percentage to be reported, the fat content may be significantly higher. In addition, the value is provided on an "as fed" basis, making comparisons among products challenging. This information is best converted to and expressed on a ME basis, either as a proportion of

calories or as grams per 1000 kcal. The nutrient profiles of veterinary therapeutic foods are typically provided in product guides, and values are expressed as averages and on a ME basis, which more accurately reflects the actual fat content of the food.

Any treats or other foods used, including those needed to administer medications, should also be restricted in fat, and should contribute no more than 10% of the daily caloric intake. Fruit (other than grapes and raisins), vegetables, or some cereals and cracker snacks without seasoning are useful options. Regardless of the inclusion of treats, absolute caloric intake should be evaluated. If the animal is overweight, caloric restriction is indicated and beneficial because it decreases the production of VLDL particles from excess dietary energy. The plasma triglyceride concentration should be reevaluated after 6 to 8 weeks of a lower-fat diet. If the reduction in triglyceride concentration is less than ideal, the dietary history should be reevaluated to ensure compliance with diet and treats, no access to other pet foods, and no additional family members or neighbors who are inadvertently providing the animal with a source of dietary fat. In addition, the medical record should be reviewed to ensure the exclusion of underlying disorders that may contribute to hypertriglyceridemia. If lower-fat commercial foods are not sufficient to control hypertriglyceridemia, a complete and balanced fat-restricted (10%-14% ME for dogs, 15%-19% ME for cats) home-prepared recipe can be formulated specifically for the animal using online software (such as at balanceit.com) or with the help of a board-certified veterinary nutritionist (see www.acvn.org, or www.esvcn.eu/college).

Supplementation with omega-3 fatty acids have been suggested to improve hypertriglyceridemia in humans by decreasing the production of VLDL particles. In addition, fish oils are poor substrates for triglyceride-synthesizing enzymes, and their use leads to the formation of triglyceride-poor VLDL particles. Some clinicians have recommended the use of long-chain omega-3 fatty acids (i.e., eicosapentaenoic

acid [EPA] and docosahexaenoic acid [DHA]) in the amount of 200 to 220 mg/kg body weight/day to assist in the management of hypertriglyceridemia, especially in dogs refractory or incompletely responsive to dietary fat restriction. The efficacy is questionable in severe cases, and overall dietary fat restriction remains the priority.

Treatment with medications, all of which have the potential for toxicity, should be undertaken with particular care. In general, drugs should not be used in animals whose serum triglyceride concentration is less than 500 mg/dL. Several classes of drugs are used to treat hypertriglyceridemia in humans including statins; however, few reports have described their use in cats and dogs. Until further studies have evaluated dose, effect, and toxicity, drug therapy is indicated only in animals that have clinical signs associated with severe elevations in triglyceride concentrations that cannot be ameliorated by dietary therapy.

Niacin (100 mg/day in dogs) reduces serum triglyceride concentration by decreasing fatty acid release from adipocytes and reducing the production of VLDL particles. Adverse effects are frequent, mainly because of the associated release of the prostaglandin prostacyclin, and include vomiting, diarrhea, erythema, pruritus, and abnormalities in liver function test results. In addition, niacin has been shown to positively impact hyperlipidemia in only a small number of dogs; larger clinical trials are lacking.

Fibric acid derivatives (clofibrate, bezafibrate, gemfibrozil, ciprofibrate, fenofibrate) lower plasma triglyceride concentrations by stimulating lipoprotein lipase activity, in addition to reducing the free fatty acid concentration, which decreases the substrate for VLDL synthesis. In humans the fibrates generally lower plasma triglyceride concentrations by 20% to 40%. Gemfibrozil has been used in the dog and cat (10 mg/kg q12h), and bezafibrate has been used in the dog (4-10 mg/kg/day). Reported adverse effects in humans include abdominal pain, vomiting, diarrhea, and abnormal liver function test results. A recent study in dogs demonstrated that bezafibrate was effective in hypertriglyceridemic dogs, although ALT activity decreased over time; other adverse effects were not reported.

The statins (lovastatin, simvastatin, pravastatin, fluvastatin, cerivastatin, atorvastatin) are hydroxymethyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors and therefore primarily suppress cholesterol metabolism. As a consequence of lower intracellular cholesterol concentrations, the hepatic LDL receptor is upregulated, thereby increasing the removal and clearance of LDL (VLDL remnant particles) from the circulation. In addition, the statins decrease hepatic production of VLDL. In humans, the statins can lower triglyceride concentrations by 10% to 15%. Adverse effects include lethargy, diarrhea, muscle pain, and hepatotoxicity. These are not commonly used, and clinical experience in dogs and cats is limited.

Chitosan has been explored as an option for controlling hyperlipidemia secondary by reducing absorption of lipids and bile salts in the intestinal lumen. It appears to be effective in lowering serum lipid concentrations in rodent models and in people. One study described positive effects of chitosan in cats with hyperlipidemia not exceeding 300 mg/dL, which was induced by feeding cholesterol orally; however, there are no studies reported in cats with naturally occurring hyperlipidemia, or in any dogs.

Hypercholesterolemia is most likely associated with the presence of an underlying disease and generally resolves with control of the altered metabolic state. Unlike the situation with humans, hypercholesterolemia is rarely a significant health concern in dog or the cat as they are at lower risk of atherosclerosis. Specific therapy is indicated only for those animals with a prolonged marked increase in the serum cholesterol concentration (i.e., >800 mg/dL) that may be associated with the development of atherosclerosis, which is typically secondary to endocrinopathy. Nutritional therapy with a diet lower in fat compared with the current and historical intake is the initial treatment of choice for severe hypercholesterolemia. The addition of soluble fiber to the diet may also help to reduce plasma cholesterol concentrations by as much as 10%, because it interferes with the enteric reabsorption of bile acids. Consequently, the fecal excretion of cholesterol increases and the liver uses intrahepatic cholesterol to increase the synthesis of bile acids.

Pharmacologic agents that can be considered for the management of severe hypercholesterolemia include bile acid sequestrates, HMG-CoA reductase inhibitors, and probucol. Bile acid sequestrates are ion exchange resins that interrupt the enterohepatic circulation of bile acids. Decreased reabsorption of bile acids stimulates the liver to synthesize bile acids, thereby reducing intrahepatic cholesterol stores. Depletion of intrahepatic cholesterol stores stimulates the hepatic LDL receptor to increase the removal of LDL and HDL particles from the circulation. Cholestyramine (1-2 g, administered orally q12h) is effective for lowering cholesterol concentrations; however, its use has been associated with constipation, it interferes with the absorption of several oral medications, and it may increase hepatic VLDL synthesis, resulting in an increase in plasma triglyceride concentrations. It may also increase the dietary requirement for sulfur amino acids because they serve as precursors for taurine synthesis in the dog, which conjugates bile acids exclusively with taurine. In cats the requirement for dietary taurine may be similarly increased. HMG-CoA reductase is the rate-limiting enzyme for cholesterol synthesis. The HMG-CoA reductase inhibitors (lovastatin, simvastatin, pravastatin, fluvastatin, cerivastatin, and atorvastatin) are the most potent cholesterol-lowering agents, and in humans may reduce cholesterol concentrations by 20% to 40%. Lovastatin (10-20 mg, administered orally q24h) may be tried in dogs with persistent, severe idiopathic hypercholesterolemia that does not respond to diet alone. Potential adverse effects include lethargy, diarrhea, muscle pain, and hepatotoxicity. Lovastatin should not be administered to dogs with hepatic disease. Probucol is a cholesterol-lowering agent whose mechanism of action is not completely clear. Probucol is no longer recommended for the management of hypercholesterolemia because its effect on lowering cholesterol

concentrations is variable and it has been associated with the development of arrhythmias. As of 1995, it was withdrawn from the market in the United States.

CHAPTER 53

Electrolyte Imbalances

HYPERNATREMIA

Etiology

Hypernatremia exists if the serum sodium concentration exceeds the reference interval, which may vary between laboratories (in general >160 mEq/L). It most commonly develops after water loss exceeds sodium loss (Box 53.1). The water loss may be pure (i.e., not accompanied by loss of electrolytes, such as that which occurs with diabetes insipidus), or it may be hypotonic (i.e., loss of both water and sodium but with the water loss predominating, such as that which occurs with gastrointestinal fluid loss and chronic kidney disease). Insufficient water intake and an abnormal thirst mechanism are usually facets of an excessive water loss. Rarely, hypernatremia may occur in animals with hypodipsia caused by neurologic disease, an abnormal thirst mechanism, or defective osmoregulation of vasopressin release.

Less commonly, hypernatremia develops after sodium retention, such as that which occurs with iatrogenic sodium overload or primary hyperaldosteronism. Primary hyperaldosteronism is caused by an aldosterone-secreting adrenal tumor or idiopathic bilateral adrenal hyperplasia but is uncommon in dogs and cats. Increased serum aldosterone concentrations cause variable hypernatremia, hypokalemia, and systemic hypertension.

Clinical Features

Clinical signs of hypernatremia originate in the central nervous system (CNS) and include lethargy, weakness, muscle fasciculations, disorientation, behavioral changes, ataxia, seizures, stupor, and coma. Clinical signs typically become apparent when the plasma osmolality exceeds 350 mOsm/kg (serum sodium concentration >170 mEq/L). Clinical signs are caused by neuronal dehydration. Hypernatremia and hyperosmolality cause fluid to shift from the intracellular to the extracellular space. As the brain shrinks, meningeal vessels are damaged and torn, causing hemorrhage, hematoma, venous thrombosis, infarction of cerebral vessels, and ischemia. This gradient flow of water from the intracellular to the extracellular compartment often maintains adequate skin turgor and gives a false impression of hydration, even though the animal has experienced a detrimental loss of fluid.

The severity of clinical signs is related to the absolute increase in serum sodium concentration and especially to the rapidity of onset of hypernatremia and hyperosmolality. Clinical signs usually do not develop until the serum sodium concentration approaches 170 mEq/L. If hypernatremia is rapid in onset, clinical signs may develop at a lower sodium concentration and vice versa. With a gradual increase in the serum sodium concentration, the cells in the CNS can adapt by producing osmotically active solutes (idiogenic osmoles) intracellularly within a few hours of cell shrinkage to reestablish osmotic equilibration between extracellular and intracellular compartments, thereby minimizing cell shrinkage.

Diagnosis

Measurement of the serum sodium concentration identifies hypernatremia. After it has been identified, the underlying cause should be sought. Careful evaluation of the history, physical examination findings, and results of complete blood count (CBC), serum biochemistry panel, and urinalysis usually yield clues to the cause. Evaluation of the urine specific gravity is especially helpful. Hypernatremia and hyperosmolality stimulate the release of vasopressin, resulting in hypersthenuria. A urine specific gravity of less than 1.008 in a dog or cat with hypernatremia is consistent with central or nephrogenic diabetes insipidus. A urine specific gravity greater than 1.030 in a dog and 1.035 in a cat implies a normal vasopressin–renal tubular axis and indicates the existence of sodium retention, primary hypodipsia-adipsia, or gastrointestinal or insensible water loss. A urine specific gravity of between 1.008 and 1.030 (dog) or 1.035 (cat) indicates the presence of partial vasopressin deficiency or impaired renal tubular response to vasopressin, most likely secondary to a primary kidney disorder.

Treatment

The goals in treating patients with hypernatremia are to restore the extracellular fluid (ECF) volume to normal, to

*Common causes.
Modified from DiBartola SP: Disorders of sodium and water: hypernatremia and hyponatremia. In DiBartola SP, editor: *Fluid, electrolyte and acid-base disorders in small animal practice*, ed 4, St Louis, 2012, Saunders Elsevier.

correct water deficits at a fluid rate that avoids significant complications, and to identify and correct the underlying cause of the hypernatremia. The initial priority is to restore ECF volume to normal. Hypernatremic animals should be resuscitated with a balanced electrolyte solution with NaCl added to the suspension to bring the solution's sodium content up to that of the animal (±6 mEq/L). To achieve this, 23.4% NaCl can be added to the fluid solution; it contains 4 mEq NaCl/mL of solution. In deficit replacement, rapid administration of fluids is contraindicated unless signs of significant hypovolemia are noted. Any fluid should be administered cautiously at a volume only large enough to correct hypovolemia. In animals with mild to moderate hypernatremia ($[Na^+]$ <180 mEq/L), sodium should be decreased at a rate of 1 mEq/L/h. With severe hypernatremia (Na >180), sodium should be corrected at a rate of 0.5 to 1 mEq/L/h. Multiple fluid solutions can be used to successfully decrease sodium safely (Table 53.1). In the presence of hemorrhagic shock, whole blood, plasma, or a colloid suspension is the ideal fluid to administer. Serum sodium concentration should be measured frequently (q4-6h) to assess response to treatment, and the status of the CNS should be evaluated frequently to observe for changes in clinical signs. Worsening neurologic status or sudden onset of seizures during fluid therapy is generally indicative of cerebral edema and the need for hypertonic saline solution or mannitol therapy (see Drugs Used in Metabolic and Electrolyte Disorders, p. 934). Once ECF deficits have been replaced, the serum sodium concentration should be reevaluated and water deficits corrected if hypernatremia persists. An approximation of the free water deficit in liters may be calculated using the following formula:

$$(\text{current}[Na^+] \div \text{normal}[Na^+] - 1) \times (0.6 \times \text{bodyweight in kg})^2$$

Because the brain adjusts to hypertonicity by increasing the intracellular solute content via the accumulation of "idiogenic osmoles," the rapid repletion of body water with ECF dilution causes translocation of water into cells and may cause cerebral edema. If slower water repletion is undertaken, brain cells lose the accumulated intracellular solutes, and osmotic equilibration can occur without cell swelling.

Maintenance crystalloid solutions (e.g., half-strength [0.45%] saline solution with 2.5% dextrose, half-strength lactated Ringer's solution with 2.5% dextrose) or 5% dextrose in water can be used to correct the water deficit in hypernatremic animals with normal perfusion and hydration, and can also be used in dehydrated animals with persistent hypernatremia after fluid deficits have been corrected.

Oral fluid administration is preferable for correcting water deficits, and fluid is administered through an intravenous (IV) route if oral administration is not possible. The water deficit should be replaced slowly. Approximately 50% of the water deficit should be corrected in the first 24 hours, and the remainder corrected over the following 24 to 48 hours. The serum sodium concentration should decline slowly, preferably at a rate of 0.5 to 1 mEq/L/h. The rate of fluid administration should be adjusted as needed to ensure an appropriate decrease in the serum sodium concentration. A gradual reduction in the serum sodium concentration minimizes the fluid shift from the extracellular to the intracellular compartment, thereby minimizing neuronal cell swelling and cerebral edema and increasing intracranial pressure. Deterioration in CNS status after the start of fluid therapy indicates the presence of cerebral edema and the immediate need to reduce the rate of fluid administration. Frequent monitoring of serum electrolyte concentrations, with appropriate adjustments in the type of fluid administered and the rate of fluid

administration, is important in the successful management of hypernatremia.

On rare occasions, a hypernatremic animal presents with an increase in ECF volume. Such animals are difficult to treat. The goal is to lower the serum sodium concentration without exacerbating an increase in ECF volume and causing pulmonary congestion and edema. To slowly correct hypernatremia in these animals, the clinician should administer loop diuretics (e.g., furosemide, 1-2 mg/kg orally or intravenously q8-12h) to promote sodium loss in the urine; this is done in conjunction with the judicious administration of D_5W.

HYPONATREMIA

Etiology

Hyponatremia is present if the serum sodium concentration is less than the reference interval (145 mEq/L, although reference ranges may vary between laboratories). It can result from excessive sodium loss, primarily through the kidney, or from increased water conservation, or both. The latter condition may be an appropriate response to a reduction in ECF volume or may be inappropriate (e.g., syndrome of inappropriate antidiuretic hormone secretion [SIADH]). In most cases hyponatremia results from abnormalities in water

balance (principally a defect in renal water excretion) rather than from abnormalities in sodium balance. Causes of hyponatremia in dogs and cats are listed in Box 53.2.

Hyponatremia must be differentiated from pseudohyponatremia, which is a decrease in the serum sodium concentration that results from laboratory methods used in the presence of normal plasma osmolality. Pseudohyponatremia occurs in the presence of hyperlipidemia or severe hyperproteinemia. An increase in the concentration of triglycerides or proteins in plasma reduces the sodium concentration in the total plasma volume, but the sodium concentration in plasma water remains the same. Methods that measure the amount of sodium in a specific volume of plasma (e.g., flame photometry) result in falsely low sodium values, whereas methods that determine the sodium concentration in the aqueous phase of plasma (e.g., direct potentiometry using ion-specific electrodes) yield an accurate sodium value. Pseudohyponatremia can usually be identified if the method used to measure the sodium concentration is known, a blood sample is examined for the presence of gross lipemia, and a CBC and a serum biochemistry panel are performed.

Hyponatremia may also occur after the concentration of osmotically active solutes (e.g., glucose, mannitol) in the ECF is increased. An increase in the concentration of osmotically active solutes in the ECF causes a fluid shift from the intracellular to the extracellular compartment and a corresponding decrease in the serum sodium concentration. For example, the serum sodium concentration decreases by approximately 1.6 mEq/L for every 100-mg/dL increase in serum glucose concentration, and this decrease may become more severe when the blood glucose concentration exceeds 500 mg/dL. Estimation of the plasma osmolality is helpful in differentiating the cause of hyponatremia. Hyponatremia is usually associated with hypo-osmolality (<290 mOsm/kg), whereas pseudohyponatremia is associated with normal plasma osmolality, and hyponatremia caused by an increase in osmotically active solutes in the ECF is associated with hyperosmolality. Plasma osmolality can be estimated using the following formula:

$$\text{Plasma osmolality (mOsm/kg)} = (2 \times \text{Na [mEq/L]}) + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{Ureanitrogen (mg/dL)}}{2.8}$$

Normal plasma osmolality in dogs and cats is approximately 280 to 310 mOsm/kg.

*Common causes.
Modified from DiBartola SP: Disorders of sodium and water: hypernatremia and hyponatremia. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders in small animal practice,* ed 4, St Louis, 2012, Saunders/Elsevier.

Clinical Features

Clinical signs of hyponatremia include lethargy, anorexia, vomiting, weakness, muscle fasciculations, obtundation, disorientation, seizures, and coma. CNS signs are the most concerning, occur when hyponatremia is severe (<120 mEq/L), and develop as changes in plasma osmolality cause fluid to shift from the extracellular to the intracellular space, resulting in neuronal swelling and lysis. The onset and severity of clinical signs depend on the rapidity with which hyponatremia develops as well as on the degree of hyponatremia. The more chronic the hyponatremia and the more slowly it develops, the more capable the brain is of compensating for changes in osmolality through the loss of potassium and organic osmolytes from cells. Clinical signs develop when the decrease in plasma osmolality occurs faster than the brain's defense mechanisms can counter the influx of water into the neurons.

Diagnosis

Hyponatremia is readily evident from measurement of serum electrolyte concentrations. However, hyponatremia

must be differentiated from pseudohyponatremia (discussed in a previous section). Hyponatremia is not a diagnosis per se but rather a manifestation of an underlying disorder. As such, a diagnostic evaluation to identify the cause, as well as appropriate therapy to correct the hyponatremia, should be initiated. In most dogs and cats the cause of hyponatremia is readily apparent after evaluation of the history, physical examination findings, CBC, serum biochemistry panel, and urinalysis findings, but further diagnostic tests may be necessary. Careful assessment of urine specific gravity and plasma osmolality and of the hydration status of the animal will help to localize the problem (see Box 53.2).

Treatment

The goals of therapy are to treat the underlying disease and, if necessary, to increase serum sodium concentration and plasma osmolality. The goals of treatment directed at the hyponatremia are to correct body water osmolality and restore cell volume to normal by raising the ratio of sodium to water in ECF using IV fluid therapy, water restriction, or both. The increase in ECF osmolality draws water from cells, thereby reducing their volume. The approach to treatment and the type of fluid used depend on the underlying cause, the severity of the hyponatremia, and the presence or absence of clinical signs (see Table 53.1). Chronic hyponatremia in an asymptomatic animal is best treated conservatively. Lactated Ringer's or Ringer's solution can be used for mild hyponatremia (serum sodium concentration >130 mEq/L) and physiologic saline solution for more severe hyponatremia (serum sodium concentration <130 mEq/L). Physiologic saline solution is typically used in symptomatic animals with severe hyponatremia.

Fluid and electrolyte balance should gradually be restored over 24 to 48 hours, with periodic assessment of serum electrolyte concentrations and the patient's CNS status. The general goal is to increase the serum sodium concentration slowly toward the lower end of the reference range at a rate no greater than 0.5 to 1.0 mEq/L/h. The more acute and severe the hyponatremia, the more slowly the serum sodium concentration should be corrected. A rapid increase in the serum sodium concentration to levels greater than 125 mEq/L is potentially dangerous and should be avoided in animals with acute, severe hyponatremia (serum sodium concentration <120 mEq/L) and neurologic signs. For these animals, the serum sodium concentration should be gradually increased to 125 mEq/L or higher over 6 to 8 hours. Because loss of brain solute represents one of the compensatory mechanisms for preserving brain cell volume during dilutional states, an increase in serum sodium concentration toward normal is relatively hypertonic to brain cells that are partially depleted of solute as a result of hyponatremia. Consequently, raising the serum sodium concentration rapidly to greater than 125 mEq/L can cause CNS damage.

The major complication of treatment of hyponatremia is myelinosis, which results from neuronal shrinkage away from the myelin sheath as water moves out of the neuron during correction of hyponatremia. Clinical signs include paresis, ataxia, dysphagia, and obtundation and often do not manifest until several days after treatment of hyponatremia. The prognosis for recovery is guarded.

HYPERKALEMIA

Etiology

Hyperkalemia is present if the serum potassium concentration exceeds 5.5 mEq/L (although reference ranges may vary between laboratories) and is considered severe and potentially life-threatening when it exceeds 7.5 mEq/L. Hyperkalemia can develop after increased potassium intake (uncommon) or translocation of potassium from the intracellular to the extracellular space (uncommon), or as a result of impaired potassium excretion in the urine (common; Box 53.3). Impaired urinary excretion of potassium is usually caused by chronic kidney disease or hypoadrenocorticism. Iatrogenically induced hyperkalemia is also common in dogs and cats, typically resulting from excessive IV administration of potassium-containing fluids. Generally the IV rate of potassium administration should not exceed 0.5 mEq/kg body weight per hour. Pseudohyperkalemia refers to an increase in potassium in vitro and can occur in the setting of severe hypernatremia (if dry reagent methods are used), leukocytosis (white blood cell count >100,000/μL), or thrombocytosis (>1 × 10^6/μL), and in the setting of hemolysis in Akitas (and possibly Shiba Inus and Kindos) and in English Springer Spaniels with phosphofructokinase deficiency. Collection of blood in heparinized tubes rather than in clot tubes and prompt separation of plasma from cells help to prevent pseudohyperkalemia. Obtaining blood from fluid lines or catheters contaminated with potassium-containing fluids may yield falsely increased potassium concentrations.

Clinical Features

The clinical manifestations of hyperkalemia reflect changes in cell membrane excitability and the magnitude and rapidity of onset of hyperkalemia. Mild to moderate hyperkalemia (serum potassium concentration <6.5 mEq/L) is typically asymptomatic. Generalized skeletal muscle weakness develops as the hyperkalemia worsens. Weakness occurs after a hyperkalemia-induced decrease in resting cell membrane potential to the level of the threshold potential, thereby impairing repolarization and subsequent cell excitation. The most prominent manifestations of hyperkalemia are cardiac in nature. Hyperkalemia causes decreased myocardial excitability, an increased myocardial refractory period, and slowed conduction—effects that may cause potentially life-threatening cardiac rhythm disturbances (Box 53.4).

Diagnosis

Measurement of serum potassium concentration or evaluation of an electrocardiogram (ECG) can identify hyperkalemia. Once it has been identified, a careful review of the history, physical findings, CBC, serum biochemistry panel, and urinalysis usually yields clues to the cause. The most

common causes of hyperkalemia in the dog and cat are iatrogenic, most notably excessive potassium administration in IV fluids; renal dysfunction, especially acute oliguric-anuric kidney disease, urethral obstruction (tomcats), and rupture within the urinary system leading to uroabdomen; and hypoadrenocorticism. It can be a diagnostic challenge to differentiate renal dysfunction from hypoadrenocorticism because both disorders can result in a similar clinical picture. A baseline serum cortisol concentration can be used to rule out hypoadrenocorticism, but an adrenocorticotropic hormone (ACTH) stimulation test is needed to confirm hypoadrenocorticism when the baseline cortisol concentration is less than 2 μg/dL (55 nmol/L). Small rents in the urinary bladder can be difficult to identify, and contrast-enhanced diagnostic imaging studies (i.e., radiographic, computed tomography [CT], magnetic resonance imaging [MRI]) or surgical exploration is frequently necessary to confirm their presence.

Treatment

For most animals, therapy for hyperkalemia is directed at treating the underlying cause. Symptomatic therapy for hyperkalemia should be initiated if the serum potassium concentration is greater than 7 mEq/L, or if pronounced cardiac toxicity (i.e., complete heart block, premature ventricular contractions, arrhythmias) is identified on an ECG (Table 53.2). Rapid institution of therapy in animals with marked hyperkalemia could mean the difference between

TABLE 53.2

Treatment Options for Hyperkalemia in the Dog and Cat

TREATMENT	DOSAGE	ROUTE OF ADMINISTRATION	DURATION OF EFFECT
Physiologic saline	≥60-100 mL/kg/day	IV	Hours
Dextrose	5%-10% in IV fluids *or* 1-2 mL of 50% dextrose/kg	IV, continuous IV, slow bolus	Hours Hours

Sodium bicarbonate	1-2 mEq/kg	IV, slow bolus	Hours
10% Calcium gluconate	0.5 mL/kg to 1.5 mL/kg over 5-10 minutes with ECG monitoring	IV, slow bolus	30-60 minutes Monitor heart
β_2 adrenergic agonist	Terbutaline 0.01 mg/kg	IV slowly	2 hours

IV, Intravenous.

life and death. The goals of symptomatic therapy are to reverse the cardiotoxic effects of hyperkalemia and, if possible, to reestablish normokalemia. Asymptomatic animals with normal urine output and chronic hyperkalemia (<7 mEq/L) may not require immediate treatment, but a search for the underlying cause should be initiated.

IV fluid administration in amounts designed to correct fluid deficits and to cause volume expansion rehydrates the animal, improves renal perfusion and potassium excretion, and dilutes the blood potassium concentration. Physiologic saline solution is the fluid of choice for this purpose. Potassium-containing fluids (e.g., lactated Ringer's solution) can be used if physiologic saline solution is not available because the low potassium concentration in these fluids (see Table 53.1) in relation to that in blood will still have a dilutional effect on the blood potassium concentration. Dextrose can be added to the fluids to make a 5% to 10% dextrose-containing solution, or 1 to 2 mL/kg of 50% dextrose can be administered by slow IV bolus. Dextrose stimulates insulin secretion, which in turn promotes the movement of glucose and potassium from the extracellular to the intracellular space. Fluids containing more than 5% dextrose should be given into a central vein to minimize the risk of phlebitis.

Rarely, additional therapy may be required to block the cardiotoxic effects of hyperkalemia (see Table 53.2). Sodium bicarbonate and regular insulin given with dextrose act to shift potassium from the extracellular to the intracellular space. IV calcium infusions block the effects of hyperkalemia on cell membranes but do not lower the blood potassium concentration. β_2 adrenergic agonists (e.g., albuterol, terbutaline) can be administered as an adjunct treatment, driving potassium intracellularly by increasing sodium and potassium adenosine triphosphatase (ATPase) activity. These therapies constitute aggressive, short-term, life-saving measures that can reestablish normal cardiac conduction until more conventional therapy (i.e., IV fluids) has the time to become effective.

For more chronic, mild to moderate hyperkalemia due to kidney disease, especially those with proteinuria and/or on ACE inhibitors, a potassium-restricted homemade diet can be effective in controlling serum potassium concentrations. In these cases, consultation with a board-certified veterinary nutritionist should be pursued to ensure a balanced and appropriate diet (see www.acvn.org or www.esvcn.eu/college).

HYPOKALEMIA

Etiology

Hypokalemia is present when the serum potassium concentration is less than 3.5 mEq/L, although reference ranges may vary between laboratories. Hypokalemia can develop after decreased dietary potassium intake (uncommon), translocation of potassium from the ECF to the intracellular fluid (common), or increased potassium loss in urine or gastrointestinal secretions (common; Box 53.5). Iatrogenic hypokalemia is also common in dogs and cats. Pseudohypokalemia is uncommon and depends on the method used to measure the serum potassium concentration. Hyperlipidemia, hyperproteinemia (>10 g/dL), hyperglycemia (>750 mg/dL), and azotemia (urea nitrogen concentration >115 mg/dL) can potentially cause pseudohypokalemia.

Clinical Features

Most dogs and cats with mild to moderate hypokalemia (i.e., 3.0-3.5 mEq/L) are asymptomatic. Clinically severe hypokalemia primarily affects the neuromuscular and cardiovascular systems owing to hypokalemia-induced initial hyperpolarization followed by hypopolarization of cell membranes. The

*Common causes.
Modified from DiBartola SP, Autran de Morais H: Disorders of potassium: hypokalemia and hyperkalemia. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders in small animal practice,* ed 4, St Louis, 2012, Saunders Elsevier.

most common clinical sign of hypokalemia is generalized skeletal muscle weakness. In cats ventroflexion of the neck (see Chapter 67), forelimb hypermetria, and a broad-based hindlimb stance may be observed. The timing of onset of hypokalemia-induced weakness is extremely variable among animals. Cats seem more susceptible than dogs to the deleterious effects of hypokalemia. In dogs, signs may not be evident until the serum potassium concentration is less than 2.5 mEq/L, whereas in cats signs can be seen when the serum potassium concentration is between 3 and 3.5 mEq/L.

Cardiac consequences of hypokalemia include decreased myocardial contractility, decreased cardiac output, and disturbances in cardiac rhythm. Cardiac disturbances assume a variable clinical expression, often evidenced only by electrocardiography (see Box 53.4). Other metabolic effects of hypokalemia include hypokalemic nephropathy, which is characterized by chronic tubulointerstitial nephritis, impaired renal function, and azotemia and manifests clinically as polyuria, polydipsia, and impaired urine concentrating capability; hypokalemic polymyopathy, which is characterized by increased serum creatine kinase activity and electromyographic abnormalities; and paralytic ileus, which manifests clinically as abdominal distention, anorexia, vomiting, and constipation. Hypokalemic nephropathy and polymyopathy are most notable in cats.

Diagnosis

Measurement of the serum potassium concentration identifies hypokalemia. Once it has been identified, a careful review of the history, physical findings, CBC, serum biochemistry panel, and urinalysis usually provides clues to the cause (see Box 53.5). If the cause is not readily apparent after review of this information, other less likely causes for hypokalemia should be considered, such as renal tubular acidosis, or another renal potassium-wasting disorder, primary hyperaldosteronism, and hypomagnesemia. To help differentiate renal from nonrenal sources of potassium loss, the clinician may need to determine the fractional excretion of potassium on the basis of a single urine and serum potassium and creatinine concentration or may need to evaluate 24-hour urine potassium excretion (see Chapter 39).

Treatment

Therapy is indicated if the serum potassium concentration is less than 3.5 mEq/L, if clinical signs related to hypokalemia are present, or if a serum potassium loss is anticipated (e.g., insulin therapy in diabetic ketoacidosis [DKA]) and the animal's ability to compensate for the loss is impaired. The goal of therapy is to reestablish and maintain normokalemia without inducing hyperkalemia.

Potassium chloride is the compound most commonly used for parenteral potassium supplementation, in part to help promote chloride as well as potassium repletion. IV administration is preferred, although potassium chloride can be given subcutaneously as long as the concentration of potassium does not exceed 30 mEq/L. In dogs and cats with normal renal function, the maintenance amount of potassium supplementation is approximately 20 mEq/L of fluids. The amount of potassium first added to fluids depends on the animal's serum potassium concentration (Table 53.3) and the amount of potassium already present in the fluids (see Table 53.1). The rate of IV potassium administration should not exceed 0.5 mEq/kg/h. The rate of potassium administration can be increased cautiously to 1.0 mEq/kg/h in patients with profound hypokalemia and normal or increased urine output. Close ECG monitoring is recommended.

It is difficult to estimate the amount of potassium required to reestablish normal potassium balance on the basis of the serum potassium concentration because potassium is primarily an intracellular cation. As such, serial measurement

TABLE 53.3

Guidelines for Potassium Supplementation in IV Fluids

SERUM K^+ (mEq/L)	TOTAL mEq OF K^+/L OF FLUIDS	MAXIMUM FLUID INFUSION RATE (mL/kg/h)*
>3.5	20	25
3.0-3.5	30	16
2.5-3.0	40	12
2.0-2.5	60	8
<2.0	80	6

*Total hourly potassium administration should not exceed 0.5 mEq/kg body weight.

of the serum potassium concentration is important during treatment and should initially be done every 6 to 12 hours depending on the severity of the hypokalemia and the rate of potassium administration. Adjustments in potassium therapy should be made accordingly, with the goal of establishing a normal serum potassium concentration and then maintaining the serum potassium concentration in the normal range as treatment is withdrawn. Clinical signs of hypokalemia usually resolve within 1 to 5 days after correction of hypokalemia.

Depending on the underlying cause, long-term oral potassium supplementation may be required to prevent recurrence of hypokalemia. Potassium gluconate powder or capsules are commonly used as an oral dietary potassium supplement for dogs and cats with minimal gastrointestinal side effects. The recommended dose is 2.2 mEq of potassium per 100 calories of required energy intake per day or 2 mEq of potassium per 4.5 kg of body weight twice a day. Subsequent adjustments in dosage are made on the basis of clinical response and serum potassium concentrations. Fruits such as kiwi and bananas are also a good source of potassium. Ten inches (25 cm) of banana contains approximately 10 mEq of potassium.

HYPERCALCEMIA

Identification

Hypercalcemia is present if the serum calcium concentration is greater than 12 mg/dL (dog) and 11 mg/dL (cat) or if the serum ionized calcium concentration is greater than 1.5 mmol/L (dog) and 1.3 mmol/L (cat), although reference ranges may vary between laboratories. The serum total and ionized calcium concentrations are higher in puppies than in adult dogs. A mild increase in serum total calcium (i.e., <13 mg/dL), ionized calcium (i.e., <1.55 mmol/L), and phosphorus (i.e., <10 mg/dL) concentrations in a clinically healthy puppy, together with an increase in serum alkaline phosphatase activity and normal urea nitrogen and creatinine concentrations, should be considered normal. The serum total calcium concentration does not fluctuate with age in cats, but the serum ionized calcium concentration may be higher (<0.1 mmol/L) in cats younger than 2 years of age than in older cats.

Most automated and in-house serum chemistry analyzers measure the total serum calcium concentration, which consists of biologically active, ionized calcium (55%), protein-bound calcium (35%), and calcium complexes (10%). A drawback to this is that alterations in the plasma protein concentration may alter the total serum calcium concentration, yet the ionized calcium concentration remains normal. For this reason, serum albumin and total protein concentrations should be measured when the total serum calcium concentration is determined in the dog. Simple quantitative changes in albumin and total plasma proteins do not cause hypocalcemia or hypercalcemia in dogs, even though total serum calcium levels may appear to be low or high on the biochemistry panel. Historically, the following formulas have been used to estimate the total serum calcium concentration in dogs with hypoalbuminemia or hypoproteinemia:

$$\text{Adjusted calcium (mg/dL)} = \text{Serum calcium (mg/dL)} - \text{Serum albumin (g/dL)} + 3.5$$

or

$$\text{Adjusted calcium (mg/dL)} = \text{Serum calcium (mg/dL)} - (0.4 \times \text{Serum total protein [g/dL]}) + 3.3$$

These formulas are not used in dogs younger than 24 weeks of age, because high values may be obtained, nor are they used in cats, because there is no linear relationship between serum total calcium and serum albumin and total protein concentration in cats. These formulas yield a rough estimate of the total serum calcium concentration and were developed without verification by serum ionized calcium measurements. Subsequent studies identified a poor correlation between adjusted total calcium results and corresponding serum ionized calcium concentrations, suggesting that adjusted total serum calcium concentrations are not reliable indicators of calcium homeostasis, and that measurement of serum ionized calcium concentration is preferred, especially in animals with hypoproteinemia.

The biologically active, ionized fraction of calcium can be determined directly; this approach bypasses the influence of plasma proteins on the total serum calcium concentration. Ionized calcium measurements are superior to serum total calcium measurements for assessing calcium in dogs and cats. Automated equipment that uses a calcium ion-selective electrode allows accurate measurement of ionized calcium in blood, plasma, or serum. Ionized calcium results can be affected by many variables, including method of sample collection (samples collected anaerobically provide more precise results); amount and type of heparin, if used (may underestimate or overestimate ionized calcium results);

and change in sample pH (ionized calcium decreases as pH increases). Protocols established by the clinical chemistry laboratory for submitting blood samples for ionized calcium determination should be followed to ensure accurate results. Handheld point-of-care analyzers typically report ionized calcium values that are less than those reported from bench-top machines.

Etiology

Hypercalcemia is relatively common in dogs and cats. Persistent hypercalcemia usually results from increased calcium resorption from bone or kidney or increased calcium absorption from the gastrointestinal tract. Humoral hypercalcemia of malignancy (HHM), the most common cause of hypercalcemia, occurs when the tumor produces substances that promote osteoclastic activity and renal calcium reabsorption. These substances include parathyroid hormone (PTH); PTH–related peptide (PTHrP); 1,25-dihydroxyvitamin D; cytokines, such as interleukin-1 and tumor necrosis factor; prostaglandins; and humoral factors that stimulate renal 1α-hydroxylase. Tumors may also induce hypercalcemia through local osteolytic activity after they metastasize to bone. Less commonly, hypercalcemia develops as the result of impaired loss of calcium from the serum (e.g., reduced glomerular filtration) or reduced plasma volume (e.g., dehydration).

The list of differential diagnoses for hypercalcemia in dogs and cats is relatively short (see Table 47.2, p. 761). In the dog HHM (especially lymphoma), hypoadrenocorticism, chronic kidney disease, hypervitaminosis D, and primary hyperparathyroidism are the most common diagnoses. In the cat, idiopathic hypercalcemia, HHM (especially lymphoma and squamous cell carcinoma), and chronic kidney disease are the most common diagnoses. Calcium oxalate urolithiasis and consumption of acidifying diets are commonly identified in cats with hypercalcemia, but their role, if any, in causing the disorder is unknown.

Hypercalcemia can develop in dogs and cats with chronic kidney disease and, less commonly, acute kidney injury. The pathogenesis of hypercalcemia associated with chronic kidney disease is complicated. The development of autonomously functioning parathyroid glands or an alteration of the set point for PTH secretion after prolonged stimulation of renal secondary hyperparathyroidism, decreased PTH degradation by renal tubular cells, increased PTH-mediated intestinal absorption of calcium, increased PTH-mediated osteoclastic bone resorption, decreased renal excretion of calcium, and increased protein-bound or complexed fractions of calcium is believed to contribute to the hypercalcemia of renal failure. Prolonged hypercalcemia, especially in conjunction with concurrent high-normal to increased serum phosphorus concentration, can also cause nephrocalcinosis and exacerbate kidney disease and azotemia. Determining whether the kidney disease is primary or secondary in a dog with hypercalcemia, hyperphosphatemia, and azotemia poses an interesting diagnostic challenge (see the Diagnosis section).

Clinical Features

Although all tissues can be affected by hypercalcemia, the neuromuscular, gastrointestinal, renal, and cardiac systems are the most important clinically. Secondary nephrogenic diabetes insipidus, loss of the renal concentration gradient, and metastatic mineralization of the kidney cause polyuria and polydipsia. Decreased excitability of the central and peripheral nervous systems in conjunction with decreased excitability of gastrointestinal smooth muscle causes lethargy, anorexia, vomiting, constipation, weakness, and (rarely) seizures. In rare instances, cardiac arrhythmias may develop in animals with severe hypercalcemia (i.e., >18 mg/dL). Prolongation of the PR interval and shortening of the QT interval may be found on electrocardiographic readings recorded in animals with milder hypercalcemia.

Clinical signs are often absent with mild increases in the serum calcium concentration, and hypercalcemia is discovered only after a serum biochemistry panel is performed, often for unrelated reasons. When clinical signs do develop, they initially tend to be insidious in onset. The severity of clinical signs depends in part on the severity, rate of onset, and duration of the hypercalcemia. Clinical signs become more severe as the magnitude of the hypercalcemia increases, regardless of the rate of onset or duration. Clinical signs are usually mild with serum calcium concentrations less than 14 mg/dL, are readily apparent with concentrations greater than 14 mg/dL, and become potentially life-threatening (i.e., cardiac arrhythmias) when the serum calcium concentration exceeds 18 to 20 mg/dL. Clinical signs resulting from the development of calcium phosphate or calcium oxalate uroliths may be noted.

Diagnosis

Hypercalcemia should always be reconfirmed, preferably from a nonlipemic blood sample obtained from the dog or cat after a 12-hour fast, before an extensive diagnostic evaluation is undertaken. Results of CBC, serum biochemistry panel, and urinalysis, in conjunction with the history and physical examination findings, often provide clues to the diagnosis (see Table 47.2). Special attention should be paid to serum electrolytes and renal parameters. Hypoadrenocorticism-induced hypercalcemia typically occurs in conjunction with mineralocorticoid deficiency; hyponatremia, hyperkalemia, and prerenal azotemia should be present. The serum phosphorus concentration is in the lower half of the normal range or low with HHM and primary hyperparathyroidism (Fig. 53.1). If the serum phosphorus concentration is increased and renal function is normal, hypervitaminosis D and bone osteolysis from metastatic or primary bone neoplasia are the primary differentials.

Determining whether kidney disease is primary or secondary to hypercalcemia caused by another disorder when hyperphosphatemia and hypercalcemia coexist with azotemia can be difficult. Chronic, and less commonly acute, kidney disease can cause hypercalcemia. Alternatively, disorders that cause persistent hypercalcemia with a concurrent high-normal to increased serum phosphorus concentration

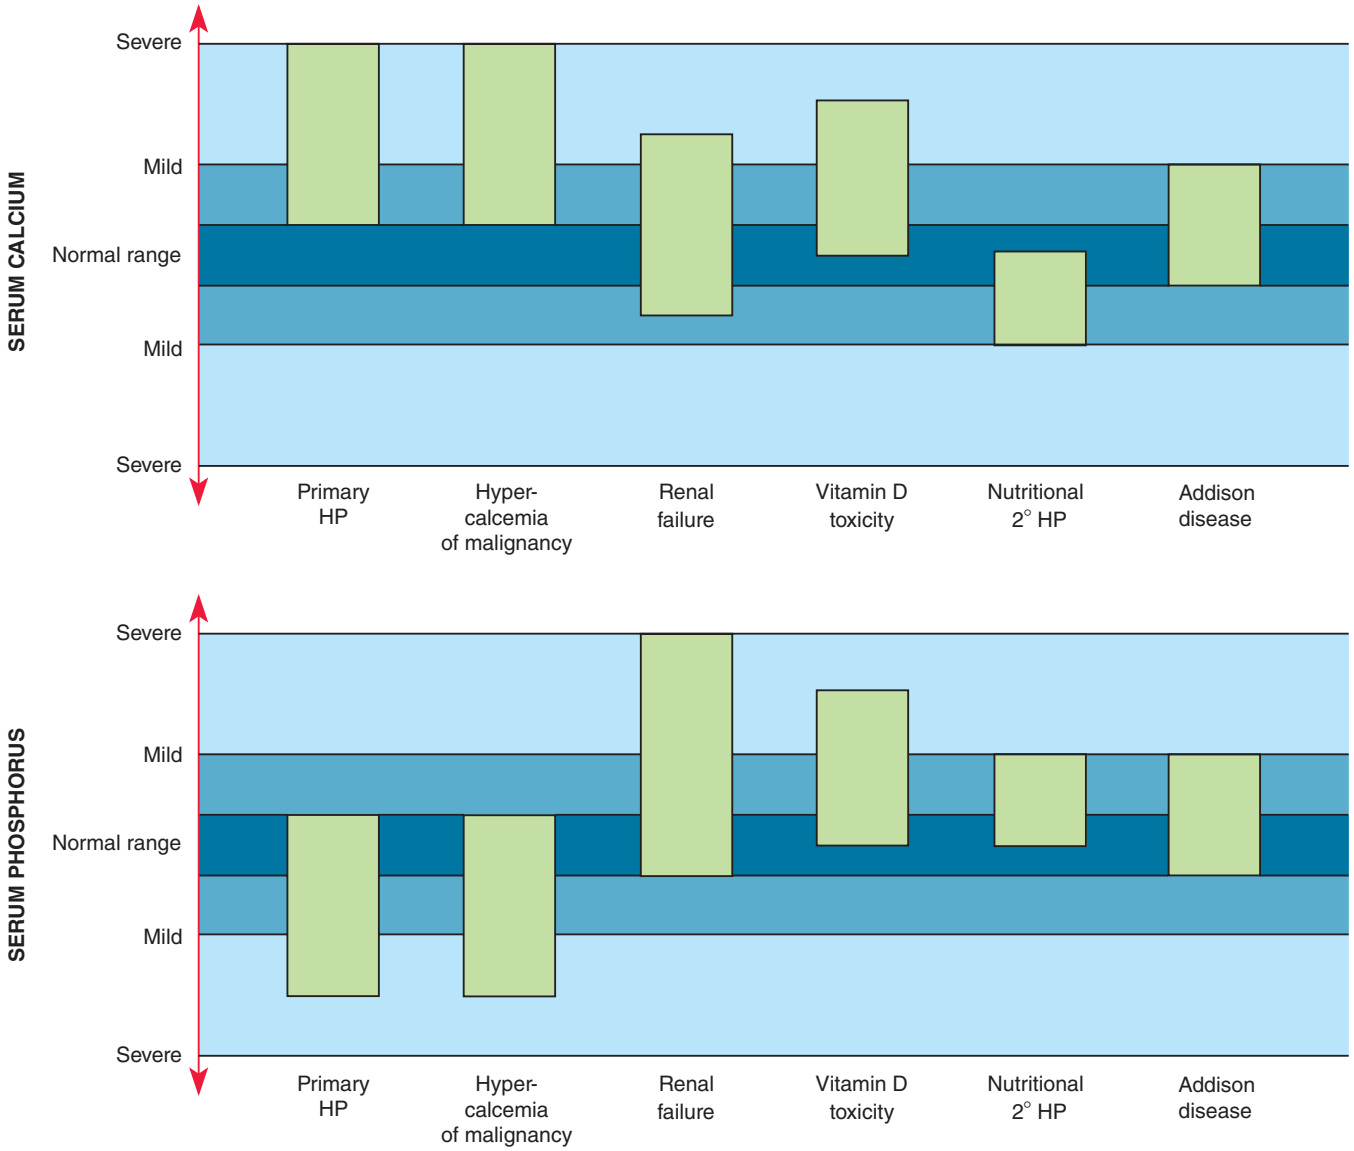

FIG 53.1
The range in serum calcium and phosphorus concentrations for the more common causes of hypercalcemia and/or hyperparathyroidism in the dog. *HP,* Hyperparathyroidism; *2° HP,* secondary hyperparathyroidism. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, Saunders Elsevier.)

can cause progressive mineralization of the kidney and eventual chronic kidney disease. Measurement of the serum ionized calcium concentration may help identify dogs and cats with kidney disease–induced hypercalcemia; serum ionized calcium concentrations are typically normal or decreased in kidney disease and increased in hypercalcemia caused by other disorders. However, autonomous hypersecretion of PTH by the parathyroid gland and an increase in serum ionized calcium (i.e., tertiary hyperparathyroidism) may occur albeit uncommonly in dogs and cats with chronic kidney disease and long-standing renal secondary hyperparathyroidism.

Hypercalcemia of malignancy and primary hyperparathyroidism are the primary differentials when hypercalcemia and normal to low serum phosphorus concentrations are identified. The most common malignancy is lymphoma. A careful review of the history and physical examination findings may provide clues to the diagnosis. Systemic signs of illness suggest hypercalcemia of malignancy. Dogs and cats with primary hyperparathyroidism are usually healthy, and clinical signs are mild. The appendicular skeleton, peripheral lymph nodes, abdominal cavity, and rectum should be carefully palpated for masses, lymphadenopathy, hepatomegaly, splenomegaly, or pain on digital palpation of the long bones. Diagnostic tests helpful in identifying an underlying malignancy include thoracic and abdominal radiographs; abdominal ultrasound; cytologic evaluation of aspirates of the liver, spleen, lymph nodes, and bone marrow; determination of

serum ionized calcium, PTH, and PTHrP concentrations; and cervical ultrasound.

Sternal and hilar lymphadenopathy is common with lymphoma-induced hypercalcemia and can be readily identified with thoracic radiographs. Radiographs of the thorax and abdomen can also be used to evaluate bones; discrete lytic lesions in the vertebrae or long bones suggest multiple myeloma. Hyperproteinemia, proteinuria, and plasma cell infiltration in the bone marrow suggest multiple myeloma. Cytologic evaluation of peripheral lymph node, bone marrow, and splenic aspirates can be helpful in identifying lymphoma; involvement of the peripheral lymph nodes or spleen by lymphoma can be present without causing their enlargement. Ideally, the largest lymph node should be evaluated. Normal lymph node, bone marrow, and splenic aspirates do not rule out lymphoma.

Measurement of serum ionized calcium, PTH, and PTHrP levels from the same blood sample is helpful in differentiating primary hyperparathyroidism from HHM. Excessive secretion of biologically active PTHrP plays a central role in the pathogenesis of hypercalcemia in most forms of HHM. An increased serum ionized calcium concentration, a detectable serum PTHrP concentration, and a nondetectable serum PTH concentration are diagnostic for HHM. Lymphoma is the most common cause of detectable PTHrP concentrations, but other tumors, including apocrine gland adenocarcinoma and various carcinomas (e.g., mammary gland, squamous cell, bronchogenic), can also cause hypercalcemia by this mechanism. In contrast, an increased serum ionized calcium concentration, a normal to increased serum PTH concentration, and a nondetectable PTHrP concentration are diagnostic of primary hyperparathyroidism. Ultrasonographic examination of the parathyroid complex may reveal enlargement of one or more parathyroid glands (see Fig. 47.2, and Video 47.1). Most parathyroid adenomas measure 4 to 8 mm in greatest diameter, although parathyroid adenomas can exceed 2 cm. In contrast, the parathyroid glands should be small (<2 mm in diameter) or undetectable with hypercalcemia of malignancy.

Trial therapy to determine the cause of hypercalcemia is strongly discouraged. If the dog or cat is stable, eating, and not significantly ill, it is recommended to wait a few days to weeks and retest. Most of the causes of hypercalcemia are not occult, so the veterinarian is reminded to complete a thorough history (including toxin and supplement exposure), physical exam, cervical and abdominal ultrasonography, and assessment of PTH and PTHrP assays. Very rarely in dogs the clinician is left with nebulous results and must consider surgical exploration of the neck or trial therapy with L-asparaginase to see if hypercalcemia is alleviated.

Idiopathic hypercalcemia is a common diagnosis in young and middle-aged cats established by ruling out other causes of hypercalcemia. Hypercalcemia is usually mild (<13 mg/dL), and cats are usually asymptomatic. Serum phosphorus concentration and renal parameters are normal. The cause is unknown. Results of a complete diagnostic evaluation, as described previously, are unremarkable. Serum PTH concentrations are in the normal range or low; primary hyperparathyroidism has not been confirmed in any of these cats. Increased serum PTHrP, 25-hydroxyvitamin D, or calcitriol concentrations have not been identified. Nephrocalcinosis and urolithiasis may develop, presumably secondary to increased urinary calcium excretion. Consistently effective treatment has not been identified primarily because the pathogenesis of this problem remains unknown. In addition, the course of the disease is sometimes waxing and waning, which complicates confident correlation of improvement to treatments. Serum calcium concentrations have decreased in some cats following a dietary change to a high-fiber diet, a diet designed for kidney disease, or a diet designed to manage calcium oxalate urolithiasis, or after prednisolone treatment (initial dose, 5 mg q24h), but the response has been unpredictable and often short-lived. Preliminary trials with oral bisphosphonates (e.g., alendronate) have been promising in some cats with idiopathic hypercalcemia (see Treatment section). Serum calcium, phosphorus, and renal parameters should be monitored periodically in affected cats and appropriate therapy initiated if hypercalcemia progressively worsens, deterioration in renal function occurs, or both (see Chapter 41).

Treatment

Medical therapy should be directed at eradicating the underlying cause of the hypercalcemia. Supportive therapy to decrease the serum calcium concentration to less toxic levels is indicated if clinical signs are severe, if serum calcium concentration is greater than 17 mg/dL (dog) or 16 mg/dL (cat), if serum ionized calcium is greater than 1.8 mmol/L (dog) or 1.7 mmol/L (cat), if the calcium-phosphorus solubility product ([Ca] × [Pi]) is greater than 60 to 70 (implying metastatic mineralization of soft tissues), or if azotemia is present. In dogs and cats, correction of fluid deficits, saline diuresis, diuretic therapy with furosemide, and corticosteroids are the most commonly used modes of therapy (Box 53.6). Prerenal azotemia is common in dogs with hypercalcemia secondary to water restriction imposed by owners concerned about the polyuria and polydipsia. Therefore diuretics should never be administered before volume replenishment is completed.

The supportive therapy implemented should not interfere with attempts to establish a definitive diagnosis. As a general rule, saline diuresis followed by diuretic therapy can be initiated without compromising the results of diagnostic tests. Because of the high incidence of lymphoma in animals with hypercalcemia, glucocorticoids should not be administered unless the cause of the hypercalcemia has been identified.

Calcitonin may be useful in the treatment of animals with severe hypercalcemia and could be used in lieu of prednisone for treating hypercalcemia in animals without a definitive diagnosis. Calcitonin inhibits osteoclast activity. It has been used most commonly to treat hypercalcemia in dogs with cholecalciferol rodenticide toxicosis. The decrease in serum total calcium concentration after calcitonin administration is relatively small (≤3 mg/dL), and adverse reactions

BOX 53.6

Nonspecific Therapy for Control of Hypercalcemia

Acute Therapy

1. Correct fluid deficits
2. Physiologic saline diuresis, 60-180 mg/kg/day IV
3. Furosemide, 1-2 mg/kg IV, PO q6-12h
4. Once diagnosis has been established: prednisone, 1-2 mg/kg q12h PO or dexamethasone 0.1-0.2 mg/kg IV q12h

Additional Therapy if Above Fails

1. Calcitonin-salmon, 4-6 IU/kg SC q8-12h
2. Pamidronate, 1-2 mg/kg in 150 mL of 0.9% NaCl IV over 2-4 hours
3. Peritoneal dialysis, hemodialysis

Long-Term Therapy

1. Furosemide (see above)
2. Prednisone (see above)
3. Low-calcium-containing diet
4. Intestinal phosphate binders if hyperphosphatemia present (see Chapter 41)
5. Bisphosphonates (pamidronate [see previous]; etidronate, 5-15 mg/kg once to twice daily PO)

IV, Intravenous; *IM,* intramuscular; *PO,* by mouth; *SC,* subcutaneous.

include anorexia and vomiting. Although the onset of action of calcitonin may be rapid, its effect may be short-lived (hours), and resistance often develops within a few days, presumably because of downregulation of calcitonin receptors. The transitory effect of calcitonin and its expense have limited its usefulness for treating hypercalcemia.

Bisphosphonates inhibit bone resorption by decreasing osteoclast activity and function and inducing osteoclast apoptosis. Pamidronate has been used to treat dogs and cats with a variety of disorders causing hypercalcemia, including cholecalciferol rodenticide toxicosis, hypercalcemia caused by lymphoma, myeloma, osteosarcoma, primary hyperparathyroidism, and nocardiosis. The IV administration of pamidronate has a rapid onset of action and is effective in lowering serum total and ionized calcium concentrations. The only adverse reaction reported with pamidronate is renal toxicity, which appears to be uncommon. Factors that affect onset of renal toxicity in humans include type of bisphosphonate administered, rate of infusion, and hydration status of the patient. Administration of pamidronate before a definitive diagnosis has been obtained should not adversely affect establishing the cause of the hypercalcemia.

The oral bisphosphonate alendronate has been used to treat idiopathic hypercalcemia in cats that have failed to respond to changes in diet and oral prednisolone. Alendronate is not recommended until the serum calcium concentration exceeds 13 mg/dL. Oral alendronate is not as effective as injectable. The currently recommended treatment protocol developed by Dr. Dennis Chew is one 10-mg capsule per cat administered once weekly after a strict 12-hour fast, immediately followed by 6 mL of water taken orally and placement of butter on the nose to promote salivation and swallowing. The cat should not be fed for 2 hours or longer after administration of alendronate. Food interferes with absorption of the medication, and alendronate can cause esophageal erosions. Serum ionized calcium concentration should be measured initially 2 to 3 weeks after treatment is begun and the blood sample obtained just before the next treatment is given, to assess efficacy and to monitor for hypocalcemia. Increasing the dose to 20 mg once a week should be considered if minimal improvement in hypercalcemia is noted after 6 to 8 weeks of treatment.

If prolonged supportive therapy is required (e.g., in an animal with nontreatable malignancy), furosemide, corticosteroids, and a low-calcium diet (consult with a board-certified veterinary nutritionist for current options) can be used to help control the hypercalcemia. Non–calcium-containing intestinal phosphorus binders (e.g., aluminum hydroxide) should be administered if hyperphosphatemia is present. Oral or IV administration of bisphosphonates, as needed to control hypercalcemia, may also be considered.

HYPOCALCEMIA

Etiology

Hypocalcemia is present if the serum total calcium concentration is less than 9 mg/dL in adult dogs and less than 8 mg/dL in adult cats, or if the serum ionized calcium concentration is less than 1.0 mmol/L, although reference ranges may vary between laboratories. Hypocalcemia develops with increased demands of reproduction (e.g., preparturient or puerperal tetany), decreased calcium resorption from bone or kidney (e.g., primary hypoparathyroidism), decreased calcium absorption from the gastrointestinal tract (e.g., malassimilation syndromes), or increased precipitation-chelation of serum calcium (e.g., ethylene glycol toxicity, acute pancreatitis). The acute onset of hyperphosphatemia can also cause hypocalcemia. The most common causes of hypocalcemia in dogs and cats are hypoalbuminemia, puerperal tetany, acute and chronic kidney disease, malassimilation syndromes, critical illness (e.g., sepsis, systemic inflammatory response syndrome [SIRS]), and primary hypoparathyroidism (especially after thyroidectomy in hyperthyroid cats; see Table 47.3). The serum total calcium concentration is typically decreased in animals with concurrent hypoalbuminemia for reasons discussed in the section on hypercalcemia. Depending on the underlying cause, the serum ionized calcium concentration may or may not be decreased. Serum ionized calcium should be measured before a diagnosis of hypocalcemia is rendered in an animal, especially if a decreased serum albumin concentration is present.

Clinical Features

Animals with hypocalcemia range from being asymptomatic to showing severe neuromuscular dysfunction. Serum total

calcium concentrations between 7 and 9 mg/dL are usually clinically silent; dogs and cats with clinical signs usually have serum calcium values less than 7 mg/dL (ionized calcium <0.8 mmol/L), but severity of hypocalcemia and the presence of clinical signs are unpredictable and depend on the magnitude, rapidity of onset, and duration of hypocalcemia.

The most common clinical signs are directly attributable to a hypocalcemia-induced increase in neuronal excitability and include nervousness, behavioral changes, focal muscle twitching (especially ear and facial muscles), muscle cramping, stiff gait, tetany, and seizures. Seizures are not usually associated with loss of consciousness or urinary incontinence. Early indicators of hypocalcemia, especially in cats, include lethargy, anorexia, intense facial rubbing, and panting. Exercise, excitement, and stress may induce or worsen clinical signs. Additional physical examination findings may include fever, a "splinted" abdomen, cardiac abnormalities (e.g., weak femoral pulses, bradycardia, tachycardia), and cataracts.

Diagnosis

Hypocalcemia should be confirmed before diagnostic tests are begun to identify the cause, preferably by measuring the serum ionized calcium concentration. The list of differential diagnoses for hypocalcemia is relatively short, and the history, physical examination findings, CBC, serum biochemistry panel, urinalysis, and tests for pancreatitis (e.g., canine pancreatic lipase immunoreactivity [cPLI], abdominal ultrasound) usually provide the clues necessary to establish the diagnosis (see Table 47.3, p. 765). Primary hypoparathyroidism is the most likely diagnosis in the nonazotemic, nonreproductive dog or cat with clinical signs of hypocalcemia and normal serum magnesium concentration. The finding of a low or undetectable baseline serum PTH concentration confirms this diagnosis. Hypermagnesemia and hypomagnesemia can impair the secretion of PTH and PTH actions on its receptor, so measurement of serum magnesium (preferably ionized magnesium) is important, especially in animals with refractory hypocalcemia.

Treatment

Therapy should be directed at eradicating the underlying cause of the hypocalcemia. Administration of calcium may not be indicated if the patient is stable, no clinical signs of hypocalcemia are noted, and the serum calcium concentration is stable. Vitamin D, calcium, or both are indicated if clinical signs of hypocalcemia are present, if the serum total calcium concentration is less than 7.5 mg/dL, if the serum ionized calcium concentration is less than 0.8 mmol/L, or if hypocalcemia has developed quickly and is progressively decreasing. If hypocalcemic tetany is present, calcium should be administered intravenously slowly to effect (Box 53.7). Calcium gluconate is the preferred agent because it is not caustic if administered outside of the vein, unlike calcium chloride. Auscultation and electrocardiographic monitoring are advisable during calcium administration; if bradycardia or shortening of the QT interval occurs, the IV infusion should be stopped briefly. Calcium-rich fluids should be infused with caution in dogs or cats with hyperphosphatemia because these fluids can increase the probability of mineralization of soft tissues, most notably in the kidney.

Once signs of hypocalcemic tetany have been controlled with IV calcium, oral vitamin D, oral calcium, or both may be needed to prevent the recurrence of clinical signs. If the cause of hypocalcemia is readily reversible and the hypocalcemia is anticipated to be short-lived (e.g., weaning puppies from a bitch with puerperal tetany), oral calcium combined with IV calcium gluconate as needed may be all that is

BOX 53.7

Treatment of Hypocalcemia in Dogs and Cats

Immediate Treatment of Symptomatic Hypocalcemia

Calcium gluconate 10% solution
Dosage: 0.5-1.5 mL/kg IV slowly to effect
Monitor for bradycardia and arrhythmias
Goal: to resolve clinical signs of hypocalcemia

Parenteral Treatment to Prevent Symptomatic Hypocalcemia

Continuous IV infusion of 10% calcium gluconate
- Initial dosage: 60-90 mg elemental calcium/kg/day
- 10 mL of 10% calcium gluconate provides 93 mg of elemental calcium
- Administer via syringe pump in separate IV line
- Do not add to fluids containing lactate, acetate, bicarbonate, or phosphates
- Monitor serum ionized or total calcium q8-12h, and adjust infusion rate accordingly
- Goal: to avoid clinical signs of hypocalcemia while correcting the cause and/or waiting for oral calcium and vitamin D therapy to take effect

Oral Vitamin D and Calcium Treatment for Hypocalcemia

1,25-Dihydroxyvitamin D_3 (calcitriol) is preferred because of its fast onset of action
- Available as 0.25-µg and 0.50-µg capsules
- Initial dosage: 0.02-0.03 µg/kg/day
- Monitor serum ionized or total calcium q12-24h, and adjust dosage or frequency of administration accordingly
- Goal: to avoid clinical signs of hypocalcemia and development of hypercalcemia; target total calcium concentration is between 9 and 10 mg/dL

Oral calcium gluconate, calcium lactate, or calcium carbonate tablets
- Various tablet strengths available, ranging from 30-500 mg calcium/tablet
- Initial dosage: approximately 25-50 mg of Ca/kg q24h, dose often divided
- Typically used in conjunction with vitamin D
- Dosage and frequency of administration adjusted on the basis of serum ionized or total calcium concentration

IV, Intravenous.

necessary to prevent the recurrence of clinical signs. An IV continuous-rate infusion (CRI) of calcium, in addition to oral calcium, vitamin D, or both, is recommended for animals with disorders causing prolonged severe hypocalcemia (e.g., primary hypoparathyroidism, postparathyroidectomy for primary hyperparathyroidism). For IV CRI, calcium gluconate should be administered at an initial dosage of 60 to 90 mg of elemental calcium/kg/day. Ten milliliters of 10% calcium gluconate provides 93 mg of elemental calcium. Approximately 1, 2, or 3 mg/kg/h elemental calcium is provided when 10, 20, or 30 mL of 10% calcium gluconate, respectively, is added to 250 mL of fluids and administered at a maintenance rate of 60 mL/kg/day (2.5 mL/kg/h). Calcium salts should not be added to fluids that contain lactate, acetate, bicarbonate, or phosphates because calcium salt precipitates can result. The serum calcium concentration should be monitored every 8 to 12 hours and the calcium infusion adjusted accordingly with the goal of gradually decreasing and then discontinuing the infusion once the serum total calcium concentration is consistently greater than 8 mg/dL, or the serum ionized calcium concentration is greater than 0.9 mmol/L.

Long-term maintenance therapy may be necessary to control hypocalcemia. It is most commonly required for the control of primary hypoparathyroidism and hypoparathyroidism after bilateral thyroidectomy in cats with hyperthyroidism. Oral vitamin D administration is the primary mode of treatment for the management of chronic hypocalcemia (see Box 53.7). Vitamin D works by stimulating intestinal calcium and phosphorus absorption and, together with parathyroid hormone, by mobilizing calcium and phosphorus from bone. Oral calcium supplements are needed early in maintenance therapy in addition to vitamin D.

The aim of maintenance therapy is to keep the serum calcium concentration between 9 and 10 mg/dL (dog) and between 8 and 9 mg/dL (cat), which controls clinical signs, lessens the risk of hypercalcemia, and provides some stimulus for remaining or ectopic parathyroid tissue to become functional. The serum calcium concentration should be monitored closely (initially q24-48h) and adjustments in therapy made accordingly. Vitamin D therapy is required permanently in animals with primary hypoparathyroidism and in animals that have undergone total parathyroidectomy. Vitamin D therapy usually can be tapered and discontinued if only partial or transient parathyroid damage has occurred. Regardless, calcium supplementation often may be tapered and stopped. (See Chapter 47 for more information on the treatment of hypocalcemia.) Appropriate use and selection of diets to support gestation and lactation are critical for optimizing successful reproduction in cats and dogs and to help prevent and treat calcium imbalances.

HYPERPHOSPHATEMIA

Etiology

Hyperphosphatemia is present when the serum phosphorus concentration is greater than 6.0 mg/dL in the adult dog and cat, although reference ranges may vary between laboratories. Young dogs (<12 months) especially of large and giant breeds and young cats (<6 months) have higher serum phosphorus concentrations than adults, which should gradually decrease to adult values (e.g., typical laboratory reference ranges) by 12 months of age. Bone growth and an increase in renal tubular reabsorption of phosphorus mediated by growth hormone are believed to contribute to this age effect. Hyperphosphatemia can result from increased intestinal phosphorus absorption, decreased phosphorus excretion in the urine, or a shift in phosphorus from the intracellular to the extracellular compartment. Translocation of phosphorus between intracellular and extracellular compartments is similar to that of potassium. The most common cause of hyperphosphatemia in dogs and cats is decreased renal excretion secondary to kidney disease (Box 53.8).

BOX 53.8

Causes of Hyperphosphatemia in Dogs and Cats

Physiologic Causes

Young growing animal*

Increased Input

Hypervitaminosis D*
- Excess supplementation
- Cholecalciferol rodenticides

Jasmine toxicity
Excess dietary intake
Osteolytic bone lesions (neoplasia)

Decreased Loss

Acute or chronic kidney disease*
Uroabdomen
Hypoparathyroidism*
Hyperthyroidism
Hyperadrenocorticism
Acromegaly

Transcellular Shifts (ICF to ECF)

Metabolic acidosis
Tumor cell lysis syndrome
Tissue trauma or rhabdomyolysis
Hemolysis

Iatrogenic Causes

IV phosphorus administration
Phosphate-containing enemas
Diuretics: furosemide and hydrochlorothiazides

Laboratory Error

Lipemia
Hyperproteinemia

ECF, Extracellular fluid; *ICF,* intracellular fluid; *IV,* intravenous.
*Common causes.
Modified from DiBartola SD, Willard MD: Disorders of phosphorus: hypophosphatemia and hyperphosphatemia. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders in small animal practice,* ed 4, St Louis, 2012, Saunders Elsevier.

Clinical Features

Hyperphosphatemia is a marker of underlying disease. By itself, hyperphosphatemia usually does not cause clinical signs. An acute increase in serum phosphorus may cause hypocalcemia and its associated neuromuscular signs. Sustained hyperphosphatemia can cause secondary hyperparathyroidism, fibrous osteodystrophy, and mineralization of soft tissues. Fortunately, most causes of hyperphosphatemia cause a decrease in serum calcium concentration so that the calcium-phosphorus solubility product ([Ca] × [Pi]) remains less than 60. The risk of soft tissue mineralization increases when the [Ca] × [Pi] solubility product exceeds 60. Chronic kidney disease is the most common cause of sustained hyperphosphatemia and an increase in the solubility product above 60. History, physical examination, and results of CBC, serum biochemistry panel, urinalysis, and serum T_4 concentration (cats) will usually reveal the cause.

Treatment

Hyperphosphatemia usually resolves with correction of the underlying disease. In dogs and cats with kidney disease, hyperphosphatemia can initially be lowered with aggressive fluid therapy. Low-phosphorus diet with orally administered phosphate binders is the most effective way to treat sustained hyperphosphatemia caused by kidney disease (see Chapter 41).

HYPOPHOSPHATEMIA

Etiology

Hypophosphatemia is present when the serum phosphorus concentration is less than 3 mg/dL in the dog and cat, although reference ranges may vary between laboratories. Hypophosphatemia usually is not clinically worrisome until the serum phosphorus concentration is less than 1.5 mg/dL. Hypophosphatemia results from decreased phosphorus absorption in the intestinal tract, increased urinary phosphorus excretion, or translocation from the extracellular to the intracellular compartment. Hypophosphatemia is commonly associated with humoral HHM (i.e., lymphoma), primary hyperparathyroidism, and aggressive therapy for DKA (Box 53.9). Clinically significant hypophosphatemia is most likely to occur within the first 24 hours of therapy for diabetic ketoacidosis, when a shift of potassium and phosphorus from the extracellular to the intracellular compartment occurs. The nature of the translocation of phosphorus between intracellular and extracellular compartments is similar to that seen with potassium. Factors that promote a shift of potassium into the intracellular compartment (e.g., alkalosis, insulin, glucose infusion) promote a similar shift in phosphorus. During therapy for DKA, the serum phosphorus concentration can decline to severe levels (i.e., <1 mg/dL) as a result of the dilutional effects of fluid therapy and the intracellular shift of phosphorus after initiation of insulin and bicarbonate therapy. It is interesting to note that the initial serum phosphorus concentration usually is normal or only mildly decreased because metabolic acidosis of DKA results in a shift of phosphorus from the intracellular to the extracellular compartment.

Modified from DiBartola SD, Willard MD: Disorders of phosphorus: hypophosphatemia and hyperphosphatemia. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders in small animal practice*, ed 4, St Louis, 2012, Saunders Elsevier.

Clinical Features

Clinical signs may develop when the serum phosphorus concentration is less than 1.5 mg/dL, although signs are variable and severe hypophosphatemia is clinically silent in many animals. Hypophosphatemia primarily affects the hematologic and neuromuscular systems in the dog and cat. Hemolytic anemia is the most common sequela to hypophosphatemia. Hypophosphatemia decreases the erythrocyte concentration of adenosine triphosphate (ATP), which increases erythrocyte fragility, leading to hemolysis. Hemolysis usually is not identified until the serum phosphorus concentration is 1 mg/dL or less. Hemolytic anemia can be life-threatening if not recognized and treated. Neuromuscular signs include weakness, ataxia, and seizures, as well as anorexia and vomiting secondary to intestinal ileus.

Treatment

For most dogs and cats, hypophosphatemia resolves after correction of the underlying cause. Phosphate therapy

probably is not indicated for asymptomatic animals in which the serum phosphorus concentration is greater than 1.5 mg/dL and is unlikely to decrease further. Phosphate therapy is indicated if clinical signs or hemolysis is identified, or if the serum phosphorus concentration is less than 1.5 mg/dL, especially if a further decrease is possible. Phosphate supplementation is not indicated in dogs and cats with hypercalcemia, oliguria, or suspected tissue necrosis. If renal function is in question, phosphorus supplementation should not be provided until the status of renal function and the serum phosphorus concentration are known.

The goal of therapy is to maintain the serum phosphorus concentration greater than 2 mg/dL without causing hyperphosphatemia. Injectable potassium phosphate solution is available; however, unless urgent due to severity, oral phosphate supplementation is preferred (e.g., K-Phos Neutral or Phospha 250 Neutral); bovine milk contains 0.032 mmol/mL of elemental phosphorous and can be used for oral phosphate supplementation, balanced commercial diets, or a combination of these. IV phosphate supplementation is usually required to correct severe hypophosphatemia, especially in animals with diabetic ketoacidosis. Potassium phosphate solutions are typically used. If potassium supplementation is contraindicated, sodium phosphate solutions can be substituted. Potassium and sodium phosphate solutions contain 3 mmol of phosphate per milliliter and either 4.4 mEq of potassium or 4 mEq of sodium per milliliter. The initial dosage of phosphate is 0.01 to 0.03 mmol/kg/h, preferably administered by constant-rate infusion in calcium-free IV fluids (i.e., 0.9% sodium chloride). In dogs and cats with severe hypophosphatemia, it may be necessary to increase the dosage to 0.03 to 0.12 mmol/kg/h. Because the dose of phosphate necessary to replete an animal and the animal's response to therapy cannot be predicted, it is important to initially monitor the serum phosphorus concentration every 4 to 8 hours and adjust the phosphate infusion accordingly. Adverse effects from overzealous phosphate administration include iatrogenic hypocalcemia and its associated neuromuscular signs, hypernatremia, hypotension, mineralization of soft tissues, and renal failure. Serum total or preferably ionized calcium concentration should be measured at the same time as serum phosphorus concentration and the rate of phosphate infusion decreased if hypocalcemia is identified.

HYPOMAGNESEMIA

Etiology

Hypomagnesemia is present if serum total and ionized magnesium concentrations are less than 1.5 mg/dL and 0.4 mmol/L, respectively, although reference ranges may vary between laboratories. Hypomagnesemia results from decreased oral intake, increased loss from the gastrointestinal tract (e.g., malabsorption syndromes), increased renal loss (e.g., postobstructive diuresis), endocrine causes (e.g., diabetes mellitus), or translocation of the cation from the extracellular to the intracellular compartment. The most common causes of clinically significant hypomagnesemia in dogs and cats include disorders leading to small intestinal malassimilation; renal disorders associated with high urine output; the osmotic diuresis of diabetic ketoacidosis; and the shift of potassium, phosphorus, and magnesium from the extracellular to the intracellular compartment that occurs within the first 24 hours of therapy for DKA (Box 53.10). Magnesium is predominantly an intracellular cation. The nature of the translocation of magnesium between intracellular and extracellular compartments is similar to that of potassium in that factors that promote a shift of potassium into the intracellular compartment (e.g., alkalosis, insulin, glucose infusion) promote a similar shift of magnesium.

Clinical Features

Hypomagnesemia is reported to be the most common electrolyte disorder in critically ill dogs and cats, and magnesium deficiency may predispose animals to a variety of cardiovascular, neuromuscular, and metabolic complications. Clinical signs of hypomagnesemia do not usually occur until serum total and ionized magnesium concentrations are less than 1.0 mg/dL and 0.4 mmol/L, respectively, and even at these low levels many animals remain grossly asymptomatic. However, magnesium deficiency can result in several nonspecific clinical signs, including lethargy, anorexia, muscle weakness (including dysphagia and dyspnea), muscle fasciculations, seizures, ataxia, and coma. Concurrent hypokalemia, hyponatremia, and hypocalcemia occur in animals with hypomagnesemia, although the prevalence of these electrolyte abnormalities may differ between species. These electrolyte abnormalities may also contribute to the development of clinical signs. Magnesium is a co-factor for all enzyme reactions that involve ATP, most notably the sodium-potassium ATPase pump. Deficiencies in magnesium may cause potassium-losing nephropathy and increased urinary potassium losses, and the resultant hypokalemia may be refractory to appropriate potassium replacement therapy unless hypomagnesemia is corrected. Magnesium deficiency may inhibit PTH secretion from the parathyroid gland and may promote calcium uptake into bone, resulting in hypocalcemia. Magnesium deficiency also causes the resting membrane potential of myocardial cells to be decreased and leads to increased Purkinje fiber excitability, with consequent generation of arrhythmias. Electrocardiographic changes include a prolonged PR interval, a widened QRS complex, a depressed ST segment, and peaked T waves. Cardiac arrhythmias associated with magnesium deficiency include atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation. In addition, hypomagnesemia predisposes animals to digitalis-induced arrhythmias.

Diagnosis

Many disorders and predisposing factors in dogs and cats are associated with hypomagnesemia (see Box 53.10). However, measurement of serum total vs. ionized magnesium is somewhat controversial. Serum total magnesium represents 1% of

BOX 53.10

Causes of Hypomagnesemia and Magnesium Depletion in Dogs and Cats

Gastrointestinal Causes

Inadequate intake
Chronic diarrhea and vomiting*
Malabsorption syndromes
Acute pancreatitis
Cholestatic liver disease
Nasogastric suction

Renal Causes

Chronic kidney disease
Renal tubular acidosis
Postobstructive diuresis
Drug-induced tubular injury (e.g., aminoglycosides, cisplatin)
Post–renal transplant
Prolonged intravenous fluid therapy*
Diuretics*
Digitalis administration
Concurrent electrolyte disorders
- Hypercalcemia
- Hypokalemia
- Hypophosphatemia

Endocrine Causes

Diabetes mellitus and diabetic ketoacidosis*
Hyperthyroidism
Primary hyperparathyroidism
Primary hyperaldosteronism

Miscellaneous Causes

Acute administration of insulin, glucose, or amino acids
Sepsis
Hypothermia
Massive blood transfusion
Peritoneal dialysis, hemodialysis
Parenteral nutrition

*Common causes.
Modified from Bateman S: Disorders of magnesium: magnesium deficit and excess. In DiBartola SP, editor: *Fluid, electrolyte, and acid-base disorders in small animal practice*, ed 4, St Louis, 2012, Saunders/Elsevier.

the body's magnesium stores, and serum ionized magnesium represents 0.2% to 0.3% of total body magnesium stores. As a result, serum total and ionized magnesium concentrations do not always reflect total body magnesium status. A normal serum magnesium concentration may exist despite an intracellular magnesium deficiency. However, a low serum magnesium concentration would support the presence of a total body magnesium deficiency, especially when clinical signs or concurrent electrolyte abnormalities are consistent with hypomagnesemia. A serum ionized magnesium concentration determined with the use of an ion-selective electrode has been recommended based on the assertion that it more accurately assesses total body magnesium content than measurement of serum total magnesium. However, some lines of evidence in dogs, cats, and humans indicate that evaluation of total magnesium or the ratio or ionized to total magnesium is indicated with suspected chronic deficiency, because ionized magnesium may be preserved at the expense of total magnesium concentrations. Assessing an animal's magnesium status is problematic because no simple, rapid, and accurate laboratory test is available to gauge total body magnesium status. A parenteral magnesium tolerance test involving IV infusion and measurement of magnesium in urine to estimate retention has been described in dogs to identify those with poor total body status, but this has not been standardized in clinical practice. In dogs and cats with low serum magnesium concentration, a review of the history, physical examination, CBC, serum biochemistry panel, and urinalysis usually provides clues to the underlying cause (see Box 53.10).

Treatment

Treatment of hypomagnesemia usually involves ill dogs and cats that are hospitalized and have inappetence and/or excessive fluid loss from the gastrointestinal tract or kidneys. Treatment of hypomagnesemia may also be indicated during treatment of DKA in dogs and cats with refractory hypokalemia, hypocalcemia, or both, in dogs and cats with refeeding syndrome, and in dogs or cats in heart failure with concurrent ventricular arrhythmias that are being treated with loop diuretics, digitalis, or both.

Parenteral solutions of magnesium sulfate (8.12 mEq of magnesium per gram of salt) and magnesium chloride (9.25 mEq of magnesium per gram of salt) are available commercially. The IV dose for rapid and slow magnesium replacement is 0.5 to 1 mEq/kg/day and 0.3 to 0.5 mEq/kg/day, respectively, administered by constant-rate infusion in 5% dextrose in water or 0.9% sodium chloride. Magnesium is incompatible with solutions containing bicarbonate or calcium. Kidney function should be assessed before magnesium is administered, and the magnesium dose should be reduced by 50% to 75% in azotemic animals. The use of magnesium with digitalis cardioglycosides may cause serious conduction disturbances. Serum magnesium, calcium, and potassium concentrations should be monitored every 8 to 12 hours. The goal of magnesium therapy is the resolution of clinical signs or refractory hypokalemia and hypocalcemia. Parenteral administration of magnesium sulfate may cause significant hypocalcemia due to the chelation of calcium with sulfate; therefore, magnesium chloride should be given if hypocalcemia is also present or a calcium infusion may be necessary. Other adverse effects of magnesium therapy include hypotension; atrioventricular and bundle branch blocks; and, in the event of overdose, respiratory depression and cardiac arrest. Overdoses are treated with IV calcium gluconate (see Box 53.7). Oral supplementation for more chronic or less severe cases is indicated and often well tolerated although a laxative effect may be seen; magnesium oxide, citrate, gluconate, chelate, or a mix of forms in an oral

tablet supplement product to provide 1 to 2 mEq/kg body weight per day has been sufficient to maintain total magnesium in the normal range in dogs in the experience of the authors.

HYPERMAGNESEMIA

Etiology

Hypermagnesemia is present if serum total and ionized magnesium concentrations are greater than 2.5 mg/dL and 1.5 nmol/L, respectively, although reference ranges may vary between laboratories. It is an uncommon clinical problem owing to the remarkable ability of the kidney to efficiently eliminate excessive magnesium. Hypermagnesemia may occur in dogs and cats with kidney disease and post–renal azotemia and iatrogenically after excessive intake of magnesium (e.g., IV administration). Because excess magnesium is rapidly excreted by the healthy kidney, iatrogenic hypermagnesemia usually occurs in animals with chronic kidney disease. Hypermagnesemia has also been reported in cats with thoracic neoplasia and pleural effusion and in dogs with hypoadrenocorticism, primary hyperparathyroidism, and hypothyroidism. The mechanism involved in the development of hypermagnesemia in these cats and dogs is unknown.

Clinical Features

Hypermagnesemia usually results in varying degrees of neuromuscular blockade. Nonspecific clinical manifestations of hypermagnesemia include lethargy, weakness, and hypotension. Loss of deep tendon reflexes and electrocardiographic changes, consisting of prolonged PR intervals, widening QRS complexes, and heart block, occur at higher serum magnesium concentrations. Serious complications, including respiratory depression, apnea, cardiac arrhythmias, and cardiac arrest, occur when serum magnesium concentrations exceed 12 mg/dL. At these high levels, magnesium acts as a nonspecific calcium channel blocker.

Diagnosis

Measurement of the serum magnesium concentration identifies hypermagnesemia. Unlike magnesium depletion, serum concentrations cannot be normal if there is an increase in magnesium stores. A correlation between increased serum magnesium concentrations and the severity of total body excess has not been reported.

Treatment

Treatment begins with discontinuation of all exogenous sources of magnesium. Additional treatment depends on the severity of the hypermagnesemia, the clinical presentation, and the status of renal function. Most dogs and cats with healthy kidneys require only supportive care and observation. Treatment aimed at improving renal function is indicated in animals with concurrent chronic kidney disease (see Chapter 41). Saline diuresis and administration of loop diuretics (e.g., furosemide) will accelerate renal magnesium excretion. Administration of IV calcium gluconate is indicated in dogs and cats with cardiac arrhythmias or significant hypotension (see Box 53.7).

PART EIGHT ▪ Reproductive System Disorders

Autumn P. Davidson

CHAPTER 54

The Practice of Theriogenology

Theriogenology is the branch of veterinary medicine concerned with reproduction, including the physiology and pathology of male and female reproductive systems of animals and the clinical practice of veterinary obstetrics, gynecology, and andrology. Clinical small animal theriogenology primarily revolves around the production of healthy purebred puppies and kittens from privately owned breeding stock. Less commonly, veterinary participation in large-scale commercial breeding programs is sought. Generally, small animal theriogenology is a rewarding subspecialty in veterinary internal medicine. Although demanding of the clinician's time and expertise, the breeder client tends to be very loyal and compliant. A good reproductive practice generates its own referrals and usually is quite busy. Obstetrics and pediatrics are undeniably rewarding parts of the specialty for veterinarians and their staff. Reproductive practice incorporates the fields of physiology, endocrinology, embryology, genetics, metabolism, nutrition, pediatric and maternal critical care, anesthesia, pharmacology, and anatomy. The field is uniquely both medical and surgical, and involves both intact and neutered dogs and cats (Boxes 54.1 and 54.2).

THE PREBREEDING CONSULTATION

Veterinary participation benefits dog and cat breeding programs not only by providing medical and surgical intervention when indicated but also by promoting good animal husbandry with preventive medicine. Proper genetic counseling and screening for selection of breeders minimizes inherited defects. Optimizing the prebreeding condition of the dam and sire involves health and reproductive system examinations, nutrition evaluation, parasite control, and infectious disease prevention. Ovulation timing and breeding management improve conception rates and litter size. Obstetrics promotes eutocia and improves neonatal survival. Postpartum preventive medicine minimizes morbidity and mortality of both the dam and her offspring. Periodic physical examination and semen evaluation is advised in the valuable stud dog.

Breeding soundness consultations for canine or feline breeding animals should include evaluation of the temperament, physical condition, health and breeding history, infectious disease status (canine brucellosis, herpes virus; feline leukemia virus [FeLV], feline immunodeficiency virus [FIV], feline infectious peritonitis [FIP], and feline toxoplasmosis), vaccination status, diet, current medications, and any supplements, as well as available genetic screening appropriate for the breed (Box 54.3). A review of kennel or cattery husbandry should be completed (canine: housing, parasite control, diet, supplements, medications; feline: light cycles, housing, cat density, diet, parasite control, supplements, medications). Proper perinatal nutrition and body condition for the prospective dam should be addressed. In bitches, a change from an adult diet to a diet formulated for pregnancy and lactation (usually labeled as nutritionally complete for all life stages or complete nutrition for growth, pregnancy, and lactation) should occur at the fourth to sixth week of gestation and continue through weaning. Bitches' energy requirements during pregnancy increase in the last trimester. A change to a diet high in essential fatty acids at the time of breeding has been advocated to improve litter size and neonatal viability (Kelley et al., 2004). The amount fed must be managed to maintain proper body condition, because obesity negatively impacts labor. Supplements should be discouraged because they generally unbalance a commercially prepared diet. The pregnancy and lactation diet should be one previously tested and found to be adequate by the Association of American Feed Control Officials (AAFCO) standards, not one simply "formulated to meet AAFCO standards." A protein level of 27% to 34% dry matter (preferably animal-based sources), at least 18% fat with a balanced supply of both n-6 and n-3 fatty acids, and 20% to 30% carbohydrates with optimum vitamins and minerals (avoiding deficiencies and excesses) is advisable. Queens uniquely experience linear weight gain during pregnancy; they should

conditions, or genetic traits. To increase access to information on diagnosing hereditary diseases in dogs and cats, a web application has been developed to collect, organize, and display information on available DNA tests and other supporting information, including gene and chromosomal locations, mutations, primary research citations, and disease descriptions. There are currently 131 molecular genetic tests available for hereditary diseases in dogs and cats offered by 43 laboratories worldwide (Box 54.4).

The physical examination should pay specific attention to the external genitalia. Bitches and queens should be evaluated for vestibule-vaginal malformations that could interfere with copulation or whelping, either via digital or vaginoscopic examination (Fig. 54.1). Abnormalities of the development of the müllerian duct or with the normal fusion between the müllerian duct and the urogenital sinus during embryogenesis can result in atresia of the tubular genitalia or formation of septa. Septa can be circumferential (hymen-like) or dorsoventral bands, both usually located just cranial to the urethral papilla. Dorsoventral bands, if narrow, can usually be easily resected with vaginoscopy before breeding and whelping, even during proestrus (Fig. 54.2). Sedation of a short general anesthetic is sometimes required. Thicker bands and circumferential strictures are difficult to resolve

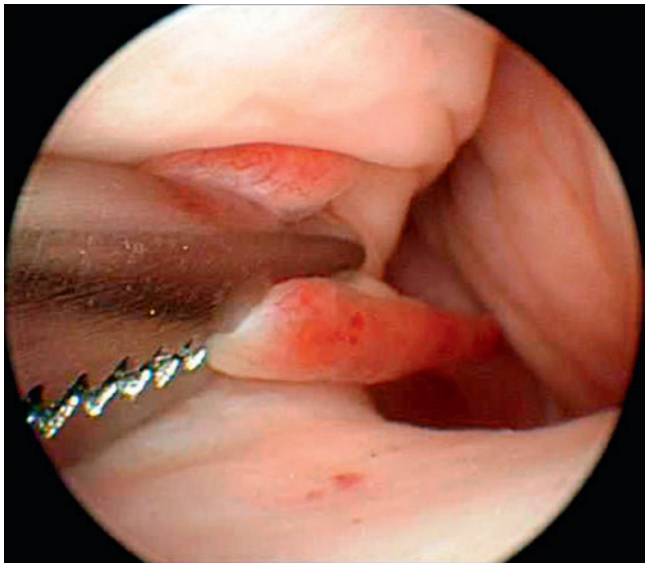

FIG 54.2

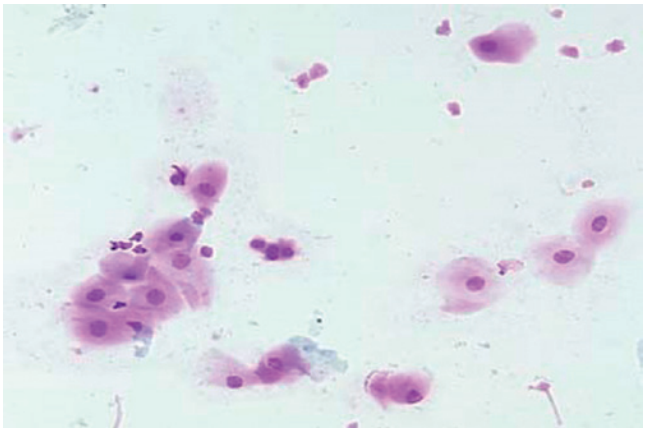

FIG 54.3
Anestrus vaginal cytology showing scant cellularity, parabasal cells, and occasional neutrophils.

surgically because they require an episiotomy and commonly reform and restrict. Artificial insemination and elective cesarean section are usually advised. Rarely anomalous uterine structures (agenesis, duplication) accompany vaginal septa and preclude breeding. The heritability of these septa is not known. Both bitches and queens should be evaluated for mammary gland normalcy and nipple duct patency. Dogs and toms should be evaluated for normal testicular descent into the scrotum, lack of a persistent penile frenulum, or penile hair ring (tom) (see Chapter 56), and normal testicular, epididymal, and prostatic (dog) palpation. In both species the prepuce should be retracted to inspect the penile mucosa. Semen evaluation should be performed in the dog (see later).

ESTROUS CYCLE OF THE BITCH

Puberty occurs between 6 and 24 months in the bitch, later in large breeds. The normal canine reproductive cycle can be categorized into four phases: anestrus, proestrus, estrus, and diestrus, each having characteristic behavioral, physical, and endocrinologic patterns (Table 54.1). The interestrous interval is normally 4 to 13 months, with 7 months as the average. The anestrus phase of the estrous cycle is marked by uterine involution and endometrial repair. The normal bitch is not attractive or receptive to male dogs. No overt vulvar discharge is present, and the vulva is small. Vaginal cytology is predominated by small parabasal cells, with occasional neutrophils and small numbers of mixed bacteria (Fig. 54.3). The endoscopic appearance of vaginal mucosal folds is flat, thin, and red. The physiologic controls terminating anestrus are still under investigation but involve spontaneous deterioration of luteal function and decline of prolactin secretion. It has been shown that the administration of dopamine agonists shortens the interestrous interval, which in some instances is associated with inhibition of prolactin release (prolactin is luteotrophic). The natural termination of anestrus is induced by an increase in the pulsatile gonadotropin-releasing hormone (GnRH)–induced secretion of pituitary gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Hypothalamic GnRH secretion is itself pulsatile, its intermittent secretion a physiologic requirement of gonadotropin release. Mean concentrations of FSH are moderately elevated and those of LH slightly elevated during anestrus. At late anestrus, the pulsatile release of FSH increases, causing proestrus folliculogenesis. Estrogen concentration is basal (2-10 pg/mL) and progesterone at nadir (<1 ng/mL) at late anestrus. Anestrus normally lasts from 1 to 6 months.

During proestrus, the bitch becomes attractive to male dogs but is still not receptive to breeding, although she may become more playful. A serosanguineous to hemorrhagic vulvar discharge of uterine origin is present, and the vulva is mildly enlarged. Vaginal cytology shows a progressive shift from small parabasal cells to small and large intermediate cells, superficial-intermediate cells, and finally superficial (cornified) epithelial cells, reflecting the degree of estrogen influence (Fig. 54.4). Red blood cells (RBCs) are usually but not invariably present. The vaginal mucosal folds appear edematous, pink, and round (Fig. 54.5). FSH and LH are low during most of proestrus, rising during the preovulatory surge. Estrogen rises from basal anestrus concentration (2-10 pg/mL) to a peak (50-100 pg/mL) at late proestrus, whereas progesterone remains basal (<1 ng/mL) until rising at the LH surge (1.5-4 ng/mL). Proestrus lasts from 3 days to 3 weeks, with a 9-day average. The follicular phase of the ovarian cycle coincides with proestrus and very early estrus.

During estrus, the normal bitch displays receptive or passive behavior, enabling breeding. This behavior correlates with decreasing estrogen and increasing progesterone concentrations. Serosanguineous to hemorrhagic vulvar discharge may diminish to variable degrees. Vulvar edema

TABLE 54.1

Salient Characteristics of the Canine Estrous Cycle

STAGE	LENGTH	BEHAVIOR	IMPORTANT HORMONES	VAGINAL CYTOLOGY	VAGINOSCOPY	REPRODUCTIVE ACTIVITY	DISCHARGE, VULVA

tends to be maximal (Fig. 54.6). Vaginal cytology remains predominated by superficial cells; RBCs tend to decrease but may persist throughout (Fig. 54.7). Vaginal mucosal folds become progressively wrinkled (crenulated) in conjunction with ovulation and oocyte maturation (Fig. 54.8). Estrogen concentrations reduce markedly after the LH peak, while progesterone concentrations steadily increase (usually 4-10 ng/mL at ovulation), marking the luteal phase of the ovarian cycle. Estrus lasts 3 days to 3 weeks, with an average of 9 days. Estrous behavior may precede or follow the LH surge; its duration is variable and may not coincide precisely with the fertile period. Ovulation of primary oocytes occurs 2 days after the LH surge; oocyte maturation occurs 2 to 3 days later. The life span of secondary oocytes is 2 to 3 days.

During diestrus, the normal bitch becomes refractory to breeding, with diminishing attraction of male dogs. Vulvar discharge diminishes and edema slowly resolves. Vaginal cytology is abruptly altered by the reappearance of parabasal epithelial cells and frequently neutrophils (Fig. 54.9). The appearance of vaginal mucosal folds becomes flattened and flaccid. Estrogen concentrations are variably low, and progesterone concentrations steadily rise to a peak of 15 to 80 ng/mL before progressively declining in late diestrus. Progesterone secretion is dependent on both pituitary LH

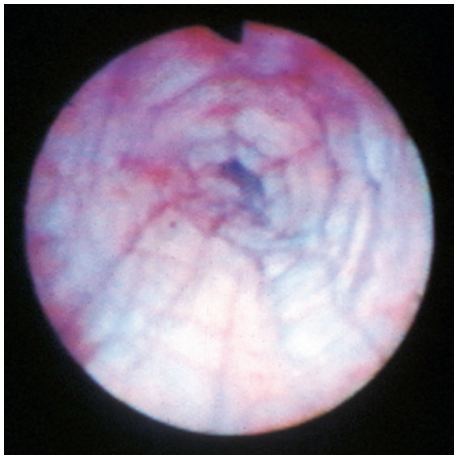

FIG 54.8

and prolactin secretion. Proliferation of the endometrium and quiescence of the myometrium occur under the influence of elevated progesterone. Diestrus usually lasts 2 to 3 months in the absence of pregnancy. Parturition terminates pregnancy 64 to 66 days after the LH peak. Prolactin concentrations increase in a reciprocal fashion to falling progesterone at the termination of diestrus or gestation, reaching much higher values in the pregnant state. Mammary ductal and glandular tissues increase in response to prolactin levels.

CANINE OVULATION TIMING: EVALUATION OF THE ESTROUS CYCLE TO IDENTIFY THE OPTIMAL TIME TO BREED

Individual bitches can have nonproblematic variations of the normal estrous cycle, be presented at variable times during their estrous cycle for evaluation, or exhibit pathologic variations in their cycle. Each of these scenarios requires veterinary interpretation. Considerable variation exists within the normal range of events in the reproductive cycle. The clinician must differentiate between bitches with normal estrous cycles but unexpected patterns and those with true abnormalities. This usually entails monitoring a bitch during an entire estrous cycle. Detection of individual variation within the normal range of events in a fertile bitch can be crucial to providing effective counseling concerning breeding management. Evaluation of the estrous cycle for true abnormalities is an important part of the workup of the apparently infertile bitch (see Chapter 55).

SERUM HORMONE INTERPRETATION

Estrogen

During the follicular phase of the ovarian cycle, increasing estrogen causes an increased turnover rate of vaginal epithelial cells, resulting in the progressive cornification seen on vaginal cytology and thickening of the vaginal wall in preparation for copulation with an interlocking tie (Fig. 54.10). Also seen is progressive edema of the vaginal mucosa, seen with endoscopic examination. Estrogen assays are performed by many commercial laboratories. However, the information given is of little value for ovulation timing, because peak estrogen levels are variable from bitch to bitch, and even relative changes do not correlate to ovulation or the fertile period. Estrogen is best assessed by serial vaginal cytologies and vaginoscopy. Estrogen levels do not indicate the fertile period, because ovulation is triggered by the LH surge, not an estrogen peak. Examination of the cells on the surface of the vaginal epithelium will give information about the stage of the estrous cycle, primarily by showing the presence or absence of an estrogen effect. It is important to always begin ovulation timing with vaginal cytologic evaluation to confirm the bitch is actually in heat and to identify the proper time to initiate cost-effective serial progesterone testing. Serum

hormone testing during proestrus—when vaginal cytology is primarily parabasal and intermediate cells—is costly and not contributory to actual ovulation timing.

Competence in vaginal cytologic analysis should be acquired by any clinician offering reproductive services, because commercial laboratory interpretation of serial cytologies is costly and not timely. Proper technique is important to obtain cells representative of the hormonal changes occurring. The sample should be collected from the cranial vagina, because cells from the clitoral fossa, vestibule, urethral papilla, or vestibulovaginal junction are not as indicative of the stage of the cycle (Figs. 54.11 and 54.12). The vaginal cytology swab should be rolled onto a slide without overlap or smearing (Fig. 54.13). Under the influence of increased estrogen levels, the number of layers making up the vaginal epithelium increases dramatically, presumably to provide protection to the mucosa during copulation. As estrogen rises during proestrus, the maturation rate of the epithelial cells increases, as does the number of keratinized cornified epithelial ("superficial") cells seen on a vaginal smear. Full cornification continues throughout estrus until the diestrual shift occurs, signifying the first day of diestrus. The vaginal smear then changes abruptly from full cornification to 40% to 60% immature (parabasal and intermediate) cells over a 24- to 36-hour period, accompanied by neutrophils. If vaginal cytologic examination is performed until the diestrual shift is observed, a retrospective analysis of the date of the LH surge (7-10 days previously), ovulation and ova

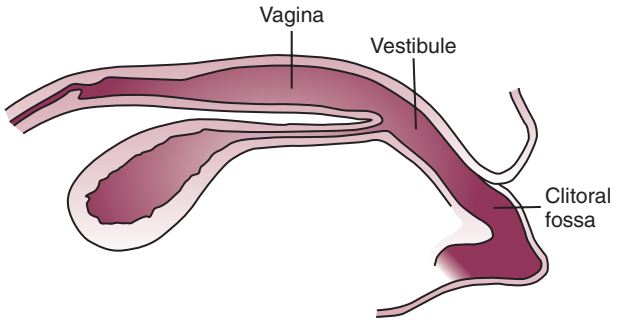

FIG 54.11
Schematic showing the anatomic orientation of the vestibule and vagina of the bitch.

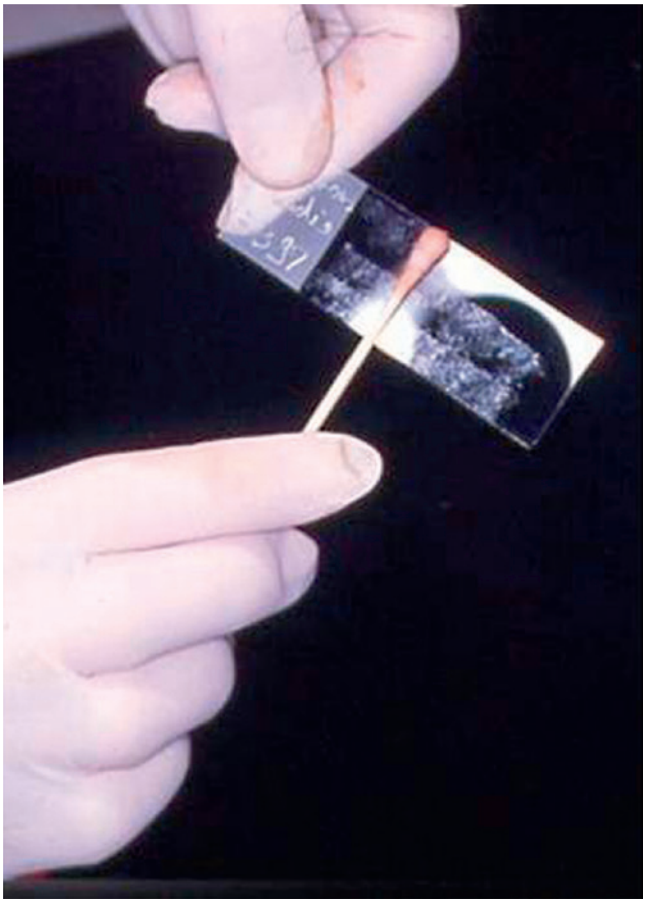

FIG 54.13

maturation (~24-48 hours after the LH surge), and the fertile period (~3-6 days after the LH surge) can be obtained. It is the least expensive way to perform ovulation timing, albeit retrospective. It can also be very useful if evaluation of gestational age becomes important, because parturition occurs 56 to 58 days from the diestrual shift.

Luteinizing Hormone

At the end of the follicular phase of the estrous cycle, a marked increase in LH over its usual basal values occurs over a 24- to 48-hour period, followed by a return to baseline. This surge in LH is thought to take place in response to the decline in estrogen/progesterone ratio that occurs as estrogen levels decrease and progesterone rises. The LH surge triggers ovulation and thus makes it the central endocrinologic event in the reproductive cycle of the bitch, with all events after being consistent between bitches. Daily serial measurement of LH to identify the exact date of the LH surge is therefore the most accurate diagnostic tool for timing breedings. Affordable semiquantitative in-house kits (Status-LH [Synbiotics/Pfizer/Zoetis]) are available for measuring serum LH levels in the dog, identifying the preovulatory LH surge and thus the time of ovulation and the true fertile period. LH testing is the most accurate means of ovulation timing and should be considered the gold standard. However, samples must be drawn daily at about the same time of day, because the LH surge may have a duration of only 24 hours in many bitches and could be missed if even one day was skipped. Commercially available LH kits can be subject to variable operator interpretation, so the same person should run the tests if possible. Serum progesterone testing must always be done in concert with LH testing in the event that the LH surge is missed.

Progesterone

Unique to the bitch, progesterone begins to rise at approximately the time of the LH surge (actually before ovulation), enabling indirect detection of the LH surge. Rising progesterone acts synergistically with declining estrogen to reduce edema of the vulva and vagina, which can be appreciated on vaginoscopic exam, and to cause the bitch to accept copulation. Other observable clinical signs of ovarian luteinization (production of progesterone) are minimal. Serial blood samples performed every 2 days once vaginal cytology is roughly 70% superficial cells can be used to identify the initial rise in progesterone (usually > 1.5 ng/mL), which indicates the LH surge has occurred. Progesterone can be assayed by radioimmunoassay (RIA) or chemiluminescence at most veterinary commercial laboratories. Several in-house semiquantitative kits are also available. Human laboratories are acceptable if previously cross-checked with a veterinary laboratory for comparability. By examination of the range and overlap of progesterone values at different points in proestrus and estrus, it becomes clear that no one absolute value of progesterone correlates to any particular event. Progesterone varies at the point of the LH surge from 0.8 to 3.0 ng/mL, from 1.0 to 8.0 ng/mL at ovulation, and from 4.0 to more than 30.0 ng/mL during the fertile period. However, if accurate serial quantitative progesterone assays are obtained, the LH surge may be estimated as the first day a distinct increase in progesterone concentration is seen, commonly between 1.5 and 4.0 ng/mL. This will not be as accurate as actual identification of the LH surge by use of an LH assay, but estimation of the LH surge using progesterone results is still very useful and often more widely available, less costly, and more convenient. When timing breedings using semiquantitative in-clinic progesterone assays, only a range of progesterone is obtained, not an actual number, making it difficult to accurately identify the exact day of the initial rise in progesterone or the true fertile period. Technical problems with these kits have occurred, so these assays should only be used for ovulation timing for routine natural or fresh artificial breedings involving fertile dogs, where a wider margin of error is acceptable. A safe rule of thumb to follow is that when kit testing indicates progesterone has risen above 2.0 ng/mL, breeding should begin. Optimal ovulation timing for chilled semen breedings, breedings involving subfertile bitches or stud dogs, or frozen semen breedings should utilize quantitative progesterone assays from commercial laboratories; the cost difference is minimal. Regardless of which assay is used, an additional test should always be performed 2 to 4 days after the initial rise is detected to indicate that the cycle has progressed as expected, functional corpora lutea have formed, and ovulation has occurred; progesterone concentration should be over 5.0 ng/mL.

Vaginoscopy may be performed throughout the cycle as an adjunct to vaginal cytologic analysis and hormonal assays, especially when evaluating an unusual cycle or if only one breeding is planned. Vaginoscopy is especially useful if a bitch is initially presented late, after the day of the LH surge, with greater than 90% superficial cells on vaginal cytology and progesterone of above 3.0 ng/mL. Maximal crenulation (puckering of the vaginal mucosa) occurs when the ova are mature and most fertilizable, and can be judged quickly with vaginoscopy. The vagina of the bitch is relatively long compared with other domestic animals; the total length from the cervix to the vulva (including the vestibule) has been reported to be 10 to 14 cm in an 11-kg bitch. The canine cervix is not accessible by digital palpation per vaginam nor can it be visualized with an ordinary vaginal speculum or otoscope; both are too short. Consequently, equipment for visualizing the entire vagina and approaching the canine cervix or accessing the uterus from the vagina must be long (e.g., up to 29 cm for large breeds, 33 cm for giant breeds) (Fig. 54.14). In addition, the presence of vaginal mucosal folds and the position of the cervix in the bitch require the use of rigid equipment to access the cervix; pediatric proctoscopes suffice for visualization of the vaginal mucosa, but fiberoptic vaginoscopes permit superior optics and multiple channels for sampling and insemination (Figs. 54.15, 54.16, 54.17). Hormone-induced changes in the vaginal mucosa enable estrual bitches to tolerate vaginoscopy without sedation or anesthesia.

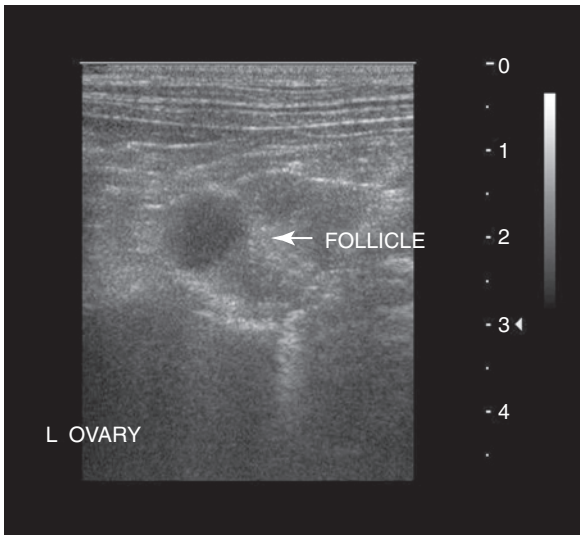

FIG 54.18
Normal sagittal canine left ovary in the follicular phase of the estrous cycle. The developing follicles *(arrow)* will increase in size over time to the point of ovulation.

Ultrasonography can be used to identify ovulation in the bitch, but early attempts were discouraging. The small size of the ovaries and their similarity to close structures make them difficult to visualize. Recent improvements in scanhead technology and operator expertise have made ovarian ultrasound more effective. During proestrus, multiple anechoic follicular cystic structures can be identified, enlarging with time (up to 1.0 cm in diameter). These structures ultimately have distinct thin walls and anechoic fluid centers with distal enhancement (Fig. 54.18). The surface of the ovary may become irregular or lumpy. The anechoic fluid-filled follicles acutely become hypoechoic to hyperechoic corpora hemorrhagica at the time of ovulation, progressing over several days to a thicker walled corpora lutea (Fig. 54.19). The ovarian follicles do not collapse in the bitch and queen. During diestrus the ovaries may be lobular; the corpora lutea are obvious hypoechoic structures of variable size. Results show a close correlation to ovulation as predicted by LH and progesterone testing. The main drawback is that imaging must be performed 2 to 3 times daily when ovulation is anticipated.

CLINICAL PROTOCOL: VETERINARY BREEDING MANAGEMENT

Clients usually delay breeding the maiden bitch until after 2 years of age for ethical reasons and to complete genetic screening; bitches are physiologically capable of breeding in their first estrous cycle. Breeder clients should be advised to notify the clinic when they first notice a bitch for which timing is planned is in season, based on vaginal discharge or vulvar swelling/attraction to males. Even the most astute owner can fail to notice the true onset of proestrus for a few days, so early clinical evaluation (on day 3-5 after the onset of the heat cycle) with vaginal cytology is advised. The type of breeding anticipated should be determined because it dictates the types of testing to be done. Early proestrus should be documented by vaginal cytologic analysis (<50% cornification/superficial cells). A baseline progesterone level might be informative if the true onset of the cycle is unknown (baseline is < 1.0 ng/mL). Vaginal cytology should be performed every 2 to 4 days until a significant progression in the percent of superficial cells is seen, usually above 70% superficial cells. At that point, appropriate serial hormonal assaying should begin. For routine breedings (natural, fresh, or fresh chilled artificial insemination with fertile dogs), progesterone testing may be done every other day until a rise in progesterone above 2.0 ng/mL is identified. The day of the initial rise in progesterone is identified as "day zero." Two natural breedings or artificial inseminations are advised between days 3 through 6, ideally 48 hours apart. Which 2 days are chosen depends upon overnight chilled semen shipping options and the involved clients' and veterinarians' schedules. As described, confirmation of progesterone rise above 5.0 ng/mL by the time of breeding is optimal. Vaginal cytologic examination should always be performed on the day of artificial insemination to confirm previous timing; 90% to 100% superficial cells should be present. If clients delay in bringing dogs to the veterinarian for assistance with breeding until after several days of failed attempts, vaginal cytology must still be performed to confirm the bitch is still in estrus. Progesterone testing will then confirm whether she is postovulatory and breeding is timely, but an initial artificial insemination is advised while awaiting progesterone results. A shift to less than 50% superficial cells indicates diestrus has begun. Only intrauterine inseminations performed on the first day of diestrus have been successful in producing pregnancy.

When increased accuracy of ovulation timing is necessary (i.e., for frozen semen breedings or breedings with subfertile stud dogs or brood bitches), LH testing is recommended. Once the LH surge is identified, breeding days may be planned. The day of the LH surge is also day zero. Two natural, fresh, or chilled semen artificial breedings are advised from days 3 through 6. Frozen semen inseminations are advised on day 5 or 6 of the fertile window owing to the short life span of cryopreserved thawed sperm. In addition, at least one progesterone assay should be performed after the LH surge is identified to document that progesterone levels continue to rise and are above 5.0 ng/mL before breeding. If client economics dictate minimal testing, serum can be batched on a daily basis and quantitative progesterone tests performed initially as advised earlier. When the initial rise in progesterone is identified, the batched serum can be specifically evaluated for the day of the LH surge, confirming identification of day zero.

Clinicians may be questioned about using vaginal glucose content and electrical conductivity for ovulation timing. Increased glucose has been identified in vaginal secretions as an inconsistent finding; it is thought to be a result of insulin antagonism that occurs secondary to altered hormone concentrations at the time of the progesterone rise. This finding is not reliable, however, and is not recommended for ovulation timing. Measurement of electrical conductivity of vaginal mucus is used routinely to time breedings in foxes and has been studied in several other species, including the dog. It was found that electrical resistance increases as estrus approaches and then plateaus at a maximal level for several days, changes that may be due to rising estrogen. Although it appeared that ovulation occurred at some point during this period of maximum electrical resistance, it has not been shown to be correlated to the LH surge or the fertile period, so it cannot be recommended for accurate ovulation timing. Ovulation timing is not usually performed in the queen whose estrual behavior is obvious; in fact vaginal swabbing can induce ovulation. Estrus cytology in the queen is similar to the bitch, but superficial cells retain their nuclei (Fig. 54.20). Serum progesterone can be used to confirm ovulation if >5.0 ng/mL.

Behavior and other observations (flagging, attractiveness to males) should also be made at each examination, but less weight should be put on these parameters (Videos 54.1 and 54.2). The clinician should keep in mind that the most accurate ovulation timing occurs when information from several

Slide covers, glass pipettes
Fresh semen extender solution, warmed to body temperature
Lubrication jelly, not spermicidal
Light microscope 10×, 40×, 100×

tests is pooled (vaginal cytologies, vaginoscopy, and progesterone or LH tests).

THE DOG AND TOM

SEMEN COLLECTION

If a natural breeding cannot be accomplished (mismatched mate size, geriatric or inexperienced stud) or is precluded by geography (shipped extended and chilled semen), or frozen semen is to be used, veterinary participation may be sought for artificial insemination. Both intravaginal and intrauterine artificial insemination techniques are successful in the bitch. Neither is commonly performed clinically in the queen, hampered by the technical demands of semen collection in the tom (special training to an artificial vagina [AV], electroejaculation, or chemically [100 µg/kg medetomidine IM]-induced ejaculation with urethral catheterization) and ovulatory status (usually induced) of the queen (Zambelli et al., 2006; Zambelli et al., 2007). Most veterinarians have not developed semen collection and insemination skills in school. Successful artificial insemination requires proper collection technique, appropriate semen handling, and correct insemination procedure. Semen evaluation should be performed regularly in valuable stud dogs. Special training is required to develop additional skills in semen chilling, advanced methods of artificial insemination, and semen freezing (cryopreservation). Cryopreservation of canine semen is routinely performed both by veterinarians and technicians. According to the American Kennel Club (AKC) only a licensed veterinarian should perform artificial insemination of cryopreserved semen. Several proprietary programs train individuals for canine cryopreservation. Research and debate concerning semen extenders, freeze buffers, and the role of prostatic fluid in sperm function are ongoing.

Successful collection of fresh canine semen usually requires a quiet room, a rug or mat for good footing, an estrual or teaser bitch, and minimal special equipment (Box 54.5). Attempts to put the dog at ease before the collection may include simple measures like the veterinarian and assistant not wearing their white laboratory coats. Medical procedures (vaccination, temperature evaluation, rectal examinations, venipuncture) should be performed *after* the collection or by another veterinarian. When performing semen collections, one should try to approximate the stud dog's usual breeding environment as closely as possible. Collection should be performed on the floor except in toy breeds accustomed to being collected on a table. Repeat visits allow the stud dog to relax, and he will soon learn what he is there for. Semen quality is generally better when an estrous teaser bitch is present and cooperative, and the stud's libido is highest. Stud dogs can withhold the sperm-rich (middle or second) portion of the ejaculate if they are uncomfortable. Semen collection equipment (AVs, semen collection tubes) is commercially available. Make sure all collection equipment is at room temperature, dry and clean, and free of spermicidal agents.

Support the teaser bitch in a standing position, restraining her head as necessary. Allow the stud to familiarize himself with the surroundings, the bitch, and the handlers. Position yourself next to the stud as he approaches the bitch. Right-handed people usually work best on the stud's left side. Allow the stud to mount, placing the AV in front of his penis with the left hand as he thrusts toward the bitch. If he does not mount or thrust, gently massaging the penis through the prepuce with the right hand will stimulate an erection. When he is 50% erect or less, push the prepuce behind the bulbus glandis. If this cannot be done easily, pull the dog off the bitch, walk him away to allow detumescence, and bring him back to the bitch to try again. Ejaculation within the prepuce is painful. During thrusting, reposition your hands to provide gentle constant pressure just behind and incorporating the bulbus glandis, keeping the AV over the penis. Rapid thrusting coincides with penetration. After achieving full erection, coinciding with the tie, the stud will dismount and try to step over the bitch and your arm to turn. Help the stud by lifting his leg over your arm and swinging the penis 180 degrees so it is directed backwards between his legs. Keep the dogs standing near each other during the ejaculation phase so the stud believes a breeding is occurring. Visualize the semen as

it flows into the clear tubes. There are three fractions in the ejaculate. The first is clear, from seminal vesicles. The second fraction is white sperm-rich fluid (SRF). The third fraction is clear and is prostatic fluid. The SRF is usually released at the end of rapid thrusting after the dog has turned. Semen evaluation requires the collection of only the first and second fractions. Evaluation of a small amount of the more voluminous prostatic fluid is adequate. If collecting for fresh artificial insemination, avoid collecting the clear prostatic fluid.

The total volume of SRF in a large dog is generally no more than 1 to 2.5 mL. After collection is complete, leave the AV on the stud until his erection has diminished. This keeps the penis more comfortable. Apply some water-soluble lubrication to the base of the penis, under the AV, to facilitate return of the penis within the prepuce. Always check to make sure the paraphimosis (penis extruded outside of the prepuce) resulting from artificial semen collection resolves. It is not necessary to walk the dog; he will lose the erection in 5 to 15 minutes. Care must be taken to ensure that the stud dog has adequately recovered from his erection before he is retired; preputial skin and hair can strangulate the tip of the penis.

SEMEN ANALYSIS

Semen analysis should include evaluation of sperm morphology, motility, and concentration. If the clinician is uncomfortable with semen evaluation, the sample or a representative aliquot can be submitted to a commercial laboratory for analysis, but motility must be judged immediately postcollection. Normal canine semen has 70% (or greater) progressively forward-moving sperm with moderate speed and good-quality motility. To evaluate motility, place a drop of the sperm-rich fraction (second) on a warmed slide, using a pipette. Top with a coverslip and observe under ×10 to ×40 magnification. Sperm should swim across the slide in a relatively straight path, with minimal gyrations (good-quality motility) and brisk speed (moderate to fast motility). No sperm-to-sperm agglutination should occur, but agglutination to egg yolk particles in extenders or other cells in semen can be normal. If motility is poor, prepare another drop on a new slide and double-check. Observe individual live, unstained sperm cells under ×40 magnification for morphology. Abnormal sperm can have coiled tails, proximal droplets, abnormal shape to heads, double tails or heads, and altered acrosomes (Figs. 54.21 and 54.22). The acrosome is difficult to visualize without phase contrast microscopy. Iatrogenic damage can cause detached heads and bent tails. Observing fresh sperm before staining permits evaluation for stain-induced morphologic abnormalities. Prepare another slide with the pipette as you would a peripheral blood smear, air dry, and stain for morphologic analysis. Both Wright-Giemsa and eosin-nigrosin stains are commonly used. At least 100 to 200 sperm should be tallied for morphology, noting both normal cells and sperm cells with head abnormalities (misshapen, double), neck abnormalities (proximal droplets), and tail abnormalities (distal droplets, coiled, double). Using a differential cell counter labeled for

FIG 54.21
Canine spermatozoa, phase contrast microscopy.

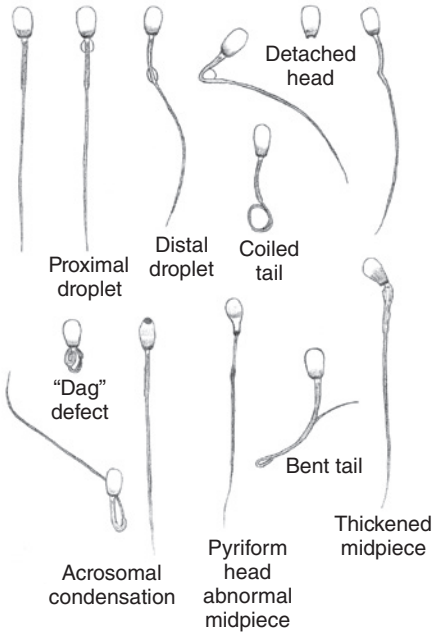

FIG 54.22
Schematic of sperm morphology showing common abnormalities.

semen morphology with the previously mentioned categories is helpful. If a high number of morphologic abnormalities occur poststaining, a different methodology may be advisable. Note the presence of epithelial cells, white blood cells (WBCs), and RBCs as well (record as 1-4+/HPF). Sperm counts can be performed by using a hemocytometer and Unopette. Alternatively, the automated Spermcue (MOFA Inc.) produces a very accurate automated sperm count. Multiply the number of sperm per milliliter by the volume of the SRF to obtain the number of sperm per ejaculate. Normal dogs have 200 to 400 million (up to a billion) sperm per ejaculate. Normal toms' average semen volume varies by the method of collection (10.5-233 μ/L); sperm count 21 to 57

million per ejaculate. Higher numbers of morphologically normal sperm can be associated with the breeding season in cats. In general, felids are frequently affected by teratospermia, with normal toms having ~40% abnormal spermatozoa. This is thought to be a result of decreased genetic variation (Pukazhenthi et al., 2006).

FRESH, FRESH CHILLED, AND FROZEN ARTIFICIAL INSEMINATIONS (AI)

VAGINAL AI

With the bitch standing and comfortably restrained, using digital guidance or a pediatric proctoscope, an insemination pipette is passed dorsal to the urethral papilla and as far into the vaginal vault as it will comfortably go. Vaginal inseminations are best accomplished using a clean mare uterine infusion pipette, which is rigid and allows placement of the semen near the cervix in the cranial vagina. Care must be taken to not contaminate the semen with water, disinfectant chemicals, or spermicidal lubricants. A 5F to 10F polypropylene urinary catheter can also be used. Nonlatex syringes are advised when handling semen.

Maneuvering the pipette over and under vaginal mucosal folds usually must be done. Once the pipette is in place, the bitch's hindquarters are elevated onto an assistant's lap in a wheelbarrow position. The bitch's abdomen should not be compressed; the assistant should restrain the bitch by firmly holding her hocks in a comfortable position. The syringe of semen is then attached to the pipette, elevated, and slowly infused. If the semen will not infuse, back the pipette out slightly. A small amount of air in the syringe will empty the pipette contents into the vagina. It is not necessary to continue elevating the bitch's hindquarters after insemination as this does not impact conception or litter size; walking the bitch for 10 minutes without allowing her to sit or urinate is optimal.

INTRAUTERINE AI

Cryopreservation and subsequent thawing diminish semen quality and longevity post-thaw, necessitating special insemination technology. Frozen thawed semen has to be placed close to the site of fertilization (fallopian tubes) for acceptable conception rates; intrauterine insemination is highly recommended. The process and resultant quality of canine cryopreservation have improved with time; insemination techniques remained challenging until transcervical endoscopic intrauterine access was developed. Data supporting the benefit of intrauterine deposition of frozen thawed semen exists (40%-90% conception rates). We extrapolate that better conception rates will occur with intrauterine insemination of chilled, extended, or otherwise compromised (subfertile) semen as well.

The normal anatomy of the vagina and cervix in the bitch hampered transcervical access to the canine uterus until rigid cystourethroscopes were developed and adapted for vaginoscopy. Historically, intrauterine insemination required an invasive procedure (laparotomy or laparoscopy) in the bitch. In addition to its invasiveness, laparotomy requires general anesthesia, which many clinicians and clients find objectionable for an elective procedure such as artificial insemination (Fig. 54.23). Laparoscopic approach to the canine uterus has been used infrequently, especially in the practice setting, because of its relative invasiveness (multiple incisions, insufflation) and because it requires special equipment, expertise, and anesthesia. In some countries, elective surgeries such as these are not considered ethical.

Transcervical insemination is becoming more common, with techniques developed in Scandinavia and New Zealand. The Norwegian catheter is a 20- to 50-cm steel catheter with a 0.5- to 1-mm tip with a protecting nylon sheath, and is used with a 6- to 20-mL syringe. Transcervical catheterization is accomplished by passage of the Norwegian catheter through the vagina and blindly into the cervix by palpation and manipulation of the cervix through the abdominal wall. This technique requires training and expertise. Perforation of the uterus or vagina could occur, and introduction of vaginal flora into the abdomen is possible. Good success rates have been reported using this technique.

Transcervical insemination with fiberoptic visualization of the caudal cervical os permitting catheterization is optimal. After visualization, a polypropylene catheter is passed

FIG 54.23
Surgical insemination: injection of semen into the uterine horn.

through the channel of the scope, through the cervical os, and then into the uterine lumen (Figs. 54.24, 54.25, 54.26). Visualization of the cervix requires manipulation of vaginal folds and scope, and catheterization of the cervix takes expertise and requires practice. Sedation is usually unnecessary. This technique has a moderate learning curve. Once practiced enough to gain expertise, it is highly rewarding and often can be performed in a matter of minutes. Transcervical catheterization for intrauterine insemination is best accomplished with the estrual bitch standing on a nonskid surface under light restraint and with gentle support of the abdomen to inhibit sitting. The scopes were developed to be used in the standing bitch. The operator should work from a sitting position, with the arms raised to the level of the vulva to minimize muscle fatigue. An adjustable examination table and chair can facilitate operator comfort. Participation of the breeder client for restraint and observation is generally rewarding (Video 54.3). Concerns surrounding potential introduction of vaginal flora into the uterine lumen using transcervical insemination have not been realized thus far and are unlikely, given recent knowledge that normal vaginal flora can be found in the uterus during proestrus and estrus. Certainly vaginal flora is introduced into the uterine lumen with natural breedings; the uterus has an inherent ability to normalize its flora after estrus. Maintenance of the equipment is minimal; 10 minutes' soaking of the immersible parts in dilute (1:1000) chlorhexiderm solution and thorough rinsing with distilled water is optimal. Stronger disinfectants raise concerns because of their spermicidal potential. As with all reproductive procedures, the success is greatly influenced by the timing of ovulation in the bitch and the quality of the semen from the male. An increased number of inseminations (not limited by anesthesia and invasive surgery) may improve conception and is now feasible with this equipment and technique.

ESTROUS CYCLE OF THE QUEEN

Puberty in the queen usually occurs at 9 to 10 months of age but may occur as early as 4 months or as late as 2 years. Because queens are seasonal breeders, the season in which the kitten was born influences the age at which puberty occurs. Cyclicity is dependent on the photoperiod, with queens requiring 12 hours or more of light to maintain normal cyclicity. Cyclicity and folliculogenesis stop abruptly in queens exposed to less than 8 hours of light but resume an average of 16 days after returning to a 14-hour photoperiod. Seasonality is more pronounced in queens exposed to natural lighting, especially at higher latitudes. Long-haired breeds tend to be more seasonal than short-haired breeds. The phases of the feline estrous cycle are proestrus, estrus, interestrus, diestrus or pseudopregnancy, and anestrus.

Proestrus precedes estrus and lasts 1 to 2 days but is recognized in fewer than 20% of queens. During proestrus, the female is attractive to but not willing to accept the male. The queen may rub against objects, vocalize, and assume a lordosis; she will place her front quarters on the ground, elevate her hindquarters, and lift her tail to one side. When the dorsal caudal area is stroked, she will tread with her hind legs.

Estrus is the period of sexual receptivity and lasts an average of 7 days (3-16) and then subsides for an average of 9 days (3-14). The external genitalia have no conspicuous changes in appearance, but behavioral changes are pronounced during estrus. Because of the relatively short length of proestrus, the ability to inadvertently induce ovulation by mechanical vaginal stimulation, and the less dramatic cellular changes observed in the queen, vaginal cytology is not used as commonly in the queen as it is in the bitch. Behavioral observations should dictate the best time to place the queen with the tom. Estrus duration is unaffected by breeding or ovulation. If vaginal cytology is desirable, flushing a small amount (<1.0 mL) of saline in and out of the vagina provides better results than using a swab. Interestrus is the period between successive estrus periods if ovulation does not occur. If the queen is not bred or otherwise stimulated to ovulate, estrus will occur every 2 to 3 weeks during the appropriate photoperiod. If the queen ovulates, corpora lutea are formed and secrete progesterone. If the queen is not pregnant, diestrus (pseudopregnancy) results and lasts 35 to 40 days. Anestrus is the seasonal period when the cat does not cycle; artificial lighting can alter its occurrence.

Queens are induced ovulators and ovulate in response to vaginal stimulation; however spontaneous ovulation can occur in the queen. Ovulation is most commonly triggered by copulation or mechanical stimulation of the vagina, which causes a reflex stimulation of the hypothalamus via pathways in the spinal cord. The hypothalamus releases GnRH, which then causes a release of LH from the anterior pituitary. LH then stimulates ovulation and the development of corpora lutea. Other forms of stimulation can occasionally be responsible for ovulation; active corpora lutea have been found in cats unexposed to males or artificial coital stimuli. Ovulation depends on adequate LH release, with both a peak concentration and duration of elevation being important. The LH release occurs within minutes of coitus and peaks about 1 to 2 hours later. Release of LH is partially dependent upon the duration of prior exposure to estrogen (time in estrus), so the LH response varies depending on the day of estrus at which coitus occurs. Multiple copulations result in higher concentrations of plasma LH and are more likely to result in ovulation than a single mating. The duration of elevated LH in plasma also determines whether ovulation occurs, with LH decreasing to baseline values within 12 to 24 hours after a single mating or after multiple matings at less than 2-hour intervals. However, LH remains elevated up to 38 hours after multiple mating intervals every 3 hours. To achieve sufficient LH release, repeated breeding at a reasonable interval should be encouraged. The LH response to a single mating can vary substantially, and neither single nor multiple copulations can ensure ovulation. To increase the likelihood of ovulation, breeders should try to maximize the number of matings and breed on successive days of estrus. Ovulation occurs 24 to 60 hours postcoitus and may vary depending on the mating pattern. Ideally, if the onset of estrus has been detected, breeding should occur on days 2 to 3.

Three alternatives following estrus are possible in the queen: (1) ovulation does not occur, and an average 9-day (4-22) interestrus occurs before the next proestrus; (2) ovulation occurs without fertilization, resulting in a 35- to 40-day pseudopregnancy and a 1- to 10-day interestrus; or (3) pregnancy. Pseudopregnancy occurs when ovulation and corpora lutea formation occur but not conception. The corpora lutea produce progesterone, with levels rising rapidly from basal concentrations to a peak of 16 to 17 ng/mL 18 to 25 days postovulation. After the peak, progesterone concentrations decline to basal at approximately 40 days postovulation. The normal pseudopregnancy duration lasts 35 to 40 days. The corpora lutea appear to have a preprogrammed finite life span in that they are not subject to regression from uterine sources of prostaglandins. Lactation (pseudogenetra) at the end of pseudopregnancy is less common in the queen. Induction of pseudopregnancy eliminates the so-called constant estrus seen in nonovulating queens; the duration of that estrus is not changed. After pseudopregnancy, the queen will go through a 2- to 4-week anestrus and either return to estrus if she is cycling or transition into a prolonged seasonal anestrus.

Gestation in the cat is 63 to 66 days when measured from a fertile mating. Because kittens born before 60 days of gestation have little chance of survival, it is important that gestation progress to 63 days for maximum kitten viability. Because queens are induced ovulators, clients should be counseled to recognize the signs of estrus and place queens with tomcats for the minimal time to accomplish a fertile mating (usually 2-3 days), making evaluation of the length of gestation more predictable. Unlike in the pseudopregnant queen, corpora lutea do not regress in the pregnant queen; despite placental progesterone production, the ovaries are needed to maintain pregnancy past day 50. As in the bitch, progesterone concentrations vary over time. Prolactin from the anterior pituitary also appears to be required for pregnancy maintenance.

OBSTETRICS

PREGNANCY DIAGNOSIS

Early pregnancy evaluation permits optimal obstetrics (Table 54.2). Pregnancy detection by abdominal palpation (best at

TABLE 54.2

Methods for Pregnancy Diagnosis

GESTATIONAL AGE (FROM LH SURGE)	METHOD
25+ days	Abdominal ultrasound, abdominal palpation
>20-31 days	Witness Relaxin (Pfizer/Zoetis)
>50 days	Radiography

approximately 30 gestational days) confirms the presence of an enlarged, presumably gravid uterus, but gives little other information. Produced by the placenta, the hormone relaxin is elevated in both canine and feline pregnancies. A serum relaxin assay (Witness Relaxin Assay [Synbiotics/Pfizer]) is available for pregnancy diagnosis after about 25 to 31 days of gestation, but it can be falsely negative with small litter size. Radiography (55+ days of gestation, the later the better) can confirm the presence of fetuses. Before fetal skeletal mineralization, other causes for uterine enlargement (hydrometra, mucometra, pyometra) cannot be ruled out radiographically. Radiography cannot be used to assess fetal viability in a timely fashion. Once profound postmortem changes have occurred, radiography can detect intrafetal gas accumulation or abnormal skeletal arrangement, suggesting fetal death. A single lateral projection is preferred; counting both fetal spines and fetal skulls most accurately provides litter size. A ventrodorsal projection should only be made if the litter size is difficult to determine on the lateral view, or if fetal positioning in relation to the pelvic canal needs evaluation at term. A fetal count radiograph carries little risk of teratogenic results in the fetuses (30-50 mrem).

Ultrasound is the optimal method to evaluate for conception, fetal health, and litter size and is best performed around 30 days after breeding (~35 days gestation). In later gestation (>50 days) the fetuses are so large the uterine horns overlap, making an accurate litter size evaluation difficult. Serial pregnancy ultrasound can identify resorption and early fetal death, as well as intrauterine pathology. Transabdominal pregnancy ultrasound is performed with the bitch or queen in comfortable, padded dorsal recumbency and does not require sedation or clipping. A variable frequency scanhead (6.0-8.0 MHz) typical of most small animal clinics is adequate. Doppler is not required. The normal uterus is best located by scanning transversely between the urinary bladder and the colon. The cervix and uterine body are seen as a continuous hypoechoic round structure dorsal to the anechoic urinary bladder and ventral to the hyperechoic crescent-shaped colon. A full urinary bladder acts as an acoustic window to improve uterine imaging. Once the uterine body has been identified, the uterine horns can be located by scanning in transverse toward each kidney. Definite ultrasonographic diagnosis of pregnancy in the queen based on the appearance of a "fetal pole" (the actual fetus) can be made at 15 to 17 days postcoitus, although gravid uterine enlargement (4-14 days) and the presence of a gestational sac (11-14 days) can be detected even earlier (Fig. 54.27). Ultrasonographic detection of the canine blastocyst (a 2-3 mm spherical hypoechoic structure surrounded by a hyperechoic rim within the uterus containing the fetus) occurs at 19 to 20 days post-LH surge (Fig. 54.28). Ultrasonography permits evaluation of early fetal cardiac motion (21-22 days post-LH surge), fetal movement (31-32 days post-LH surge), and the fetal heart rate, enabling assessment of viability. By 30 days' gestation pregnancy diagnosis with ultrasonography is straightforward.

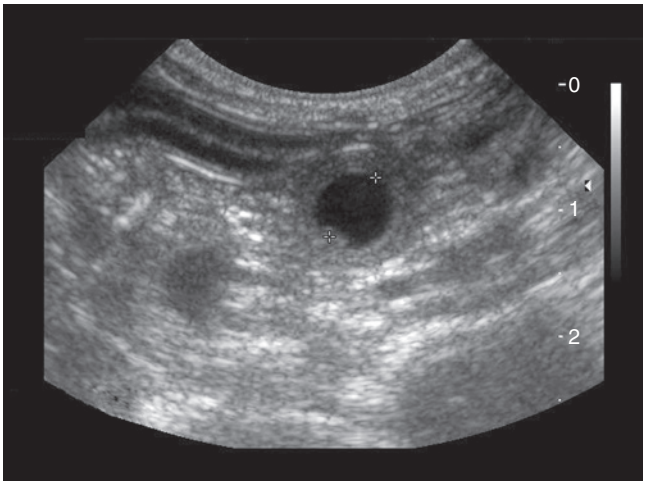

FIG 54.27

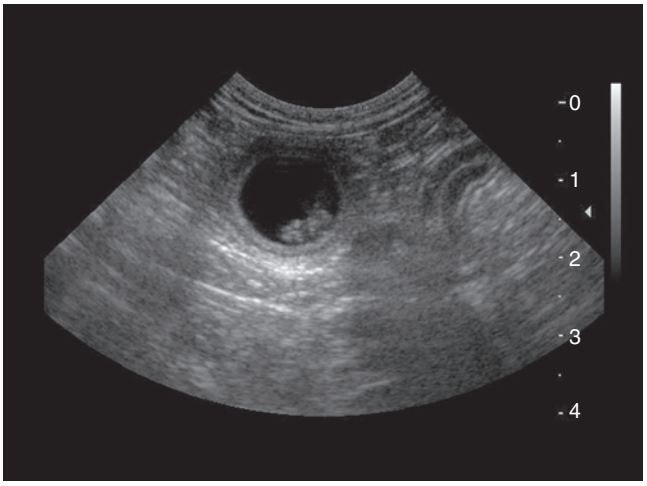

FIG 54.28
Pregnancy ultrasound canine; gestational age 20 days.

GESTATIONAL LENGTH AND FETAL AGE DETERMINATION

Determining gestational age can be of vital importance if an elective cesarean section is planned or prolonged gestation suspected. Accurate determination of gestational length can be difficult, especially if numerous copulations occurred and no ovulation timing was performed. Prolonged gestation is a form of dystocia. Gestation in the bitch is more challenging to calculate than in the cat, because bitches are spontaneous ovulators. Normal gestation in the bitch is 56 to 58 days from the first day of diestrus, 64 to 66 days from the initial rise in progesterone from baseline, or 64 to 66 days from the LH surge. Normal gestation can actually be 58 to 72 days from the first instance the bitch permitted breeding. Breed and litter size can influence gestational length. Predicting gestational length without prior ovulation timing is difficult because of the disparity between estrual behavior and the

actual time of conception in the bitch, and the length of time semen can remain viable in the bitch reproductive tract (often > 7 days). Breeding dates and conception dates do not correlate closely enough to permit very accurate prediction of whelping dates, and clinical signs of term pregnancy are not specific. Radiographic appearance of fetal skeletal mineralization varies at term, and fetal size varies with breed and litter size. Because the queen is an induced ovulator (ovulation follows coitus by 24-36 hours), gestational length can be predicted more accurately from breeding dates, assuming copulation provided adequate coital stimulation for the LH surge and subsequent ovulation, and a limited number of copulations were permitted. The gestational length of queens ranges from 52 to 74 days from the first to last breeding. The mean gestational length is 65 to 66 days. Because of the poor outcome with the delivery of premature puppies and kittens, elective intervention is best delayed until stage I labor has begun (see Chapter 55) or prolonged gestation is confirmed ultrasonographically.

Fetal age determination by ultrasonography is accomplished by either the first appearance of certain visible structures or by measuring certain parameters. Measurements such as the gestational sac diameter, fetal occipitosacral (crown-rump) length, and fetal head (biparietal) diameter can be obtained ultrasonographically, relate closely to fetal age, and permit estimation of gestational length and parturition dates, especially useful if ovulation timing was not performed (Figs. 54.27, 54.29, 54.30; Video 54.4). Variation in breed size (especially in the dog), brachycephalic canine and feline breed variation, and individual variation in measuring technique are sources of inaccuracy in predicting fetal age with ultrasound (Box 54.6).

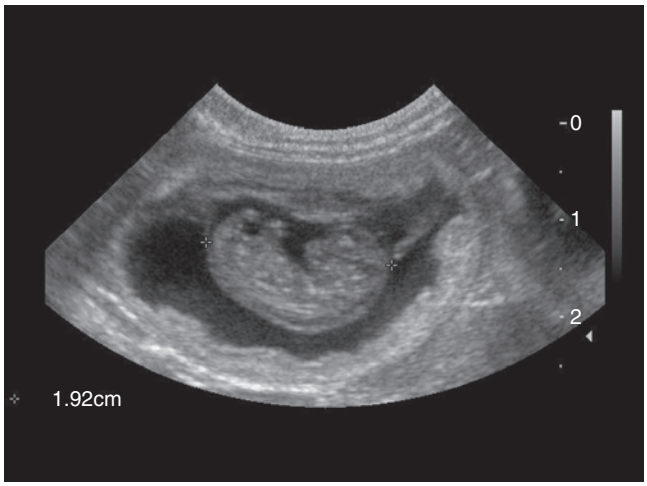

FIG 54.29
Pregnancy ultrasound feline; gestational age 30 days. Cursors mark the occipitosacral (crown-rump) length in centimeters.

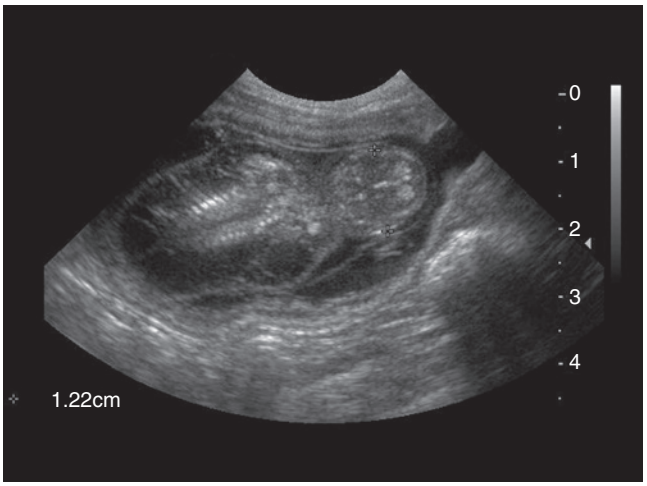

FIG 54.30
Pregnancy ultrasound canine; gestational age 39 days. Cursors mark the biparietal (head) diameter in centimeters.

BOX 54.6

Formulas to Predict Gestational Age and Days Before Parturition in the Dog and Cat

Gestational age (GA) is based on days post–luteinizing hormone (LH) surge in the dog and days postbreeding in the cat. Gestational sac diameter (GSD), crown-rump length (CRL), head diameter (HD), and body diameter (BD) measurements are in centimeters. Days before parturition (DBP) is based on 65 ± 1 days post-LH surge in the dog and 61 days postbreeding in the cat.

Gestational Age in the Dog (±3 Days)
Less than 40 days

GA = (6 × GSD) + 20
GA = (3 × CRL) + 27

Greater than 40 days

GA = (15 × HD) + 20
GA = (7 × BD) + 29
GA = (6 × HD) + (3 × BD) + 30

Days before parturition in the dog

DBP = 65 − GA

Gestational Age in the Cat (±2 Days)
Greater than 40 days

GA = 25 × HD + 3
GA = 11 × BD + 21

Days before parturition in the cat

DBP = 61 − GA

Novel feline gestational aging using crown-rump length

Y = 0.2423 × GA − 4.2165
Y is mean litter CRL (cm)
GA is the gestational age
(Solve for GA)

CHAPTER 55

Clinical Conditions of the Bitch and Queen

NORMAL VARIATIONS OF THE ESTROUS CYCLE

LATER THAN TYPICAL PUBERTY

The onset of the first estrous cycle occurs after a bitch attains 70% of her adult height and body weight. Small breeds generally begin their first estrous cycle between 6 and 10 months of age; large breeds can begin as late as 18 to 24 months, which causes owner concerns. Family histories (dam and female siblings) can help predict the anticipated onset of reproductive cycling. Efforts at differentiating delayed puberty (as perceived by an owner) from an actual failure to have reproductive cycles should be postponed until a bitch is at least 2 to 2.5 years old. Bitches with delayed puberty generally have normal reproductive cycles once initiated. Housing such a bitch with another cycling bitch can promote her proestrus secondary to the pheromone-related "dormitory effect." Estrous induction protocols (later in this chapter) can be attempted if the bitch is mature (i.e., at least 24-30 months of age) and breeding is desired.

Puberty in the queen usually occurs at 9 to 10 months of age. Puberty can occur as early as 4 months or as late as 2 years; because cats are seasonal breeders, the season in which the kitten was born influences the age at which puberty occurs. Cyclicity is dependent on the photoperiod, with queens requiring 12 hours or more of light to maintain normal cycling.

SILENT HEAT CYCLES

The occurrence of a silent heat cycle must be ruled out during evaluation of a bitch suspected of failing to have estrous cycles. Fastidious bitches with minimal vulvar swelling, scant vulvar discharge, and few behavioral changes can have proestrus/estrus that escapes human detection ("silent"), especially in the absence of an intact male dog. Diestrus normally lacks clinical signs. Proestrus and estrus tend to become more apparent as the bitch ages. Performing weekly vaginal smears to detect cytologic proestrus, housing the bitch near an intact male, or using white bedding can aid in prospective detection of a silent heat, permitting proactive ovulation timing and breeding (see Chapter 54). Intact male dogs typically note pheromones produced days to weeks before the onset of proestrus and spend more time sniffing the bitch or her urine. Performing monthly progesterone assays permits retrospective identification of estrus but will not facilitate breeding in that cycle unless acquired before diestrus. Silent heat cycles must be differentiated from true primary anestrus. True primary anestrus in the bitch that fails to experience an estrous cycle is most likely due to a disorder of sexual development and is uncommon.

SPLIT HEAT CYCLES

Bitches with split heat cycles, in which proestrus and possibly early estrus occur without ovulation or progression to diestrus, can be thought to have abnormally short cycles, lack of sexual receptivity, or infertility if breedings were forced or artificial insemination performed without confirming ovulation. Waves of folliculogenesis with increased estrogen production but without ovulation occur in split heats. Follicular atresia follows, no luteal phase with progesterone production occurs, and normal sexual receptivity fails to develop. These cycles typically occur in young bitches and are characterized by periods of hemorrhagic vulvar discharge typical of proestrus, attractiveness to males, and usually no receptivity. In young bitches, split cycles are thought to be due to immaturity. These cycles can also occur in mature bitches with a history of normal past cycles, usually in association with stress. Increased endogenous cortisol levels associated with stress (travel, shipping, kenneling) may inhibit the luteinizing hormone (LH) surge and associated ovulation. Two to 10 weeks after a split cycle, another proestrus typically begins and could proceed to ovulation. Eventually most young bitches with split heats progress through a normal estrus to diestrus. The condition is not associated with reproductive pathology in the young or stressed bitch, and no treatment is recommended. Breeding a bitch in surroundings familiar to her is advised if stress might have altered a previous cycle. Delaying shipping of a bitch for breeding until after the LH surge (progesterone initial rise) has occurred is optimal. Using shipped semen (chilled,

extended) is a better alternative. Serial vaginal cytologies documenting the influence of estrogen on vaginal mucosa early in the cycle, and progesterone assays performed 1 to 2 weeks later documenting folliculogenesis without ovulation or luteinization (i.e., serum progesterone [<1.0 ng/mL]), confirm the diagnosis of a split heat. Occasionally split cycles occur on a regular basis in a mature bitch. This not only makes them difficult to breed but is likely associated with abnormalities of the hypothalamic-pituitary-ovarian axis.

ABNORMALITIES OF THE CANINE ESTROUS CYCLE

Abnormal estrous cycles result in either a prolongation or an abbreviation of a phase of the cycle, or an alteration in the normal sequence of events. An owner's interpretation of a bitch's behavior and physical characteristics may not equate with the actual physiologic events, necessitating prospective documentation of the cycle through vaginal cytologic evaluation, vaginoscopy, behavioral evaluation, and serum LH and progesterone levels as described (see Chapter 54).

PROLONGED PROESTRUS/ESTRUS

Prolonged proestrus or estrus occurs when a bitch displays vulvar bleeding for more than 30 to 35 consecutive days, accompanied by attractiveness to males. Greater than 80% to 90% superficial cells are present on vaginal cytology. Such bitches are variably receptive to breeding. Prolonged proestrus and/or estrus results from a persistent production of estrogens, with or without small elevations in progesterone. If present, progesterone enhances the presence of sexual receptivity. Endogenous sources of prolonged estrogen exposure in the bitch, with or without progesterone, include ovarian follicular cysts and secretory neoplasias. Secretory anovulatory follicular ovarian cysts tend to be solitary, lined with granulosa cells, and exceed normal preovulatory follicles in size when measured ultrasonographically, ranging from 1 to 5 cm in diameter. Bilateral follicular cysts may indicate a problem with the hypothalamic-pituitary-ovarian axis. Follicular cysts tend to occur in bitches younger than 3 years of age. Ovarian neoplasias capable of producing estrogen occur and include tumors of epithelial origin (cystadenomas and adenocarcinomas) as well as tumors of gonadal-stromal origin (granulosa-theca cell tumors). Ovarian neoplasia tends to occur in bitches older than 5 years of age. Ovarian tumors can occur unilaterally or, less commonly, bilaterally. Functional cystic ovarian pathology and ovarian neoplasia and can occur simultaneously. Cysts found in the contralateral ovary and endometrial hyperplasia accompanying a functional tumor occur most frequently with gonadal-stromal origin tumors.

Other than hyperestrogenism, there are few differential diagnoses for prolonged vulvar bleeding in the bitch. Vulvar bleeding secondary to infection, inflammation, or neoplasia of the genitourinary tract, a vaginal foreign body, or a coagulopathy should be differentiated from prolonged proestrus or estrus. Rare reports of vaginal vascular ectasia causing hemorrhage exist. Excessive exogenous administration of estrogen may be encountered when an ovariohysterectomized bitch is treated for urethral sphincter incompetence with estrogenic compounds or from attempts to prevent unwanted pregnancy using diethystilbesterol or estradiol cypionate in the intact bitch. Small dogs can acquire estrogen exposure iatrogenically from owners using transdermal or aerosolized topical hormone replacement therapy. Recognized sequelae to chronic estrogen exposure include bone marrow dyscrasias, predisposition to the cystic endometrial gland hyperplasia/pyometra complex, and development of ovarian cysts. After confirmation of endogenous hyperestrogenism is obtained through history and vaginal cytologies (which can be confirmed with serum estrogen measurement), abdominal ultrasonography is recommended to evaluate ovarian pathology (Fig. 55.1). Normal preovulatory follicles measure 4 to 9 mm in diameter, smaller than follicular cysts and most functional ovarian neoplasias. Analysis of the estrogen and progesterone levels in fluid from abnormal cystic ovarian structures obtained via ultrasound guidance can be contributory to the diagnosis but is not necessary if serum levels have been obtained. Histologic analysis of tissues obtained surgically confirms the diagnosis and is always indicated.

Because follicular cysts may spontaneously undergo atresia or luteinization, not all bitches experiencing prolonged proestrus or estrus require treatment. Progression of the follicular cyst to an atretic follicle or a corpora lutea can be monitored ultrasonographically, via vaginal cytologic analysis, and by serum estrogen and progesterone measurements. Therapy aimed at terminating prolonged proestrus or estrus becomes necessary if spontaneous regression fails to occur, vaginal bleeding is a continuing nuisance, estrus behavior and the attraction of males is unacceptable, or other complications develop (blood loss anemia, marrow dyscrasias, vaginal hyperplasia). Medical and surgical options exist for treatment of persistent pathologic follicular cysts. Medical

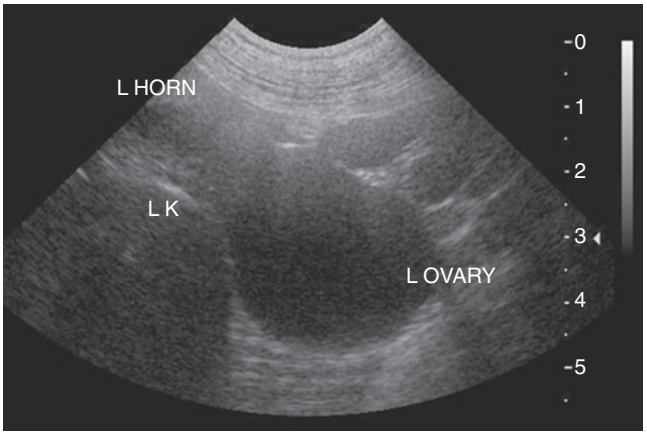

FIG 55.1
Follicular ovarian cyst *(L ovary). LK,* Left kidney, *L Horn,* left uterine horn.

therapies should not place the reproductive health of the bitch at risk. Progesterone treatment of bitches with functional follicular cysts puts the bitch at increased risk for development of cystic endometrial hyperplasia/pyometra and is not advised. Use of gonadotropin-releasing hormone (GnRH; 50-100 µg/bitch intramuscular [IM] q24-48h for up to 3 doses) or human chorionic gonadotropin (hCG; 500-1000 International Units [IU]/bitch IM) has been advocated as effective in inducing cyst regression or luteinization, but results are usually disappointing. GnRH does not appear to be antigenic in the bitch and may be the preferred treatment. Successful induction of cyst regression or luteinization is reflected by a reduction in vulvar discharge, change in vaginal cytology reflecting reduced estrogen effect, diminished attractiveness to males, and normalization of behavior. Serum estrogen concentrations fall and increased progesterone concentrations occur if luteinization results. Ultrasonographic monitoring of ovarian morphology shows regression of hypoechoic structures. Unfortunately, medical treatment of prolonged proestrus or estrus is usually unrewarding; surgical removal of the cyst is the most expedient means of managing the problem. Removal of the cyst alone is optimal, but resection of the associated ovary is usually necessary. Histologic evaluation of the removed tissue confirms the diagnosis and, importantly, permits evaluation for evidence of neoplasia that might warrant additional therapy and a different prognosis. Failure of medical therapies to resolve prolonged proestrus or estrus does not necessarily indicate that ovarian neoplasia is more likely than a follicular cyst. Effective therapy should not be delayed once the diagnosis is made, because prolonged hormonal stimulation of the endometrium contributes to subfertility.

PROLONGED INTERESTROUS INTERVALS

Bitches exhibiting prolonged interestrous intervals (interpreted as a failure to cycle) can have prolongation of either anestrus or diestrus; clinical differentiation is indicated.

PROLONGED ANESTRUS

Prolonged anestrus occurs when no ovarian activity is present for longer than 16 to 20 months in a bitch having previously experienced normal estrous cycles with 6 to 12 month intervals (secondary anestrus). An actual failure to continue to cycle must be differentiated from silent heats, which are normal but not apparent to owners. Bitches do not experience menopause. Underlying disease and iatrogenic causes for failure to cycle should be ruled out by a careful history, physical examination, and database including evaluation of thyroid function (see later). The mechanism by which anestrus is normally terminated in the bitch is not well understood. Dopamine inhibits prolactin secretion. Prolactin concentrations decrease from late diestrus to late anestrus. Both follicle-stimulating hormone (FSH) and LH have been reported as the hormone initiating proestrus folliculogenesis (Maenhoudt, 2012). The dopamine agonists bromocriptine (Parlodel [Novartis]) and cabergoline (Galastop [Vetem]) (5 µg/kg PO q 24h until proestrus is documented) can be used to shorten anestrus in both the normal bitch with inconveniently long interestrous intervals and those with secondary anestrus of unknown etiology; their success in the latter is less predictable. The mechanism by which dopamine agonists induce proestrus could be a direct reduction in prolactin concentration, or more likely a direct dopaminergic action on either the gonadotropic axis or on ovarian gonadotropin receptors. Medical estrous induction can be attempted; contributory pathology can reduce its effectiveness.

PROLONGED DIESTRUS

Prolonged diestrus occurs when progesterone levels remain elevated for longer than 9 to 10 weeks. The clinical behavior of the bitch cannot be differentiated from one experiencing prolonged anestrus. The value of vaginal cytologies, serial serum progesterone levels, and the ultrasonographic appearance of the ovaries and uterus becomes apparent in establishing a diagnosis. Prolonged diestrus occurs secondary to the presence of a luteinized (progesterone-secreting) ovarian cyst or neoplasia (luteoma). Progesterone provides negative feedback to the pituitary-hypothalamic axis, preventing the stimulation of normal ovarian activity. Luteinized cysts can be single or multiple, involving one or both ovaries. Abdominal ultrasonography can identify encapsulated hypoechoic structure(s) within the affected ovary(ies) (Fig. 55.2). Serum progesterone concentrations above 1.0 to 5.0 ng/mL confirm the diagnosis. Treatment with the natural prostaglandin $PGF_{2\alpha}$ (Lutalyse [Pharmacia]) or the synthetic analog cloprostenol (Estrumate [Schering-Plough]) usually causes only a transient decline in serum progesterone levels, indicating partial luteolysis. Surgical removal of the cyst(s) and histologic analysis is the recommended treatment (Fig. 55.3, *A*, 55.3, *B*). Separation of the cyst from the affected ovary is optimal but technically difficult; ovariectomy is usually indicated. Evaluating the presence and extent of accompanying cystic endometrial hyperplasia (CEH) is advisable and can provide valuable information to the owner concerning future fertility of the bitch, which is even more guarded than after

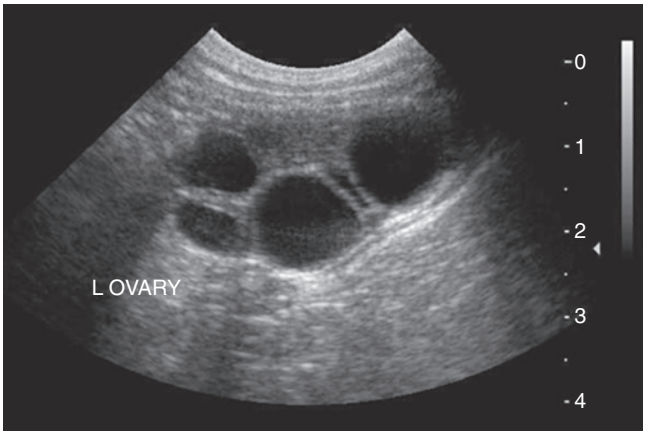

FIG 55.2
Multiple luteal ovarian cysts. *L ovary,* Left ovary.

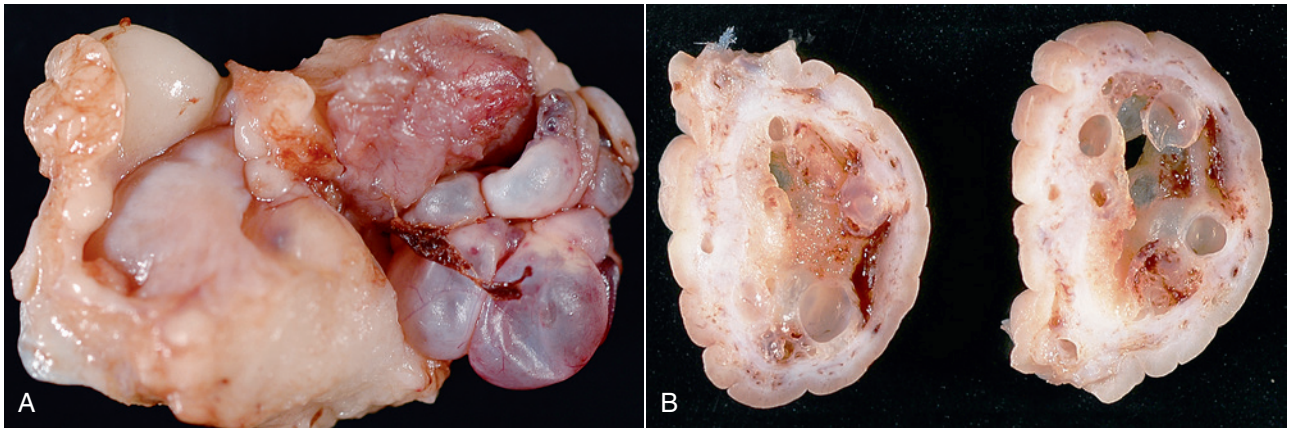

FIG 55.3

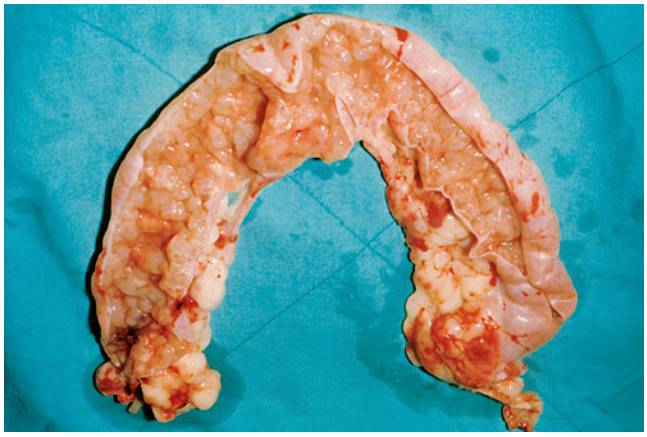

FIG 55.4
Gross specimen, same bitch, cystic endometrial hyperplasia.

resolution of follicular cysts. Cystic endometrial hyperplasia, if present, may resolve partially after elimination of the cyst but still contributes to subfertility (Fig. 55.4). Unfortunately, concern exists that uterine biopsy during diestrus could contribute to pyometra (Schlafer and Gifford, 2008).

Nonfunctional ovarian cysts may cause failure to cycle owing to their mass effect. Rete ovarii cysts and subsurface epithelial structure cysts are examples of nonfunctional ovarian cysts. Increases in plasma estrogen or progesterone concentrations will not be identified, although these cysts have the potential to produce a wide variety of other steroidal compounds without apparent systemic effect. This diagnosis, initially suspected using abdominal ultrasonography, is confirmed by histologic evaluation of surgically removed tissues.

Premature ovarian failure can result in permanent anestrus. Although the functional longevity of the ovaries of bitches is not known, on average the decline in function would not be expected before 7 to 10 years of age. Bitches can reproduce late in life. Prolonged anestrus due to premature ovarian failure could be supported by documenting markedly elevated FSH and LH concentrations, as would be seen after ovariohysterectomy. Such increases indicate a lack of negative feedback to the pituitary and hypothalamus, without any other identifiable cause for anestrus. Immune-mediated oophoritis, diagnosed by ovarian histopathology, could result in prolonged anestrus. A mononuclear infiltrate predominated by lymphocytes, plasma cells, and macrophages has been reported to occur in both ovaries in a bitch experiencing estrous cycle abnormalities. This is an extremely rare disorder.

Hypothyroidism is a potential cause for prolonged interestrous intervals or failure to cycle, but the diagnosis should be well supported by other clinical signs (lethargy, weight gain, bilaterally symmetric alopecia) and clinical pathologic data (hypercholesterolemia, nonregenerative anemia), as well as confirmation of subnormal serum thyroid (total T_4 and free T_4 by equilibrium dialysis) concentrations, ideally supported by elevated endogenous canine thyroid-stimulating hormone (cTSH) concentrations (see Chapter 48). Bitches with circulating antithyroid antibodies may have artificially elevated total T_4 concentrations due to cross-reactivity. Hypothyroid bitches placed on adequate replacement therapy should begin to cycle within 6 months of becoming euthyroid. The presence of immune-mediated thyroiditis is thought to have a genetic basis in some breeds and may occur with other immune-mediated endocrinopathies. Currently this is evaluated by periodic measurement of thyroglobulin autoantibodies (TGAA). The breeding soundness of such bitches should be addressed with clients. Glucocorticoids can feed back on pituitary gonadotropins FSH and LH, causing a failure to cycle, so administration of any steroid medication must be discontinued by taper in a bitch with prolonged anestrus.

SHORTENED INTERESTROUS INTERVALS

Bitches with short (<4.5 months) interestrous intervals can fail to conceive because of incomplete uterine involution and repair, precluding implantation. Classically, bitches

experiencing shortened interestrous intervals are normal in other respects. Ovulation and luteinization occur, and the secondary oocyte is fertilized but fails to implant successfully. Documentation of this disorder requires serial vaginal cytologic evaluations during estrus and diestrus, and serum progesterone concentrations during the luteal phase of at least two consecutive cycles. Currently, there is no reliable, commercially available, consistent preimplantation method of confirming fertilization in the dog. The occurrence of folliculogenesis without ovulation (split heat) and hypoluteiodism (premature luteal failure) should be ruled out. Both require evaluation of serum progesterone concentrations. In the former, ovulation has not occurred and progesterone remains at baseline (<1.0 ng/mL); and in the latter, progesterone concentrations are not maintained above 5.0 ng/mL for the normal length of diestrus (45+ days). True shortened interestrous intervals occur because anestrus is abbreviated. A defect in the hypothalamic-pituitary-ovarian axis could exist, causing interference with the normal maintenance of anestrus. An imbalance of dopamine versus prolactin concentrations have been theorized as contributing to this syndrome. One suggested therapy consists of prolonging anestrus through the use of progestational drugs during the first 3 days of the impending proestrus; this is undesirable because an increased risk of pyometra can occur. Similarly, the advocated use of anabolic compounds to prevent cycling has never been studied critically; the fertility of bitches previously treated with anabolics is not known, and side effects (epiphora, vaginitis, clitoral hypertrophy, hepatopathy, and aggression) do occur.

EXAGGERATED PSEUDOCYESIS (PSEUDOPREGNANCY)

Owners often interpret nonpregnant bitches showing overt signs of pseudocyesis as abnormal. Signs exhibited during overt pseudocyesis include weight gain, mammary gland development and lactation, mucoid vulvar discharge, inappetence, restlessness, nesting, and mothering of inanimate objects. Radiography (after 50+ days of diestrus) or ultrasonography can establish the presence or absence of fetuses. Alternatively, owners could be concerned about bitches showing overt signs of pseudocyesis because they find the behavior or physical symptoms objectionable in a bitch they know is not pregnant.

Pseudocyesis is a normal physiologic phenomenon experienced by any nonpregnant bitch completing the luteal portion of an estrous cycle. These signs are the result of progesterone concentrations declining and prolactin, a luteotroph, increasing. The clinical expression of pseudocyesis varies from indiscernible to (rarely) potentially serious. Clinical signs of pseudocyesis usually are reported from 6 to 12 weeks after estrus. Signs of pseudocyesis are often reported by owners when giving reproductive histories as if its occurrence indicates a reproductive disorder, when in fact pseudocyesis establishes that the bitch has a normal hypothalamic-pituitary-ovarian axis and estrous cycle. Bitches that exhibit signs consistent with a diagnosis of pseudocyesis are probably under the influence of prolactin. Similar concentrations can be demonstrated in bitches that have no clinical signs, suggesting that the former may have increased target organ concentrations or heightened peripheral sensitivity to the hormone. The condition is self-limiting, usually regressing in 1 to 3 weeks, and therapy is not recommended unless the signs are unusually prolonged or pronounced, such as causing mastitis. Unusually persistent cases of inappropriate lactation should be evaluated for hypothyroidism, in which elevated thyrotropin-releasing hormone (TRH) may cause increases in prolactin.

Therapy for pseudocyesis, when recommended, is usually directed at decreasing or eliminating lactation. Therapy is pursued to reduce the likelihood of mastitis occurring secondary to milk stasis, or to diminish lactation-induced household soiling. Minimal measures are recommended. Mammary stimulation via licking, mothering behavior, or warm or cold compressing should be discontinued. Dopamine antagonists, of which phenothiazines are a class, enhance prolactin secretion and should not be administered. Mild sedation with a nonphenothiazine tranquilizer may be helpful. A variety of hormonal and medical therapies have been employed to reduce or stop lactation in pseudopregnant bitches. Side effects, in most cases, outweigh the benefit of most of these medications. Therapy with gonadal hormones, progesterone, estrogen, or testosterone is not recommended owing to complications of repetitive cycles of pseudocyesis, symptoms of proestrus or estrus, and virilization behavior, respectively. Ergot alkaloids are potent prolactin inhibitors (dopaminergic) and can be used to abbreviate exaggerated pseudocyesis. Bromocriptine can be administered at 0.01 to 0.05 mg/kg/day in divided doses until lactation ceases. Vomiting, depression, and anorexia are commonly reported side effects, usually more problematic than the lactation. Cabergoline, administered at 5 µg/kg/day, given divided or once daily for 3 to 5 days effectively decreases prolactin concentrations and diminishes signs of pseudocyesis with fewer side effects but is expensive and must be compounded for use in all but giant breeds. Acupuncture has been suggested to reduce the signs of pseudocyesis. Fasting/water deprivation has no effect on pseudocyesis. Permanent resolution of clinical pseudocyesis requires ovariectomy.

VAGINAL HYPERPLASIA

Estrogen produced during folliculogenesis normally causes a generalized hyperplastic response of the vaginal mucosal epithelium and cornification of the vaginal epithelial cells in preparation for the copulatory lock. This estrogen response can induce a hyperplastic vaginal periurethral mass in some bitches that can prolapse through the vulvar cleft if large enough. The exposed vaginal tissue becomes traumatized and contaminated, and urethral obstruction at the level of the papilla can occur (Fig. 55.5, *A*). Follicular luteinization can be attempted to prematurely decrease estrogen production with GnRH (50-100 µg/bitch IM q 24-48h for up to 3 doses) or hCG (500-1000 IU/bitch IM q 24-48h for up to 3 days); this can compromise fertility if a breeding is

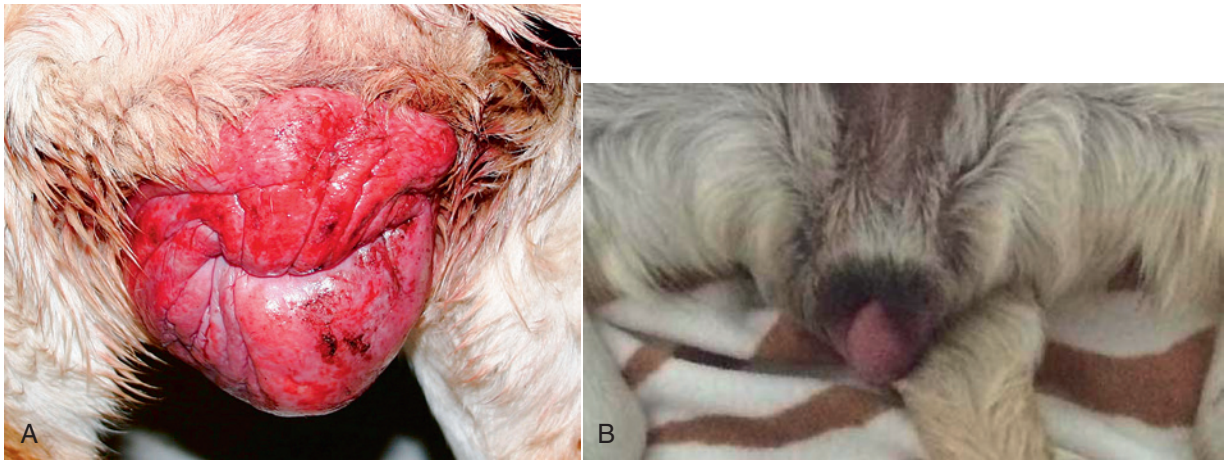

FIG 55.5
Vaginal hyperplasia. **(A)** Labrador Retriever bitch. Note mucosal hyperemia and abrasion secondary to prolapse of vaginal tissue. **(B)** Recurrence at parturition causing obstruction of the distal birth canal.

planned. It is doubtful that medical intervention is of benefit insofar as most bitches resolve this condition post ovulation when estrogen levels normally decline. Successful surgical methods of amputating the hyperplastic tissues have been reported. Prolonged (>1 month) vaginal hyperplasia/prolapse most commonly occurs with ovarian pathology (follicular ovarian cysts), requiring ovariectomy for resolution. Artificial insemination may be required because of vaginal hyperplasia, which can recur at term secondary to increased estrogen levels associated with parturition (Fig. 55.5, *B*). The heritability of this condition is not known.

MANIPULATION OF THE ESTROUS CYCLE

PREVENTION OF ESTROUS CYCLES

The best method to prevent estrous cycles in bitches and queens not intended for future breeding remains ovariectomy or ovariohysterectomy. Contraceptive vaccines generating antibodies to GnRH are under development and can be used in both male and female dogs and cats, but these are not yet commercially available. Temporary contraceptive measures for bitches and queens intended for future breeding are problematic; progestins and anabolic compounds have undesirable side effects and risks (e.g., endometrial hyperplasia/pyometra, diabetes mellitus, mammary hyperplasia; hepatopathy, behavioral changes, endometrial atrophy) and are not advised. GnRH agonists (leuprolide, lutrelin, deslorelin) have been shown to suppress gonadal activity in both male and female dogs, with few side effects. These agonists act by causing a downregulation of the GnRH receptors, often after an initial proestrus/estrus induction. Chronic suppression of LH and FSH concentrations and suppression of gonadal hormone secretion and gametogenesis eventually occurs (Trigg et al., 2006). The final result is a chemical castration of males and a protracted anestrus in females that is reversible. None of these products are universally available commercially in the United States. Depot forms of leuprolide acetate (Lupron [Tap Pharmaceutical]) are available on the human market but remain extremely expensive. Although these products are effective and safer than previous options, their lack of availability and high cost make them impractical.

ESTRUS INDUCTION

Many protocols exist in the veterinary literature for estrus induction in the bitch and queen. Most have disappointing clinical results or use agents that are no longer commercially available or are too cumbersome for clinical application. Estrus (behavior and attractiveness) induction is straightforward with estrogenic compounds, but estrus followed by ovulation of fertilizable oocytes that implant successfully is difficult in the bitch and queen.

Fertile estrus can be induced most reliably in the bitch using dopamine agonists. At least 90 days of anestrus (progesterone < 1.0 ng/mL) must be allowed for adequate uterine involution permitting implantation. Oral (PO) bromocryptine at 30-50 µg/kg per day in divided doses can induce a fertile proestrus in 17 to 49 days, but side effects (nausea and diarrhea) are common and usually unacceptable. Cabergoline at 5 µg/kg PO q24h can induce fertile proestrus in 4 to 34 days, with fewer side effects. The drug must be discontinued after 48 to 96 hours of proestrus (determined cytologically) to prevent downregulation of the hypothalamic-pituitary-ovarian axis. Fertile estrus induction has also been documented with GnRH analogs (lutrelin, deslorelin, leuprolide) that can also be administered as long-acting dosage forms via subcutaneous (SC) injections, mini pumps, inhalants, or implants. Both expense and side effects may limit use of these products. A synthetic sustained-release GnRH analog (deslorelin) was marketed for several years for equine patients and shown to be effective in canine patients, but it is currently not universally commercially available. Substitutions (Ovuplant [Fort Dodge]) are not U.S. Food and Drug Administration (FDA) approved and can have unreliable results. Side effects

have included premature luteal failure, shortened diestrus, and pregnancy loss. Long-term use is also associated with pituitary overstimulation, downregulation of GnRH receptors, suppression of LH, decreased progesterone secretion, and decreased luteal responsiveness to LH.

Feline estrus induction protocols exist in the literature but are affected by photoperiod, previous length of anestrus versus nonpregnant diestrus, and unpredictable maturity of postovulatory oocytes. Manipulation of photoperiod alone is difficult in the cattery setting and not very effective. Estrus induction in a cat colony is reportedly most successful if preceded with progestin administration to inhibit folliculogenesis, but this increases the risk of endometrial disease, diabetes, and mammary pathology, and cannot be advocated for pets. Estrus induction most commonly has been accomplished using equine chorionic gonadotropin (eCG) at 100 IU IM, followed in 80 to 84 hours with an injection of the LH-like hormone hCG (Follutein [Bristol-Meyers Squib]) at 75 to 100 IU IM. In the queen, administration of exogenous hormones such as GnRH (Cystorelin [Ceva]) or hCG can be used to increase the likelihood of ovulation but requires the presence of mature ovarian follicles (i.e., estrus). Both hormones stimulate ovulation by bypassing the vaginal-hypothalamic neural pathway. Administration of 25 µg of GnRH IM, or 75 to 100 IU hCG IM, in midestrus can induce ovulation in some queens (Pelican et al., 2006). GnRH or hCG administration may be useful when a tom has low libido, and a sufficient number of copulatory stimuli are not achieved (Wiebe and Howard, 2009).

PREGNANCY TERMINATION

Termination of pregnancy in the bitch is often requested by owners after unwanted mating, less commonly in queens. Because an estrual bitch has been found with a male, a successful mating is presumed to have occurred. Only one third of bitches become pregnant after a single unplanned mating. For this reason, therapy should be delayed until unwanted pregnancy is confirmed at about 30 days (see Chapter 54). Vaginal cytologic examination can be performed to document estrus by the presence of 90% to 100% cornified superficial cells. Further identification of sperm cells in a vaginal swab within 48 hours of mating can be used to confirm that mating has occurred but not necessarily conception. Unless there is a valid reason for keeping a reproductively intact animal, the veterinarian should highly recommend ovariohysterectomy/pregnancy termination once the female is in early diestrus. Ovariectomy during diestrus can induce acute decline in serum progesterone and growth hormone, and a reflex increase in prolactin, resulting in mild signs of pseudopregnancy that owners should be warned about.

Once pregnancy has been documented in a reproductively valuable bitch or queen, options for safe pregnancy termination can be discussed. Extensive counseling with the owner is required to establish which therapeutic option is best suited for the animal. Treatment options should be assessed by comparing safety, efficacy, cost, and compliance by the owner. Owners should understand that in all cases, the animal should be confined after treatment, and in future cycles to avoid further unwanted pregnancies. Medical pregnancy termination protocols are more effective during the second half of gestation (35-45 days gestation) when luteolysis occurs most readily. Later in gestation (>50 days), pregnancy termination protocols can cause abortion of live premature fetuses that die after parturition but could be distressing to owners or staff, necessitating their euthanasia. Lactation commonly occurs in dams after later gestational pregnancy termination and may necessitate antiprolactin therapy if discomfort or mastitis occur. All pregnancy termination protocols necessitate monitoring for completion with serial ultrasound (Fig. 55.6). Ultrasonography is important in defining the end point of any of the following protocols to confirm evacuation of all fetuses. Premature discontinuation of treatment could result in retention of nonviable fetuses or eventual whelping or queening of remaining fetuses.

Estrogens

In general, limited drugs are used to terminate pregnancy in bitches or queens during estrus. Estradiol cypionate (ECP [Pharmacia]), estradiol benzoate (Intervet), and diethylstilbestrol (DES) were used extensively for this purpose but are not currently commercially available from manufacturers. Use of estrogens during diestrus significantly increases the risk for the bitch or queen to develop a pyometra. Because of potential side effects (irreversible aplastic anemia, pyometra, prolonged estrus), lack of availability, and better alternatives, estrogens are no longer recommended for mismate injections. Estradiol cypionate is not considered safe in cats.

Antiestrogens

The antiestrogen tamoxifen citrate (Nolvadex [Zeneca]) has been evaluated as mismate drug but was associated with a high frequency of pathologic changes in the reproductive tract, including endometritis and ovarian cysts, and is not advised.

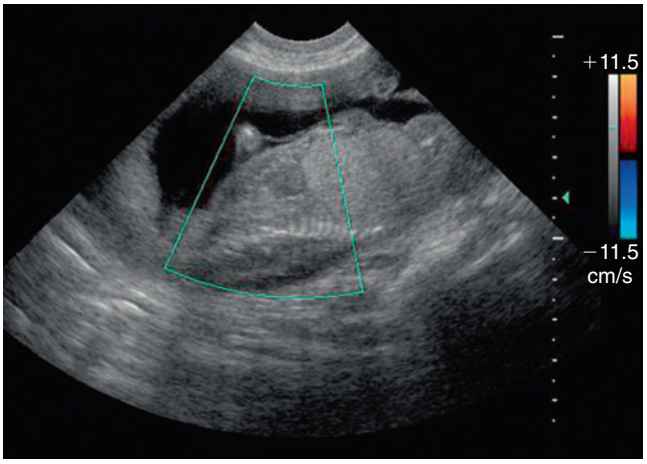

FIG 55.6
Fetal death before uterine evacuation. A lack of cardiac motion is evident; Doppler is useful but not essential for evaluation of fetal viability.

Prostaglandins

After confirmation of pregnancy, the natural prostaglandin $PGF_{2\alpha}$ (Lutalyse [Pharmacia]) has been administered to bitches and queens to lyse the corpora lutea and evacuate the uterus, causing pregnancy termination. Prostaglandins are associated with physical side effects that reflect the physiologic effects of endogenous prostaglandins and include emesis, salivation, tachypnea, diarrhea, urination, trembling, and nesting behavior. These reactions diminish in severity and duration as treatment progresses. The onset of vaginal discharge is often the first indicator that pregnancy termination has begun. Natural prostaglandins must be given for a significant length of time (often >7 days), adding to the overall cost of therapy. A dosage of 0.1 mg/kg SC q8h for 2 days, followed by 0.2 mg/kg SC q8h to effect, is recommended for induction of abortion in the bitch. Synthetic prostaglandins may have fewer side effects and require a shorter treatment period and are now preferred by this author to the natural prostaglandins. Cloprostenol (Estrumate [ICI, UK]), a synthetic prostaglandin, is dosed at 1-3 µg/kg SC q48h for 3+ doses and has been successful in terminating pregnancy in bitches and queens after 30 days' gestation. Although prostaglandins are not approved for use in domestic dogs or cats, they are recognized as a standard of care. Administration of prostaglandins in the clinic rather than by owners at home is advised because of their narrow therapeutic window, but pregnancy termination can be performed on an outpatient basis, especially with synthetic prostaglandins. Successful termination of pregnancy and evacuation of fetuses must be confirmed with ultrasound.

Combination prostaglandin therapy in the bitch with intravaginal misoprostol, prostaglandin E2 (Cytotec [Searle]), can reduce the mean time to abortion to under 5 days. Combination therapies appear to act synergistically: $PGF_{2\alpha}$ at 0.1 mg/kg to 0.2 mg/kg SC q8h in combination with intravaginal misoprostol at 1 to 3 µg/kg q24h (100 µg tablet dissolved in 5 mL water) shortened the treatment time to induce abortion in dogs by an average of 2 days over $PGF_{2\alpha}$ used alone. Misoprostol is thought to act as a cervical softening agent and has prolonged higher blood levels when administered intravaginally rather than orally. Side effects (nausea, cramping, diarrhea) are minimized with intravaginal administration as well.

The prognosis for resumption of estrous cycles and successful pregnancies after prostaglandin-induced abortion is good. Most bitches experience a return to proestrus 4 months (abbreviated diestrus) after prostaglandin-induced abortion. The onset of estrous cycles in the queen is more variable, reflecting the influence of length of daylight on a seasonally polyestrous species.

Dexamethasone

Dexamethasone has more recently been administered to terminate pregnancy in bitches. Dexamethasone is thought to have a direct antiprogesterone effect or to increase endometrial and placental prostaglandin synthesis and release. When used in pregnancies less than 40 days, only mild side effects are generally seen (mild vulvar bleeding, anorexia, panting, polydipsia, polyuria). Some bitches become markedly polydipsic and polyuric. Its efficacy, few and transient side effects, low cost, availability, and ease of administration have made dexamethasone the agent of choice when finances are limited. Oral doses of 0.2 mg/kg bid until fetal loss (confirmed ultrasonographically) occurs can be used. Abbreviated diestrus results. Because of the immunosuppressant effects of dexamethasone, postabortion metritis can occur; clients should be warned to monitor for its signs (malodorous discharge, lethargy, anorexia, fever).

Dopaminergic Compounds

Dopaminergic agents such as cabergoline (Dostinex, Pharmacia) are very effective if given later in pregnancy (>40 days gestation) but in small animals can be difficult to dose without compounding. Cabergoline is available in generic tablets that contain 0.5 mg (500 µg) of drug. Cabergoline inhibits prolactin, a potent luteotroph, and can result in 100% efficacy if given 40 days after the LH surge at 5 µg/kg PO q24h for 7 to 9+ days. The combination of a synthetic prostaglandin and a dopaminergic agent are most efficacious. Cloprostenol (1-3 µg/kg SC given on days 1 and 3) and cabergoline (5 µg/kg PO q24h) for 2 to 10 days to effect is the author's preferred protocol for canine pregnancy termination; in the queen $PGF_{2\alpha}$ at 2.5 mg/cat SC q 24h and cabergoline 50 µg/cat PO q 24h is highly effective within 3-6 days.

Antiprogestational Agents

Antiprogestational agents, mifepristone (RU486, Mifeprex [Danco]) and aglepristone (Alizine [Virbac]), are noted to be very effective (85%-100%) in pregnancy termination and lack the severe side effects noted with some other agents. Aglepristone blocks uterine progesterone receptors; serum progesterone levels remain unchanged. These products do not appear to affect long-term fertility, are rapid in onset, and can be given as an outpatient medication. Unfortunately they are not readily available in the United States and remain very expensive. As these agents become more cost-effective and availability improves, antiprogestational agents may eventually become the treatment of choice in the United States. Aglepristone has the best efficacy used early in gestation (21-45 days). In the bitch, aglepristone is dosed at 10 mg/kg SC, given twice, 24 hours apart. No more than 5 mL of the 30 mg/mL solution should be given in one SC site, owing to tissue irritation. In the queen, aglepristone is dosed at 15 mg/kg SC given twice, 24 hours apart; the higher dose is due to poorer bioavailability and faster metabolic clearance in the feline. After 45 days gestation, combination therapy with cloprostenol and cabergoline is advised.

PREPARTUM DISORDERS

DRUG THERAPY DURING PREGNANCY

The pharmacologic armament for treating reproductive disorders is not large, especially if limited to those drugs

for which sound studies provide support. Breeder clients often request therapies they have heard about through the grapevine or on the Internet, usually anecdotal and often without clinical data supporting their use. The consequences of mistreating pregnant or nursing bitches or neonates should limit the clinician to prescribing therapies with sound scientific rationale in most cases. During the first month of pregnancy, organogenesis takes place, and the impact of potentially teratogenic drugs is most critical. At therapeutic levels, most drugs in the maternal bloodstream are capable of crossing the placenta to reach fetal circulation. Even before implantation, drugs in maternal circulation reach embryos. Any drug that reaches the fetal circulation must be metabolized and excreted by the immature fetal kidney and/or through subfunctional hepatic metabolism. Clinicians should evaluate the package insert on any drug before prescribing its use in pregnant bitches. Cautions for use in pregnant or lactating individuals will be outlined as "safe, untested/unknown, or problematic." Extrapolation across species may not be reliable (i.e., tested in laboratory mice). Dose reduction of many drugs is advised, but guidelines are lacking (Wiebe and Howard, 2009).

VACCINATION DURING PREGNANCY

Shelter personnel may be faced with the dilemma of vaccinating a pregnant bitch or queen upon admission to a facility. Bitch and queen owners commonly request booster vaccinations before breeding. Historically, vaccination in pregnancy has been advised against in small animal medicine, because of the paucity of data concerning vaccine safety and efficacy during gestation, and because it is accepted that no substance should be administered unnecessarily during pregnancy. However, when the immunity of the dog or cat is unknown, the risk of maternal, fetal, and neonatal infection must be weighed against that of vaccination. The U.S. Centers for Disease Control and Prevention states that risk to a developing fetus from vaccination of the mother during pregnancy is primarily theoretical, that no evidence exists of risk from vaccinating pregnant women with inactivated viral or bacterial vaccine or toxoids, and that the benefits of vaccinating pregnant women usually outweigh potential risks when the likelihood of disease exposure is high. Further research in vaccination of pregnant dogs and cats is needed; extrapolating from the human field is advised at this time. The shelter environment provides an example of likely disease exposure in the face of unknown vaccination history, warranting vaccination of pregnant dogs upon admission with canine distemper virus, parvovirus, and bordetella bronchiseptica (intranasal/oral), and cats with feline viral rhinotracheitis, calicivirus, and panleukopenia. Inactivated, subunit, recombinant, polysaccharide conjugate vaccines should be selected for use in the pregnant dog/cat if available. Client-owned bitches should not be boosted during pregnancy if they have been vaccinated within the previous 3 years, queens (recombinant) if within 1 year.

SEMEN PERITONITIS

The differential diagnoses for a sexually intact bitch with acute onset of signs of abdominal pain include pyometra, uterine rupture, and uterine torsion. Acute peritonitis secondary to deposition of semen into the abdominal cavity should also be considered in the estrual bitch with acute signs of abdominal pain and a history of possible exposure to an intact male dog, or with a recent history of artificial insemination. Semen is forced into the uterus during the copulatory lock because of the large amount of prostatic fluid in the final fraction of the canine ejaculate. Normally the semen should not enter the peritoneal cavity of bitches after mating, but in the case of mates mismatched in size or a diseased uterus, semen could be forced into the peritoneal cavity through a tear in the uterus or vagina or through the fallopian tubes. Intraperitoneal deposition of semen results in peritonitis because prostatic fluid contains a large amount of foreign antigens. Severe suppurative peritonitis and the systemic inflammatory response syndrome are likely sequelae (Fig. 55.7, *A*, 55.7, *B*). Stabilization followed by exploratory

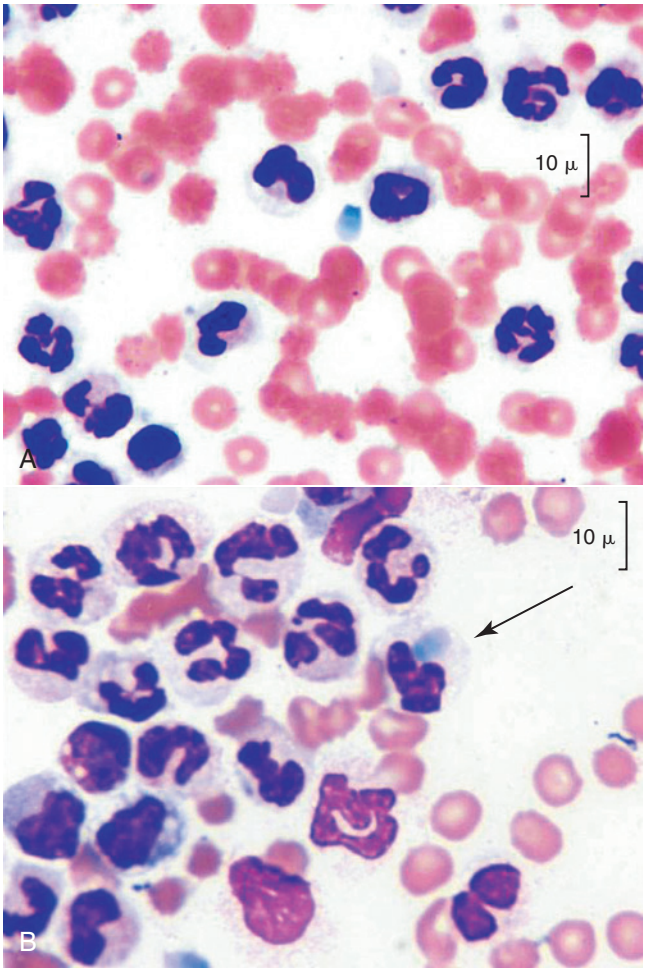

FIG 55.7

laparotomy and lavage of the abdomen are indicated. Inspection of the vagina (endoscopically) and uterus (grossly) for perforation should be carefully performed. This syndrome has high morbidity and mortality for the bitch.

PREGNANCY LOSS

The prepartum period is defined as 9 weeks before term. Pregnancy loss most commonly occurs with idiopathic premature labor, infectious causes, or significant maternal disease or trauma.

IDIOPATHIC PRETERM LABOR

Late-term gestational loss attributed to preterm or premature labor occurs in both bitches and queens. Both hypoluteoidism (inadequate production of progesterone to maintain pregnancy) and inappropriate uterine activity (myometrial irritability) accompanied by cervical changes (softening) have been implicated in the pathophysiology of preterm birth in veterinary medicine, but the syndrome is not well understood or adequately researched. Premature labor is defined as uterine activity and cervical changes leading to the loss of pregnancy via resorption or abortion before term for which no metabolic, infectious, congenital, traumatic, or toxic cause is identified. Progesterone levels can be normal for pregnancy (5-90 ng/mL) when increased myometrial contractility is first detected. Premature deliveries occur when progesterone levels are less than 2.0 ng/mL. Premature labor is often a retrospective diagnosis achieved after thorough evaluation of the dam and stillborn fetuses has been performed. This evaluation should include metabolic screening of the dam for systemic disease, infectious disease (brucellosis) evaluation, histopathology and microbiologic evaluation of expelled fetuses and placentae, and review of kennel/cattery husbandry, including nutrition, medications, and environmental factors. All results are normal or negative. Dams experiencing premature myometrial activity in one pregnancy might or might not exhibit it during subsequent pregnancies, but the syndrome can be a chronic cause of failure to successfully reproduce. In human medicine, preterm birth complicates 10% to 12% of human pregnancies, but it accounts for 80% of fetal morbidity and mortality (Dyson et al., 1998). Women with histories of preterm deliveries appear to be at risk for the same in subsequent pregnancies.

Tocolytic therapy inhibits myometrial contractility and is indicated in the management of premature labor when no contributory pathology is identified. Contraindications to tocolytic therapy in women include severe preeclampsia, placental abruption, intrauterine infection, lethal congenital or chromosomal abnormalities, advanced cervical dilation, and evidence of fetal compromise or placental insufficiency. Tocolytic agents inhibit myometrial contractions and include beta mimetics (terbutaline, ritodrine), magnesium sulfate, calcium channel blockers, and prostaglandin synthetase inhibitors (indomethacin, ketorolac, sulindac). Contraindications to beta mimetics in women include maternal cardiac arrhythmias, poorly controlled diabetes mellitus, and hyperthyroidism—unlikely conditions in breeding bitches or queens. The main contraindication to tocolytic therapy in veterinary medicine is undetected uterine, fetal, or placental pathology, making forced maintenance of the pregnancy problematic for the dam.

Dams with historical late-term loss of pregnancy with no apparent pathology should be prospectively evaluated for premature myometrial activity midgestation, using uterine monitoring, for example, tocodynamometry (Healthdyne) (Fig. 55.8, *A*, 55.8, *B*). Elaboration of prostaglandins from the endometrium and placenta associated with premature myometrial activity can result secondarily in luteolysis. Premature uterine activity endangering fetal survival can be identified before significant luteolysis occurs, and intervention is indicated if the pregnancy is otherwise normal. Pharmacologic intervention to decrease myometrial activity is indicated with tocolytic agents. Terbutaline (Brethine [Ciba Geigy]) at 0.03 mg/kg PO q8h has been used to suppress uterine contractility in bitches and queens with historical preterm loss of otherwise normal pregnancies (Figs. 55.9, *A*, 55.9, *B*, 55.10). The dose is ideally titrated to effect using tocodynamometry. Diltiazem (Cardizem [Bioval Laboratories]) at 0.5 mg/kg PO q8h (canine) and 1.5-2.5 mg/kg PO q8h (feline) can be used if response to terbutaline is inadequate. Therapy is discontinued 24 to 48 hours before term to allow labor to proceed. In the author's experience, poor quality labor requiring cesarean section is common posttocolytic therapy. An elective cesarean section should be discussed with clients.

Canine and feline pregnancy maintenance requires serum progesterone levels of greater than 2.0 ng/mL. Serum progesterone levels during pregnancy normally range widely from 5-15 to 90 ng/mL, declining gradually during the latter half of gestation and falling abruptly at term to <2.0 ng/mL (usually the day before or the day of parturition). Progesterone promotes development of endometrial glandular tissue, inhibits myometrial contractility (causes relaxation of myometrial smooth muscle), blocks the action of oxytocin, inhibits formation of gap junctions, and inhibits leukocyte function in the uterus. In several species, local changes in progesterone level or the ratio of progesterone to estrogen in the placenta, decidua, or fetal membranes is important in the initiation of labor. Progesterone antagonists administered at term can result in an increased rate of spontaneous abortion. In the bitch, the corpora lutea are the sole source of progesterone, whereas in the queen, placental progesterone production occurs in the latter half of gestation. Canine luteal function is autonomous early in pregnancy but supported by luteotrophic hormones (LH and prolactin) after the second week of gestation. Hypoluteiodism, primary luteal failure occurring before term gestation, is a potential but not yet documented cause of late-term abortion in otherwise normal bitches and queens. It has been documented that the induction of abortion in a normal but undesired pregnancy requires a reduction of plasma progesterone levels to less than 2.0 ng/mL. The diagnosis of gestational loss caused by premature luteolysis/luteal insufficiency

FIG 55.8

is difficult, requiring documentation of inadequate plasma progesterone levels before abortion for which no other cause is found. Progesterone levels diminish in response to myometrial activity and fetal death, so documentation of a low progesterone level after an abortion does not establish the diagnosis of hypoluteiodism as the primary cause for reproductive failure. Administration of progesterone to maintain pregnancy in dams with primary fetal abnormalities, placentitis, or intrauterine infection can cause continued fetal growth with the possibility of dystocia and sepsis. Administration of excessive progesterone to maintain pregnancy in a dam not actually requiring therapy can delay parturition and diminish lactation, endangering the life of the bitch and her fetuses, and can masculinize female fetuses (see Chapter 56, Fig. 56.35). Historically, premature pregnancy loss has been treated by administering injectable natural progesterone or oral synthetic progestagens. In women, prevention of preterm delivery or recurrent miscarriage appears to be based on the use of only the natural metabolite of progesterone, 17α-hydroxyprogesterone caproate (17P). Total serum concentrations of progesterone can be monitored only when supplemented with the natural product. Progesterone in oil is given intramuscularly at 2 mg/kg q72h. Altrenogest (Regumate [Hoechst-Roussel]), a synthetic progestagen manufactured for use in the mare, is dosed orally at 0.088 mg/kg q24h. Both forms of supplementation must be discontinued in a timely fashion so as not to interfere with normal parturition, within 24 hours of the due date with the oral synthetic product, and within 72 hours with the natural injectable depot form. This requires accurate identification of gestational length via prior ovulation timing (see Chapter 54). Less accurate identification of gestational length can be made from breeding dates, radiography, or ultrasound (see Chapter 54). The unfavorable side effects of exogenous progesterone supplementation must be outlined to clients and make its use in premature labor unattractive. Studies have shown that early tocolytic therapy prevents luteolysis and precludes the use of progestational compounds in preterm labor (Davidson, 2015).

PREGNANCY LOSS ASSOCIATED WITH INFECTIOUS DISEASE

CANINE BRUCELLOSIS

Brucellosis is the primary contagious infectious venereal disease of concern in canine reproduction. Canine brucellosis is caused by *Brucella canis,* a small, gram-negative, non–spore-forming aerobic coccobacilli. *B. canis* was first isolated by Leland Carmichael in 1966. *Brucella abortus, Brucella melitensis,* and *Brucella suis* have occasionally caused canine infections but are comparatively rare. *B. canis* causes reproductive failure in both the male and female dog. Screening for *B. canis* infection is an important part of the prebreeding evaluation of any dog and should be included in the initial diagnostics in any case of canine abortion, orchitis, epididymitis, and apparent infertility in bitches or dogs. Because the incidence of canine brucellosis is low in many geographic locations, breeder compliance with regular screening can wane, making continued veterinary vigilance important. Notably, neutered and maiden or virgin dogs can also be infected. *B. canis* can also occasionally cause systemic disease

(e.g., discospondylitis) in dogs not used for reproduction. Transmission occurs through direct exposure to bodily fluids containing an infectious dose of organism (semen, lochia, aborted fetuses/placentas, milk, and urine). Transmission is primarily oral, nasal, conjunctival, and secondarily venereal (i.e., through mucous membranes), the former associated with ingestion or aerosolization of infectious materials. The aerosol route is especially important if kennel conditions are crowded. Transplacental transmission and direct cutaneous inoculation can occur.

Canine brucellosis has high morbidity but low mortality in the adult dog. The clinical systemic signs are often subtle (suboptimal athletic performance, lumbar pain, lameness, weight loss, lethargy). The primary clinical sign of canine brucellosis in the breeding bitch is pregnancy loss, which can occur early (day 20) in gestation and result in fetal resorption, or more commonly later in gestation (generally 45-59 days), resulting in abortion. Bitches with pregnancy loss early in gestation can appear to be infertile (failed to conceive) unless early ultrasonographic pregnancy evaluation is performed. Nongravid bitches can be asymptomatic or show regional lymphadenomegaly (pharyngeal if orally acquired, inguinal and pelvic if venereally acquired).

The diagnosis of canine brucellosis is based on suggestive clinical signs and the results of serology studies; culture of blood, urine, or tissues; and histopathology and/or polymerase chain reaction (PCR) assays. Because no single antemortem test has 100% sensitivity and serologic assays lack specificity, a combination of diagnostic assays is often required to make a diagnosis. Antibodies to *Brucella* do not become detectable until 2 to 12 weeks after infection, so a window of time exists in which an infected dog can elude diagnosis with any serologic assay used. Assays used for screening purposes are usually rapid and inexpensive but can suffer from low specificity (high rate of false-positive test results) due to strong cross-reactivity between surface LPS antigens of *B. canis* and those of other nonpathogenic infectious agents. Up to 50% to 60% of dogs may have false-positive test results because of cross-reacting antibodies to other microorganisms such as *Bordetella, Pseudomonas, Escherichia coli,* and *Moraxella* spp. Examples of screening assays include the rapid slide agglutination test (RSAT), the semiquantitative 2-mercaptoethanol modified RSAT (ME-RSAT), and the semiquantitative tube agglutination test (TAT). If the test result is positive, a confirmatory assay should be performed. This could include tests such as the specific cytoplasmic agar gel immunodiffusion (AGID) assay, blood culture, or a reliable PCR assay.

Brucellosis is a zoonotic disease and may be a reportable disease in either the dog or human in certain jurisdictions. Infected dogs and bitches should be removed from breeding programs and quarantined. Eradication of the disease in kennel situations has not been successful without removal (culling) of all infected (current or historically) dogs. Because of the zoonotic potential of the disease and difficulty in actually eradicating the infection, euthanasia of affected dogs has been advised. Infection in household or small hobby kennel dogs often results in client requests for alternatives to euthanasia. Neutering decreases the amount of organism shed in semen and uterine discharge but does not eradicate the infection. Urine shedding can persist, and the organism can be found in internal organs and the bloodstream. Antibiotic therapy has not been historically rewarding, likely because the organism is intracellular and bacteremia periodic. Antibiotic therapy may reduce antibody titers without clearing the infection. Relapses are common. Combination therapy with tetracyclines (doxycycline or minocycline 25 mg/kg bid PO for 4 weeks) and dihydrostreptomycin (10-20 mg/kg bid IM or SC for 2 weeks, given during weeks 1 and 4) or an aminoglycoside (gentamicin 2.5 mg/kg bid IM or SC for 2 weeks, given during weeks 1 and 4) has been advocated as being the most successful, but unavailability, nephrotoxicity, parenteral therapy requirements, and expense remain problematic. Recently one study reported a slightly encouraging outcome of therapy with enrofloxacin (Enrofloxacin [Bayer], 5 mg/kg bid PO for 4 weeks, often for multiple courses) in a small group of infected dogs and bitches. Enrofloxacin was not completely efficacious in eliminating *B. canis,* but it maintained fertility and avoided the recurrence of abortions, transmission of the disease to subsequently whelped puppies, and dissemination of microorganisms during parturition (Wanke et al., 2006). Ultimately, however, most treated dogs remained culture positive. Combinations of enrofloxacin and doxycycline may be a more effective alternative for dogs unable to tolerate aminoglycoside, but studies are lacking. A combination of doxycycline and rifampin has been used successfully to treat human brucellosis but may not be well tolerated by dogs because of gastrointestinal adverse effects.

Private breeders should require screening testing of all bitches presented for breeding and confirmatory negative testing if positive results occur during screening before accepting a bitch into their kennel. Stud dogs should be screened appropriately at least annually. Because of the potential for nonvenereal transmission, screening of maiden dogs and bitches before breeding is also recommended.

ABORTION ASSOCIATED WITH OTHER BACTERIA

Opportunistic intrauterine aerobic and anaerobic bacteria, usually of vaginal origin, can cause septic abortion in the bitch and queen. *Escherichia coli* is the most common organism found in the bitch with septic abortion. Controversies exist about the role of mycoplasmas and ureaplasmas. The most common intrauterine bacterial-associated causes of abortion in the queen include *Streptococcus sp., Escherichia coli, Campylobacter spp,* and *Salmonella spp.* Bacterial abortion is associated with placentitis and fetal death, commonly in a progressive manner; the prognosis for fetal survival is guarded. Pregnancy termination and medical uterine evacuation along with appropriate antibiotic therapy can salvage the bitch or queen for future breeding.

PROTOZOAL DISEASE

Toxoplasmosis/Neosporosis/ Cryptosporidiosis

Toxoplasma gondii and *Neospora caninum* have been associated with abortion (toxoplasmosis) and resorption (neosporosis) in the bitch; *T. gondii* causes feline abortion. Transplacental transmission with placental vasculitis and necrosis occurs. Loss of pregnancy results; in rare cases neonates survive but are weak, with neurologic (ocular),

gastrointestinal, and respiratory disorders. Toxoplasmosis can be spread venereally. The diagnosis is based on serology and PCR. *Cryptosporidia canis* and *C. felis* develop in the microvillus border of epithelial cells in the digestive, respiratory, and genitourinary tracts and can cause abortion. The diagnosis is made with the direct immunofluorescent antibody (IFA) test or PCR.

CANINE VIRAL-ASSOCIATED PREGNANCY LOSS

Herpes Virus

Adequate exposure of a non-immune bitch to canine herpesvirus (CHV-1) during the last 3 weeks of gestation can result in infection of the dam and subsequently her neonates. Venereal transmission is believed to be rare and community (respiratory) transmission more common. Signs in the bitch are usually limited to a mild, clear upper respiratory discharge and transient sneezing; however, reports of a more severe respiratory form of CHV-1 exist in adult dogs, often with other viral coinfections (Piewbang et al., 2017). Infection in the naïve pregnant bitch commonly results in late term abortion or neonatal death within the first few weeks of life. The recently infected bitch has inadequate time to form protective maternal antibodies and allow passive immunity (transplacental or transmammary) to be acquired by the neonates. Incompletely developed immune systems and inadequate thermoregulation during the first weeks of life make neonates vulnerable to systemic viral infection. Adequate ingestion of colostrum must occur promptly postpartum for puppies to acquire passive immunity. The transmission of protective immunity (placental or colostral antibodies) between a bitch and her puppies depends upon the prior existence of adequate serum maternal antibodies. CHV-1 can evade the immune system and become latent in the nervous system; immunosuppression during pregnancy can promote viral reactivation, but if this occurs it will likely boost the immune response and increase the level of colostral antibodies available to neonates.

Transmission of herpesvirus from an infected, viremic dam to neonates occurs subsequent to contact with infectious vaginal fluids or oronasal secretions. Signs in the neonate are progressive and severe, and include anorexia (poor weight gain), dyspnea, abdominal pain, incoordination, diarrhea, serous to hemorrhagic nasal discharge, and petechiation of the mucous membranes. The mortality rate in untreated litters infected in utero or during birth is commonly 100%, with deaths occurring during the first few days to 3 weeks of life. Infection in neonates born to a non-immune bitch may also result from contact with CHV-1 from another dog shedding the organism in the vicinity. Older naive (>3-4 weeks of age) puppies exposed to herpesvirus may have an inapparent infection; some authors have reported concerns with later central nervous signs including blindness and deafness. Subsequent litters of the bitch infected during a previous pregnancy are usually resistant to infection, having acquired adequate circulating maternal antibodies via colostrum. Bitches can be screened before breeding for CHV-1 titers; negative serology should prompt strict hygiene and isolation during the last 3 weeks of pregnancy and the first month postpartum. Vaccine development is hampered by the poor immunogenicity of the herpesvirus, as evidenced by other herpesviral vaccines developed for different species, such as feline and bovine rhinotracheitis. A commercial CHV vaccine is currently available in Europe; it has not been subjected to nonproprietary critical evaluation.

Minute Virus

Canine Minute Virus (canine parvovirus type 1) causes resorption and abortion after transplacental transmission. Any fetuses surviving to term can have anasarca and myocarditis, with poor neonatal survival. The diagnosis is based on virus isolation, immunofluorescence, or PCR.

FELINE VIRAL-ASSOCIATED PREGNANCY LOSS

Leukemia Virus (FeLV), Panleukopenia Virus (FPV), Herpes Virus (FHV), Infectious Peritonitis (FIP), and Feline Immunodeficiency Virus (FIV)

Viral-associated pregnancy loss is in the queen is more common than bacterial; reproductive failure can be associated with feline leukemia virus (FeLV), feline panleukopenia virus (FPV), feline herpes virus (FHV), feline infectious peritonitis (FIP), and feline immunodeficiency virus (FIV). Viral transmission can occur transplacentally, via oronasal contact, and in some cases can be transmammary. Infection can result in resorption, mummification, or abortion of fetuses, as well as neonatal death. Abortion PCR and culture panels are commercially available. The queen and tom cat should be FIV antibody- and FeLV antigen-screened and appropriately vaccinated. The most effective management system to prevent infectious causes of pregnancy loss in the queen include rigorous health maintenance of both the queen and tom, routine annual screening for underlying health problems, retrovirus status, and excellent nutrition. Queens should be maintained in a closed colony environment and new additions to the colony quarantined.

Vector Borne Disease

Babesiosis and leishmaniasis have both been implicated in canine abortion.

METABOLIC DISORDERS

HYPEREMESIS GRAVIDARUM

Bitches can experience a transient loss of appetite and sometimes have periodic vomiting during the second and third weeks of gestation. This usually resolves spontaneously, but sometimes marked anorexia hinders adequate nutrition during gestation. Antiemetic therapy can be helpful with

metoclopramide at 0.1 to 0.2 mg/kg PO or SC bid. Alternative antiemetic drugs may not be safe or recommended for pregnancy; clinicians must evaluate risk versus benefit. In uncommon cases, force-feeding must be undertaken. Hyperemesis gravidarum in women is believed to occur secondary to an acute elevation of human chorionic gonadotropin; no pregnancy gonadotropin has been identified in the bitch.

GESTATIONAL DIABETES

Gestational diabetes occurs infrequently in the bitch and is attributed to the antiinsulin effect of progesterone (mediated by increased levels of growth hormone) during the luteal phase. Polydipsia, polyuria, and polyphagia with weight loss occur. High-fiber diets promote euglycemia in the bitch, but the diet must remain balanced for pregnancy and lactation. Insulin may be indicated. Oversized fetuses can result from their increased production of insulin in response to maternal hyperglycemia and may cause dystocia due to fetal-maternal mismatch (Fig. 55.11). Gestational diabetes can resolve postpartum when progesterone levels decline; if not, it is reclassified as type I diabetes. Ovariohysterectomy is indicated postweaning as recurrence with diestrus is likely.

PREGNANCY TOXEMIA

Pregnancy toxemia in the bitch is due to altered carbohydrate metabolism in late gestation, resulting in ketonuria without glycosuria or hyperglycemia. The most common cause is poor nutrition or anorexia during the last half of gestation. Hepatic lipidosis can occur. An improved plan of nutrition can resolve the condition in most cases, but termination of the pregnancy may be indicated in severe cases.

VASCULITIDES

Pregnancy Thrombosis

Pregnancy is a recognized hypercoagulable state that becomes problematic in women with genetic prothrombosis. Hypercoagulability has also been recognized in pregnant dogs. Affected bitches have an increased tendency for thrombosis, as evidenced by an elevated D-dimer level, with variable clinical appearances. Ultrasound can be used to document thrombosis, which occurs commonly in the caudal vena cava, resulting in venous congestion in the pelvic limbs (Fig. 55.12). Antithrombotic therapy with low molecular weight heparin is well documented in women but undocumented in the bitch and can easily result in congenital defects (aspirin-induced cleft palates) or loss of pregnancy due to placental or fetal hemorrhage. Warfarin is contraindicated in pregnancy because it crosses the placenta. The condition is believed to be inherited in women; affected bitches should be removed from the breeding pool.

Pregnancy Edema

Marked edema of the distal pelvic limbs, caudal mammary glands, and perineum has been observed, usually in large-breed bitches with large litter size (Figs. 55.13, 55.14). These bitches are not hypoalbuminemic. Venous thrombosis should be ruled out with Doppler ultrasonography. Vaginal hyperplasia can occur at term and be mistaken for pregnancy edema. Mild elevation of estradiol at the end of gestation in the bitch can induce reformation of vaginal hyperplasia, seen more commonly during estrus, and can cause compromise of the birth canal. Elective cesarean section is then indicated. Vaginal hyperplasia can be confirmed by digital examination of the vagina, finding a mass originating cranial to the urethral papilla. If pregnancy edema is confirmed, mild exercise (walking or swimming) can be helpful. Diuretics are contraindicated; furosemide can cause a decrease in placental intervillous blood flow and spironolactone is a pregnancy category D (positive evidence of fetal risk) drug in humans. Mild sodium restriction can help. Severe edema of the perineum can cause dystocia (Fig. 55.15).

Mammary edema in a Labrador Retriever bitch in the eighth week of gestation.

PARTURITION AND PARTURIENT DISORDERS

Although many bitches and queens deliver in the home or kennel/cattery setting without difficulty, requests for veterinary obstetric assistance are becoming more common. The increased financial and emotional value of stud dogs, brood bitches, toms, queens, and their offspring to the pet fancier makes preventable loss of even one neonate undesirable. Breeding colonies in academic, scientific, and industrial facilities have to maximize neonatal survival for financial and ethical reasons. Veterinary involvement in canine and feline obstetrics has several goals: to increase live births (minimizing stillbirths due to difficulties in the birth process), minimize morbidity and mortality in the dam, and promote increased survival of neonates during the first week of life.

FIG 55.15
Marked vulvar and perineal edema in a Boxer bitch at term gestation. Cesarean section was performed.

Neonatal survival is directly related to the quality of labor. Optimal management of whelping/queening requires an understanding of normal labor and delivery in the bitch and queen, as well as the clinical ability to detect abnormalities in the birthing process.

EUTOCIA

Bitches typically enter stage I labor within 24 hours of a decline in serum progesterone to below 2.0 to 5.0 ng/mL, which occurs in conjunction with elevated circulating prostaglandins and is commonly (~60% detection) associated with a transient drop in body temperature, usually to below 100° F (33.7° C). Queens typically enter stage I labor 24 hours after serum progesterone falls to less than 2.0 ng/mL. Monitoring serial progesterone concentrations for impending labor is problematic because in-house canine kits enabling rapid results are inherently less accurate between 2.0 and 5.0 ng/mL, and a rapid decline in progesterone levels can occur over a period of a few hours. Commercial laboratories offering quantitative progesterone by chemiluminescence typically have a 12- to 24-hour turnaround time, which is not rapid enough to enable decisions about an immediate indication for obstetrical intervention. If progesterone is <2 ng/mL, labor is imminent.

Stage I labor in the bitch normally lasts from 12 to 24 hours, during which time the uterus has myometrial contractions of increasing frequency and strength, associated with cervical dilation. No abdominal effort (visible external contractions) is evident during stage I labor. Bitches and queens can exhibit changes in disposition and behavior during stage I labor, becoming reclusive, restless, and nesting intermittently, often refusing to eat and sometimes vomiting. Panting and trembling can occur. Vaginal discharge is clear and watery, sometimes voluminous.

Stage II labor in the bitch is defined to begin when external abdominal efforts can be seen, accompanying myometrial contractions to culminate in the delivery of a neonate. Presentation of the fetus at the cervix triggers the Ferguson reflex, promoting the release of endogenous oxytocin from the hypothalamus. Typically these efforts should not last longer than 1 or 2 hours between puppies, although great variation exists. The entire delivery can take from 1 to more than 24 hours, but normal labor is associated with shorter total delivery time and shorter intervals between neonatal births. Vaginal discharge can be clear, serous to hemorrhagic, or green (uteroverdin). Typically bitches continue to nest between deliveries and may nurse and groom neonates intermittently. Anorexia, panting, and trembling are common.

Stage III labor is defined as delivery of the placenta. Bitches and queens typically vacillate between stages II and III of labor until the delivery is complete. During normal labor, all fetuses and placentae are delivered vaginally, although they are not be delivered together in every instance.

The stages of labor in the queen can be similarly defined. Stage I labor in the queen is reported to last 4 to 24 hours and stages II and III from 2 to 72 hours, although completion of delivery of neonates within 24 hours is expected with normal queening.

DYSTOCIA

Dystocia is difficulty with normal vaginal delivery of a neonate from the uterus and must be diagnosed in a timely fashion for medical or surgical intervention to improve outcome. Dystocia results from maternal factors (uterine inertia, pelvic canal anomalies, intrapartum compromise), fetal factors (oversize, malposition, malposture, anatomic anomalies), or a combination of both. For effective management, prompt recognition of dystocia and correct identification of etiologic factors are essential to making the best therapeutic decisions (Fig. 55.16).

Uterine inertia is the most common cause of dystocia. Primary uterine inertia results in the failure of delivery of any neonates at term and is thought to be multifactorial, including metabolic defects at the cellular level. Intrinsic failure to establish a functional, progressive level of myometrial contractility occurs. A genetic component could be present. Secondary uterine inertia results in cessation of labor once initiated and consequential failure to deliver the entire litter. Secondary inertia can be due to metabolic or anatomic (obstructive) causes and is also thought to have a genetic component when no contributory cause can be identified.

Birth canal abnormalities such as vaginal strictures, stenosis from previous pelvic trauma or particular breed conformation, and intravaginal or intrauterine masses can cause obstructive dystocia. In most cases, canal abnormalities can be detected in the prebreeding examination and resolved or avoided by elective cesarean section (see Chapter 54).

Causes of intrapartum compromise rendering the dam unable to complete delivery include metabolic abnormalities such as hypocalcemia and hypoglycemia, systemic inflammatory reaction, sepsis, and hypotension (due to hemorrhage or shock).

Fetal factors contributing to dystocia most commonly involve mismatch of fetal and maternal size, fetal anomalies, and fetal malposition and/or malposture. Prolonged gestation with small litter size can cause dystocia due to an oversized fetus(es). In one study, induction of parturition was successfully performed at gestational day 59 using aglepristone (15 mg/kg SC bid [Alzine, Virbac]); this could be used in bitches with small litters and anticipated delayed parturition (Baan et al., 2005). Fetal anomalies such as twinning, hydrocephalus, and anasarca similarly can cause dystocia (Figs. 55.17, 55.18). Fetal malposition (ventrum of fetus proximal to the dam's dorsum) and fetal malposture (flexed neck and scapulohumeral joints most commonly) promote dystocia because the fetus cannot transverse the birth canal smoothly.

An efficient diagnosis of dystocia is dependent upon taking an accurate history and performing a thorough physical examination in a timely manner. The clinician must quickly obtain a careful reproductive history detailing breeding dates, any ovulation timing performed, historical and recent labor, as well as a general medical history. The physical examination should address the general status of the patient and include a digital and/or vaginoscopic pelvic examination for patency of the birth canal, evaluation of litter and fetal size (radiography most useful), assessment of fetal viability (Doppler or real-time ultrasound, ideally), and uterine activity (tocodynamometry most useful).

TOCODYNAMOMETRY

The canine and feline uterus each have characteristic patterns of contractility, varying in frequency and strength before and during different stages of labor. Serial tocodynamometry in the bitch and queen permits evaluation of the progression of labor (Fig. 55.19). During late term, the uterus may contract once or twice an hour before actual stage I labor is initiated. During stage I and II labor, uterine contractions vary in frequency from 0 to 12 per hour, and in strength from 15 to 40 mm Hg, with spikes up to 60 mm Hg. Contractions during active labor can last 2 to 5 minutes. Recognizable patterns exist during prelabor and active (stages I-III) labor. Aberrations in uterine contractility can be detected during monitoring. Abnormal, dysfunctional labor patterns are often associated with maternal morbidity and fetal distress (Figs. 55.20, *A*, 55.20, *B*, 55.21, *A*, 55.21, *B*). Completion of labor (or lack thereof) can be evaluated via tocodynamometry. Fetal viability is evaluated best by external doppler fetal heart rate monitoring or ultrasonography; 180 to 220 beats/min are normal, persistent deceleration (<180 beats/min) reflects stress (Fig. 55.22).

Medical Therapy

Medical therapy for dystocia, based on administration of oxytocin and calcium gluconate, can be guided and tailored by maternal and fetal monitoring. Oxytocin generally increases the frequency of uterine contractions, whereas

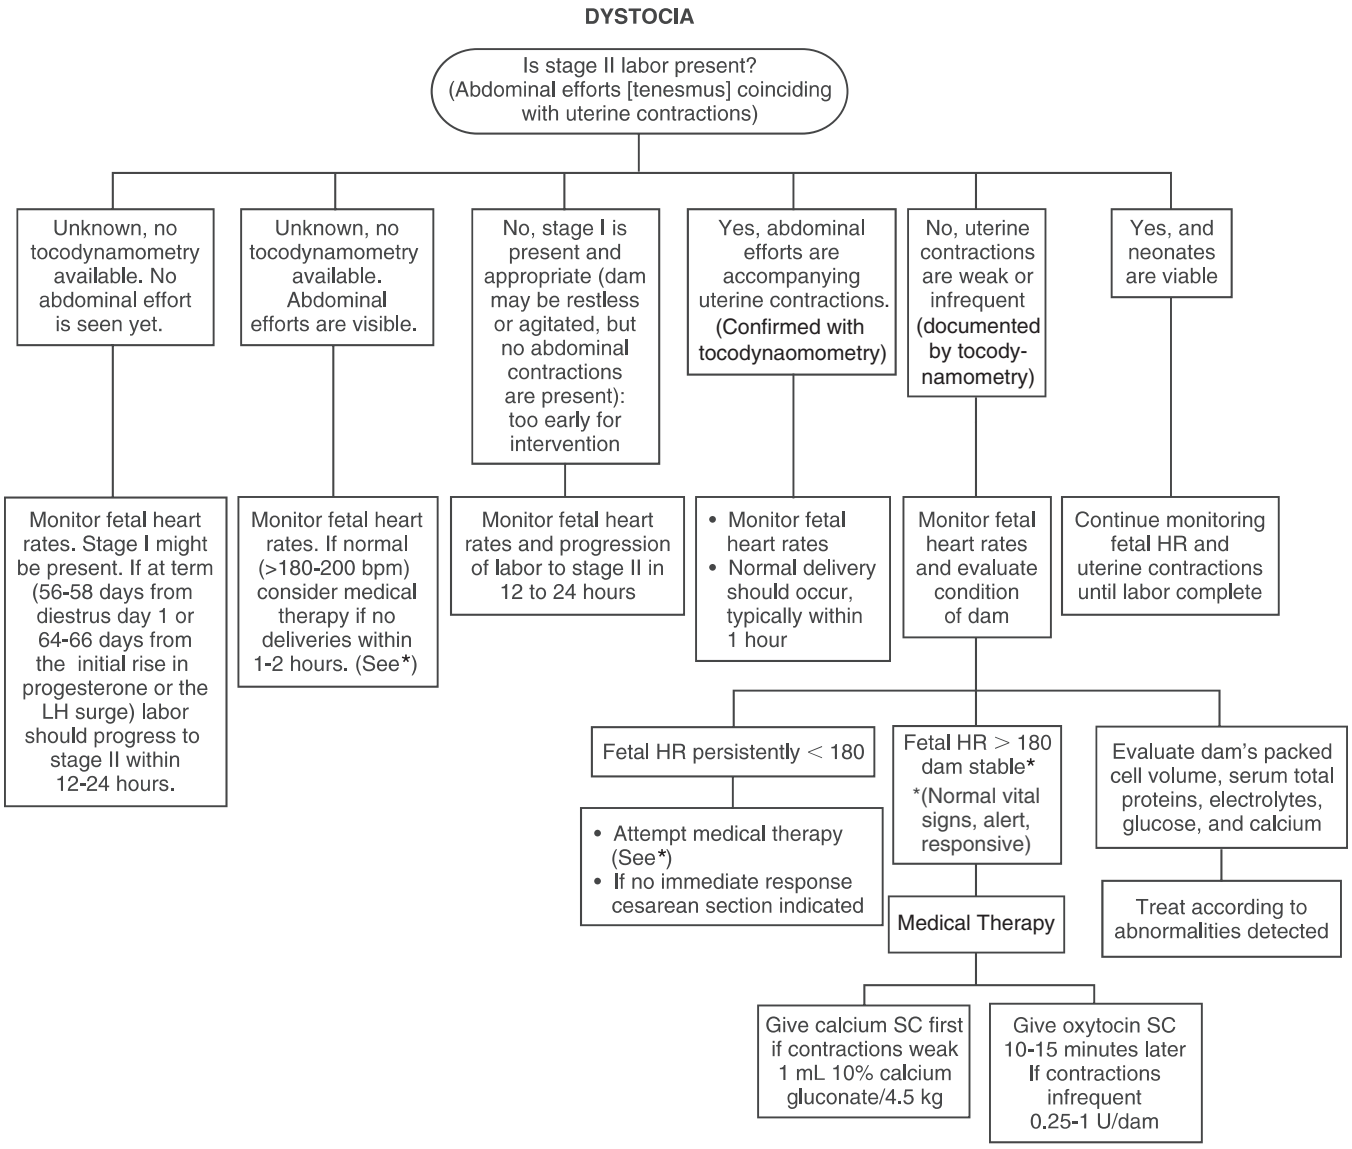

FIG 55.16
Flowchart showing recognition, categorization, and management of dystocia.

FIG 55.17
Canine twins, a rare condition. Malpresentation resulted in dystocia and fetal death.

calcium increases their strength. Calcium gluconate 10% solution with 0.465 mEq Ca^{++}/mL (see Fujisawa) is given SC at 1 mL/5.5 kg body weight as indicated by the strength of uterine contractions (best measured with tocodynamometry), but generally no more frequently than every 4 to 6 hours. Oxytocin, 10 USP units/mL (American Pharmaceutical Partners), is effective at minidoses, starting with 0.25 units SC or IM per bitch or queen regardless of weight, to a maximum dose of 5 units. The dose can be gradually increased to effect (delivery) or until fetal distress is detected; generally no more than 2 units is necessary. Higher doses of oxytocin or intravenous (IV) boluses can cause tetanic, ineffective uterine contractions that can further compromise fetal oxygen supply by placental compression. The frequency of oxytocin administration is dictated by the labor pattern, and it is generally not given more frequently than every 30 to 60 minutes. Calcium is given before oxytocin in most cases, improving contraction strength before increasing

contraction frequency. The action of oxytocin appears to be improved when given 10 to 15 minutes after giving calcium. Most bitches/queens are eucalcemic, suggesting that the benefit of calcium administration is at a cellular or subcellular level.

Cesarean Section

Surgical intervention (cesarean section) is indicated if a bitch or queen fails to respond to medical management, or if fetal distress is evidenced despite adequate to increased uterine contractility (suggesting mismatch of maternal birth canal to

FIG 55.22
Fetal heart rate (HR) monitoring in an Airedale bitch during the eighth week of gestation. Normal fetal HR should be over 180 beats/min.

fetal size, or fetal malposition or malposture incompatible with vaginal delivery), or if aberrant contractile patterns are noted by uterine monitoring (Fig. 55.23). If fetal heart rates decline in response to administration of calcium or oxytocin, further medical management is contraindicated. Well-orchestrated cesarean sections result when anesthetic and neonatal resuscitative protocols are established and coordinated, and the preoperative preparation of the dam optimized. The dam can be debilitated and require careful anesthetic management, there often is be little time for routine preanesthetic preparation, and the dam might have been fed recently. Minimally, the hematocrit, total solids, serum calcium, and glucose concentrations should be evaluated preoperatively. IV fluid support at an operative rate is indicated (5-10 mL/kg/h).

Preoxygenation by mask (5-10 minutes) is always indicated. Initial preparation of the abdomen (clipping and first scrubbing) can be undertaken during this time. Atropine is undesirable as a premedication anticholinergic because it crosses the placenta (can exacerbate fetal myocardial hypoxemia) and causes relaxation of the lower esophageal sphincter making maternal aspiration more likely. However, an anticholinergic is indicated for the dam because of the anticipated vagal stimulation during manipulation of the gravid uterus. Glycopyrrolate (Robinul [AH Robins] at 0.01-0.02 mg/kg SC) does not cross the placenta and is preferred. Most dams are tractable or exhausted and do not need preanesthetic tranquilization, which has a depressant effect on the fetuses. Phenothiazine tranquilizers are transported rapidly across the placenta and are depressants. α_2-adrenoceptor agonists such as dexmedetomidine and xylazine are contraindicated because of their severe cardiorespiratory depressant effects. Similarly, the respiratory depressant effect of opioids makes them unpopular before removal of the fetuses. If tranquilization is necessary with an intractable dam, narcotic sedatives are preferable because their effects can be reversed (IV or IM naloxone, 1-10 µg/kg) during neonatal resuscitation. Metoclopramide (0.1-0.2 mg/kg) can be administered subcutaneously or intramuscularly to the dam before induction of anesthesia to reduce the risk of vomiting during the procedure. Dissociative induction agents such as ketamine and the barbiturates are best avoided because they produce profound depression of the fetuses. Propofol (Rapinovet [Bayer Animal Health] at 6 mg/kg IV to effect) appears to be the most useful induction agent; because of its rapid redistribution it has a limited effect upon the neonates. Alfaxalone (Alfaxan [Jurox]) at 2 mg/kg IV (canine) and 5 mg/kg IV (feline) is an alternative. Mask induction actually produces *more* maternal and fetal hypoxemia than IV propofol induction. For maintenance of anesthesia, volatile agents are preferable, especially those with low partition coefficients, such as isoflurane and sevoflurane. These agents show rapid uptake and elimination by the animal and may have a better cardiovascular margin of safety than the more soluble agents (e.g., halothane). Nitrous oxide may be used to reduce the dose of other anesthetic agents. It is transferred rapidly across the placenta, and although it has minimal effects upon the fetus in utero, it may result in a significant diffusion hypoxia after delivery. Using a local anesthetic (bupivacaine 1-2 mg/kg, lidocaine (canine only) up to 2 mg/kg diluted to necessary volume) line block in the skin and SC tissues before incising permits more rapid entry into the abdomen while the dam is making the transition from propofol induction to inhalant maintenance, and helps with postoperative discomfort. Care must be taken not to inadvertently administer bupivacaine or lidocaine into a mammary vessel. Local (epidural) anesthetic techniques require expertise and monitoring for severe hypotension. Sedatives could still be required to enable positioning for surgery. Epidural lidocaine is preferable (bupivacaine has too long a duration of action and is a more potent negative inotrope) at 2 to 3 mg/kg, not to exceed a maximum volume of 6 mL; adding epinephrine 5 µg/mL intensifies and prolongs the block achieved. Inadvertent penetration of the dura mater can occur.

Ovariohysterectomy at the time of cesarean section is an option for the surgeon and owner but results in longer

anesthetic time for the dam, delayed nursing for the neonates, and increased loss of blood in the dam, and should be postponed unless indicated (devitalized uterus, uncontrollable hemorrhage). Postoperative hemorrhage due to surgical error is more common if ovariohysterectomy has been performed. There is evidence that estrogen acts in a permissive fashion for prolactin receptors in the mammary glands, making ovary removal at cesarean section undesirable. If uterine viability is questionable, however, an ovariohysterectomy should be performed. In the normal dam the uterus will begin to involute shortly after removal of the fetuses, but if this is not the case oxytocin may be administered (0.25-1 unit per dam) to facilitate involution and arrest any hemorrhage; this also promotes milk letdown.

Postsurgical discomfort should be addressed in the dam. Once the fetuses are removed, narcotic analgesia can be administered parenterally to the dam. Postoperatively, nonsteroidal antiinflammatory drugs (NSAIDs) are not advisable because of their uncertain metabolism by the nursing neonates with immature renal and hepatic metabolism. Narcotic analgesia is preferable. Oral narcotics such as tramadol (Ultram [Janssen Pharmaceuticals]) at 10 mg/kg/day in divided doses provide fair to good postoperative analgesia for nursing bitches, with minimal effect in the neonates. In all cases, clients should be advised to closely monitor bitches postoperatively until normal maternal behavior emerges. After cesarean section, bitches can be clumsy and inattentive to the neonates and can even become aggressive, because the normal mechanisms of maternal bonding have been bypassed. The neonates should be allowed to nurse colostrum as soon as possible under close supervision (Fig. 55.24, see Chapter 57).

POSTPARTUM DISORDERS

Normally, dams stay very close to their offspring during the first 2 weeks postpartum, leaving the whelping/queening box briefly if at all to eat and eliminate. They are alert and content to remain with their offspring. Some protective dams may show aggression to housemate animals or even people with whom they are normally tolerant; such behavior tends to dissipate after 1 or 2 weeks of lactation. Lactation typically presents the greatest nutritional and caloric demand of the female's life. Weight loss and dehydration may occur and impact lactation if food and water are not made readily available. Sometimes this entails leaving both in the nest box with a nervous dam. Partial anorexia can be exhibited during the last weeks of gestation and in the immediate postpartum period, but the appetite should return and increase as lactation progresses. Poor appetite during the last weeks of gestation can be due to displacement of the gastrointestinal tract by the gravid uterus. Partial anorexia early in the postpartum period can occur secondary to digestive upset after the consumption of numerous placentae. Diarrhea can occur secondary to increased rations and rich food (bacterial overgrowth secondary to carbohydrate malassimilation).

FIG 55.24
Golden Retriever neonates nursing during the postoperative period after cesarean section. Close monitoring is indicated during this period. Nursing enables acquisition of colostrum.

Marked postpartum effluvium is normal in the bitch, usually occurring at 4 to 6 weeks after whelping and sparing only the head. This is usually more marked than that which occurs in conjunction with the typical estrous cycle, and can cause owner concern, especially in conjunction with the weight loss typically associated with peak lactation.

The body temperature of the dam may be mildly elevated (<39.44° C, 103° F) in the immediate postpartum period, reflecting normal inflammation associated with parturition, but should return to normal levels within 24 to 48 hours. If a cesarean section took place, differentiating normal postsurgical inflammation from fever associated with pathology may be difficult. The physical examination and a complete hemogram help the clinician differentiate between the two. Normal postpartum lochia is brick red in color and nonodorous, and diminishes over several days to weeks (Fig. 55.25, *A*). The mammary glands should not be painful; rather they are symmetric and moderately firm without heat, erythema, or palpable firm masses. If expressed, normal colostrum is yellow to white; milk is gray to white in color and of more watery consistency.

INAPPROPRIATE MATERNAL BEHAVIOR

Appropriate maternal behavior is critical to neonatal survival and includes attentiveness, facilitation of nursing, retrieving neonates, grooming, and protecting neonates. Although maternal behavior is instinctual, it can be negatively influenced by anesthetic drugs, pain, stress, and excessive human interference. Maternal bonding is a pheromone-mediated event initiated at parturition. Whelping and queening should take place in quiet familial surroundings, with minimal human interference yet adequate supervision. Dams with good maternal instincts exhibit caution when entering or moving about the nest box so as not to traumatize neonates by stepping or lying on them. A guardrail along the inside of the whelping box prevents inadvertent smothering of canine neonates (Fig. 55.25, *B*). The neuroendocrine reflex regulating mammary gland myoepithelial cell contraction and subsequent milk ejection is mediated by oxytocin and activated by neonatal suckling. During stress, epinephrine

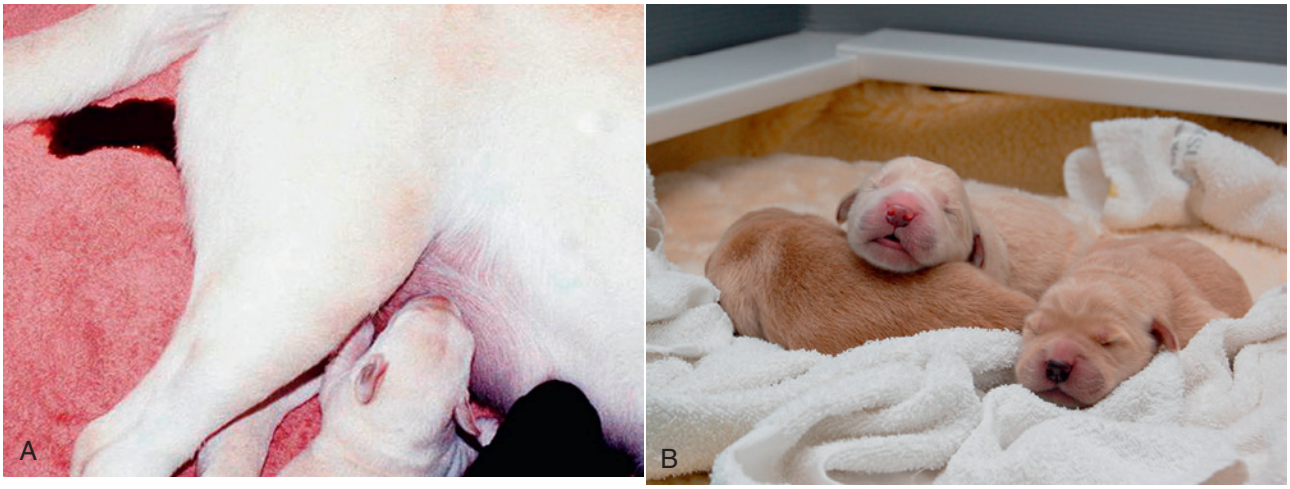

FIG 55.25
(A) Normal lochia, red-brown in color and not malodorous. **(B)** Placement of a guard rail along the inner perimeter of the whelping box helps prevent the dam from lying on puppies.

induces vasoconstriction, blocking the entry of oxytocin into the mammary gland and preventing milk ejection. A nervous, agitated dam will likely have poor milk availability. Dopamine antagonist tranquilizers with minimal prolactin interference (acepromazine 0.01-0.02 mg/kg), administered at the lowest effective dose to minimize neonatal sedation, can improve maternal behavior and milk ejection in nervous dams.

Piling of neonates near their dam facilitates maintenance of their body temperature (neonates cannot thermoregulate/shiver for up to 4 weeks of age) and makes nursing readily available. Normal maternal behavior includes gentle retrieval of neonates who have become dispersed and isolated across the nest box. Grooming of the neonates immediately after parturition stimulates their cardiovascular and pulmonary function and removes amniotic fluids. Dams demonstrating little interest in resuscitating neonates can have poor maternal behavior throughout the postnatal period. Later, maternal grooming stimulates reflex neonatal urination and defecation and maintains the neonatal coat in a clean, dry state. Occasionally, excessive protective behavior or fear-induced maternal aggression can occur. Mild tranquilization of the dam with an antianxiety agent can help, but neonatal drug administration via the milk can be problematic. Benzodiazepines (diazepam 0.55-2.2 mg/kg), γ-aminobutyric acid (GABA) synergists, are reportedly superior to phenothiazines for fear-induced aggression. The role of newer antianxiety pharmaceuticals in maternal aggression has not been described in a controlled setting.

METABOLIC DISORDERS

Eclampsia

Puerperal tetany or eclampsia occurs most commonly during the first 4 weeks postpartum but can occur in the last few weeks of gestation. The condition occurs in bitches more frequently than queens. Puerperal tetany can be life-threatening, and is caused by a depletion of ionized calcium in the extracellular compartment. Predisposing factors include improper perinatal nutrition, inappropriate calcium supplementation, and heavy lactational demands. Small dams with large litters are at increased risk. Excessive prenatal calcium supplementation can lead to development of puerperal tetany by promoting parathyroid gland atrophy and inhibiting parathyroid hormone release, thus interfering with the normal physiologic mechanisms to mobilize adequate calcium stores and utilize dietary calcium sources. Thyrocalcitonin secretion is stimulated. Use of a balanced growth (puppy/kitten) formula commercial feed without additional vitamin or mineral supplementation is optimal during the second half of gestation and throughout lactation. Supplementation with cottage cheese should also be avoided because it disrupts normal calcium-phosphorus-magnesium balance in the diet.

Metabolic conditions favoring protein binding of serum calcium (e.g., alkalosis due to prolonged hyperpnea during labor or dystocia) can promote or exacerbate hypocalcemia. Hypoglycemia and hyperthermia can occur concurrently. Therapeutic intervention should be initiated immediately upon recognition of the clinical signs of tetany without waiting for biochemical confirmation. Signs preceding the development of tetany, tonic-clonic muscle contractions include behavioral changes, salivation, facial pruritus, stiffness/limb pain, ataxia, hyperthermia, and tachycardia. Immediate therapeutic intervention should be instituted with a slow IV infusion of 10% calcium gluconate (1-20 mL) given to effect. Cardiac monitoring for bradycardia and arrhythmias should accompany administration; their occurrence warrants temporary discontinuation of the infusion and a slower subsequent rate. Actual seizures should not occur from hypocalcemia; hypoglycemia should be investigated. Corticosteroids are undesirable because they promote

calciuria, decrease intestinal calcium absorption, and impair osteoclasia. Hypoglycemia should be corrected if present, and exogenous treatment for hyperthermia given if necessary.

Once the immediate neurologic signs are controlled, a SC injection of the equal volume of calcium gluconate, diluted 50% with saline is given and repeated q6-8h until the dam is stable and able to take oral supplementation. Calcium gluconate or carbonate (10-30 mg/kg q8h) should be instituted. Each 500-mg calcium carbonate tablet (Tums) supplies 200 mg calcium. Efforts to diminish lactational demands on the dam and improve her plane of nutrition are indicated. If response to therapy has been prompt, nursing can be gradually reinstituted until the neonates can be safely weaned, usually at a slightly early age (3 weeks), and concurrent supplementation with commercial bitch/queen milk replacement is encouraged. Bottle feeding should precede nursing, and nursing limited to 10 min q4-6h rather than continuously. Giving calcium throughout lactation (but not prepartum) may be attempted in dams with a history of recurrent eclampsia (calcium carbonate 500-4000 mg/dam/day, divided).

UTERINE DISORDERS

Uterine Trauma

Complete or partial prolapse of the uterus is an uncommon postpartum condition in the bitch, occurring rarely in the queen experiencing dystocia. The diagnosis is based on palpation of a firm, tubular mass protruding from the vulva postpartum, and inability to identify the uterus with abdominal ultrasonography. The prolapsed uterine tissues are at risk for maceration and infection from exposure and contamination (Fig. 55.26). The size of most bitches and queens precludes manual replacement; laparotomy and ovariohysterectomy are usually indicated. Vaginal hyperplasia and prolapse, secondary to a hypersensitivity of focal (periurethral) vaginal mucosa to estrogen, can recur near parturition and can be differentiated by physical examination or vaginoscopy (see Fig. 55.5, *B*).

Rupture of the uterus occurs most commonly with very large litters causing marked stretching and thinning of the uterine wall, especially in multiparous dams with dystocia. Immediate laparotomy for retrieval of fetuses and repair or removal of the uterus, as well as culture and lavage of the abdominal cavity, is indicated. The uterus should be carefully examined at any cesarean section for any areas with or prone to rupture. Peritonitis or hemoabdomen can result from an undetected uterine tear. A unilateral hysterectomy can be considered if the damaged area is limited and the dam valuable to a breeding program; these females can be prone to uterine torsion as a consequence.

Subinvolution of Placental Sites

The persistence of serosanguineous to hemorrhagic vaginal discharge beyond 16 weeks postpartum can indicate subinvolution of the placental sites of attachment (SIPS) in the bitch. Histologically, fetal trophoblastic cells have persisted in the myometrium instead of degenerating, endometrial vessel thrombosis is lacking, and normal involution of the uterus is prevented. Normal interplacental regions exist. Eosinophilic masses of collagen and dilated endometrial glands protrude into the uterine lumen, oozing blood (Fig. 55.27). The cause is unknown, blood loss is usually minimal, intrauterine infection not present, and fertility is unaffected. Treatment is generally not necessary; recovery is spontaneous and symptoms mild. In the uncommon situation where vaginal bleeding from SIPS is copious enough to cause serious anemia, coagulopathies (likely defects in the intrinsic pathway or thrombocytopenia/thrombocytopathies), uterine trauma, neoplasia of the genitourinary tract, severe metritis, and excessive hemorrhage from prematurely separated placental sites should be ruled out. Cytology of vulvar discharge (trophoblast cells can be evident), vaginoscopy to localize

FIG 55.26

the source of hemorrhage, coagulation testing, and abdominal ultrasound assist in the diagnosis. Therapy with prostaglandins has not been substantiated. The preventive value of oxytocin given in the immediate postpartum period is also unproven but not likely harmful. Laparotomy and ovariohysterectomy are curative. Histologic examination of the uterus is indicated to confirm the diagnosis.

Postpartum Endometritis

Acute infection of the postpartum endometrium should be suspected if lethargy, anorexia, decreased lactation, and poor mothering are reported and are accompanied by fever and malodorous vulvar discharge (Fig. 55.28). Endometritis is serious and sometimes preceded by dystocia, contaminated obstetrical manipulations, or retained fetuses and/or placentae. Hematologic and biochemical changes often suggest septicemia, systemic inflammation reaction, and endotoxemia. Cytology of vulvar discharge is hemorrhagic to purulent (Fig. 55.29). Ultrasound of the abdomen allows evaluation of intrauterine contents and the uterine wall; endometritis is characterized by thickened, corrugated endometrium with echogenic fluid in the lumen (Fig. 55.30). Postpartum metritis is best differentiated from the normal postpartum uterine enlargement by a failure of normal progressive decrease in uterine lumen contents and horn width. The canine uterus involutes and repairs for up to 16 weeks, making the normal postpartum ultrasonographic appearance challenging; serial evaluations (q24-48h) are helpful. Retained fetuses and placentae can also be identified with ultrasound.

A guarded cranial vaginal culture is likely representative of intrauterine flora and should be submitted immediately for both aerobic and anaerobic culture and sensitivities; this permits retrospective assessment of empirically selected antibiotic therapy. Bacterial ascension from the lower genitourinary tract is more common than hematogenous spread, and *E. coli* is the most common causative organism in both bitches and queens. Empirical selection of a broad-spectrum bactericidal antimicrobial (potentiated amoxicillin such as ticarcillin, 15-25 mg/kg IV q8h, or cefazolin, 22 mg/kg IV q8-12h) must take into consideration that nurslings will be treated as well. Additional therapy consists of IV fluid and electrolyte support as indicated and pharmacologic uterine evacuation, either with synthetic prostaglandins (cloprostenol at 1-3 µg/kg q12-24h) or natural $PGF_{2\alpha}$ (0.1-0.2 mg/kg q 12-24h) for 3 to 5 days to effect. Oxytocin is unlikely to promote effective uterine evacuation when administered more than 24 hours postpartum. Nurslings should be hand-reared if the dam is seriously sick or requires antibiotics contraindicated for neonates. An ovariohysterectomy may be indicated if the bitch's condition

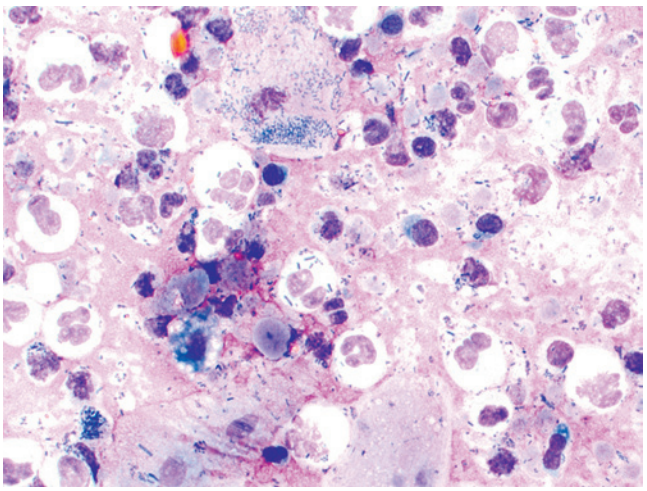

FIG 55.29

permits and she is poorly responsive to medical management; however, this is uncommon. Therapy of postpartum metritis is best monitored by serial evaluations of uterine luminal contents with ultrasound along with hematology, biochemistry, and clinical parameters (appetite, fever, vulvar discharge). Metritis can become chronic and cause infertility. Mild cases, when the bitch is eating, able to take oral antibiotics (Clavamox [14 mg/kg q12h] or cephalexin [10-20 mg/kg q8-12h]), and is still providing good maternal care, can be successfully managed on an outpatient basis, preserving home care of the litter. Bitches with metritis should be evaluated clinically for mastitis as well, owing to the potential for bacteremic contamination of the lactating mammary glands.

MAMMARY DISORDERS

Agalactia

Agalactia is defined as a failure to provide milk to neonates. Primary agalactia, a lack of mammary development during gestation, results from a failure of milk production and is uncommon. A defect in the pituitary-ovarian-mammary gland axis is suspected. Administering progesterone compounds late in gestation can interfere with normal development of the mammary glands, precluding lactation. Secondary agalactia, a lack of milk availability due to a failure of letdown and ejection, is more common. Mammary development is marked, but milk cannot be readily expressed through the teat sphincter. The normally scant production of colostrum in the immediate postpartum period should not be confused with agalactia. Agalactia can occur secondary to premature parturition, severe stress, malnutrition, debility, metritis, or mastitis. Treatment includes providing supplementation to the neonates while encouraging suckling to promote milk letdown, providing optimal levels of nutrition and adequate hydration to the dam and resolution of any underlying disease. Pain management after cesarean section is indicated. If detected early, milk letdown can often be induced pharmacologically. Minidose oxytocin, 0.25-1 unit per injection, is given subcutaneously every 2 hours. Neonates are removed for 30 minutes preinjection and then encouraged to suckle, or gentle stripping of the glands is performed postinjection. Metoclopramide, 0.1-0.2 mg/kg SC, is given q12h to promote prolactin release and mild production. Therapy is usually rewarding within 24 hours. Some authors advise a much higher dose of metoclopramide, risking neurologic side effects; the author has not found this necessary. The use of domperidone (Motilium [Janssen Pharmaceuticals]) at 2.2 mg/kg PO q12h PO from 6 days prepartum to 7 days postpartum resulted in normal lactation in a queen previously agalactic.

Galactostasis

Galactostasis causes engorgement and edema of the mammary gland, with associated discomfort making further nursing unlikely, and can become self-perpetuating. Galactostasis occurs secondary to inverted or imperforate teats, failure to rotate nurslings, litter loss, an unusually small litter, ineffective nursing, and rarely with pseudocyesis (Fig. 55.31). Warm compresses, cleansing/lubricating the nipple, gentle expression of the affected gland, and rotating neonates is advised. With the loss of a litter, antiprolactin therapy with cabergoline (1.5-5 μg/kg/day, divided bid) can be helpful. Galactostasis likely increases the potential for mastitis to develop.

FIG 55.31
Inverted nipple with associated pyoderma, Old English Sheepdog bitch.

Mastitis

Mastitis, septic inflammation of the mammary gland, can be acute and fulminate or chronic and low grade, involving a single or multiple mammary glands. Coliforms, staphylococci, and streptococci are most commonly isolated in both bitches and queens. The source of bacteria is cutaneous, exogenous, or hematogenous. Mastitis can be comorbid with metritis. Mild mammary discomfort and heat, galactostasis, cutaneous inflammation, and the presence of an intramammary mass effect are the earliest signs. Milk is commonly discolored red or brown due to the presence of red and white blood cells. The dam exhibits pain, reluctance to nurse or lie down, anorexia, and lethargy. Fever can be marked and may precede other clinical signs. Advanced cases can present in septic shock, with abscessed or necrotic glands. The diagnosis is based upon physical examination. Milk cell counts in bitches are not predictive of mastitis.

Culture and sensitivity of milk collected aseptically from affected glands allows retrospective evaluation of empirical antibiotic selection. Therapy should begin immediately and consists of broad-spectrum bactericidal antimicrobials and gentle physical therapy. Analgesics may be indicated; neonates tolerate opioid analgesia in the dam. First-generation cephalosporins (cephalexin, 10-20 mg/kg q8-12h) and β-lactamase-resistant penicillins (Clavamox 14 mg/kg q12h) are advised and safe for neonates. Antibiotic therapy may be warranted until weaning and can preclude further nursing if

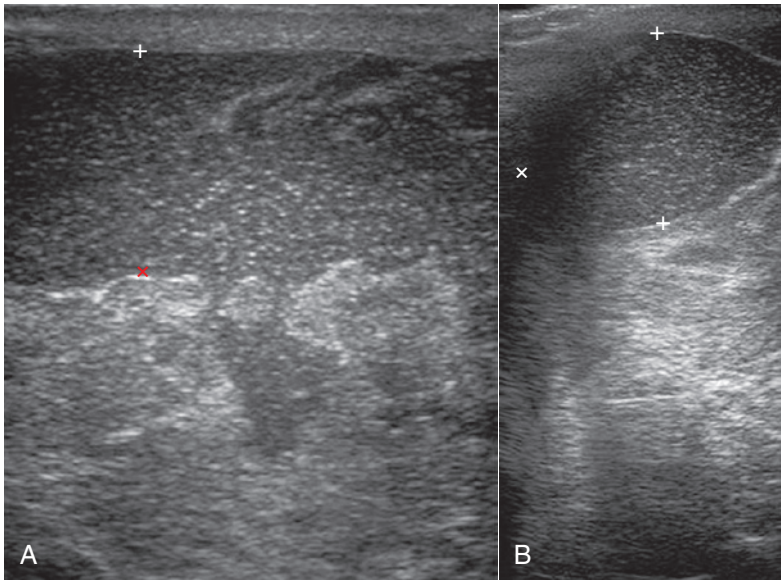

FIG 55.32
Ultrasonographic evaluation of mastitis (cursors). **(A)** Cellulitis. **(B)** Abscessation, surgery is indicated.

sensitivities force the choice of a drug potentially toxic to neonates. Warm compresses or whirlpool therapy of the affected gland, with gentle stripping of milk, can potentially avert abscessation and rupture of the gland. Serial ultrasonography can help identify abscessation (Fig. 55.32, *A*, 55.32, *B*). Severe necrosis warrants debridement or mastectomy when the dam is stabilized, as well as more aggressive wound management. Antiprolactin therapy (cabergoline, 1.5-5 µg/kg/day, divided bid) may be indicated in severe cases to reduce lactation. There is no evidence that nursing from affected glands is problematic for neonates; they tend to avoid glands that are difficult to obtain milk from and are already exposed to flora in the box. The affected gland should be protected from trauma from nest box edges and neonatal claws. Mastitis can recur in subsequent lactations regardless of preventive measures. Early detection and treatment is optimal, rather than prophylactic, antibiotics, which tend to favor development of resistant organisms rather than preventing mastitis.

FIG 55.33
Feline mammary hyperplasia of 6 weeks' duration in a 5-month-old queen. (Image courtesy Dr. Cheri Johnson.)

Feline Mammary Fibroadenomatous Hyperplasia

Feline mammary fibroadenomatous hyperplasia is a non-neoplastic progesterone-mediated condition usually found in pregnant or pseudopregnant queens or in neutered male or female cats given exogenous progestins, most commonly methylprednisolone acetate (Depo-Medrol [Upjohn]). Progestins are most commonly used for behavioral or antiinflammatory therapy in cats. Cats present with mammary enlargement involving one or more glands; the enlargement is due to rapid proliferation of mammary duct epithelium and stroma (Fig. 55.33). Hyperplastic mammary tissue may undergo spontaneous regression or progress to mastitis with abscessation and gangrene. Mammary hyperplasia must be distinguished from mammary neoplasia, by cytology or biopsy. Ovariohysterectomy (if intact) prevents recurrence. NSAID (licensed for use in felines) and antimicrobial therapy, as well as antiprolactin therapy (cabergoline 1.5-5 µg/kg PO q24h for 5-7 days), can be helpful. Mastectomy can be indicated in severe cases. Progestin therapy should be discontinued in neutered cats. More recently, the progesterone antagonist aglepristone (Alizine [Virbac]) has been used successfully to treat fibroadenomatous hyperplasia (10-15 mg/kg SC on days 1, 2, and 8) but is not yet available in the United States.

DISORDERS OF THE REPRODUCTIVE TRACT IN OVARIOHYSTERECTOMIZED BITCHES AND QUEENS

Despite the majority of client-owned pets in the United States being neutered, veterinarians are commonly confronted with disorders of the (residual) genitourinary tract.

CHRONIC VESTIBULOVAGINITIS IN THE OVARIOHYSTERECTOMIZED OR OVARIECTOMIZED BITCH

These bitches present with variable vulvar discharge that is mucoid to hemorrhagic or purulent, and usually accompanied by signs of discomfort (licking, scooting, pollakiuria). Perivulvar and vulvar dermatitis are also frequently present. The condition is invariably seen in ovariectomized bitches of any age, and at variable times from the spay procedure. The history usually includes multiple therapeutic efforts without resolution, although transient improvement can occur. The duration is generally chronic, from weeks to months, sometimes lasting years.

The etiology of chronic vestibulovaginitis is usually multifactorial, and the primary cause is often masked and exacerbated by previous therapies, including long-term antimicrobial use, self-mutilation, and topical irrigations. The vaginal mucosa is erythemic and nodular showing lymphoid follicles; biopsy frequently shows nonspecific lymphoplasmacytic inflammation, but sometimes suppurative (neutrophilic) or eosinophilic inflammation is predominant (Fig. 55.34). Vaginal cultures can show overgrowth of an atypical bacterial species (pure gram-negative cultures, resistant organisms, *Pseudomonas* spp.) or pure culture of *Mycoplasma* spp. if antibiotics have been used extensively. Occasionally a yeast overgrowth is identified. Primary bacterial vaginitis is rare.

The most common documented etiologies of chronic vestibulovaginitis include:

1. Extensive perivulvar dermatitis associated with redundant dorsal and lateral vulvar folds
2. Granulomatous uterine stump (rule out stump pyometra)
3. Vaginal foreign bodies (foxtails, bone fragments)
4. Chronic urinary tract infection with urethritis/vestibulitis/vulvitis
5. Cystic, urethral, vaginal, or vestibular neoplasia

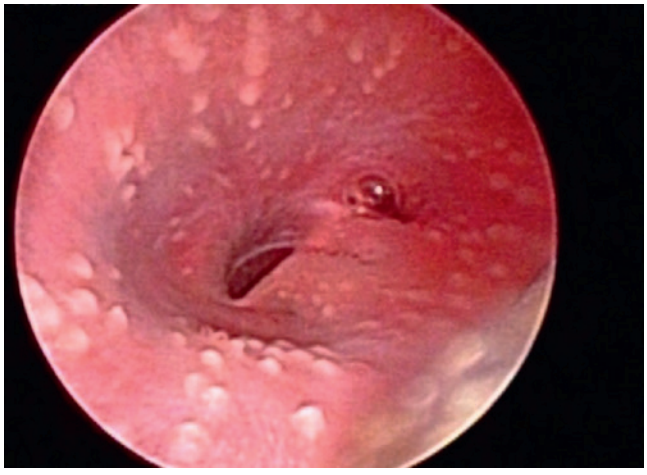

FIG 55.34
Vaginoscopic image of lymphoid follicles in the cranial vagina in an ovariohysterectomized bitch with chronic vestibulovaginitis.

Vaginal strictures are commonly identified and implicated but are rarely causal in this author's opinion. Most are cranial to the urethral papilla, and the pathology caudal. A minimum database should be performed on these chronically affected bitches, involving a complete blood count (CBC) and serum chemistries, including a urinalysis (preferably acquired by cystocentesis), and culture or culture "if indicated." A careful vulvovaginal examination under adequate (heavy) sedation or anesthesia, with endoscopic equipment allowing evaluation of the entire vaginal vault, should be performed. This usually means a rigid cystourethroscope with saline insufflation is a necessity. Otoscopes and vaginal speculums do not permit adequate evaluation of the entire vaginal vault. Pediatric proctoscopes lack the sensitive optics of cystourethroscopes. It is important to observe the undisturbed perivulvar anatomy and then retract surrounding skin to expose the perivulvar region to evaluate for significant dermatitis (Fig. 55.35, *A*, 55.35, *B*). Vaginoscopy permits localization of pathology and identification of foreign bodies, masses, or anatomic anomalies. Contrast radiography (vaginogram, urethrogram, cystogram, IV pyelogram) and/or ultrasound of the entire genitourinary tract can be helpful in localizing the problem and eliminating differential diagnoses. Ultrasound is preferable because it does not require anesthesia and is the best method to noninvasively evaluate the uterine stump, bladder, and urethra (Fig. 55.36, *A*, 55.36, *B*). Ideally ultrasound should be performed before vaginoscopy; saline insufflation can iatrogenically introduce fluid into the uterine stump, making its appearance suspect.

Vaginal cytology, cytologic evaluation of vulvar discharge, guarded vaginal swabs for aerobic bacterial and *Mycoplasma* cultures, and pinch biopsy of affected vaginal mucosa may be helpful in better defining the problem. If estrogen influence is detected with vaginal cytology (superficial cells), evaluation for an ovarian remnant is indicated (see later). If vulvar discharge is purulent and the ultrasonographic appearance of the uterine stump suggests abscessation, evaluation for stump pyometra with serum progesterone and close inspection for ovarian structures with abdominal ultrasound is indicated (see later). Identification of any contributory anatomic abnormalities is important (e.g., significant caudal vaginal strictures causing urine pooling or accumulation of secretions, masses, redundant dorsal or lateral vulvar folds, anomalous ureteral anatomy). It is helpful to evaluate the bitch in a normal standing position to accurately assess external anatomy, followed by another examination after she has urinated, and again after recumbency for urine pooling and scalding. The presence of urine pooling in the vaginal vault, noted only when the bitch is under anesthesia, can be misleading. The presence of redundant vulvar folds is also difficult to ascertain when the bitch is anesthetized and positioned for vaginoscopy, but the presence of perivulvar dermatitis implicates external anatomic contribution to chronic vestibulovaginitis.

General therapeutic guidelines apply to most cases. Discontinuation of topical irrigations, prevention of self-mutilation

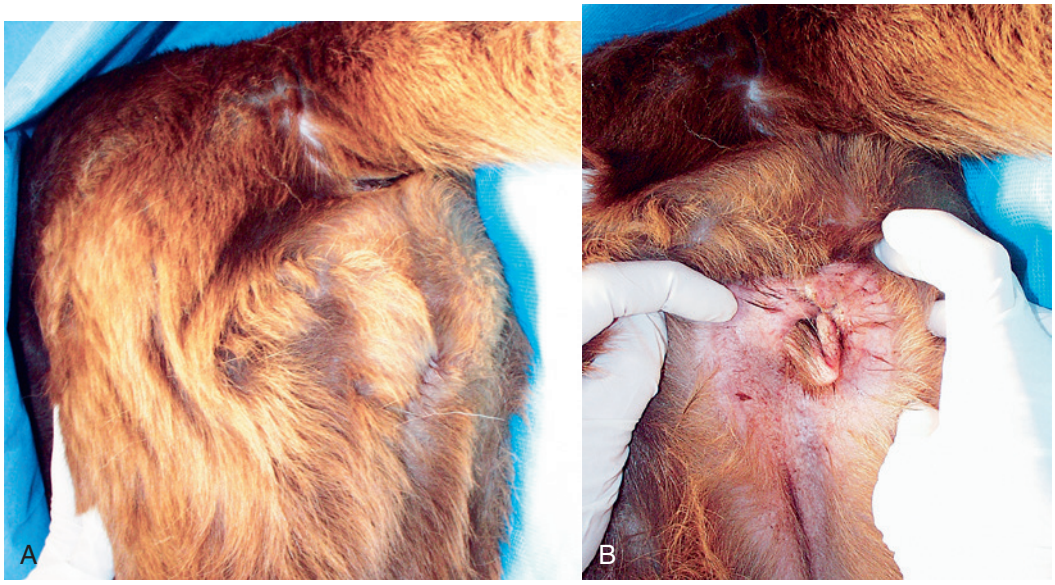

FIG 55.35

with Elizabethan collars, and initiation of antimicrobial therapy only when indicated by proper interpretation of culture and sensitivity testing should be undertaken. Antimicrobial therapy should be limited to those cases where pathogens have been identified as displacing normal flora. Analgesia and antiinflammatory therapies are indicated in most cases. A short antiinflammatory course of corticosteroids can be useful in diminishing vaginal inflammation, but the subsequent propensity for urinary tract infection must be kept in mind, and problems with long-term use limit usefulness. NSAIDs such as carprofen (Rimadyl [Pfizer]), meloxicam (Metacam [Boehringer Ingelheim]), firocoxib (Previcox [Merial]) or grapiprant (Galliprant® Aratana) are preferred. Narcotics (tramadol) or gabapentin may be necessary short term for adequate analgesia. If a specific cause is identified, resolution is more straightforward. Surgical correction with careful postoperative control of self-mutilation is indicated if anatomic abnormalities (redundant dorsal and lateral vulvar folds, significant vaginal stricture, granulomatous uterine stump, clitoral hyperplasia) have contributed to or caused the condition (Fig. 55.37). The identification and removal of foreign bodies should cure chronic vestibulovaginitis. Appropriate management of chronic urinary tract infection (if identified) should resolve associated vaginitis.

FIG 55.37
Postoperative image of corrected redundant dorsal vulvar hooding (Fig. 55.35).

Therapy of urogenital neoplasia can include surgery, chemotherapy, or both.

If no anatomic, foreign body, infectious, granulomatous, or neoplastic cause can be discerned, oral estrogen replacement therapy is often helpful in establishing normal mucosal integrity and eventual normalization of the vaginal vault. The condition is similar to atrophic vaginitis in women. The prevalence of atrophic vaginitis is particularly high among postmenopausal women who experience decreased ovarian estrogen production. This common menopausal condition is caused by estrogen-related changes to the vaginal epithelium and can adversely affect quality of life. Women improve with vaginal estrogen application, difficult in the dog. Oral diethylstilbestrol (compounded DES) or an FDA-approved estriol (Incurin [Merck]; off label) is advised in bitches. The dose is empirical and usually the same as used for urinary incontinence due to sphincter incompetence (DES 0.035 mg/kg PO every 3-4 days; Incurin 1-2 mg PO q24h, taper as possible). Several weeks of therapy may be required before improvement is recognized. Side effects are uncommon; mild overdosage results in signs of proestrus (attraction to male dogs, vulvar swelling); myelosuppression is highly unlikely if the dosage is conservative as suggested.

OVARIAN REMNANT SYNDROME/ HYPERESTROGENISM

Ovarian remnant syndrome (ORS) causes behavioral and/or physical signs of estrus in a bitch or queen having previously undergone ovariohysterectomy. It is caused by the presence of functional residual ovarian tissue and is reported to be responsible for 17% of all postovariohysterectomy complications. It is more common in cats. No breed predisposition or geographic distribution has been reported. The signs of estrus usually occur months to years after ovariohysterectomy but can begin within days after surgery. In bitches, signs reported include attraction of male dogs, swelling of the vulva, mucoid to sanguineous vulvar discharge, passive interaction with male dogs, and flagging; some even allow copulation. Of note, the signs are usually cyclical or periodic (i.e., every 6 months) rather than constant as occurs with chronic vestibulovaginitis or exogenous estrogen exposure. In queens, signs reported include vocalization, lordosis, restlessness, head rubbing, rolling, tail deviation, and treading the hind limbs; the queen may allow copulation. Queens demonstrate typical behavioral signs of estrus in a cyclical (seasonally polyestrous) fashion.

The most common cause is a previous failure to remove both ovaries completely. There is no correlation with age at ovariohysterectomy, difficulty of surgery, obesity of patient, or experience of the surgeon. The presence of anatomically abnormal ovarian tissue (fragmentation into the broad ligament) is possible but uncommon, and a supernumerary ovary is very rare. Experimentally, functionality returns to ovarian tissue removed from its vascular supply and replaced into or onto the lateral abdominal wall. The clinician needs to consider multiple differentials, including inflammation or infection of the genitourinary tract, vaginal hemorrhage due to foreign body, trauma, a uterine stump granuloma or pyometra, neoplasia of the genitourinary tract, vascular anomalies of the genitourinary tract, a coagulopathy, exogenous estrogen administration, and an endogenous extraovarian source of estrogen associated with adrenal pathology (rare). Exposure to exogenous estrogen is not uncommon in small dogs whose owners use transdermal hormone replacement therapy, usually on their forearms. In this case, the signs of hyperestrogenism would be more constant than the cyclical nature of an ovarian remnant. Ovarian remnants can undergo neoplastic transformation; external signs of hormonal influence then become chronic rather than episodic (Fig. 55.38, *A*, 55.38, *B*).

A minimum database should be performed: CBC and serum chemistries, including a urinalysis (preferably acquired by cystocentesis), and culture or culture "if indicated" of the urine is advised. Pancytopenia is possible from estrogen toxicity. Critical observation of behavioral and physical signs of estrus together with vaginal cytologic analysis and/or measurement of serum progesterone or estradiol concentrations can confirm the presence of functional ovarian tissue. Vaginal cytology will identify estrogen effect: vaginal mucosal cornification is a bioassay for elevated plasma estradiol concentrations (see Chapter 54). Note that peak estradiol concentrations triggering behavioral estrus range from 20 to more than 70 pg/mL; however, vaginal cytology findings closely correlate with serum estradiol, and this study is much less expensive to perform. A serum progesterone level >2.0 ng/mL (measured 1-3 weeks after behavioral estrus) is consistent with functional luteal tissue. GnRH (50 µg IM bitch, 25 µg IM queen) or hCG (500-1000 IU IM) can be used to attempt to induce ovulation or luteinization for diagnostic purposes or to end estrus. Serum progesterone is measured 2 to 3 weeks later; this is

often unrewarding because of the refractory nature of the ovarian remnant. In the queen, if ovulation or luteinization is stimulated during behavioral estrus, serum progesterone levels >2.0 ng/mL are consistent with adequate coital stimulation and functional luteal tissue. Serum LH is elevated in ovariectomized females; it is only elevated in intact females during the 12 to 24 h surge. Serum Anti-Müllerian Hormone (AMH) assays are now commercially available, have excellent correlation with ORS in postpubertal females, and will differentiate exogenous estrogen exposure from ORS (Themmen et al., 2010).

Ultrasound should be used to support a diagnosis of ORS based on history, clinical signs, vaginal cytology, and serum hormone tests; ultrasound also gives the surgeon guidance (Video 55.1). Imaging should begin in a sagittal plane slightly caudolateral to the kidneys (where remnant ovarian tissue is expected). Remnant ovarian tissue may be visible only during the follicular phase (anechoic cystic structures) or the luteal phase (hypoechoic or isoechoic cystic structures) (Fig. 55.38, *C*). Ectopic ovarian tissue can be difficult to locate and image using ultrasonography and often requires operator expertise. The adrenal glands should be evaluated at the same time for normal size and shape.

Exploratory laparotomy with the goal of removal of residual ovarian tissue confirms and resolves the problem. The identification of residual ovarian tissue is facilitated by the presence of active follicles or resultant corpora lutea. The clinician should schedule the surgical procedure during estrus of when progesterone is elevated. All visible ovarian tissue should be removed and evaluated by histopathology. If no visible ovarian tissue is identified, all residual tissue at the ovarian pedicles should be resected and submitted for histopathology. Removal of functional luteal tissue may induce transient signs of pseudopregnancy in dogs and cats postoperatively. If profound, antiprolactin therapy (cabergoline 5 µg/kg q24h to effect) can be offered. Successful removal of remnant ovarian tissue should result in cessation of clinical signs of estrus.

Medical therapy is often requested by clients not eager to permit another surgical procedure. Progestational or androgenic compounds used to suppress follicular ovarian activity are not recommended because of undesirable side effects (mammary neoplasia, diabetes mellitus, undesirable behavior). Immunocontraception or GnRH agonist administration will offer a viable alternative to laparotomy when perfected and commercially available in the United States.

INFERTILITY/SUBFERTILITY IN THE BITCH AND QUEEN

Infertility of the bitch or queen refers to the inability to conceive and produce viable offspring; subfertility refers to small litter size. With the exception of developmental abnormalities (see Chapter 56), the majority of bitches brought to a veterinarian for reproductive evaluation for infertility are actually healthy and fertile. Perceived infertility in the bitch is most commonly due to inappropriate breeding management, poor husbandry, or stud dog problems rather than inability of the bitch to conceive. Queens presented for infertility are more likely to actually be infertile; appropriate husbandry and good breeding management have usually taken place using a fertile male. A complete history should be obtained so that problem areas with breeding management or husbandry can be identified and corrected (Box 55.1). Recent fertility of the male(s) used should be verified (litters produced within the last 4 months, not just semen evaluation). The bitch's breeding and general health history including her environment, other animals, housing arrangements, routine prophylactic therapy (vaccinations, heartworm prevention, deworming regimen), current medications, all supplements, diet, and any travel history should be obtained. Of particular interest are age, date(s) of onset of previous cycles (if any), method of ovulation timing used in the past (if any), results of ovulation timing and dates of breeding/insemination based on those results, methods of breeding/insemination, previous pregnancy (if any), method of pregnancy diagnosis or exclusion, date of any pregnancy loss (if known), number of prior litters, litter size, and the reproductive history of the bitch or queen's dam and female siblings. Unless adequate breeding management with a proven currently fertile male, good husbandry, and a documented failure to conceive can be shown, the female should then be managed and monitored (including ovulation timing) through her next cycle before infertility is diagnosed. A sire producing normal litter size for the breed should be used. If failure to conceive persists despite correction of identified problems with husbandry and the male, and incorporation of ovulation timing, then acquired infertility in the bitch and queen usually implicates endometrial pathology rather than pituitary-gonadal or ovarian disorders.

MICROBIOLOGY AND FEMALE FERTILITY

Breeders commonly express concern that infertility or subfertility is related to vaginal and uterine flora, requesting pre-breeding vaginal cultures and antimicrobial therapy based on the results. Stud dog owners specifically fear that a bitch will expose their male to pathologic bacteria and damage his fertility. It has been shown that normal flora is exchanged during natural breedings, without any detriment to either the bitch or the stud dog or to their fertility or fecundity. The normal female reproductive tract harbors a variety of aerobic bacterial (including *Mycoplasma*) populations in the vaginal vault and uterus (Box 55.2). Mixed vaginal cultures can be present in healthy fertile bitches; the most common isolates include *Pasteurella multocida,* β-hemolytic streptococci, *Escherichia coli,* and *Mycoplasma* spp. The only bacterial species proven to be a specific cause of infertility in the bitch is *Brucella canis*. Recent development of transcervical uterine cannulation has enabled intrauterine cultures and biopsies to be collected noninvasively and can provide more accurate evaluation of actual infectious problems in the uterus than cranial vaginal cultures acquired with guarded swabs; however, problems with interpretation persist. During normal canine estrus, bacteria ascend the reproductive tract and are present within the uterus, subsequently regressing spontaneously. Vaginal and intrauterine cultures must both be interpreted with caution because many bacterial populations represent normal bacterial flora and do not indicate disease or explain infertility. Indiscriminant use of antibiotics before and during pregnancy is counterproductive and associated with development of resistant organisms; it is not contributory to improved fertility or fecundity. It is unjustified to treat all positive vaginal cultures with antimicrobials or to assume that all positive vaginal or uterine bacterial cultures are associated with infertility. As a general rule, growth of bacteria from the vagina or uterus in conjunction with clinical signs

of excessive malodorous or abnormal vaginal discharge, vaginal mucosal inflammation, peripheral leukocytosis, and systemic illness is significant and warrants treatment with antimicrobial agents. If possible, a uterine cytologic specimen or biopsy should be examined for evidence of inflammation or infection.

CYSTIC ENDOMETRIAL HYPERPLASIA/ PYOMETRA COMPLEX

Uterine pathology (e.g., CEH) must be considered as a cause of infertility in bitches and queens once all other possibilities have been excluded. CEH is a hormonally dependent, predictable condition in the bitch that results from repeated cycles of progesterone stimulation inducing endometrial glandular proliferation and secretion. Glandular changes may be focal or diffuse and may interfere with implantation and placentation. Definitive diagnosis of CEH requires biopsy at an affected site or can be confirmed by histopathology post ovariohysterectomy. The CEH-pyometra complex is a progesterone-mediated uterine disorder of both bitches and queens. During the luteal phase of the estrous cycle, progesterone suppresses the leukocyte response to infectious stimuli in the uterus, decreases myometrial contractility, and stimulates endometrial gland development and activity. During diestrus, the nongravid uterus is flaccid and contains endometrial gland secretions that are a growth medium for bacteria. Bacteria reach the uterus via ascension from the distal portion of the genitourinary tract, or less commonly by hematogenous spread. Failure to clear transient bacterial inhabitants from the uterus after estrus can result in pyometra, a septic inflammatory condition of the uterus. *E. coli* is most commonly isolated from both bitches and queens with pyometra (Hagman and Greko, 2005; Chen et al., 2003). Strong correlation exists between the onset of clinical signs of pyometra and recent heat in both species; because queens are induced ovulators, their incidence may be lower.

Pyometra can occur with or without purulent vulvar discharge, depending on the patency of the cervix. Closed-cervix pyometra is more serious because of the potential for leakage of purulent fluid through the fallopian tube(s) or uterine rupture and resultant septic peritonitis. The classic clinical signs of pyometra include variably copious vulvar discharge, partial to complete anorexia, vomiting, lethargy, weight loss, an unkempt appearance, and polydipsia/polyuria. Most pets are considered ill (lethargic, anorexic) by their owners at the time of examination. Abnormalities detected most frequently by physical examination include a mucopurulent to hemorrhagic vulvar discharge, a palpably enlarged uterus, and pyrexia. Some bitches and queens have no physical signs of disease other than abnormal vulvar discharge. Clinicopathologic evaluation most commonly demonstrates neutrophilic leukocytosis, hyperfibrinogenemia, and hyperglobulinemia. Azotemia and low urinary specific gravity can reflect nephrogenic diabetes insipidus secondary to endotoxin elaboration by *E. coli*. Urine should *not* be obtained by cystocentesis if pyometra is suspected. Cytologic examination of the vulvar discharge shows septic inflammation (Fig. 55.39). Plasma progesterone is typically 5.0 ng/mL or higher, typical of diestrus, although pyometra can also be initially diagnosed in early anestrus as well. Abdominal radiography can identify a large, tubular, soft tissue density compatible with uterine enlargement. Ultrasonography is indicated to differentiate the enlarged fluid-filled uterus of pyometra from early pregnancy. Ultrasonographic evaluation of the uterus provides important information concerning uterine wall thickness and composition (presence of cystic structures), lumen size and content, and overall organ symmetry and position. CEH is characterized by endometrial thickening with focal anechoic structures noted in the uterine wall, representing dilated cystic glands and tortuous glandular ducts (Fig. 55.40). With advanced disease, these changes do not disappear ultrasonographically during anestrus. Fluid accumulation in the uterine lumen may represent hydrometra, mucometra, or developing pyometra and can be very difficult to differentiate (echogenicity may suggest cellularity) (Figs. 55.41, *A*, 55.41, *B*, 55.42). Because of the potential for peritonitis, centesis of the uterus is not advocated. One study found that measurement of the circulating

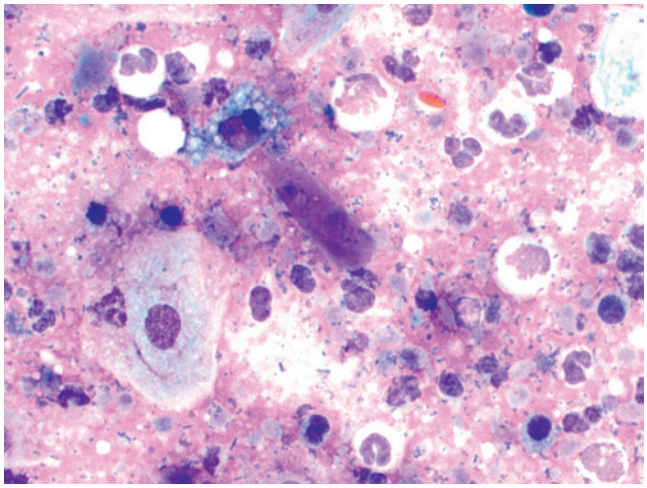

FIG 55.39

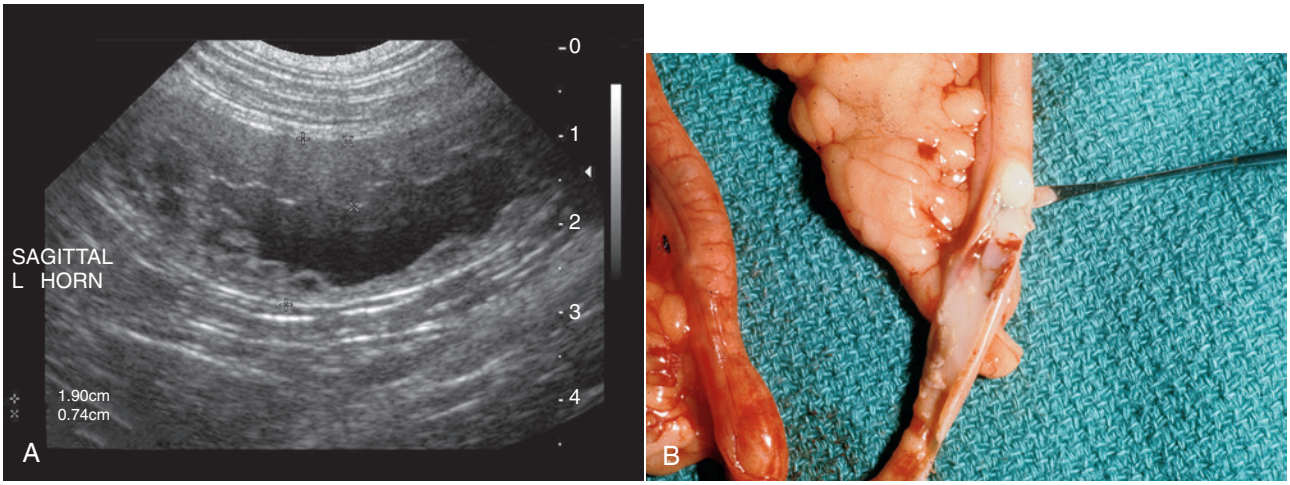

FIG 55.41
Mucometra. **(A)** Ultrasound image of the sagittal left uterine horn. Cursors measuring the full thickness (+; 1.90 cm) and wall thickness (x; 0.74 cm). **(B)** Gross specimen; endometrial cysts and mucoid luminal content (Courtesy Dr. P. Olson).

$PGF_{2\alpha}$ metabolite (15-keto-13,14-dihydro-$PGF_{2\alpha}$) differentiated between CEH and pyometra when clinical signs were absent (Hagman et al., 2006). Uterine enlargement with pyometra is variable. Pyometra can occur in one uterine horn, with a viable pregnancy in the other.

The treatment of choice for pyometra, after stabilization of the patient with IV fluids and antibiotics, is ovariohysterectomy, a challenging surgery and an undesirable option for valuable breeding bitches or queens (Fig. 55.43). Medical treatment of open-cervix pyometra, identified clinically by the presence of vulvar discharge, can be offered in the case of young, valuable breeding females who are stable (Table 55.1). Systemic antibiotic treatment alone is ineffective in resolving clinical signs. Medical management of open-cervix pyometra with prostaglandins (natural prostaglandin $PGF_{2\alpha}$ or the synthetic prostaglandin cloprostenol) has been successfully employed in both the bitch and queen. Successful treatment of pyometra using prostaglandins results from their effect on the uterine myometrium, cervix, and corpora lutea. These agents stimulate uterine motility in dogs and cats, and this myotonic effect increases intrauterine pressure. Administration of prostaglandins should cause movement of uterine contents toward the cervix because of the distribution of prostaglandin receptors within the myometrium. Restricting the use of prostaglandins to treatment of open-cervix pyometra should reduce the potential for complications

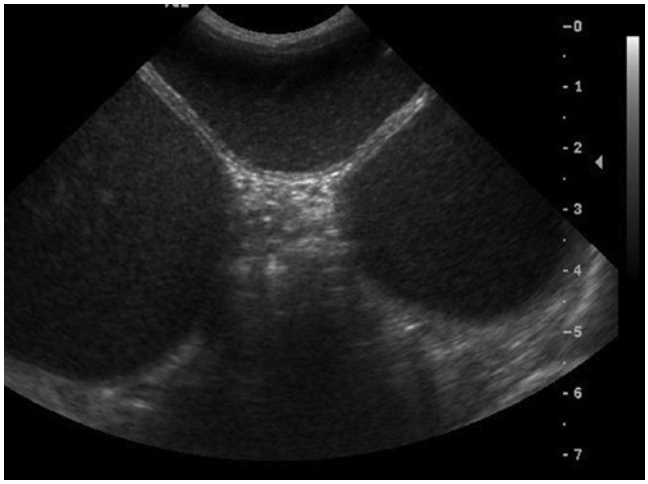

FIG 55.42

(peritonitis) attributable to myometrial contraction of a fluid-filled uterus against a closed cervix. Prostaglandins induce luteolysis or decreased luteal steroidogenesis. The presence of live fetuses should be ruled out by use of ultrasound before prostaglandin administration because of the drug's abortifacient potential. The prognosis for concurrent pyometra and pregnancy is guarded to poor. Management is limited medically to antibiotics, and intrauterine fetal death and premature labor are common. Adverse reactions observed after $PGF_{2\alpha}$ administration reflect the physiologic effects of endogenous prostaglandins. Endogenous prostaglandins are derived from arachidonic acid by the action of cyclooxygenase and mediate many normal physiologic processes, including vasodilation, hemostasis, pulmonary

TABLE 55.1

Medical Therapy of Open Cervix Pyometra

DRUG	DOSAGE	SIDE EFFECTS
$PGF_{2\alpha}$	0.1-0.2 mg/kg SC q12-24h to effect	Cat: Vocalization, panting, drooling, vomiting, defecation Dog: Panting, nesting, drooling, vomiting, defecation
Cloprostenol	1-3 mcg/kg SC q12-24h to effect	Diminished, vomiting most common

vasoconstriction and bronchodilation, gastrointestinal tract secretion, renal blood flow and glomerular filtration rate, inflammation, hyperalgesia, and fever. The contractile effect of prostaglandins on the myometrial, gastrointestinal, tracheobronchial, and bladder smooth musculature accounts for the clinical responses observed. Predictable physical reactions occur after SC injection of prostaglandins and include restlessness, panting, salivation, emesis, tenesmus, diarrhea, urination, and mydriasis (both bitch and queen), and grooming, lordosis, and kneading (queen). These reactions resolve within 1 hour after prostaglandin injection. Walking bitches for 10 or 15 minutes after prostaglandin administration seems to help minimize the severity of reactions. After each subsequent prostaglandin administration, reactions diminish in severity and duration; they are rarely considered severe enough to warrant discontinuation of the drug. Anticholinergic or other antiemetic premedication can reduce the severity of side effects. Candidates for prostaglandin treatment should be young (<5 years) and otherwise healthy, with evidence of a patent cervix (i.e., vulvar discharge). Potential contraindications to the use of prostaglandins include coexisting viable pregnancy, sepsis, peritonitis, significant organic disease, and the presence of mummified fetal remains. During prostaglandin treatment, bitches and queens may need to be hospitalized (as warranted by their clinical condition) to enable administration of adjunct supportive care (e.g., IV administration of fluids and antibiotics) and monitoring of adverse effects and treatment outcome. Concurrent administration of broad-spectrum bactericidal antimicrobials (potentiated amoxicillin, combination fluoroquinolone, amoxicillin, or cephalosporin) is advised. Anaerobic and aerobic culture of vaginal discharge should be submitted before antibiotic use to better guide antimicrobial selection if response to therapy is not optimal. Response to therapy depends on the degree of underlying uterine pathology rather than the dosage of prostaglandins.

The lower dosage of $PGF_{2\alpha}$ (Lutalyse [Pharmacia]) at 0.1-0.2 mg/kg q12-24h) is recommended, although the

minimal effective dose of $PGF_{2\alpha}$ has not been established. This dosage should *only* be used for natural $PGF_{2\alpha}$. Cloprostenol, a synthetic prostaglandin, is more potent in its actions than is natural $PGF_{2\alpha}$, and use of synthetic prostaglandins at the dosage recommended for natural $PGF_{2\alpha}$ may result in a fatal outcome. Synthetic prostaglandins have more uterine-specific smooth muscle stimulation and cause fewer systemic side effects, and currently are the author's choice. Administer cloprostenol (Estrumate [ICI, UK]) at 1-3 μg/kg SC q12-24h. If cervical patency is questionable (closed cervix pyometra), misoprostol (prostaglandin E2) can be administered intravaginally (Cytotec, [Searle] 100 μg tablet dissolved in 5 mL water; at 1-3 μg /kg q24h) in an attempt to relax the cervix before ecbolic therapy is instituted. Transcervical endoscopic catheterization technique is advocated by some authors to lavage viscous fluid from the uterus using LRS or 0.9% saline, or acetylcysteine 1:5 parts 0.9% saline. Great care must be taken not to overdistend or perforate the uterus. Surgical lavage is also an option but rarely used due to the success of medical therapy. Prostaglandins are not approved for use in domestic dogs and cats but are commonly used and are an acceptable form of medical therapy. Successful clinical response to medical therapy is best monitored by serial evaluations of uterine luminal contents with ultrasound, along with hematology, biochemistry, and clinical parameters (appetite, fever, vulvar discharge). Successful short-term outcome of medical therapy, defined as resolution of the signs of pyometra, should be evident at the completion of prostaglandin treatment.

At the time of release from the hospital, bitches and queens should have an improved appetite, normal rectal temperature, and diminished or no vulvar discharge. Initial reexamination should be scheduled within 2 weeks of the last prostaglandin administration, finding no clinical signs of illness. Abdominal ultrasonography should be used to evaluate for an overall reduction in uterine size and lack of fluid in the uterine horn lumens, compared with that of previous examinations. Persistence of clinical signs warrants retreatment; sequential treatment of recurrent pyometra can be successful and could be considered if the bitch's or queen's condition permits. Reported resolution of the immediate clinical signs of open cervix pyometra after therapy varies from 82% to 100%. Successful long-term response is defined as a return to normal estrous cycles and, if bred, conception and carrying a litter to term. Breeding at the next estrus is recommended to avoid the potential complications after progesterone's effects on a nongravid uterus. Prostaglandins do not resolve underlying cystic endometrial hyperplasia. The more clinically benign hydrometra and mucometra commonly precede the development of pyometra, giving a guarded to poor prognosis for fertility. The onset of proestrus in the bitch after $PGF_{2\alpha}$ therapy is variable; bitches will experience proestrus 1 or 2 months earlier than anticipated because diestrus was abbreviated by prostaglandin use. The onset of proestrus after prostaglandin treatment varies from 0.5 to 12 months in queens, due to the influence of day length on this seasonally polyestrous species. The overall recurrence rate of pyometra in bitches can be 20% to 80%, and in queens 14%, higher in older individuals. Clients should always be forewarned that successful resolution of pyometra can be followed by chronic infertility due to underlying CEH.

CHAPTER 56

Clinical Conditions of the Dog and Tom

CRYPTORCHIDISM

Cryptorchidism, a common congenital genital defect in male dogs (uncommonly tomcats), is diagnosed if either or both testes are not present in the scrotum at puberty; testes normally descend into the canine scrotum by 6 to 16 weeks of age. In the author's experience, descent can occur as late as 10 months of age, but these dogs should not be considered normal; late descent is a heritable defect as well as nondescent. Cats have prenatal testicular descent; however palpation of scrotal testes in neonatal kittens is difficult due to their small size. The testicular hormone insulin-like factor 3 (also called *relaxin-like factor*), produced by pre- and postnatal Leydig cells, mediates the transabdominal testicular descent from the caudal pole of the kidney to the inguinal canal. It induces growth and differentiation of the gubernaculum from the caudal suspensory ligament. The transabdominal migration of the fetal testis is independent of androgens, whereas the inguinoscrotal descent is subsequently mediated by testosterone, which causes regression of the cranial suspensory ligament. During the inguino-scrotal phase of migration, there is shortening of the gubernaculum and eversion of the cremaster muscle.

Unilateral cryptorchidism does not result in infertility due to the scrotal testis. Bilaterally cryptorchid dogs and cats are infertile due to the lack of normal spermatogenesis resulting from their intraabdominal temperature (~5° > scrotal). In both cases, because interstitial cells continue to produce testosterone, libido and secondary sex characteristics are normal. Cryptorchidism in dogs is inherited as a sex-limited autosomal recessive trait; cryptorchidism in cats is assumed to be heritable as well (Zhao, 2010). Unilaterally affected animals should not be bred. Both parents of affected individuals should be implicated as carriers. Because of the heritability, and the fact that intraabdominal testes have a higher incidence of neoplasia (9-14×) and subsequent torsion, bilateral orchiectomy is recommended. Bilateral orchiectomy is required to reduce testosterone-mediated behaviors. Attempts at medical therapy to induce testicular descent with gonadotropins or testosterone have been unsuccessful and are not ethical. Orchiopexy is also considered unethical in veterinary medicine; the American Kennel Club bans any dog with orchiopexy from competition. In humans, the increased incidence of neoplasia in the formerly intraabdominal cryptorchid testis persists postorchiopexy, making the procedure contraindicated medically in veterinary patients as well as being unethical. Failure of one testis to develop (true monorchidism) can occur in dogs but is rare.

In a cryptorchid cat, examination of the penis for presence of spines is an excellent diagnostic technique. Penile spines are testosterone-dependent, becoming atrophied 6 weeks postcastration. Cryptorchidism in the dog is best confirmed with appropriate hormonal testing and ultrasonography. Baseline serum testosterone levels vary normally; single levels are not diagnostic. Serum testosterone before and 48 hours after human chorionic gonadotropin (hCG) injection (250 IU IM) has been used to support complete castration if < 20 pg/mL (0.0693 nmol/L); a twofold increase suggests the presence of testicular tissue; the test results are variable and not always reliable. hCG is of human origin, therefore the potential for hypersensitivity exists. Gonadotropic-releasing hormone (GnRH) stimulation testing using commercial bovine GnRH products is based on inducing a measurable testosterone increase. GnRH is administered at 2 µg/kg IM, with blood sampling pre- and 2–3 hours postinjection; castrated dogs have testosterone concentrations <0.1 ng/mL (0.3467 nmol/L) and should not stimulate, but test results are variable and not always reliable. The luteinizing hormone (LH) test is not marketed for evaluating cryptorchidism in the dog or tom; however, it can be reliable in the author's experience. A high LH (>1 ng/mL) suggests the dog or tom is castrated. A low LH (<1 ng/mL) suggests the dog or tom is intact, with testosterone providing negative feedback to GnRH, FSH, and LH (Wheeler and Kutzler, 2010). Recently marketed, the qualitative Anti-Müllerian Hormone (AMH) test for dogs and cats is meant to distinguish between intact (cryptorchid) neutered males after they have reached the age of sexual maturity. A negative AMH test is consistent with

a neutered male, whereas a positive AMH test indicates the presence of testes.

Ultrasound localization of cryptorchid testis(es) can confirm the condition in pediatric dogs and cats with unilateral or bilateral involvement, and assist the surgeon in planning the approach (i.e., inguinal versus cranial abdominal). The retained testes can be positioned anywhere between the ipsilateral kidney and the scrotum. The right testis is more commonly cryptorchid. A systematic evaluation of the region from the caudal renal pole to the inguinal canal can identify an oval, homogenously echogenic structure with a mildly hyperechoic border representing the parietal and visceral tunics. The epididymis is usually distinctly less echoic than the testicular parenchyma, as in the scrotal testis. The cryptorchid testis will maintain the anatomic structure of the mediastinum testis, a hyperechoic slash, and normal testicular echogenicity despite being reduced in size as compared with a scrotal testis (Fig. 56.1, *A*, 56.1, *B*, Video 56.1). Ultrasound is also the method of choice to localize cryptorchidism in adult dogs and cats whose neutering status is unknown or suspected to be incomplete.

TESTICULAR TORSION

Other than malignant transformation, the most common complication of uncorrected cryptorchidism in the dog is testicular torsion, which occurs with an increased incidence in neoplastic intraabdominal testes, and presents as an acute abdomen. Ultrasound is commonly performed in dogs with acute abdominal distress. Cryptorchid testes can be positioned anywhere between the ipsilateral kidney and the inguinal canal, but tend to gravitate to the mid ventral abdomen when enlarged. Testicular torsion can appear similar to orchitis with a diffuse hypoechoic appearance to the testis; malignant transformation and gangrenous change can make their appearance less recognizable (Fig. 56.2, *A*, 56.2, *B*). Doppler examination reveals aberrant blood flow. Immediate surgical intervention for removal is indicated.

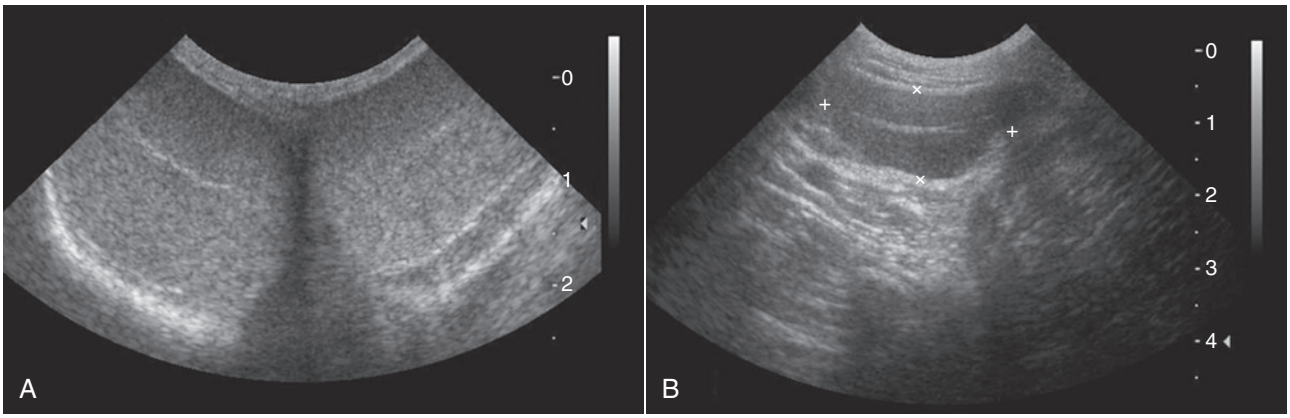

FIG 56.1
Testicular ultrasound. **(A)** Side-by-side image of normal scrotal testes. **(B)** Sagittal view of cryptorchid testis (*cursors*). Note the uniform parenchymal echotexture (similar to the spleen), mediastinum testis (hyperechoic central linear structure), and relatively smaller size in the intraabdominal (cryptorchid) testis.

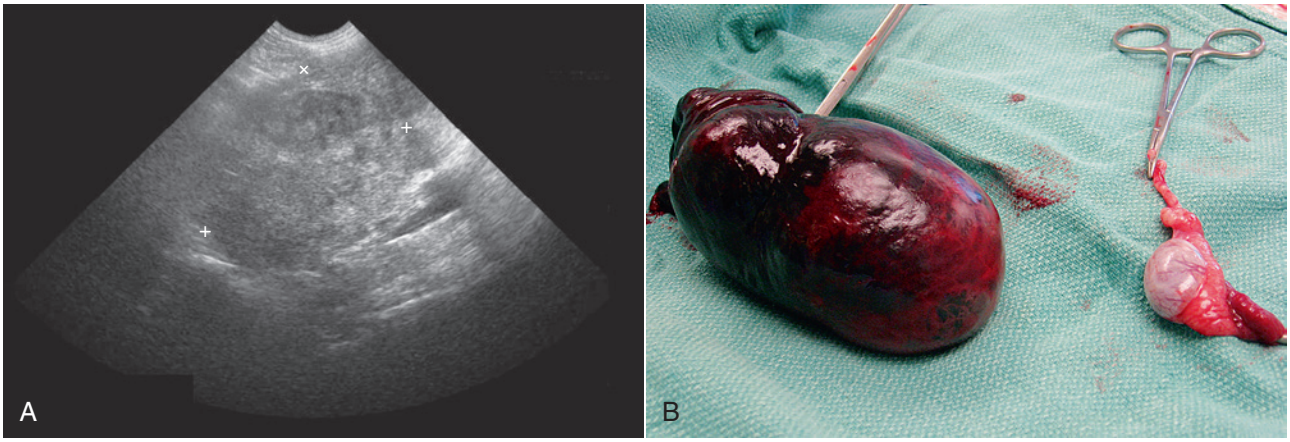

FIG 56.2
Ultrasound image of an intraabdominal mass. **(A)** A midabdominal testis (*cursors*) with complex echotexture. **(B)** A Sertoli cell tumor was identified within the enlarged and torsed intraabdominal testis after exploratory and castration. The normal scrotal testis for comparison, left.

PERSISTENT PENILE FRENULUM

Under the influence of androgens, the surfaces of the glans penis and the preputial mucosa normally separate before or within weeks of birth. If this separation does not occur, connective tissue persists between the penis and the prepuce. In dogs the persistent penile frenulum is usually located on the ventral midline of the penis. A persistent penile frenulum may cause no clinical signs, or it may be associated with preputial discharge or excessive licking of the prepuce. Persistent frenulum may cause the penis to deviate ventrally or laterally so that the dog or tomcat is unable or unwilling to mate, or it may interfere with normal tumescence (Fig. 56.3). The diagnosis is made by visual examination. Treatment is surgical excision, which can often be done using just sedation with local anesthesia as the frenulum tends to be a sheer, avascular membrane.

URETHRAL PROLAPSE

Urethral prolapse occurs most commonly in Bulldogs, French Bulldogs, and Boston Terriers, and is likely familial. Eversion of the urethral mucosa at the distal tip of the penis results in refractory hemorrhage. The condition may be associated with the increased intraabdominal pressure associated with the brachycephalic syndrome. Surgical revision is indicated as the condition will not resolve spontaneously. Preventing erection during recovery is important; breeding these dogs can cause relapse, and castration should be suggested for both therapeutic and ethical reasons.

SCROTAL DERMATITIS

Scrotal dermatitis can result from trauma, contact irritants or hypersensitivities, excessively warm bedding/heating pads, burns, frostbite, envenomation, shaving, allergic dermatopathies, or intrascrotal pathology inciting excoriation such as orchitis or epididymitis (Fig. 56.4). Scrotal dermatitis can cause thermal insult acutely affecting spermatogenesis. Chronic scrotal dermatitis can result in infertility, with visible lichenification and hyperpigmentation of the ventral scrotum. Physical examination of a dog with abnormal semen should always include close visual evaluation of the ventral scrotum. Scrotal mast cell tumors can incite local inflammation.

Appropriate topical and systemic therapies should be instituted, and prevention of excoriation by the use of Elizabethan collars encouraged. Nonsteroidal antiinflammatory drugs such as carprofen (Rimadyl® Pfizer), meloxicam (Metacam® Boehringer Ingelheim), firocoxib (Previcox® Merial), or grapiprant (Galliprant® Aratana) are useful. Narcotics (Tramadol) may be necessary short term for adequate analgesia. Broad spectrum antibiotics appropriate for pyoderma, such as cephalexin or cefpodoxime proxetil (Simplicef® Pfizer), are appropriate. The use of corticosteroids should be avoided. Normalization of spermatogenesis can take more than 60 days.

BALANOPOSTHITIS

Inflammation or infection of the preputial cavity and penis, balanoposthitis, is common in dogs and rare in cats. Normal scant white smegma in an intact male dog should not be mistaken for balanoposthitis. The causative organisms are usually members of the normal preputial flora, although overgrowth of one organism or a predominance of *Pseudomonas spp* can occur. Balanoposthitis usually causes no clinical signs other than a purulent preputial discharge that varies from mucoid to copious green pus accompanied by excessive licking. The discharge associated with balanoposthitis is not sanguineous unless the cause is neoplasia or accumulated foreign material. Lymphoid follicular hyperplasia is commonly also present and thought to develop as a result of chronic irritation (Fig. 56.5, *A*).

The diagnosis of balanoposthitis is made by physical examination of the penis and preputial cavity all the way to the fornix, in a search for foreign material, neoplasia,

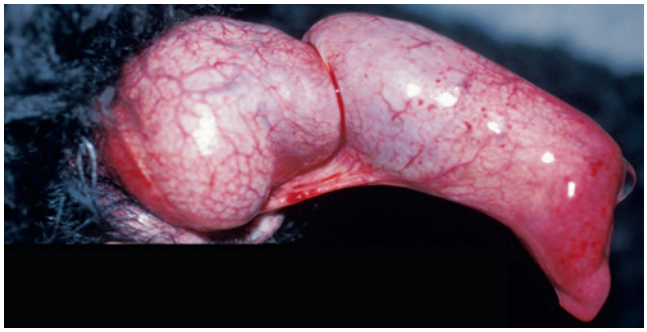

FIG 56.3

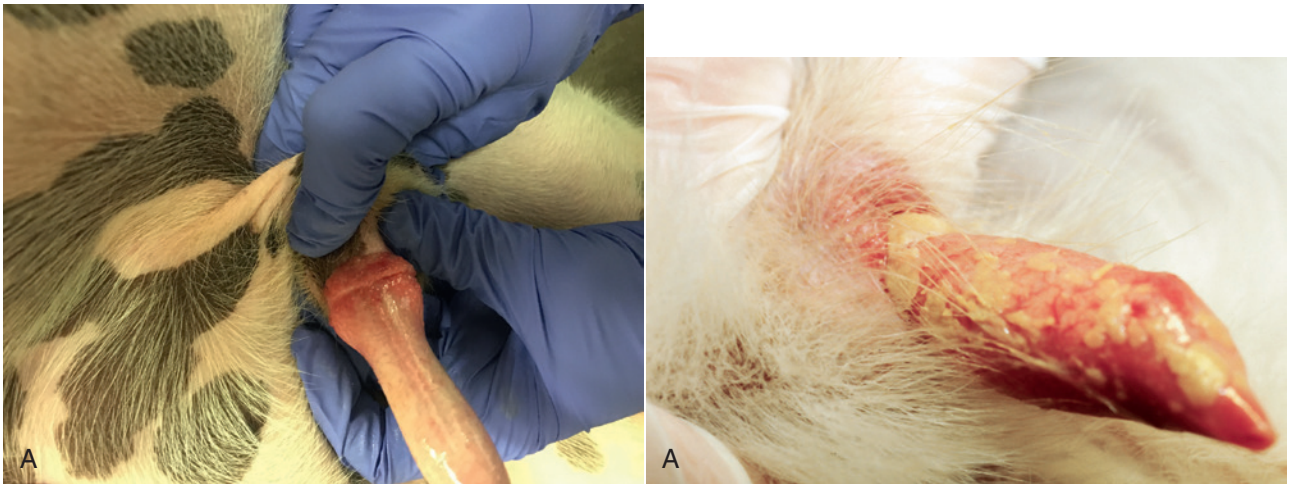

FIG 56.5
(A) Lymphoid follicular hyperplasia at the base of the penis. **(B)** Balanoposthitis. (**B** Courtesy Dr. P. Olson)

ulceration, or inflammatory nodules (Fig. 56.5, *B*). Cultures and cytologic studies are rarely helpful unless a mycotic infection or neoplastic process is suspected.

The treatment of balanoposthitis is usually conservative. The hair should be clipped from the preputial orifice and from the surrounding area if discharge has been accumulating there. Flushing the preputial cavity with dilute, gentle antiseptic solutions (e.g., chlorhexidine, povidone-iodine) can be helpful. Topical antibacterial or combination corticosteroid antibacterial medications may be instilled into the preputial cavity. In persistent or refractory cases, cytology, culture, and endoscopic examination of the prepuce and urethra should be considered. Systemic antibiotics short term can be considered, as well as nonsteroidal antiinflammatory therapy. Preputial discharge from benign prostatic hyperplasia, prostatitis, urethritis, or cystitis should be ruled out if the penis and prepuce appear normal. Penile mass lesions can cause excessive preputial discharge. Transmissible venereal tumor (TVT) is the most commonly reported penile tumor in dogs. Cytologic evaluation of TVT is supportive; biopsy is diagnostic (Fig. 56.6). The macroscopic appearance of TVT and penile papilloma virus may be similar. Penile papillomatosis often resolves spontaneously after biopsy of a lesion.

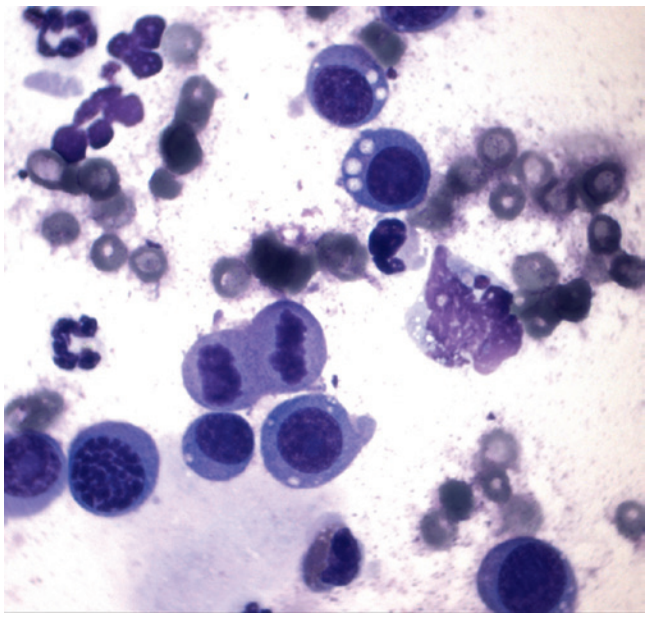

FIG 56.6

PRIAPISM, PARAPHIMOSIS, AND PHIMOSIS

Priapism is a persistent penile erection without sexual stimulation (Fig. 56.7). Priapism is categorized as either nonischemic (arterial, high flow) or ischemic (veno-occlusive, low flow). Ischemic priapism is considered an emergency as rapid penile necrosis can result; the condition is usually very painful. Either condition can result in significant trauma to the penile tissues.

Priapism can be confused with paraphimosis. Paraphimosis occurs when the penis cannot be ensheathed in the prepuce and is most commonly associated with previous but not ongoing sexual stimulation. Paraphimosis can be associated with problematic detumescence after breeding or semen collection. The penis can remain erect, or it may be markedly edematous from chronic extrusion. The urethra is usually not damaged. The unexposed penis and the uninvolved prepuce are normal and nonpainful. Long-standing paraphimosis may result in gangrene or necrosis. Paraphimosis may

FIG 56.7

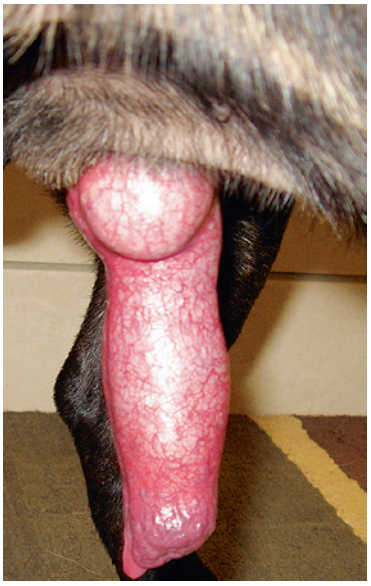

FIG 56.8
Erect canine penis post semen collection; the penile mucosa is normal in appearance.

result from too small of a preputial orifice, inadequate length of the prepuce, weakened preputial muscles, or trauma. Paraphimosis most commonly occurs in dogs after manual semen collection, as the exposed penile mucosa becomes dry during the postejaculation period (when the normal copulatory tie would occur) from exposure to air without lubrication (Fig. 56.8). Return of the penis within the prepuce is hampered, and severe edema of the exposed distal penile tissues can occur (Fig. 56.9). Clinicians should always check the stud dog before he leaves the examination room for this development. Lubricating the exposed penile tissues with water soluble gel and gentle manipulation of the prepuce is indicated. Paraphimosis may occur in longhaired cats when the penis becomes entangled in the preputial hairs; otherwise, it is uncommon in cats.

FIG 56.9
Paraphimosis, postcopulation, secondary to a small preputial opening which prevented detumescence. Note the injected, edematous penile mucosa.

FIG 56.10
Ruptured tunica albuginea causing a mass effect in the canine penis.

Priapism should also be differentiated from other causes of penile swelling, such as a hematoma, trauma, or mass lesions (Figs. 56.10, 56.11, 56.12). Penile hematomas usually form as a result of trauma or bleeding disorders. Simple visual inspection and palpation of the penis are usually sufficient to differentiate the conditions. An ultrasound and/or color-flow Doppler examination may help differentiate these disorders from priapism. Ultrasound of the perineum and the entire penile shaft is indicated to evaluate for anatomic abnormalities such as neoplasia, fracture of the os penis, hematoma formation, or thromboemboli. Priapism can be confirmed ultrasonographically (Figs. 56.13 and 56.14).

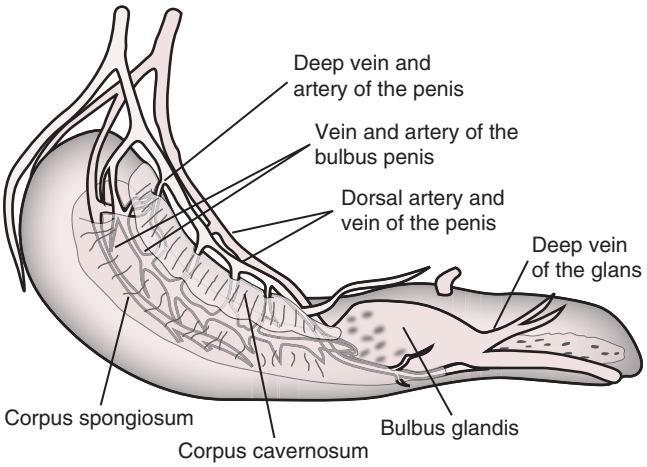

FIG 56.15
Schematic representation of relevant vascular anatomy of the canine penis. (Courtesy Dr. J. Lavely.)

The canine erection is mediated through the pelvic nerve, which arises primarily from the first and second sacral nerves (S1-S2) and is composed of parasympathetic nerve fibers. Stimulation of the pelvic nerve increases penile blood pressure, partially inhibits venous drainage, and dilates penile arteries resulting in an erection. The pudendal nerve, which arises from the sacral nerves S1-S3, is involved as well, by stimulating contraction of the extrinsic penile muscles. The hypogastric nerve, a sympathetic nerve originating from the lumbar L1-L4 spinal cord segments, may also have a regulatory role in the canine erection. The hypogastric nerve is responsible for ejaculation and prostatic fluid secretion. Sympathetic chain fibers inhibit erection. Sympathetic chain fiber stimulation increases arterial resistance, decreases corpus cavernosal pressure, and decreases venous resistance. The sympathetic inhibition of the erectile process is mediated by the α_1-adrenergic system (Fig. 56.15).

True priapism (ischemic or nonischemic) can be associated with vascular disorders (efferent or afferent) or neuropathy, or it can be idiopathic. A dysregulatory hypothesis for the pathophysiology of priapism has been postulated. Dysnergic neurostimulations of inflow and outflow penile blood vessels cause prolonged vascular or smooth muscle spasms. This dysregulation may occur at the level of the penis or at other regulatory levels of penile erection, including the central (spinal cord L1-4, S1-3) or peripheral nervous system (Lavely, 2009).

Distinguishing ischemic (proceeds to gangrene) versus nonischemic priapism and identifying and treating the underlying cause is important. If determined to be ischemic, prompt aspiration of the corpora cavernosa under sedation or anesthesia with or without irrigation should be done. Intracavernosal injections of phenylephrine should be considered. However, this may carry some risk as appropriate dosages in dogs and cats have not been determined. Starting with low dosages (1-3 mcg/kg) and cardiovascular monitoring, therefore, is important. Providing lubrication is important to limit tissue damage secondary to exposure and excoriation. An Elizabethan collar may be indicated. If intracavernosal drainage and injections are not successful or significant tissue damage has occurred, then penile amputation and perineal urethrostomy may become necessary.

Nonischemic priapism can resolve spontaneously. Thus conservative therapy, protecting penile integrity with lubrication, and an Elizabethan collar are recommended. Several systemic medications are of potential benefit, although very little controlled data exists regarding efficacy of systemic drug therapy. Gabapentin, terbutaline, or pseudoephedrine should be tried. If detumescence is not achieved after several days of treatment with one drug, switching to another may be successful.

Ischemic priapism has been reported in cats; penile amputation and perineal urethrostomy may be indicated. A traumatic cause should be considered in cats if they have a recent history of mating; it has also been reported after orchiectomy. Surgical treatment making several small incisions bilaterally in the tunica albuginea of the corpora cavernosa penis and in some parts of the corpora cavernosa followed by irrigation with heparinized saline has been reported to have some success. Skin sutures were then placed closing the approach, but the tunica albuginea was not closed. Nonischemic feline priapism can respond to medical management as in the dog (Fig. 56.16).

Phimosis is a condition in which the penis is trapped within the preputial cavity. It usually occurs as a congenital defect in which the preputial opening is abnormally small and the penis cannot protrude. Phimosis is uncommon in cats and dogs. It may be recognized in young animals as a cause of a urinary outflow tract obstruction or of the dribbling of urine that has accumulated in the preputial cavity. Phimosis may be recognized in an affected postpubertal male unable to copulate. It is treated by conservatively surgically enlarging the preputial orifice. The preputial hairs of longhaired cats may entangle the preputial orifice, causing clinical signs similar to phimosis, and is treated by clipping the preputial hairs.

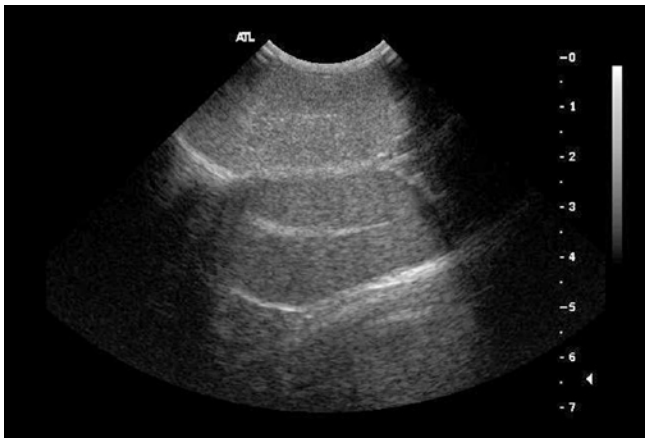

FIG 56.17
Ultrasound image of normal canine testes, sagittal view.

TESTICULAR NEOPLASIA IN STUD DOGS

Unless the dog is a valuable and still fertile stud, the discovery of a testicular mass warrants castration. If the dog is still breeding and the tumor is limited to one testis, unilateral castration can be performed. Testicular neoplasia is rare in the tom cat. Risk factors for testicular neoplasia in the dog are age (>10 years) and cryptorchidism. The early diagnosis of testicular neoplasia is often incidental and based on careful palpation of the scrotal testes. Ultrasound can detect testicular masses too small for manual detection and is therefore indicated annually in valuable breeding dogs. The normal testis is uniform in texture with echogenicity similar to the spleen (Fig. 56.17). The mediastinum testis is a thin, centrally

located, very hyperechoic line. The epididymis (head, body, tail) is less echogenic than the testis. The ductus deferens is difficult to visualize. The spermatic cord is adjacent to the head of the epididymis and has obvious, tortuous, small diameter veins. Testicular neoplasms appear as variably circumscribed masses, hypo- to hyperechoic, which may obscure the mediastinum testis (Fig. 56.18). The appearance is not specific for tumor type; masses tend to change from hypoechoic to mixed echogenicity with growth likely due to necrosis and hemorrhage. Testicular tumors commonly cause enlargement of the testis with chronicity; some cause paraneoplastic syndromes.

In dogs, Sertoli cell tumors, Leydig cell (interstitial cell) tumors, and seminomas occur with about equal frequency in scrotal testes; intraabdominal testicular neoplasia is most commonly the Sertoli cell tumor. Sertoli cell and interstitial (Leydig) cell tumors can produce hormones, particularly estrogen, which can cause paraneoplastic syndromes. Although these tumors usually are clinically silent, the production of estrogen, progesterone, and corticosteroids has also been described. Estrogen excess and feminizing syndromes may occur from the peripheral aromatization of testosterone or from the direct production of estradiol by the tumor itself. These include atrophy of the contralateral testis, bone marrow suppression, pendulous prepuce, gynecomastia, alopecia, hyperpigmentation, and squamous metaplasia of the prostate. Preputial mucosal cytology can show an estrogen effect similar to estrus in the bitch (superficial cells predominate) (Fig. 56.19). Gynecomastia and a pendulous prepuce have been referred to as feminization. Bone marrow suppression induced by estrogen is characterized by anemia, thrombocytopenia, and/or leukopenia. Thrombocytopenia occurs first. Some of the clinical signs may be related to anemia or hemorrhage as a result of the thrombocytopenia. A complete blood count is indicated to assess the possibility of bone marrow toxicity. Because most affected dogs are geriatric, a preoperative biochemical panel and urinalysis are also reasonable. Hyperestrogenism can cause atrophy of the unaffected testis resulting in azoospermia, which can be noted clinically before a testicular mass is diagnosed.

After castration, histopathology of the testicular mass with evaluation of the local lymphatics is indicated. Most testicular neoplasia in the dog is cured by castration as the potential for distant metastasis is low; local metastasis (intra-abdominal via regional lymphatics) tends to occur late with chronicity.

MICROBIOLOGY AND MALE FERTILITY

Previously fertile stud dogs producing small litter size or failing to impregnate normal bitches with good husbandry and normal breeding behavior should have semen evaluation performed (see semen collection, Chapter 54). If the semen is abnormal and associated with inflammatory cells or pain during ejaculation, it should be submitted for aerobic, anaerobic, and *Mycoplasma* spp. culture, and *B. canis* testing should always be performed (see Chapter 54). Semen is judged to be abnormal if no semen (aspermia), no sperm (azoospermia), or inadequate numbers of sperm (<200-400 million plus per ejaculate [oligospermia]) are present; if sperm motility is less than 75% to 90% progressively motile (asthenospermia); if sperm morphology reveals greater than 10% to 15% abnormal (teratospermia) forms; and especially if the semen contains excessive numbers of other cells such as white blood cells, macrophages, or red blood cells (pyospermia, hemospermia). Physical examination and clinical pathologic evaluation of the subfertile or infertile stud dog should take place *after* semen collection is accomplished; the results will usually direct subsequent diagnostics (Fig. 56.20).

Bacterial infection of the testes (orchitis), epididymides (epididymitis), or scrotum can cause alterations in

FIG 56.18

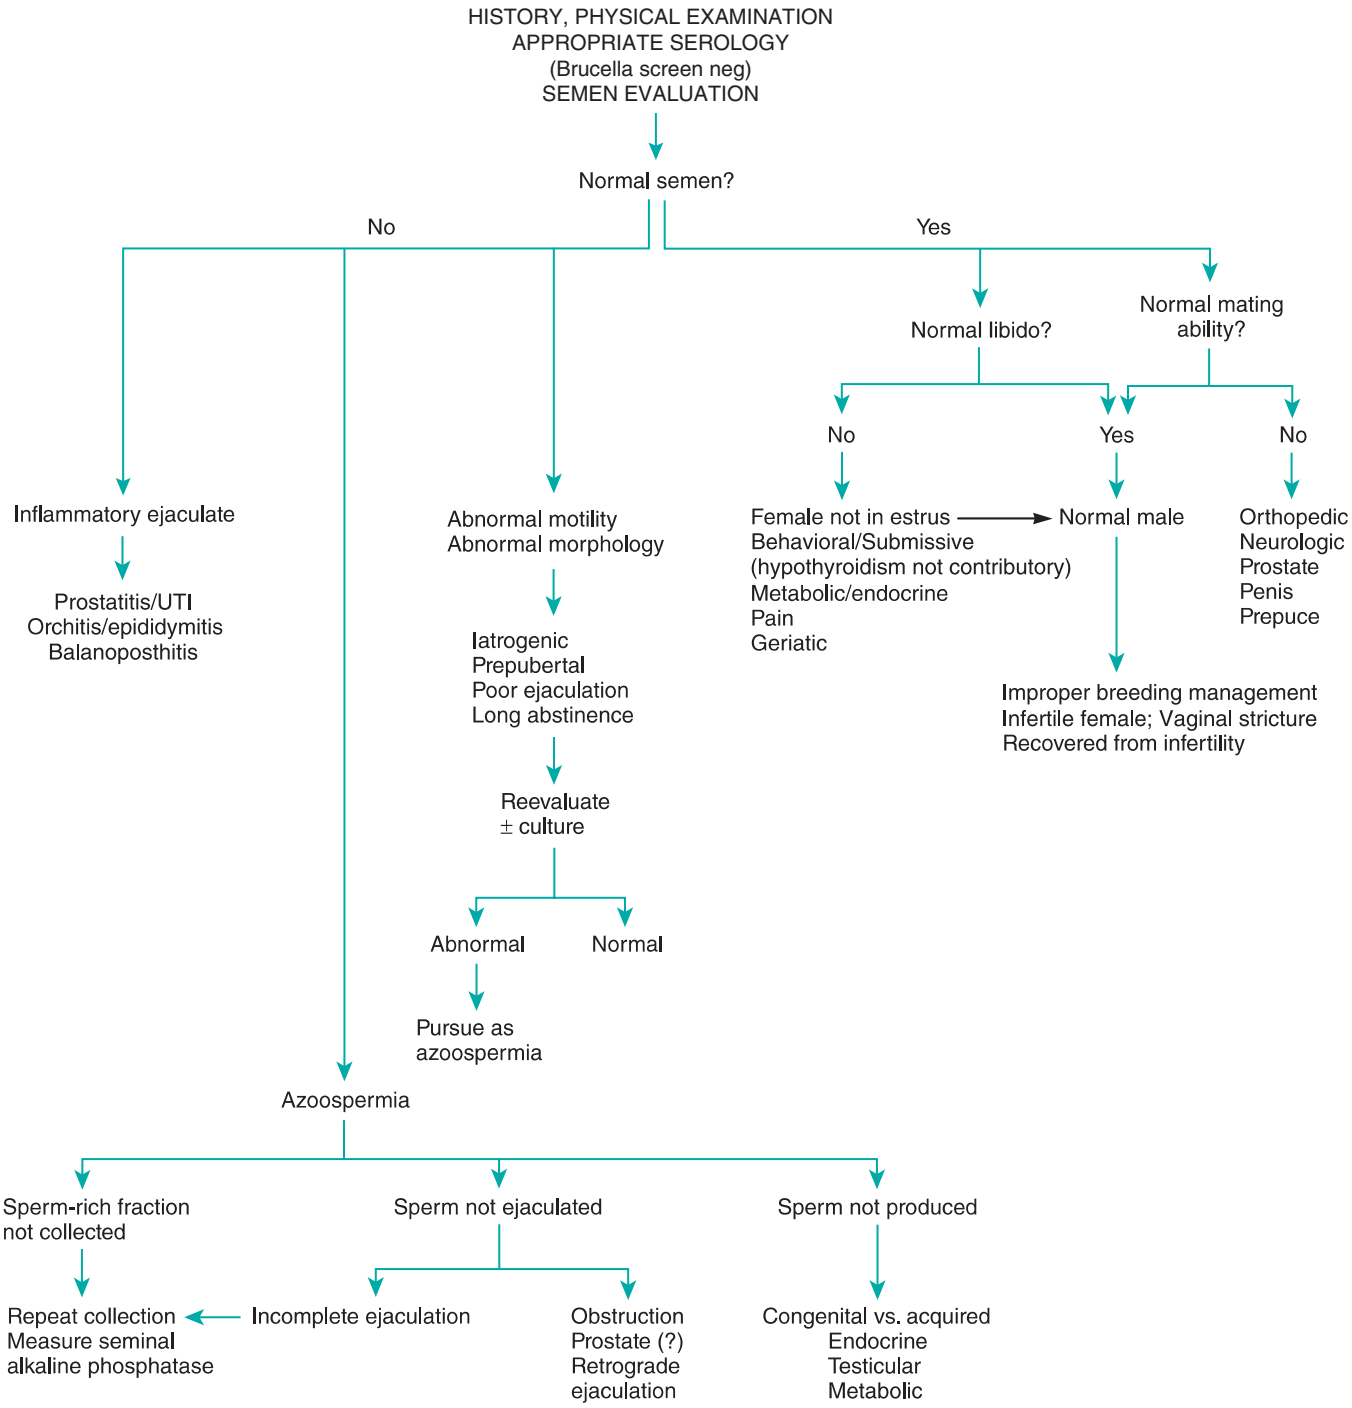

FIG 56.20
Flowchart illustrating the diagnostic pathway for male infertility.

spermatogenesis secondary to the destructive properties of the organisms themselves and as a result of local swelling and hyperthermia. Focal lesions can become generalized. Infectious prostatic disorders can cause abnormal semen due to the prostatic fluid component. The normal bacterial flora of the prepuce and distal urethra are the same organisms most frequently isolated from normal canine semen and also from dogs with bacterial orchitis, epididymitis, or prostatitis. The normal flora of the distal urethra and prepuce consist predominantly of aerobic organisms, but anaerobic organisms are also found. *Pasteurella multocida,* β-hemolytic streptococci, and *E. coli* are the organisms most commonly isolated from dogs (Table 56.1). Similar data are available for tomcats (Table 56.2). Because of this, collecting semen for culture can be misleading because normal urethral flora will contaminate the sample. The number of

colony-forming units (CFUs) per milliliter of semen attributable to urethral contamination (normal urethral flora) reportedly varies from 100 to 10,000. A separate culture of the material from a urethral swab obtained just before ejaculation could be used to identify urethral organisms. Quantitative culture of the urethra can then be compared with quantitative culture of the semen. Gentle cleansing and drying of the prepuce should precede semen collection; semen should be collected with sterile equipment (artificial vagina and collection tubes). Semen evaluation should not be performed on these samples because of the spermicidal effects of cleansing and sterilizing agents. Greater than 3 logs increase (semen versus urethra) in the number of an organism identified in both the semen and urethral cultures could be considered significant. Quantitative aerobic, anaerobic, and *Mycoplasma* cultures of both the urethra and semen are often prohibitively expensive. Specific sampling of the urine (representing the prostatic component), prostate, epididymi, and testes can be more efficient and meaningful, and can be facilitated by ultrasound-guided technique. Cytologic samples of these areas can also be acquired; suppurative inflammation of the prostate, epididymi, and testes is characterized by infiltration of neutrophils and macrophages. Concluding that an infertile or subfertile dog has infectious etiology on the basis of a positive routine ejaculate culture is unjustified without supportive data. Dogs with infectious orchitis, epididymitis, and/or prostatitis tend to have clinical signs supporting the etiology (heat, pain, redness, and swelling of the affected organ) readily apparent on the physical examination, as well as abnormal semen (Fig. 56.21). Semen collection may be difficult due to pain associated with ejaculation.

FIG 56.21
Erythemic, enlarged, painful and warm scrotum in a dog found to have acute bacterial epididymitis.

INFECTIOUS ORCHITIS AND EPIDIDYMITIS

Brucellosis

The primary acute clinical signs of canine brucellosis in the male dog involve the portions of the reproductive tract that participate in maturation, transport, and storage of spermatozoa. Epididymitis is common, with associated orchitis and scrotal dermatitis and resultant deterioration of semen quality and fertility. Chronically, testicular atrophy and infertility can occur. The organism can be found in the prostate gland and urethra and is shed intermittently in the urine. Antisperm antibodies develop in association with brucellosis-induced epididymal granulomas and can further contribute to infertility. Pyospermia develops 3 to 4 months postinfection. Chronic infections in either sex can result in uveitis or endophthalmitis, lymphadenitis, splenomegaly, discospondylitis, and occasionally dermatitis and meningoencephalitis have been reported. Bacteremia can persist for years, and subclinically infected dogs can remain infectious for long intervals. Large numbers of organisms are shed in the vulvar discharge of bitches 4 to 6 weeks postabortion. The highest concentration of organisms is shed in the semen of infected dogs 2 to 3 months after infection, with lesser amounts in the semen for years. Urine can serve as a contaminated vehicle because of the proximity of the urinary and genital tracts in the dog, with shedding present for months to years; this is more prevalent in males (see Chapter 55, Brucellosis diagnostics) (Wanke, 2004).

FIG 56.22
Sagittal ultrasound image of acute epididymitis; the epididymis (*arrows*) is mottled and enlarged (dog of Fig. 56.21).

Other Infectious Agents

Orchitis and epididymitis not associated with brucellosis can occur separately or in concert. Male dogs are typically presented because their owners noticed an enlarged scrotum. Scrotal enlargement can be due to scrotal neoplasia, scrotal dermatitis, scrotal edema, intrascrotal effusion or hemorrhage, testicular enlargement, or epididymal enlargement. Testicular or epididymal enlargement can be due to an acute infectious process or to infiltrative disease, which can be granulomatous or neoplastic. Careful palpation of the scrotum and contents may differentiate the source of enlargement; ultrasound evaluation is very helpful in recognizing pathology (Figs. 56.22, 56.23, 56.24, 56.25).

Infertile or subfertile males with contributory physical and ultrasonographic findings and positive reproductive tract cultures should be treated with appropriate antibiotic

FIG 56.23

therapy based on sensitivity profiles, keeping in mind penetration into the prostate gland. Appropriate antimicrobial therapy should continue for a minimum of 2 to 8 weeks, longer in the case of chronic bacterial prostatitis (see later section). The prognosis for fertility is guarded (but not hopeless) even with therapy—thermal damage from heat associated with inflammation impacts spermatogenesis, and the potential for sperm autoantibody formation exists after such an inflammatory process; clients should be warned of this potential complication.

PROSTATIC DISORDERS IN THE VALUABLE STUD DOG

BENIGN PROSTATIC HYPERPLASIA AND CYSTIC BENIGN PROSTATIC HYPERPLASIA

Prostatic disease is common in dogs but rare in cats. Prostatic hyperplasia occurs predictably in all intact male dogs after the age of 5 and is due to the effect of dihydrotestosterone on the prostatic parenchyma. Dihydrotestosterone causes symmetric, eccentric prostatic parenchymal hyperplasia that can become cystic. Because prostatic enlargement is eccentric, urethral compression (as seen in men) is unlikely. Tenesmus secondary to colonic compression from prostatomegaly can be seen. The most common clinical signs of benign prostatic hyperplasia (BPH) and cystic benign prostatic hyperplasia (CBPH) are blood (of prostatic origin) dripping from the urethra, hemospermia, and hematuria. The prostate is not painful upon palpation. Fertility is not impaired, but attempts at cryopreservation are compromised because the presence of hemoglobin increases sperm cell membrane fragility during the freeze/thaw process.

BPH and CBPH have a characteristic ultrasonographic appearance; a symmetric parenchymal striation with increased echogenicity is apparent, with variable hypoechoic to anechoic intraparenchymal cystic structures evident (Figs. 56.26 and 56.27). Cytology and biopsy can be used to confirm the diagnosis. The presence of intraparenchymal cysts might increase the potential for prostatic abscessation. Castration is curative.

Medical antiandrogen therapy is advised if cryopreservation is desired, defecation is difficult, or the owners find the clinical signs objectionable. Urinary outflow compromise, prostatic pain, or semen quality deterioration should prompt closer evaluation for more serious prostatic disorders such as prostatitis, prostatic neoplasia, or both. Antiandrogen therapy using the 5α-reductase inhibitor finasteride (Proscar, Propecia [Merck]) is a potentially effective option. Conversion of testosterone to dihydrotestosterone is inhibited, causing a reduction in prostatic size and cysts beginning in 1 to 8 weeks. The dose can be extrapolated from the human dose: 1.25 to 5 mg/dog orally q24h, although higher doses (0.10-0.20 mg/kg orally q24h) have been evaluated without problems other than the expense. A generic form of the drug appears to be equally effective and is less

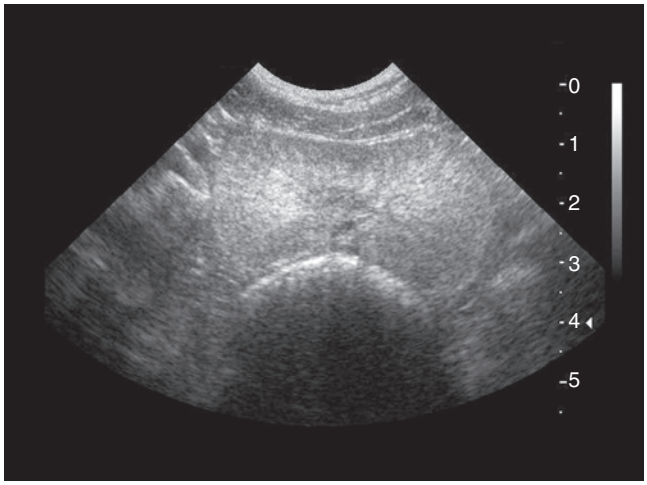

FIG 56.26
Benign prostatic hyperplasia (BPH). A transverse ultrasound image of an intact canine prostate; multiple "wagon wheel" striations radiating from the urethra to the capsule, a typical ultrasonographic finding for BPH.

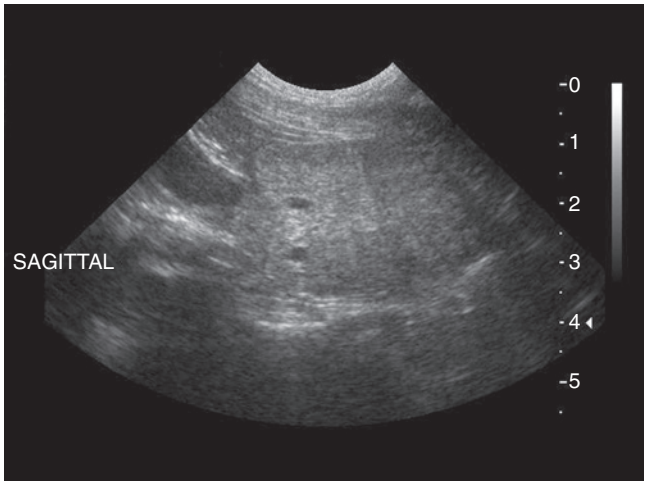

FIG 56.27
Cystic benign prostatic hyperplasia (CBPH). A sagittal ultrasound image of a canine prostate with anechoic parenchymal cysts.

expensive. Libido and semen quality are not compromised, but the prostatic fluid component of the ejaculate is markedly diminished. The effect of this on fertility with natural breedings, where prostatic fluid volume during the ejaculatory tie forces the sperm-rich component of the ejaculate into the uterus, is not known. Artificial insemination, either vaginal or transcervical, using semen extenders could be utilized if fertility seems compromised in dogs on finasteride. Alternative medical therapies such as estrogenic or progestational compounds are not advised, owing to their negative effect on testosterone concentration and spermatogenesis and induction of prostatic metaplasia (estrogen), potential for myelosuppression (estrogen), insulin and glucose dysregulation (progesterone), and mammary neoplasia (estrogen).

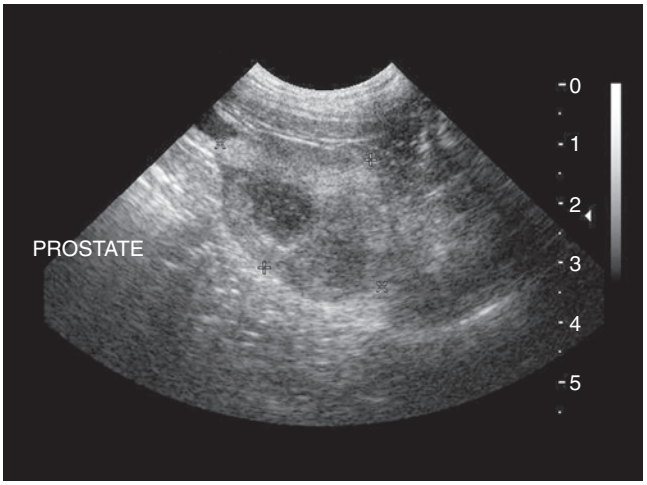

FIG 56.28
Prostatitis with abscess. A sagittal ultrasound image of an intact canine prostate (*cursors*); a hypoechoic nodule is visible within the parenchyma. The parenchymal echo texture is mixed.

Finasteride is not licensed for use in dogs but has achieved common clinical use (Laroque et al., 1994).

Infectious Prostatitis

Bacterial infection of the prostate gland can be acute and fulminate or chronic and progressive. Prostatic abscessation can occur. The prostate is painful on palpation; sublumbar lymphadenomegaly can be present. Dogs are commonly febrile, anorexic, and lethargic. Ejaculation can be painful, and affected dogs may be reluctant to breed. The semen is typically abnormal, with suppurative inflammation, hemospermia, necrospermia (dead sperm), and decreased volume evident. Because prostatic fluid normally refluxes into the urinary bladder, urinary tract infection is usually present whenever there is bacterial prostatitis. Pyuria and bacteriuria should always prompt evaluation of the prostate in any intact male dog. The most common route of infection is ascension of urethral flora, but the hematogenous route of infection is also possible. The organisms most commonly isolated from the infected prostate are *E. coli, Staphylococcus, Streptococcus,* and *Mycoplasma* spp. Occasionally, *Proteus* spp., *Pseudomonas,* or anaerobic organisms are found. Mycotic prostatitis is uncommon and usually limited to endemic regions. Septic prostatitis is best diagnosed on the basis of the findings from physical examination, followed by ultrasonography and cytology and culture of the prostate, with specific attention to any cystic structures within the parenchyma (Fig. 56.28).

Acute septic prostatitis is a serious disorder and can lead to sepsis and death. Treatment must be prompt and aggressive. Fluid therapy is necessary to correct dehydration and shock. Large prostatic abscesses are treated most effectively by surgical drainage and omentalization. Abscesses may also be drained by fine-needle aspiration under ultrasound guidance. Pending the results of culture and susceptibility,

treatment with a fluoroquinolone and potentiated amoxicillin should be initiated. Antibiotic penetration in acute prostatitis is not as problematic as in the normal prostate; in acute prostatitis, inflammation alters the blood-prostate barrier, allowing most antibiotics to penetrate. A negative culture of the urine or prostate should be obtained once therapy has been initiated to confirm effectiveness. Antibiotic treatment for acute prostatitis should be continued for a minimum of 4 weeks. Urine or prostatic fluid should be recultured a week after discontinuing antibiotic therapy and again 2 to 4 weeks later to be certain the infection has resolved. Castration should be considered. Medical castration with finasteride is an acceptable alternative if the dog stabilizes rapidly and is valuable for breeding. Relapse is common and can be diminished with the use of finasteride chronically.

Acute septic prostatitis can result in the later development of chronic septic prostatitis. Recurrent urinary tract infections imply chronic septic prostatitis. Chronic septic prostatitis may be asymptomatic, with deteriorating semen quality the only sign. The prostate may be painful, firm, and irregular on palpation. Ultrasonographic findings are nonspecific but typically will be of mixed echotexture, with hyperechoic areas reflecting fibrosis. The ultrasonographic appearance can be similar to that of prostatic neoplasia. Additionally, multiple prostatic pathologies can be present in an individual patient. The diagnosis of chronic septic prostatitis requires cytologic and microbiologic examination of urine and prostatic tissue, which may be obtained by ultrasound-guided fine-needle aspiration. Chronic bacterial prostatitis may be difficult to clear because the blood-prostate barrier is quite effective in preventing many drugs from penetrating into the prostatic parenchyma. In chronic prostatitis, only highly lipophilic agents cross into the prostate. Erythromycin, clindamycin, oleandomycin, trimethoprim-sulfonamide, chloramphenicol, carbenicillin, enrofloxacin, and ciprofloxacin are the agents most capable of achieving therapeutic concentrations in the prostate. Ciprofloxacin penetrates well into human prostate tissues, but its prostate/blood concentration ratios are not as high as enrofloxacin in dogs. Antibiotic therapy should be based on culture and susceptibility results from urine and prostatic tissue. Treatment should be continued for at least 4 weeks. Cultures should be repeated during and for several months after discontinuing antibiotic therapy to ascertain whether resistance to antibiotics or persistent infection has developed. Castration (surgical or medical) improves the response to treatment of chronic bacterial prostatitis. It has been suggested that, to avoid creating sequestration of infectious material in an involuting gland, castration should be postponed until a negative urine or prostatic culture is obtained while on antibiotic therapy.

Prostatic Neoplasia

Prostatic neoplasia is more common in neutered dogs; the disease is likely of basal cell (ductal or uroepithelial) origin and is not responsive to antiandrogen therapy. Prostatic neoplasia is suggested by the ultrasonographic findings of intraprostatic mineralization and complex parenchymal changes (Fig. 56.29). It is a disease of aged dogs, usually diagnosed late in its course, and has a poor prognosis. Urethral stent placement can provide temporary relief of obstruction secondary to prostatic neoplasia.

ACQUIRED INFERTILITY

Immune-Mediated Orchitis

Immune-mediated orchitis is characterized by an insidious onset of subfertility progressing to infertility in a previously normal male and occurs more commonly in the dog. A history of recent small litter size production and failure to impregnate bitches is common. Physical examination is normal, but the testes can be noted to be slightly small and soft, making the epididymi prominent by comparison. Ultrasound is the best method for serial testicular size determination, serial evaluations best to confirm atrophy is present (Fig. 56.30). Libido is intact. No history of infectious or systemic disease (including *Brucella spp* evaluation), fever, trauma, or toxins is present. Recent medications and supplements should be recorded to ensure none are contributory (see semen evaluation, Chapter 54).

Semen evaluation usually finds increased teratospermia, oligospermia progressing to azoospermia, and the presence of mononuclear cells. An increased number of sperm with morphologic abnormalities in the midpiece and tail are often present (Fig. 56.31). These cells have abnormal motility (asthenospermia). Early in the course, lymphocytic-plasmacytic inflammation can be found on histopathology (Fig. 56.32). Later, a lack of spermatogenesis without any evidence of an inflammatory process is present (Fig. 56.33). Testicular biopsy can confirm the disorder early in the course but is prognostic only; therapy is unrewarding.

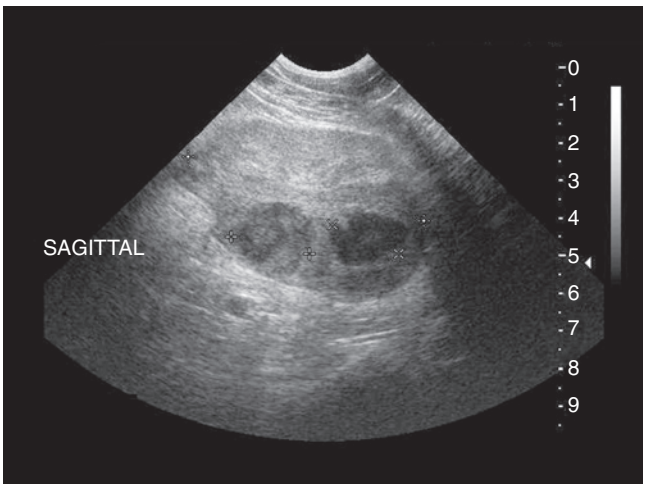

FIG 56.29
Prostatic adenocarcinoma. A sagittal image of an intact canine prostate showing characteristic BPH striations ventrally, but hypoechoic nodules (*cursors*) present within the dorsal parenchyma, illustrating the lack of specificity of ultrasound in prostatic disease. This is an unusual case of adenocarcinoma in an intact dog.

FIG 56.30
Ultrasonographic testicular measurement; *cursors* mark testicular length and width in sagittal.

FIG 56.31
Canine sperm cell showing a coiled tail (Dag defect) adjacent to two normal sperm cells.

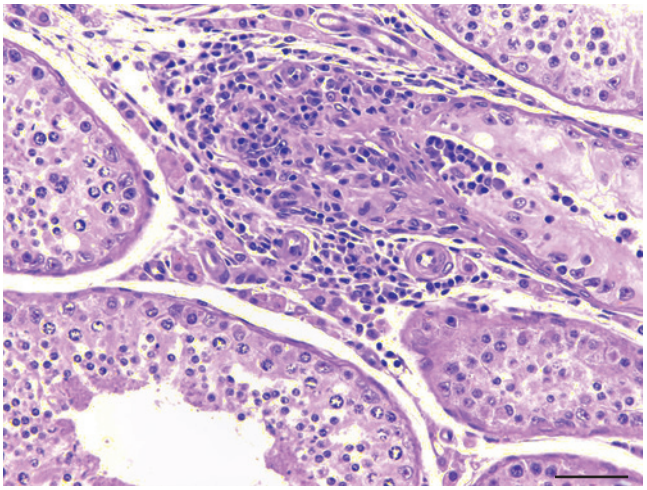

FIG 56.32
Lymphoplasmacytic inflammation shown in a testicular biopsy performed on a Toy Poodle with acquired infertility.

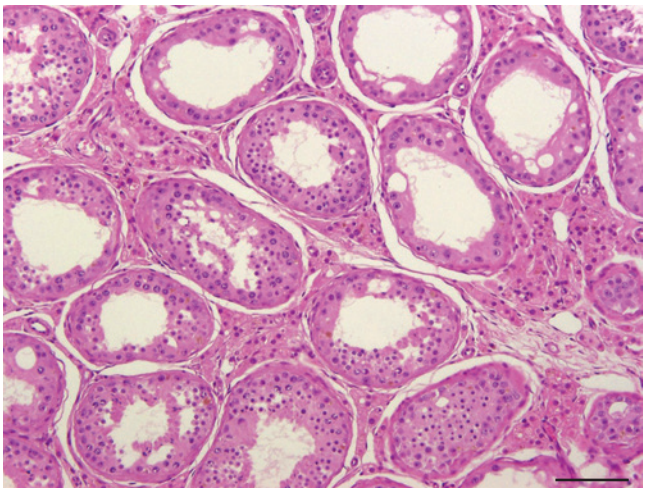

FIG 56.33
Complete lack of spermatogenesis shown in a testicular biopsy of a littermate Toy Poodle with acquired infertility.

Testicular biopsy has not been associated with a subsequent increase of antisperm antibodies. Testicular fine-needle aspiration cytology (60 mL syringe, 21 or 23-gauge butterfly needle) can be performed to evaluate normal spermatogenesis, spermatogenic arrest, Sertoli cell population, and inflammatory cell presence (Romagnoli and Schlafer, 2006) The etiology is unknown; microscopic breakdown of the sperm-bloodstream barrier is likely. Any attempt at immunosuppression inevitably targets spermatogenesis, and even staged therapy is problematic. Monitoring for other immune-mediated endocrinopathies is indicated, but their occurrence is uncommon. The disorder is noted in some breeds more frequently, suggesting a genetic component that could be associated with the degree of inbreeding present; breeding affected individuals is controversial (Davidson et al., 2015).

OBSTRUCTIVE DISORDERS OF EJACULATION

Azoospermia, a lack of sperm cells in the ejaculate, suggests a lack of spermatogenesis, spermatogenic arrest, or bilateral obstruction of the outflow of semen from the epididymi, usually in the ductuli deferentes. Incomplete ejaculation must be ruled out, because stud dogs can withhold the sperm-rich second fraction of the ejaculate voluntarily, especially if not comfortable with the collection process or clinician, or an estrual bitch is not present. Semen alkaline phosphatase (originating from the canine epididymis) can

be evaluated in azoospermic samples; a level of greater than 5000 IU/L suggests patency of the duct system and that a complete ejaculate was obtained. Cytologic examination of fine-needle aspirate of the testes (described earlier) can help evaluate for the presence of spermatogenesis in azoospermic dogs with low semen alkaline phosphatase by the identification of spermatogonia, primary and secondary spermatocytes, spermatids, and spermatozoa; if normal, an obstructive lesion is more likely. Prostatic evaluation is indicated as both ductuli deferentes course through the prostate into the prostatic urethra. Ultrasound of the reproductive tract should be performed evaluating the prostate, epididymi, and urethra for abnormalities that could interfere with semen outflow (epididymal spermatocele, prostatitis).

Retrograde Ejaculation

Normally, semen flows antegrade into the urethra, and a small amount passes retrograde into the urinary bladder. Excessive retrograde flow can result in oligospermia and is confirmed by evaluating the number of sperm in urine before and after ejaculation. Treatment with α-andrenergic agonists (ephedrine, norfenefrine, phenylpropanolamine hydrochloride) can be attempted to increase urethral sphincter pressure; neither testosterone nor estrogen should be used. Urine is toxic to sperm cells, so stud dogs should be encouraged to empty their bladders before semen collection or natural breeding.

DEFECTS OF SPERMATOGENESIS

Testicular fine-needle aspirate and cytology can also assist in the diagnosis of defects in spermatogenesis. Hypospermatogenesis and maturation defects can be detected. Defective spermatogenesis can occur secondary to direct thermal scrotal insult (scrotal dermatitis), systemic disease, fever and hyperthermia from prolonged exercise, certain drugs and toxins, and endocrinopathies. The effect of these etiologies on spermatogenesis can be reversible. Cimetidine, ketoconazole, sex steroids, glucocorticoids, anticholinergics, thiazide diuretics, propranolol, digoxin, spironolactone, diazepam, and chlorpromazine have been implicated. Re-collection and evaluation 60 days (or more) later is necessary to permit a new cycle of spermatogenesis to be identified in the ejaculate.

In addition to a careful general and focused (scrotum, testes, epididymi, and prostate) physical examination, testicular ultrasound should be performed in every patient with unexplained acquired infertility and abnormal semen analysis. It allows diagnosis of more pathologic conditions than physical examination. Subtle differences in testicular or epididymal size or symmetry, or changes in testicular or epididymal consistency, warrant an ultrasonographic evaluation that can disclose pathology (i.e., orchitis, epididymitis, testicular neoplasia) sometimes before reproductive performance has been irreversibly affected. The presence of a functional testicular neoplasia (most commonly Sertoli cell tumor) can adversely affect spermatogenesis in the unaffected testis; early unilateral castration can be curative if significant testicular atrophy has not occurred (Fig. 56.34).

FIG 56.34
Ultrasonographic identification of a small Sertoli cell tumor (*cursors*). Ultrasound guided fine needle aspirate and cytology are often helpful in identifying tumor type.

CONGENITAL INFERTILITY

HERITABLE TERATOSPERMIA

Genetic sperm defects such as acrosome defects, head defects, midpiece abnormalities, and tail defects have been described in several species including dogs and cats. Increased fertility problems in purebred dogs suggests this could be related to reduced genetic variability.

DISORDERS OF SEXUAL DIFFERENTIATION

Malformation and dysfunctionality of the reproductive tract can result from abnormalities of chromosomal sex, causing intersex conditions. Intersex animals commonly have ambiguous or inappropriate external genitalia that can be discovered readily by careful physical examination. Sexual differentiation occurs during fetal development and is dependent upon a normal chromosomal complement, followed by normal gonad and genitalia formation. The Y chromosome, containing the SRY gene, is the sex-determining chromosome. If it is present and normal, a male develops; if absent or abnormal, the fetus develops into a female or an intersex. Once fetal gonads have developed, the fetal phenotypic sexual characteristics develop as a consequence of hormones secreted.

Physical findings in individuals with disorders of sexual differentiation can include an os clitoris (commonly causing vestibulitis), hypospadias (commonly associated with incontinence and exposure phimosis), cryptorchidism, and displacement of the prepuce (caudally) or vulva (cranially). Os clitorises have been noted as an incidental finding during coxofemoral joint radiography; the reproductive status of the individuals was not reported. Normal estrous cycles can be lacking in individuals with anomalous differentiation.

FIG 56.35
Cranially displaced and malformed vulva in a female puppy exposed in utero to progestins.

Defects in the development of the internal tubular genital tract of females can also result from developmental abnormalities during embryogenesis. Ovaries, testes, or ovotestes can be present. A definitive diagnosis is based on karyotyping and histopathology of the reproductive tract. Most of these animals are sterile.

Neutering is still indicated to avoid behavioral and paraneoplastic conditions associated with hormone production. Iatrogenic causes of disorders of sexual differentiation include therapy with progestagens during pregnancy (Fig. 56.35).

In males, congenital causes of infertility should be considered in aspermic animals that have no history of siring a litter. Abnormalities of the hypothalamic-pituitary-gonadal axis, such as hypogonadotropic hypogonadism, and disorders of sexual differentiation, such as intersex, are possible causes. Males with hypogonadism have abnormally small testes with diminished (or absent) spermatogenesis and testosterone production. The secretory capacity of pituitary gonadotropins can be assessed by determining LH levels (Status-LH [Synbiotics/Pfizer]) before and 1 hour after administration of GnRH (1-2.2 μg/kg intramuscularly); normal intact male dogs have a serum LH from 0.20 to less than 20.0 ng/mL. Evaluation of resting and post-hCG or GnRH stimulation testosterone levels is often hampered by reference range variation among laboratories and the overlap between normal basal testosterone levels and hypotestosteronism. Examination of the libido of the dog or the penile spines in the tomcat can be more informative regarding the presence of testosterone.

CHAPTER 57

Neonatology and Pediatrics

Average reported neonatal mortality rates (greatest during the first week of life) vary, ranging in reports from 9% to 26%. Veterinary intervention in the prenatal, parturient, and postpartum periods can increase neonatal survival by controlling or eliminating factors contributing to puppy morbidity and mortality. Poor prepartum condition of the dam, dystocia, congenital malformations, genetic defects, postnatal injury, chilling, overheating, malnutrition, parasitism, and infectious disease all contribute to neonatal morbidity and mortality. Optimal husbandry favorably impacts neonatal survival by managing labor and delivery to reduce stillbirths, controlling parasitism, reducing infectious disease exposure, preventing injury and environmental extremes, and optimizing nutrition of the dam and neonates. Proper genetic screening for selection of breeders (both the sire and the dam) minimizes inherited congenital defects. Breeders should select for sires that have normal fecundity, producing normal-sized litters that survive to weaning.

NEONATAL RESUSCITATION

Cardiopulmonary resuscitation for neonates who fail to breathe spontaneously is challenging yet potentially rewarding. Maintaining a neonatal resuscitation kit is ideal (Box 57.1). Optimal neonatal resuscitation after birth (if the dam fails to do so) or cesarean section involves the same ABCs (airway, breathing, circulation) as any cardiopulmonary resuscitation (Box 57.2) (Video 57.1). Intervention for resuscitation of neonates after vaginal delivery should take place if the dam's actions fail to stimulate respiration, vocalization, and movement within 1 minute of birth. After removing amniotic membranes from the neonatal muzzle, promptly clear the airways by gentle suction with a bulb syringe or DeLee mucous trap while the neonate's head is lowered (Figs. 57.1, 57.2, *A*, 57.2, *B*, 57.2, *C*). Neonates should not be swung to clear airways because of the potential for cerebral hemorrhage from concussion (Grundy et al., 2009). After checking for a heartbeat, drying and stimulating the neonate to promote respiration are performed next (Fig. 57.3). The use of doxapram as a respiratory stimulant is unlikely to improve hypoxemia associated with hypoventilation and is not recommended (Moon et al., 2000). Spontaneous breathing and vocalization at birth are positively associated with survival through 7 days of age (Video 57.2). Ventilatory support should include constant flow-by O_2 delivery by face mask (Fig. 57.4, *A*). If this is ineffective after 1 minute, positive pressure with a snugly fitting mask, or endotracheal intubation and rebreathing bag (using a 2-mm endotracheal tube or a 12- to 16-gauge intravenous [IV] catheter), is advised (Fig. 57.4, *B*). Anecdotal success with Jen Chung acupuncture point stimulation has been claimed when a 27-ga or acupuncture needle is inserted into the nasal philtrum at the base of the nares and rotated when bone is contacted (Fig. 57.5). An improvement in heart rate should follow ventilation support; myocardial hypoxemia is the most common cause of neonatal bradycardia or asystole. Atropine is currently *not* advised in neonatal resuscitation. The mechanism of bradycardia is hypoxemia-induced myocardial depression rather than vagal mediation, and anticholinergic-induced tachycardia can actually exacerbate myocardial oxygen deficits. If no heartbeat is detected, direct transthoracic cardiac compressions are advised as the first step; epinephrine diluted 1:9 is the drug of choice for cardiac arrest/standstill (0.0002 mg/g administered best by the IV or intraosseous [IO] route) (Moon et al., 2000). Venous access in the neonate is challenging; the single umbilical vein is one possibility if not thrombosed. The proximal humerus, proximal femur, and proximomedial tibia offer intraosseous sites for drug administration (Fig. 57.6, *A*, 57.6, *B*).

Chilled neonates can fail to respond to resuscitation. Loss of body temperature occurs rapidly when a neonate is damp. Keeping the neonate warm is important during resuscitation and in the immediate postpartum period. During resuscitation, placing the chilled neonate's body into a warm water bath (95° F-99° F) can improve response (Fig. 57.7). Working under a heat lamp or within a Bair hugger warming device is helpful. After resuscitation, neonates should be placed in a warm box (a Styrofoam picnic box with ventilation holes is ideal) with warm bedding until they can be placed with

BOX 57.1

Neonatal Resuscitation Equipment Kit

- Syringes (tb)
- Drugs (epinephrine 0.1 mg/mL +/– 0.01 mg/mL, 2.5%-5% Dextrose, Ceftiofur*)
- Oxygen sources
- Suction (pediatric bulb syringes, DeLee mucous traps)
- Small face masks
- Towels (small)
- Heat sources (Baer, warm water blanket, infrared lamp, hair dryer, warm water bottles)
- Puppy box (Styrofoam) with heat support
- Multiple clean mosquito forceps & small scissors
- 3-0 monofilament suture for umbilical cord ligation
- Tincture of iodine 2%
- Bowls for warm water baths
- Pediatric/neonatal stethoscope
- Doppler
- Neonatal gram scale

*Naxcel®/Ceftiofur Protocol
Reconstitute with 20 mL bacteriostatic or sterile water to 50 mg/mL solution
Stable for 12 hours at room temperature (once reconstituted)
Stable for 7 days if refrigerated (once reconstituted)
Stable for 8 weeks if frozen (once reconstituted)
Freeze remainder in 1-mL increments in labeled RTT
Neonatal dose is 2.5 mg/kg (0.0025 mg/gram) SC bid for 3-5 days

FIG 57.1
Removal of amniotic membranes from the muzzle of a neonate.

BOX 57.2

Neonatal Resuscitation Protocol

A, B, Cs—Airway, Breathing & Circulation

A. Clear airway of amniotic membrane and fluid by suction. Do not swing. Place with head below thorax to improve drainage.
B. Gentle brisk towel drying to stimulate respiration. If not breathing, start positive pressure ventilation using snug face mask and 21% O_2.
C. Circulation: If HR is slow, improve ventilation/oxygenation.

Is Resuscitation Effective?

1. Is the puppy vocalizing?
2. Is the mucous membrane color improving?
3. Is the puppy moving?

Keep in mind that even a nonviable puppy can have red color in the mucous membranes from the maternal circulation and fetal hemoglobin.

Rxs if ABCs Fail

- Epinephrine (1:10,000 or 0.1 mg/mL); give 0.0002 mg/g (e.g. 500 g neonate would receive 0.1 mg (0.1 mL) IV, IO, IC. Smaller neonates could require further dilution of epinephrine to 0.01 mg/mL
- Atropine not advised
- Doxapram not advised
- Acupressure if poor respiration: 27 ga or acupuncture needle into the nasal philtrum, insert and turn

Prolonged Problematic Case

Hypothermic? Warm water bath at 95-98° F
Hypoglycemic? Rx Dextrose 2.5%-5.0% Dextrose IV, IO

Reasons to Stop

1. No pulse after 10 minutes (check with Doppler or pediatric stethoscope)
2. Agonal breathing for more than 20 minutes
3. Severe congenital defect

their dam. Neonatal dogs and cats lack thermoregulatory mechanisms until 4 weeks of age, so the ambient temperature must be high enough to facilitate maintenance of a body temperature of at least 97° F (36° C). Hypothermia negatively impacts immunity, nursing, and digestion. Postresuscitation, exogenous heat should be supplied, best in the form of an overhead heat lamp. Heating pads run the risk of burning neonates incapable of moving away from excessively hot surfaces. Chilled older neonates must be rewarmed slowly (30 minutes) to avoid peripheral vasodilation and dehydration. Tube feeding should be delayed until the neonate is euthermic; hypothermia induces ileus, and regurgitation and aspiration can result. Thermal support should continue through 4 weeks of life (Fig. 57.8, Box 57.3).

Neonates lack glucose reserves and have minimal capacity for gluconeogenesis. Providing energy during prolonged resuscitation efforts becomes critical. Clinical hypoglycemia involves blood glucose levels less than 30 to 40 mg/dL and is best treated with IV or IO dextrose at a dose of 0.1 to 0.2 mL of a 2.5% to 5.0% (25-50 mg/mL) dextrose solution. Single administration of parenteral glucose is adequate if the puppy can then be fed or if it nurses. Because of the potential for phlebitis if administered intravenously, 50% dextrose solution should only be applied to mucous membranes; however, circulation must be adequate for absorption from the mucosa. Neonates repeatedly administered dextrose should be monitored for hyperglycemia because of immature

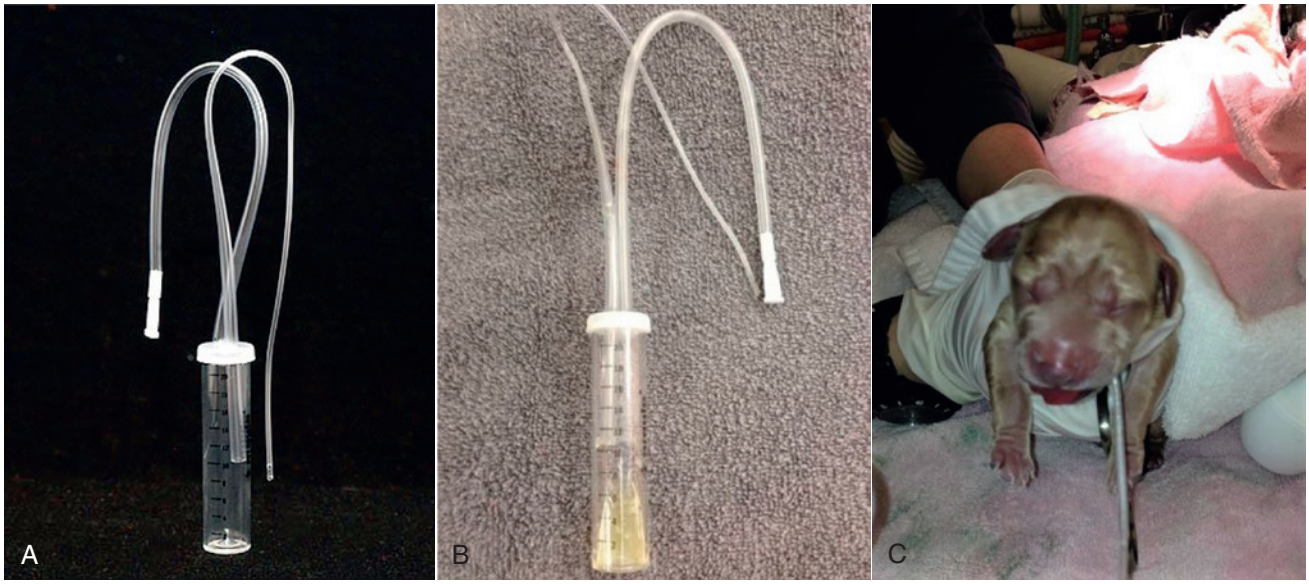

FIG 57.2
DeLee mucous trap. **(A)** Empty. **(B)** Full of fluid recovered from the neonate's airway. **(C)** Note the capped line is inserted in the resuscitators mouth, the open line into the neonatal proximal trachea.

FIG 57.3
Rubbing the neonatal muzzle stimulates respiration.

BOX 57.3

Normal Rectal Temperature of Neonates, First 4 Weeks of Life, and Associated Ambient Temperature Required

Neonatal Normal Body Temperature (Rectal)		
Week 1	95-99° F	35-37.2° C
Week 2-3	97-100° F	36.1-37.8° C
At weaning	99-101° F	37.2-38.3° C
Environmental Warmth Required		
Week 1	84-89° F	35-37.2° C
Weeks 2-3	80° F	26.7° C
Week 4	69-75° F	20.6-23.9° C
Week 5	69° F	20.6° C

metabolic regulatory mechanisms. If a neonate is too weak to nurse or suckle, a mixture of a warmed, balanced crystalloid (½ strength saline) and 2.5% dextrose may be administered subcutaneously at a dose of 1 mL/30 g of body weight until the pup can be fed or nurses. Note that 5% dextrose in lactated Ringer's or Normosol solution is hypertonic and contraindicated with dehydration. Subcutaneous administration of glucose can result in abscessation (Fig. 57.9). A balanced warmed nutrient-electrolyte solution or colostrum from the dam can be administered orally by stomach tube every 15 to 30 minutes until the neonate is capable of suckling.

The umbilicus of neonates should be treated with 2% tincture of iodine immediately after birth or resuscitation to reduce contamination and prevent ascent of bacteria into the peritoneal cavity (omphalitis, peritonitis); the alcohol-based tincture of iodine promotes faster desiccation of the umbilicus than water-based Betadine (Fig. 57.10, *A*, 57.10, *B*, 57.10, *C*, 57.10, *D*; *see* Videos 57.1, 57.2).

After resuscitation or within the first 24 hours of a natural delivery, a complete physical examination with vital signs should be performed by a veterinarian, technician, or knowledgeable breeder (Boxes 57.4 and 57.5). The oral cavity, hair coat, limbs, digits, umbilicus, and urogenital structures should be visually inspected. In the normal neonate, the

FIG 57.4

FIG 57.5
Jen Chung acupressure.

BOX 57.4

Normal Values of Body Temperature, Heart Rate, and Respiratory Rate in the Neonate

	Puppies	Kittens
Body temperature	95-99° F 35.0-37.2° C	95-99° F 35.0-37.2° C
Heart rate	200 beats/min	200-250 beats/min
Respiratory rate	10-18/min	10-18/min

BOX 57.5

Immediate Postresuscitation Neonatal Management

Check for congenital defects: cleft palates, urogenital, abdominal wall.
Umbilical care: ligate with suture, remove distally at about 0.5-1 cm from abdomen and dip entire cord remaining in 2% tincture of iodine bottle.
Be sure each puppy nurses effectively (weigh before and after) as soon as possible. If this is delayed, consider tube feeding. Best to acquire colostrum from the dam.
Do not leave neonates unattended with a dam recovering from anesthesia for 24-36 hours postsurgery, as she may be clumsy or even aggressive. Place the puppies/kittens in with dam every 1-2 hours to nurse under supervision.
Canine serum can be given to puppies or kittens that failed to receive colostrum (0.10 mL/g puppy; 0.15 mL/g kitten) weight divided prn; PO within the first 24 hours, or SC if post-24 hours (intestinal absorption diminished > 24 h).
Ceftiofur 0.0025 mg/g SC bid × 5 days may be given to puppies that may have aspirated meconium or had a stressful delivery and are at risk for sepsis.

FIG 57.6
Intraosseous catheter placement in the neonate. **(A)** Proximal humerus. **(B)** Proximal femur.

FIG 57.7
Warm water bath during the resuscitation of a chilled neonate.

FIG 57.8
Post resuscitation, neonates are kept warm in an insulated styrofoam box with a warm air blanket.

mucous membranes should be pink and moist, a suckle reflex present, the coat full and clean, and the urethra and anus patent (Fig. 57.11). The thorax should be auscultated; vesicular breath sounds and a lack of murmur are normal; subtle murmurs, if present, should resolve within 24 hours. The abdomen should be pliant and not painful. A normal neonate will squirm and vocalize when examined, and will nurse and sleep quietly when returned to the dam. Normal neonates will attempt to right themselves and orient by rooting toward their dam. Neonates are highly susceptible to environmental stress, infection, and malnutrition. Proper husbandry is critical and should include daily examination of each neonate for vigor and recording of weight. Severe congenital defects can result in morbidity and mortality; breeders may elect euthanasia if the prognosis is poor or the cost of therapy prohibitive. The hematologic values for

FIG 57.9

growing healthy dogs and cats are presented in Tables 57.1 and 57.2; the biochemical parameters from birth to approximately 8 weeks of age and up to 12 months of age in puppies in Tables 57.3 and 57.4; and the biochemical parameters from birth to approximately 8 weeks of age and up to 12 months of age in kittens in Tables 57.5 and 57.6.

Drug therapy in pediatric dogs and cats is impacted by neonatal physiology and morphology. Absorption of oral drugs is altered by high gastric pH and increased mucous content, decreased gastrointestinal motility, and decreased bile production. Drug distribution is impacted by neonatal increased body water content and decreased fat content. Lower plasma proteins decrease drug binding. The blood brain barrier is incomplete. Decreased renal and hepatic metabolic and excretory capacity persists until 4 to 6 months of age.

ANOMALIES APPARENT AT THE NEONATAL EXAM

A developmental anomaly resulting in extrusion of a portion of the gastrointestinal tract outside of the body wall, occurring within the umbilical canal (omphalocele) or lateral to the umbilical canal (gastroschisis), has been reported in humans and occurs in both dogs and cats (Fig. 57.12). The condition is usually hopeless in small pediatric veterinary patients presented to the veterinarian hours after birth; however, a 30% to 70% survival rate is reported in humans with immediate postpartum surgical intervention; the diagnosis is made prepartum with abdominal ultrasound based on the recognition of fetal gastric wall (rugal) structures or intestinal contents in an abnormal location. Earlier surgical intervention before inevitable septic contamination occurs may improve the prognosis in veterinary patients.

Gastrointestinal abnormalities are suggested by poor weight gain, regurgitation of milk through the nares, respiratory signs, and abnormal defecation. Congenital palate defects occur in dogs with an incidence of up to 25% (Fig. 57.13, *A*). Secondary cleft palate is a congenital oronasal fistula resulting in incomplete closure of the hard and soft palate. Secondary cleft palate occurs alone or in combination with primary cleft palate involving the lip and premaxilla (Fig. 57.13, *B*). Cleft palate results from incomplete fusion of the palatine shelves, most critical at 25 to 28 days gestation,

attributed to genetic (recessive or incompletely dominant polygenic inheritance), teratogenic (drugs, supplements), nutritional (folic acid deficiency), or infectious (viral) factors. Affected neonates are diagnosed by visual inspection of the face and oral cavity, and ineffective nursing/suckling results. These neonates fail to thrive, developing aspiration pneumonia and rhinitis. Feeding by orogastric tube is indicated until the puppy reaches a size permitting oral surgery, traditionally advised at 8 to 12 weeks of age. Palatoplasty in such young puppies remains difficult due to patient size and anticipated postoperative orofacial growth, often necessitating multiple surgeries. Esophagostomy or gastrostomy tube placement can facilitate feeding over time but require significant client commitment and can still result in aspiration (Fig. 57.13, *C*). Palatal prostheses are problematic in dogs. Methods to improve survival of pet puppies with cleft palates are sought by clients; survival to reproductive age in congenitally affected dogs providing a research model for the human condition avoids the need for iatrogenic or teratogenically induced models. A successful method to manage nutrition in affected dogs until adult size is attained, facilitating a single later surgical correction, has been reported. Feeding the dam's colostrum for 24 hours followed by artificial bitch milk replacer by intermittent orogastric tube is instituted. At 4 weeks of age, transition to a dry (unsoaked) commercial pediatric dog food is made. Water is made available through an overhead ball-point tube cap system. Surgery can be delayed until the puppy has achieved enough growth or may never become necessary, as some degree of closure of the cleft occurs with time (Figs. 57.14, *A*, 57.14, *B*, 57.14, *C*, 57.14, *D*, 57.15) (Davidson et al., 2014).

Enteric duplication or agenesis can be confirmed ultrasonographically in pediatric patients. Duplication is rare, can occur anywhere in the intestinal tract, and the clinical signs may be nonspecific (abdominal distension, discomfort). A fluid-filled juxta intestinal formation with variable peristalsis and contents can be seen with ultrasound. Enteric agenesis usually results in severe, life-threatening clinical signs in the neonatal period (Fig. 57.16). Ultrasonographic findings usually include marked fluid and gas distention of bowel proximal to the defect.

Umbilical hernias can be significant if large enough to permit bowel evisceration and strangulation. More commonly, omentum becomes trapped in a small umbilical hernia in pediatric dogs and cats; closure of the hernia then results in a benign mass effect often alarming to clients. Evaluation of a painful or enlarging umbilical mass with ultrasound permits differentiation of omentum from entrapped bowel, which has a typical enteric appearance.

Omphalitis resulting from bacterial umbilical contamination in the postpartum period places the neonate at risk for bacterial septicemia. The umbilicus should be closed and dry 24 hours postpartum; erythema or drainage indicates antibiotics should be instituted due to the potential for peritonitis (Fig. 57.17, *A*). Excessive umbilical attention by the dam can result in exposure of the subcutaneous (SC) tissues with risk of peritonitis (Fig. 57.17, *B*).

Anasarca, a lethal congenital edema, can occur with concurrent cardiovascular abnormalities. Generalized SC edema, with intrathoracic and intraperitoneal fluid accumulation, are present (Fig. 57.18). Congenital hereditary lymphedema causes edema of the extremities and sometimes head, and is associated with morphologic lymphatic abnormalities.

Incompletely developed immune systems during the first 10 days of life make neonates vulnerable to systemic infection (most commonly bacterial and viral). Adequate ingestion of colostrum must occur promptly postpartum for neonates to acquire passive immunity, as transplacental transfer is <5%. The intestinal absorption of immunoglobulin (IgG)

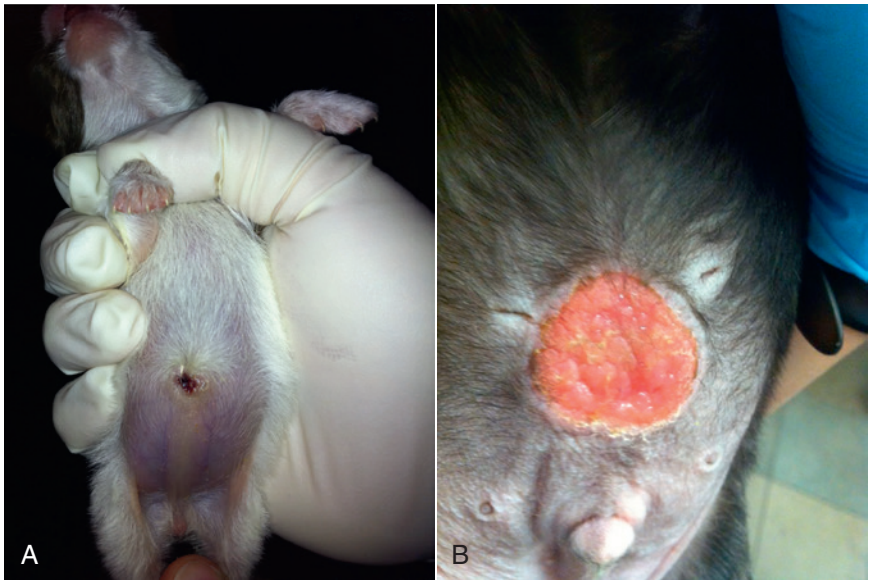

FIG 57.17

FIG 57.18
Littermates, low birth weight neonate on the left.

generally ceases by 24 hours after parturition. Colostrum-deprived canine neonates should be given 100 mL/kg (0.10 mL/gram) of serum from an immunocompetent adult to achieve adequate IgG levels. Kittens should receive 150 mL/kg (0.15 mL/gram). Blood typing is important with cats. The serum can be given orally if within the first 24 hours of life, otherwise it must be given parenterally, preferably subcutaneously, divided with both routes (Levy et al., 2001; Poffenbarger et al., 1991). Neonates should be encouraged to suckle promptly after resuscitation is completed; this usually necessitates close monitoring after a cesarean section, because the dam is still groggy from anesthesia.

FADING NEONATES

Neonatal bacterial septicemia can cause rapid deterioration resulting in death if not recognized and treated promptly. Factors that reportedly predispose a neonate to septicemia include endometritis in the dam, prolonged delivery/dystocia, feeding of replacement formulas, use of ampicillin, stress, low birth weight (<350 g for a medium-size breed of puppy, <100 g for a kitten), and chilling (body temperature <96° F) (see Fig. 57.18). The organisms most frequently associated with septicemia are *E. coli,* streptococci, staphylococci, and *Klebsiella* spp. Umbilical contamination is the most likely route of entry. Omphalitis leads to peritonitis, bacteremia, and pneumonia. Abscessation can occur later at other sites (Fig. 57.19). Premortem diagnosis can be challenging; clinical signs may not be noted owing to sudden death. Commonly, a decrease in weight gain, failure to suckle, hematuria, persistent diarrhea, unusual vocalization, abdominal distention and pain, and sloughing of the extremities indicate septicemia may be present. Prompt therapy with broad-spectrum bactericidal antibiotics; improved nutrition via supported nursing, tube, or bottle feeding; maintenance of body temperature; and appropriate fluid replacement are indicated. The third-generation cephalosporin antibiotic ceftiofur sodium (Naxcel [Upjohn]) is an appropriate choice for neonatal septicemia. It minimally alters normal intestinal flora and is usually effective against the causative organisms. Ceftiofur sodium should be administered at a dose of 0.0025 mg/gram SC q12h for no longer than 5 days. Because neonates less than 48 hours old have reduced thrombin levels, presumptive therapy with vitamin K_1 may be used

FIG 57.19
Neonatal ophthalmia; accumulation of purulent fluid under the eyelid of a 7-day-old neonate likely secondary to bacteremia.

(0.01-1 mg SC per neonate). The prognosis is guarded but not hopeless.

Incompatible blood types of the parental cats have recently been implicated as a cause of feline neonatal mortality. This incompatibility arises when queens with Type B blood give birth to kittens who inherited the sire's blood Type A. Type B is rare in mixed breed and Siamese cats but is much more common in certain purebreds such as British Shorthair and Devon Rex cats. Type B cats have naturally occurring anti-A antibodies. When the kittens nurse and absorb these antibodies, the kittens' own red blood cells are hemolyzed, leading to anemia and organ failure. The clinical course is determined by the severity of the hemolytic reaction. In all cases, the kittens are born healthy and nurse vigorously. Some kittens may die suddenly in the first day, whereas others linger longer and fade during the first week of life. Clinical neonatal isoerythrolysis (NI) is suggested by pale mucous membranes and dark red-brown urine, and is confirmed by documenting hemolytic anemia and the blood types of the parents. If NI is suspected, the kittens are removed from the queen and fostered on a Type A queen or bottle-fed for the first 2 days of life. NI can be avoided in catteries by testing the blood types of breeding animals and avoiding matings of Type B queens with Type A toms.

Canine herpes virus (CHV) is a commonly blamed cause for fading puppy syndrome resulting in neonatal death (see Chapter 55). Premortem diagnosis of CHV infection in neonates can be challenging. Postmortem diagnostics include appropriate histopathology, virus isolation, or PCR. Pathognomonic changes occurring in the kidneys include multifocal petechial hemorrhages, although this can be seen with bacterial septicemia and associated thromboembolic disorders as well. Intranuclear inclusion bodies can be difficult to find. Diagnosis by virus isolation or CHV-specific PCR is confirmatory and desirable, especially before litter mortality reaches 100%. Until recently, treatment of CHV infection in neonates has been reported to be unrewarding and rare, with recovery suspected to be associated with residual cardiac and neurologic damage. Treatment with immune serum from affected dams is reported to be ineffective in infected puppies. Successful treatment with the antiviral agent acyclovir (Zovirax [Novopharm]) has been reported (Davidson et al., 2003). Acyclovir is an antiviral agent with activity against a variety of viruses including herpes simplex. Acyclovir is preferentially taken up by susceptible viruses and converted into the active triphosphate form, inhibiting viral DNA replication. Acyclovir is poorly absorbed after oral administration and is primarily hepatically metabolized. Acyclovir can increase the toxicity of nephrotoxic drugs. The half-life in humans is approximately 3 hours. Its use in veterinary medicine is not well established, and it should be used with caution and only in situations where indicated. The safety and effectiveness in humans younger than 2 weeks of age is not established. The dose was extrapolated from that for humans (20 mg/kg by mouth [PO] q6h × 7 days).

ORPHANS' SPECIAL NEEDS

Kittens and puppies under 3 weeks of age lack voluntary elimination and must have the micturition and defecation reflexes stimulated multiple times daily using a cotton ball with mineral oil on the anogenital area. Sibling suckling secondary to the lack of normal nursing can cause dermatologic lesions; separation of the neonates in an orphaned litter may be necessary until solid food is introduced. Neonates have minimal body fat reserves and limited metabolic capacity to generate glucose from precursors. Glycogen stores are depleted shortly after birth, making adequate nourishment from nursing vital. Even minimal fasting can result in hypoglycemia. Hypoglycemia can also result from endotoxemia, septicemia, portosystemic shunts (PSS), and glycogen storage abnormalities. Oral fluid and glucose replacement may be preferable if the neonate has an adequate swallowing reflex and is not clinically compromised. The neonatal caloric requirement is 133 cal/kg/day during the first week of life, 155 cal/kg/day for the second, 175 to 198 cal/kg/day for the third, and 220 cal/kg/day for the fourth. Bottle or intermittent esophageal tube feeding must be commenced until weaning (Fig. 57.20). Commercially manufactured milk replacement formulas are usually superior to homemade versions, but none are equal to the dam's milk (Heinze et al., 2014). The use of milk obtained from the dam should be considered and is superior if available. Most replacement formulas lack appropriate calcium, amino acids, and essential fatty acids. An osmotic diarrhea (usually yellow, curdled fecal appearance) can result from overfeeding formula; constipation can also occur necessitating diluting the product

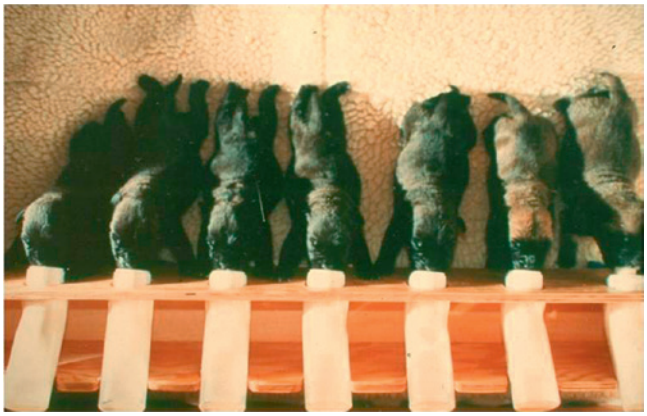

FIG 57.20

25% to 50% with water or a balanced crystalloid solution. Neonates should gain weight steadily from the first day after birth (a transient mild loss from birth weight is acceptable on day 1), with puppies gaining 1 to 3 g/day/lb (2.2 kg) of anticipated adult weight and kittens 50 to 100 g/wk. Neonatal weights should be recorded daily for the first 2 weeks, then every 3 days until 1 month of age. Healthy, well-nourished neonates are quiet and sleep when not nursing. The normal neonatal weight gain is an increase of 5% to 10% body wt/day. The limited size of neonatal stomach, and propensity for regurgitation/aspiration if overdistension from overfeeding occurs, necessitates multiple small feedings around the clock. Most commercial milk replacers deliver approximately 1.0 kcal/mL; maximum comfortable stomach capacity approximates 4 mL/100 g body weight.

PEDIATRIC SYSTEMIC ABNORMALITIES

Cardiovascular Disorders

Ventricular septal defects, mitral valve disorders, and arteriovenous fistulas are the most common congenital cardiac defects. Cardiac defects can arise from environmental stress, infection, or intoxication of the dam; however, the heritability of many has been documented. Clinical signs are often not apparent until after weaning, although affected neonates may not be as vigorous as normal littermates. Accurate cardiac auscultation should be possible at and after 6 to 8 weeks of age; echocardiography is the preferred mode of evaluation once adequate pediatric size is attained, usually at 3 to 4 months of age.

Respiratory Disorders

Primary ciliary dyskinesia, the rare immotile cilia syndrome, should be suspected in neonates exhibiting persistent or recurrent mucopurulent nasal discharge, coughing, and abnormal breath sounds without other demonstrable cause. The presence of a cleft palate, persistent right aortic arch, and congenital megaesophagus should be ruled out (Fig. 57.21). Abnormal mucociliary transport and neutrophil function result in chronic rhinitis, tracheobronchitis, and bronchopneumonia. Situs inversus can also be present. The long-term prognosis, even with supportive therapy, is poor. Neonatal dyspnea with evidence of gastrointestinal disorders can occur secondary to congenital peritoneopericardial or pleuroperitoneal diaphragmatic hernias. Thoracic wall abnormalities, such as pectus excavatum, a sternal intrusion into the thorax, can cause dyspnea and is variably associated with poor growth. Surgical correction of thoracic wall abnormalities is indicated if the neonate is symptomatic once adequate body size is attained. Reports of a neonatal respiratory distress syndrome secondary to a deficiency of surfactant exist; affected neonates died within 5 days of age. Surfactant deficiency secondary to prematurity is predictably problematic. Proper timing of elective cesarean sections is vital to avoid premature delivery of surfactant deficient neonates. The administration of corticosteroids to term pregnant bitches does not result in the formation of surfactant (Sipriani et al., 2009). Radiography of the term pregnant bitch should permit visualization of fetal dentition (Fig. 57.22).

Musculoskeletal Disorders

Neonates can be born with hind limb hyperextension of unknown etiology; because their joints are lax, simple bandaging in a flexed position for 2 to 3 days can resolve the condition (Fig. 57.23). Puppies with noticeable flattening of the sternum at 3 to 4 weeks of age are called "swimmer puppies" by breeders. Swimmer puppies fail to develop normal stepping ambulation at 14 to 21 days of life, moving instead by paddling their limbs laterally and caudally. Compression and deformation of the sternum and thorax occurs concurrently (Fig. 57.24, *A*). Obese puppies from small litters, raised on slippery surfaces, are predisposed. Treatment should be instituted immediately upon diagnosis, consisting

FIG 57.22

(D) Dorsal view of forelimb hobbles. Gait improvement was seen after 5 days in the hobbles.

of caloric restriction, physical therapy, and improved traction in the nest box. Placement of loose hobbles helps control limb movements and promotes normal ambulation within days (Fig. 57.24, *B*, 57.24, *C*, 57.24, *D*). The prognosis for swimmer puppies treated before 4 to 5 weeks of age is good.

Urogenital Disorders

Dysuria, urinary incontinence, or hematuria/pyuria can accompany neonatal urogenital disorders. The presence of a persistent urachus causes micturition through the umbilicus. Urachal diverticula can predispose the bladder to recurrent infection because of abnormal urine flow in the region; surgical excision is indicated. The diagnosis is confirmed with ultrasound (Fig. 57.25, *A*, 57.25, *B*). Renal dysplasia is a heritable problem in several canine breeds; ultrasound can identify the typical marked morphologic abnormalities in puppies at 6 to 8 weeks of age in breeds at risk (Fig. 57.26) Congenital renal polycystic disease of brachycephalic cats can similarly be identified with ultrasound in 8- to 12-week-old kittens (Fig. 57.27). Until reliable genetic markers are available for the various breed-specific congenital renal dysplasias, ultrasound provides the best method of screening young dogs and cats for these disorders; clinical signs are usually not present until early adulthood when uremia develops. Neonatal urolithiasis, with or without associated urinary tract infection, can cause outflow obstruction and

signs of acute abdominal pain. Lower urinary tract infection in neonates has the potential for ascending and causing pyelonephritis if not detected and controlled, making ultrasound-guided cystocentesis preferable when acquiring urine from pediatric patients with signs of lower tract disease.

Ectopic ureters can cause incontinence during the postpartum period; clinical signs are most evident after weaning when the dam is no longer cleaning the puppy. An ectopic ureter is defined as one which distally enters the genitourinary tract in any location other than the trigone of the bladder. Ectopic ureters are the most common cause of urinary tract infection in young dogs. Breeds reported to be at risk include the Golden Retriever, Labrador Retriever, Siberian Husky, Newfoundland, and English Bulldog. The condition should be considered heritable. Ectopic ureters are uncommon in male dogs and, if present, these animals often do not have clinical signs. This fact could be due to the increased length of the urethra in male dogs. Ectopic ureters are extremely rare in cats. Ectopic ureters can be intramural (tunnel along the bladder wall) or extramural (independent of the bladder wall) with the former being far more common in dogs.

A diagnosis of ectopia can be made by excretory urography, fluoroscopic urethrography or ureterography, abdominal ultrasonography, cystoscopy, helical computed tomography, or a combination of these diagnostic procedures. Other congenital abnormalities can also occur in dogs with ectopic ureters, including but not limited to renal agenesis or dysplasia, and hydronephrosis and/or hydroureter; therefore, it is essential to evaluate the entire urinary system using ultrasonography if cystoscopy is the only other diagnostic utilized before surgery. Accompanying urethral sphincter mechanism anomalies are commonly present in dogs with ectopia, making the prognosis for complete resolution of incontinence after resolution of the ectopic ureter guarded. Visualization of a nonvascular fluid-filled structure with a hyperechoic wall passing dorsal to the urinary bladder or obvious insertion of the structure into the proximal urethra suggest the diagnosis (Fig. 57.28, *A*, 57.28, *B*). Visualization of distinct ureteral walls, which contain smooth muscle and display pulsatile motion, supports ureteral abnormalcy such as ectopia (Video 57.3). Hydroureter and hydronephrosis can eventually result from an uncorrected ectopic ureter due to flow impedance at the abnormal site of insertion (Fig. 57.28, *C*). Urinary tract infection is commonly associated with ectopia due to urinary stasis in part of the tract and, if not detected and treated, can progress to pyelonephritis and ureteritis causing permanent

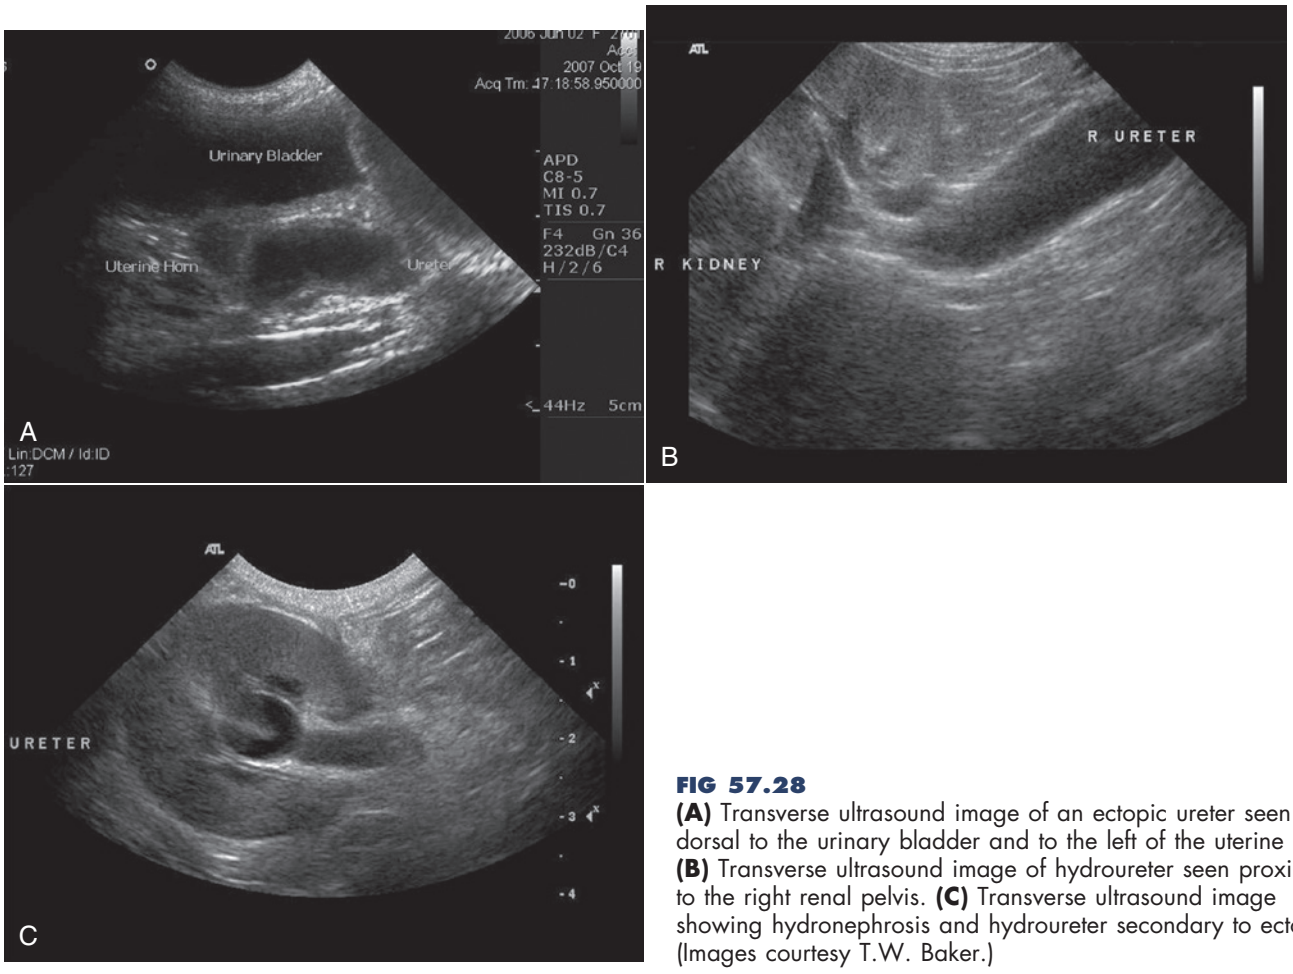

FIG 57.28

(Images courtesy T.W. Baker.)

damage to the urinary tract. Traditionally, treatment for dogs with ureteral ectopia is surgical correction (revision), and postoperative success rates vary between 50% to 75%. It has been reported that dogs weighing <20 kg have a better outcome postoperatively. Minimally invasive therapies have also been utilized in dogs with ectopic ureters such as cystoscopic-guided laser ablation for the ectopic ureter (Fig. 57.29, Video 57.4). Nephrectomy is reserved for advanced cases with irreversible renal damage ipsilaterally and normal function contralaterally, or cases with severe financial constraints. Removal of affected individuals from breeding programs and avoidance of similar pedigrees in breeding should always be discussed with the owners. Ongoing studies exist evaluating the mode of inheritance. Postoperative persistent incontinence can be managed in many cases pharmacologically with the α-adrenergic stimulant phenylpropanolamine (1.0-1.5 mg/kg PO q8-12h), or estrogen compounds that increase sensitivity of α-adrenergic receptors in the urethra (compounded diethylstilbestrol, DES, at 0.02 mg/kg PO tapered to 1-3 times weekly or estriol (Incurin [Merck] 2 mg PO daily for 14d then tapered). Time-released phenylpropanolamine is more effective than short-acting phenylpropanolamine in refractory cases of incontinence. Combination therapy with phenylpropanolamine and an estrogen compound can be superior if either fails when used as a single agent. Gonadotropin-releasing hormone (GnRH) analogues recently have been shown to improve continence in ovariectomized female dogs, most likely through interaction with GnRH, FSH, and LH receptors in the lower genitourinary tract (Reichler et al., 2003). A postoperative urine culture should always be determined before assuming that persistent incontinence is due to residual anatomic abnormalities.

Female puppies presented with mucopurulent vulvar discharge should be evaluated for the benign condition called "puppy vaginitis", a misnomer as it is not an inflammatory condition. The discharge can be accompanied by mild perivulvar dermatitis. The puppy is not typically attentive to the discharge, and there is not any associated change in urinary behavior (dysuria or polakiura). Clients often have a difficult time deciding if a puppy has normal urinary behavior or not. The age of onset ranges from 6 weeks to puberty, the duration runs days to months, and the disorder is often intermittent. Cytologic examination of the discharge is suppurative. Vaginal cultures (aerobic) generally fail to grow anything but normal flora in small mixed numbers. Similar organisms could be cultured from a littermate without signs. A urinalysis, acquired by cystocentesis, is characteristically normal (a decreased urine specific gravity is typical for young dogs lacking adult concentrating abilities), and urine culture, if performed, is negative. The clinician needs to perform enough diagnostics to rule out more significant causes of vulvar discharge and feel comfortable with the diagnosis of benign puppy vaginitis. Important rule-outs (some of which are associated with inflammation) include urinary tract infection, urine scalding, perivulvar dermatitis, redundant dorsal vulvar folds, the onset of the initial estrous cycle, vaginal foreign bodies (i.e., foxtails), and urogenital anatomic anomalies (ectopia, disorders of sexual differentiation, significant strictures distal to the urethral papilla). The specific etiology of puppy vaginitis is unknown. An imbalance of juvenile vaginal glandular epithelium is postulated. The condition is reported in the literature to resolve both with puberty and with ovariohysterectomy, two very different events endocrinologically, therefore neither is likely to truly cause resolution. Puppy vaginitis diminishes with maturity. Cleansing the perivulvar area with gentle antiseptic wipes is advised. There is no association between puppy vaginitis and adult chronic vaginitis or urinary incontinence postovariohysterectomy.

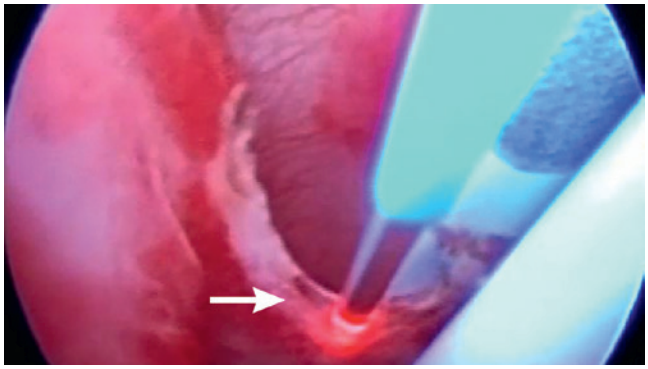

FIG 57.29
Laser ablation (*arrow*) of the bladder mucosa creating an opening for an intramural ectopic ureter.

Gastrointestinal Disorders

Pediatric patients should be presumptively dewormed at 2, 4, and 6 weeks of age for parasites (roundworms) acquired via transplacental transmission. In endemic regions, *Neospora caninum,* Babesiosis, Leishmaniasis, and Dirofilarial microfilariae can also be transmitted transplacentally. Transmammary transmission and environmental contamination with parasites can continue postpartum. Repeated deworming (every 2 weeks) is required because of this and because of the parasites' life cycles. Fecal evaluation should follow completion of routine anthelmintics at 7 to 8 weeks of age, usually when the puppy has been transferred to its new owner and veterinarian. Abnormal stools at any age should prompt a fecal parasite evaluation. Clinically significant endoparasitisms of young dogs and cats include roundworms (*Toxocara canis, Toxocara cati, Toxascaris leonina),* hookworms *(Ancylostoma caninum, Ancylostoma tubeforme, Uncinaria stenocephala),* tapeworms *(Dipylidium caninum, Echinococcus granulosus, Taenia spp.), Strongyloides stercoralis*, and protozoal organisms such as coccidia (*Isospora spp*.), *Cryptosporidium parvum*, and *Giardia sp*. Clinical signs are variable and range from asymptomatic to life-threatening; most common clinical signs include diarrhea, weight loss, or failure to gain. *Ancylostoma caninum* can be associated with severe hemorrhagic enteritis and anemia in puppies. Diagnosis of endoparasitic infestations is most commonly made by fecal flotation, and centrifugation techniques may improve

diagnostic accuracy. *Strongyloides stercoralis* may be demonstrated by either the Baermann flotation technique or observation of larvae in fresh fecal smears. Giardia infections can be diagnosed by observation of motile trophozoites in fresh fecal smears or by detection of cysts using a zinc sulfate fecal flotation; however, a more recently developed fecal ELISA test that detects Giardia antigen is the preferred diagnostic test.

Parasitic infections also reach pathogenic levels in kittens in the first month of life. Coccidia infection, which may be inapparent in adults, can cause severe diarrhea and malnutrition, resulting in rapid weight loss, hypoglycemia, and dehydration. Coccidia are highly contagious and survive in the environment despite extensive decontamination efforts. Coccidia infection is readily diagnosed by fecal floatation and should be considered in kittens that develop diarrhea in this age range or older. Treatment is with sulfadimethoxine (50 mg/kg PO first day, then 25 mg/kg PO every day for 5-20 days until asymptomatic and fecal flotation negative), which is coccidiostatic, not coccidiocidal. Recovery from coccidia infection requires an intact immune response, so treatment failures can often be traced to concurrent immunosuppressive conditions such as malnutrition, overcrowding, and poor hygiene. If coccidiosis is diagnosed in a group of cats, all of the animals should be treated. Ascariasis (round worms) also becomes significant in this age group, and large worm burdens can lead to malnutrition and poor growth.

Because maternally acquired ascaridiasis is so common, all puppies and kittens should receive routine deworming treatments with pyrantel pamoate (10 mg/kg orally, repeated in 2 weeks), regardless of fecal test results. Control of many helminth infections can be easily accomplished by monthly administration of combined anthelmintic and heartworm preventative, for example, ivermectin plus pyrantel pamoate. Treatment of Dipylidium infections must include adequate flea control as well as an appropriate anthelmintic such as praziquantel. Coccidial infections are treated with sulfa-containing drugs such as sulfadimethoxine or trimethoprim sulfa; although very frequently diagnosed and treated in the clinical setting, most canine coccidial infections are likely self-limiting. Fenbendazole is the recommended treatment for Giardia infection (50 mg/kg PO q24h for 3-7 days); although metronidazole is commonly used, it is proven less effective than fenbendazole and has greater potential for side effects in immature animals. A Giardia vaccine is also available, and it has been suggested that it may be effective in clearing refractory infections; however vaccination against Giardia failed to decrease incidence of diarrhea associated with giardiasis in one field study (Payne et al., 2002).

Diarrhea not associated with endoparasitism is not uncommon in pediatric patients after weaning; overfeeding with consequential bacterial overgrowth syndrome is the most common cause. Decreasing the amount fed, sometimes with a short course of antibiotics (amoxicillin), is effective. Infectious agents associated with diarrhea in young dogs and cats are typically either bacterial or viral. Viral infections in dogs include *canine parvovirus, canine distemper, coronavirus,* and *rotavirus,* whereas *parvovirus (Feline Panleukopenia), coronavirus,* and *retroviruses (FeLV, FIV)* are important in young cats. Bacterial organisms responsible for neonatal diarrhea can include *Salmonella spp., Escherichia coli, Clostridium spp., Yersinia enterocolitica,* and *Campylobacter spp*. Diagnosis in most patients is usually uncomplicated, and is based on typical clinical signs, serology, or demonstration of virus in feces, or specialized fecal cultures for certain bacterial organisms. It is often best to run tests for these disorders at the same time through the use of a "fecal diagnostics panel" now available at many commercial laboratories. A single fecal sample is submitted to the lab, and tests for each of these disorders are done at the same time (commonly immunologic tests and PCR tests) (see Chapter 27).

Several breeds of dogs have a reported genetic predilection to small intestinal disease. Normally, the small bowel appears sonographically as four distinct layers (Fig. 57.30, *A*, 57.30, *B*). The bowel lumen is hyperechoic, as gas and ingesta are compressed. The layer just outside the lumen is the mucosa; it is hypoechoic and normally the thickest appearing section. Outside the mucosa is the submucosa; it is hyperechoic to the mucosa and about one third the thickness. The muscularis, the bowel muscle layer, is outside of the submucosa and appears as a very thin hypoechoic black line. Reactive mesenteric lymph node enlargement is common in puppies (Fig. 57.30, *C*) An immunoproliferative enteropathy is seen in the Basenji breed, which is characterized by lymphangectasia, intermittent diarrhea, weight loss, hypoalbuminemia and hyperglobulinemia, and lymphoplasmacytic mucosal infiltrates throughout the gastrointestinal tract. Histopathology is diagnostic; however, abdominal ultrasonography can identify bowel in which disruption of the normal layering has occurred. Chinese Sharpei dogs have been identified with a lymphoplasmacytic-eosinophilic infiltrative enteropathy characterized by poor weight gain, weight loss, or intermittent diarrhea episodes, with onset of signs typically between 2 to 6 months of age. Infiltrative enteropathies can be characterized ultrasonographically as having changes in the normal bowel wall layering.

PSS are congenital malformations of the hepatic portal venous drainage system and can have either a familial (i.e., genetic) or random occurrence. Congenital PSS can be either intrahepatic or extrahepatic; breed predilections for extrahepatic shunts include Yorkshire Terrier, Maltese, Poodle, Miniature Schnauzer, Dachshund, Lhasa Apso, Pekingese, Pug, and Shih Tzu, whereas intrahepatic shunts are more commonly identified in large breed dogs such as Golden Retrievers, German Shepherds, Irish Wolfhounds, Irish Setters, and Samoyeds. PSS are uncommon in cats. Ultrasonography provides a rapid and noninvasive method for screening patients suspected to have congenital PSS. It is noninvasive and requires no anesthesia, however diagnostic accuracy is highly operator-dependent, and the PSS will be confirmed in only approximately 60% to 80% of cases. The liver may be small and difficult to image in patients with congenital PSS. Imaging the liver from the standard ventral approach can be

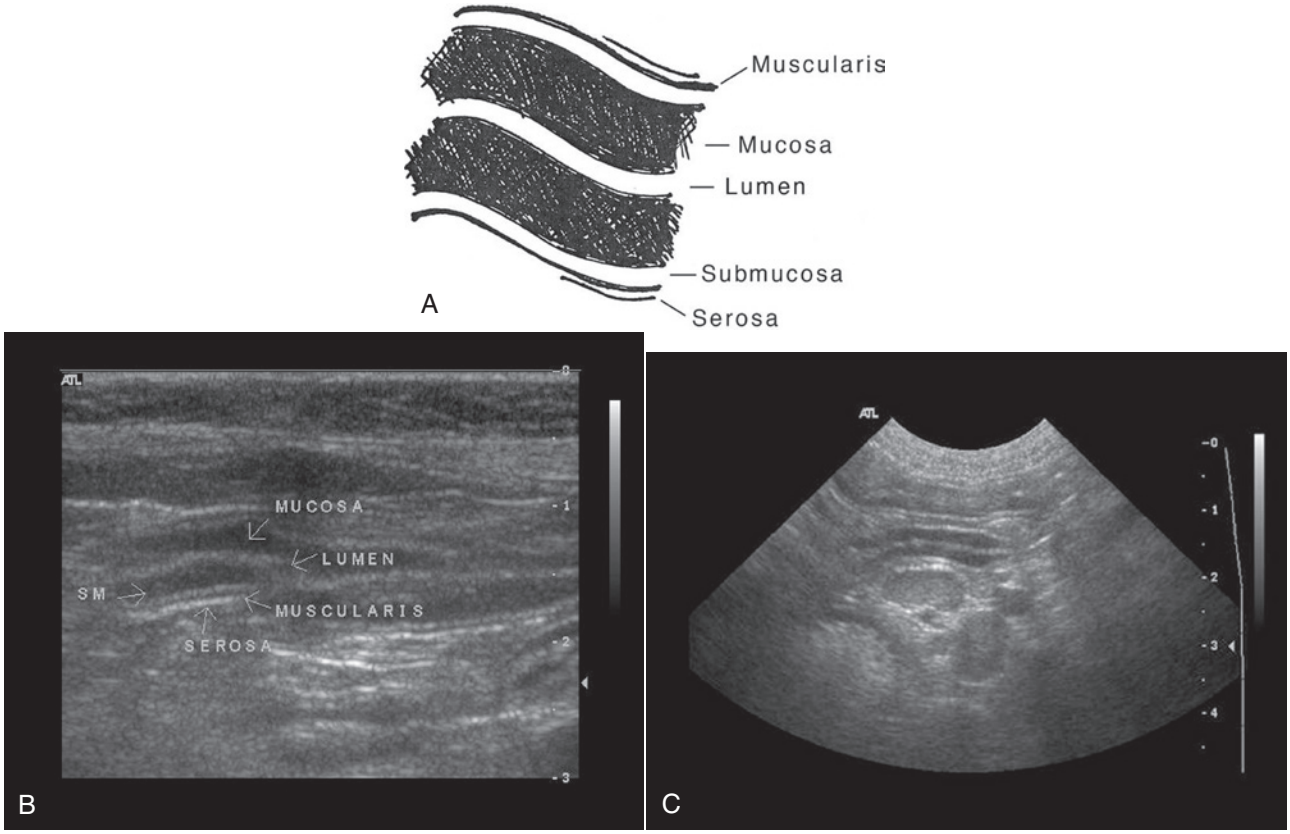

FIG 57.30
(A) Schematic of normal small bowel wall layering. The normal mucosa is the thickest layer, the submucosa less thick, and the muscularis thinner; the serosa is the thinnest layer. **(B)** Sagittal ultrasound image of small bowel with thick (normal) mucosa, less thick submucosa (SM), thin muscularis, and thinner bright serosa. **(C)** Transverse ultrasound image of sublumbar lymph nodes in the pediatric dog. Note the nodes have homogenous parenchyma and would be considered normal. (Courtesy T.W. Baker.)

improved in some cases by using the left ventral intercostal and right dorsal intercostal approaches (Fig. 57.31, *A*, 57.31, *B*, Video 57.5). The presence of ascites can facilitate the study, as can adding fluid to the stomach and positioning the patient to shift gas away from the scan head and shift abdominal organs caudally. Although scintigraphy (transcolonic portal scintigraphy or transplenic portography) is considered the most reliable noninvasive method of documenting a PSS, its availability is limited to specialty and university practices, and its use dictates special handling of the radioactive patient for at least 12 hours. Mesenteric portography, although more invasive and requiring general anesthesia, is a highly reliable method of confirming and localizing a PSS. Management is dictated by the shunt characteristics (see Chapter 27).

Intussusception is not uncommon in young dogs and cats, occurring most frequently at the ileocecocolic junction in dogs and in the jejunum in cats. Pediatric patients are prone to intussusception because they lack the intrinsic enteric neural mechanisms for aboral motility present in adult animals; instead, gastrointestinal motility is pressure-dependent and based on the sequential ingestion of food. Fasting or vomiting result in ileus and increase the risk of intussusception.

The classic transverse ultrasonographic appearance of intussusception is a multilayered series of concentric rings representing the invaginated bowel wall layers; the outer layer can be edematous (hypoechoic) and the inner layers more normal in appearance (Fig. 57.32, *A*, 57.32, *B*, 57.32, *C*, Video 57.6) Discomfort is typically displayed with abdominal palpation or when scan head pressure is placed over the affected area of bowel. Doppler evaluation of the bowel and associated mesenteric vessels can provide information about bowel viability. Serial examinations are important when evaluating the pediatric patient with a palpable abdominal mass, unanticipated clinical deterioration, or increased abdominal pain. If an intussusception is diagnosed in the pediatric veterinary patient in a timely fashion, reduction rather than resection might be possible.

Neurologic Disorders

Neonatal neurologic disorders can be inherited, or can result from intrauterine teratogens or trauma during parturition. Cerebral damage from resuscitation has been reported (see

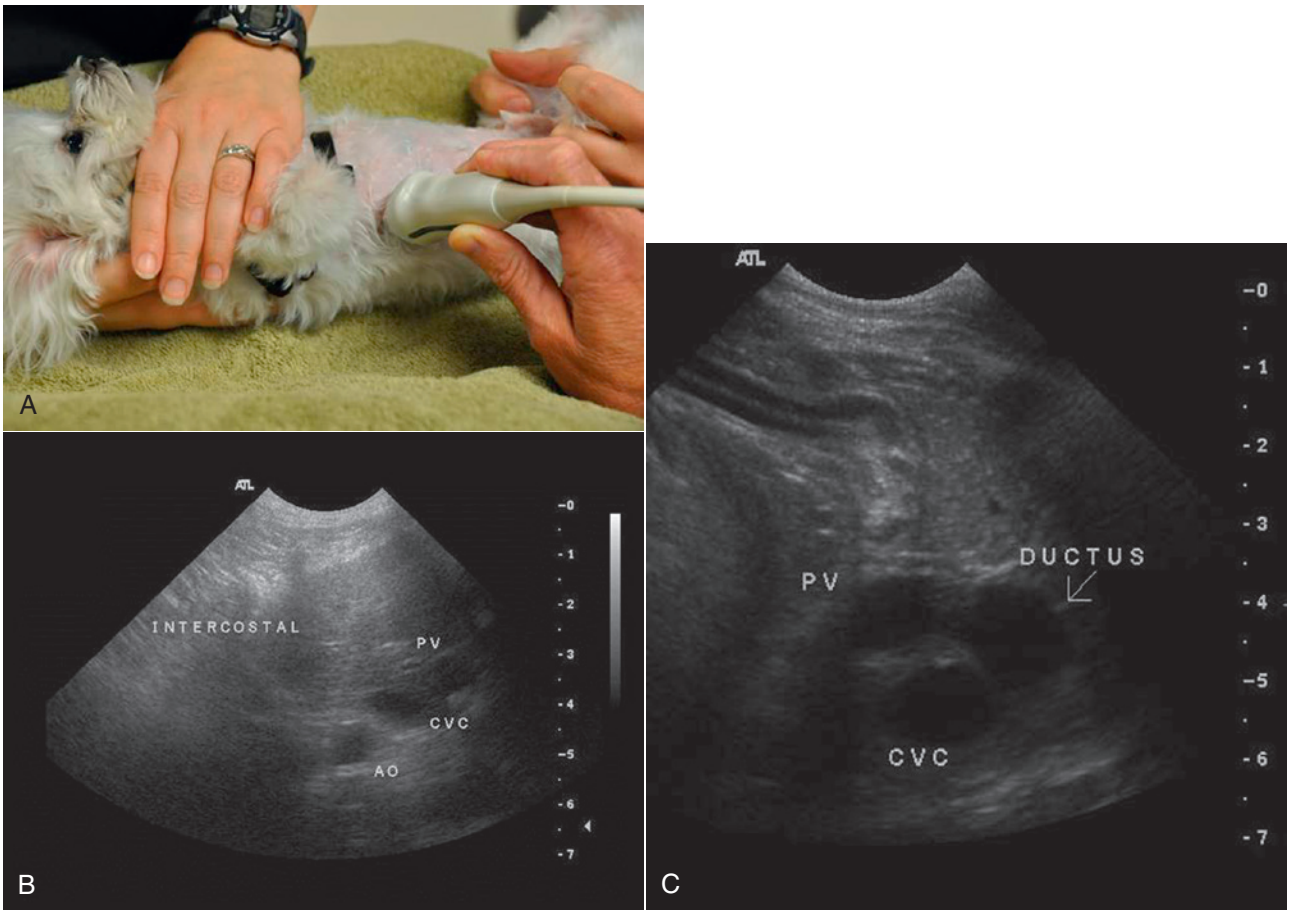

FIG 57.31
(A) Right dorsal intercostal approach to the portal triad, helpful in evaluation of small puppies for portosystemic abnormalities. **(B)** Intercostal ultrasound image showing stacking of vessels; normal anatomy. *AO*, Aorta; *CVC*, caudal vena cava; *PV*, portal vein. **(C)** Intrahepatic portosystemic shunt *(arrow)*. neonatal resuscitation earlier) (Grundy et al., 2009). The normal neurologic examination of the pediatric canine has been reported (Lavely, 2006). Weak or ataxic ambulation can indicate a neurologic or musculoskeletal abnormality. Morphologic neurologic abnormalities occur most frequently. Hydrocephalus has an increased frequency in toy and brachycephalic breeds, and can occur in cats. A domed calvarium, open fontanelle, and prominent suture lines are often present. Aqueduct atresia, birth trauma, or meningoencephalitis can cause the development of hydrocephalus. Clinical signs vary from inapparent to progressively debilitating. Ultrasound, possible through the open fontanelle typical of brachycephalics, can confirm the presence of excessive cerebrospinal fluid within the ventricles (Fig. 57.33, *A*, 57.33, *B*). Cranial and spinal dysraphism occur secondary to embryologic defects in neural tube closure. The presence of resultant neurologic defects generally warrants euthanasia. Vertebral anomalies include hemivertebrae, fused vertebrae, and butterfly vertebrae, and are usually subclinical unless spinal cord compression occurs. Cerebellar hypoplasia and abiotrophy cause truncal ataxia, hypermetria, and intention tremor at the onset of ambulation. Abiotrophy is progressively debilitating and may occur with lissencephaly. Dysmyelination and hypomyelination of the central nervous system cause tremors with onset by 1 to 2 weeks of age.

Ophthalmologic Disorders

Ocular anomalies account for 15% of all congenital defects in puppies and 9% in kittens. Eyelid agenesis occurs most commonly in kittens and is apparent at birth. Neonatal ophthalmia becomes apparent before the eyelids separate at 10 to 14 days of life (see Fig. 57.19). Bacterial infection is most likely in puppies, viral (Herpes, chlamydia) in kittens. Treatment includes gentle manual separation of the lids and topical triple antibiotic ointment (erythromycin in kittens). Microphthalmos, enophthalmos, strabismus, distichiasis, and entropion become apparent after the eyelids separate. Temporary eyelid tacking (puppy <4 months of age) with 2 to 4 vertical mattress sutures can preclude or postpone surgical correction of entropion. Congenital cataracts can be genetic, secondary to in utero conditions (drugs, toxins, nutritional), and amino acid deficiencies in artificial milk products. Epiphora can be secondary to increased lacrimation from ocular irritation or imperforate or stenotic nasolacrimal puncta. Medial canthal trichiasis causes wicking of tears onto the facial folds; this is also recognized with shallow lacrimal space seen in brachycephalic breeds. Keratoconjunctivitis sicca can be congenital in some breeds (Yorkshire Terrier) or secondary to canine distemper virus and herpesvirus in kittens. Prolapse of the third eyelid gland occurs in brachycephalic dogs and the Burmese cat; preservation of tear production is accomplished by anchoring the gland in place rather than excising it. Congenital disorders of metabolism can result in corneal opacities.

Dermatologic Disorders

Juvenile cellulitis is a progressive granulomatous pustular disorder of puppies. Immunosuppression is indicated for resolution and prevention of severe cicatricial lesions. It is most common in dogs younger than 4 months of age but is occasionally reported in dogs up to 4 years old. The eyelids, pinnae, lips, chin, muzzle, paws, abdomen, thorax, vulva, prepuce, and anus can be affected with lesions that fistulate, drain, and crust (Fig. 57.34, *A*, 57.34, *B*). Lymphadenomegaly, most commonly mandibular and superficial cervical, can be distant from the affected skin sites and is often painful

(Fig. 57.34, *C*). Pustules and lymph nodes are usually sterile when cultured. Superficial cutaneous flora can be cultured from open, draining lesions. Pyrexia, anorexia, sterile suppurative painful polyarthritis, and an inflammatory hemogram can occur. The diagnosis is confirmed by histopathologic evaluation but is commonly made on the basis of clinical appearance. Therapy consists of immunosuppression, most commonly with prednisone, which is tapered once lesions are resolved. Inadequate immunosuppression results in persistence of lesions and increased chance of permanent cicatricial lesions (Fig. 57.34, *D*). Griseofulvin (30 mg/kg PO bid) can be used as adjunctive therapy due to its immunomodulatory effects, permitting earlier tapering of corticosteroids (Shibata et al., 2004). Concurrent use of antibiotics effective against cutaneous organisms (Clavamox, cephalexin) is common. Vaccination during immunosuppression is debatable; strict hygiene should be emphasized and immunization is best accomplished once immunosuppressants are discontinued.

Endocrinologic

Congenital hypothyroidism is an uncommon disorder that can be recognized by the physical stature of 3- to 4-week-old puppies who appear as disproportionate dwarfs as compared with normal littermates, resulting from epiphyseal dysgenesis (Fig. 57.35, *A*). Persistence of deciduous dentition beyond expected teething (>12-16 weeks) can also be observed along with macroglossia (Fig. 57.35, *B*). Congenital hypothyroidism results from thyroid gland aplasia, hypoplasia, ectopia, or dyshormonogenesis most commonly. Early diagnosis is confirmed with a complete thyroid panel (TT4, fT4ED, cTSH); note that normal puppies aged 5 to 6 weeks of age have serum total thyroxine concentrations 2 to 3 times higher than adults. cTSH will differentiate between primary (elevated cTSH) and secondary (TSH deficiency) hypothyroidism. Hypercholesterolemia, hypercalcemia, and nonregenerative anemia can be present as a consequence of hypothyroidism. Replacement therapy (L-thyroxine 22-44 µg/kg

FIG 57.34

q12-24h) permits these puppies to attain normal size and mental development.

Juvenile diabetes, insulin deficient, is characterized by poor weight gain, polyuria, polydipsia, and polyphagia. Dogs usually present between 3-6 months of age with emaciation, dehydraton, and sometimes decreased vision secondary to cataract formation. A genetic basis is suspected in the Keeshonden; predisposed breeds include Puliks, Cairn Terriers, Miniature Pinschers, Standard Poodles, Miniature Schnauzers, Dachshunds, and Beagles. Insulin therapy is challenging because rapid growth causes changing insulin requirements; a combination of long-acting and regular insulin can be useful. A growth formulated diet should be fed rather than a high-fiber diet. Exocrine pancreatic deficiency can be a comorbidity. Familial in some breeds, it is usually of later juvenile onset, typified by poor weight gain, polyphagia, and abnormal stools. The diagnosis is confirmed with a TLI screen.

Juvenile pituitary disorders include congenital central diabetes insipidus and pituitary dwarfism. Central diabetes insipidus is characterized by profound polyuria and polydipsia (>100 mL/kg/day), poor housebreaking, nocturia, weight loss, and dehydration. Urine is persistently dilute (SG 1.004-1.012). Diagnostics include the modified water deprivation test or preferably (safer) the response to antidiuretic hormone supplementation. Hypoplasia of the pituitary gland causes proportionate dwarfism, infantile genitalia, delayed dental eruption, and mental retardation. The disorder is inherited as a simple recessive trait in the German Shepherd Dog. The diagnosis is made based on somatomedin C (insulin-like growth factor 1) measurement. Concurrent decreased production of other pituitary hormones can exist (thyroid stimulating hormone, adrenocorticotropic hormone, luteinizing hormone, follicle-stimulating hormone).

FIG 57.36
Facial angioedema in a 9-week-old Labrador Retriever puppy; type II hypersensitivity to vaccination.

Pediatric Vaccination

Pediatric dogs and cats should initiate vaccination at 6 to 8 weeks of age (canine DA2P ±P, feline FVRCP/FeLV), with boosters every 3 to 4 weeks until 16+ weeks of age. In dogs, vaccination with leptospirosis serovars should be added at the last two puppy vaccinations if exposure (water activity) warrants it. Pediatric dogs and cats can experience acute (type I) and delayed (type II) hypersensitivity reactions to vaccination (Fig. 57.36). These core vaccinations are repeated a year later, then at 3-year intervals until middle age. Leptospirosis, a bacterin, is an annual booster. Rabies is given at 16+ weeks of age. Additional noncore vaccination for bordetella, borreliosis, and influenza are based on exposure/geography and lifestyle.

PART NINE · Nervous System and Neuromuscular Disorders

Susan M. Taylor

CHAPTER 58

Lesion Localization and the Neurologic Examination

FUNCTIONAL ANATOMY OF THE NERVOUS SYSTEM AND LESION LOCALIZATION

Understanding nervous system structure and function allows correct interpretation of neurologic examination findings and localization of lesions to clinically significant regions of the brain, spinal cord, or neuromuscular system. Establishing an accurate neuroanatomic diagnosis is an important early step in the diagnostic evaluation of dogs and cats with neurologic signs (Box 58.1).

BRAIN

The brain consists of the cerebrum, the brainstem, and the cerebellum. The brainstem is further subdivided from rostral to caudal into the diencephalon (thalamus and hypothalamus), midbrain, pons, and medulla oblongata (Fig. 58.1). Neurologic abnormalities within the brain can usually be localized on the basis of clinical findings to one of three clinically important regions. These include (1) the forebrain (cerebrum and diencephalon), (2) the pons and medulla, and (3) the cerebellum (Box 58.2).

Forebrain

The forebrain includes the cerebral cortex, cerebral white matter, basal nuclei, and diencephalon. The cerebral cortex is important for behavior, vision, hearing, fine motor activity, and conscious perception of touch, pain, temperature, and body position (proprioception). Cerebral white matter transmits ascending sensory information and descending motor signals, and the basal nuclei are involved in maintaining muscle tone and initiating and controlling voluntary motor activity. Animals with unilateral cerebral cortex lesions usually have a relatively normal gait but mild postural reaction deficits (see discussion of postural reactions, p. 1046) and increased muscle tone in limbs on the contralateral (opposite) side of the body. There may also be contralateral loss of vision and decreased skin sensation (hypalgesia) that is most noticeable on the mucosa of the nasal septum.

The diencephalon includes the thalamus and hypothalamus, and is located deep in the brain underneath the cerebrum and above the pituitary gland, The thalamus is important in the organization and integration of sensory input and maintenance of consciousness and alertness. The hypothalamus is located ventral to the thalamus and controls autonomic and endocrine functions such as appetite, thirst, body temperature, and electrolyte and water balance, linking the nervous system to the endocrine system via the pituitary gland. The olfactory nerve, cranial nerve 1 (CN1), projects onto the hypothalamus, and the optic nerve (CN2) and optic chiasm are on the ventral surface of the hypothalamus so lesions in this region can result in loss of the sense of smell or contralateral visual deficits with normal pupillary light reflexes. Neurologic examination findings associated with forebrain lesions are listed in Box 58.3.

Pons and Medulla

The pons and medulla comprise the portion of the brainstem that contains the regulatory centers for consciousness (ascending reticular activating system) and normal respiration. This area provides a link between the spinal cord and cerebral cortex through ascending sensory and descending motor tracts. These tracts cross in the rostral midbrain, such that although unilateral forebrain lesions result in mild contralateral limb deficits, unilateral lesions of the pons, medulla, or cervical spinal cord cause much more significant ipsilateral (same-sided) spastic paresis, ataxia, and postural reaction deficits. Ten pairs of cranial nerves (3 to 12) also originate in this region, with lesions causing motor or sensory dysfunction of individual nerves. Because vestibular nuclei are located in the medulla as well as in the flocculonodular lobe of the cerebellum, lesions in this region of the brainstem commonly result in head tilt, disequilibrium, and nystagmus (see Chapter 63). Box 58.3 lists

BOX 58.1

Steps in Neurologic Diagnosis

1. Describe the neurologic abnormalities.
2. Localize the lesion.
3. Describe any concurrent nonneurologic disease.
4. Characterize the onset and progression of the neurologic disease.
5. Generate a list of differential diagnoses.
6. Use ancillary tests, if needed, to make a diagnosis and gauge the prognosis.

BOX 58.3

Signs Caused by Lesions in the Brain

Forebrain Lesions

Seizures
Altered mentation: depression, stupor, coma
Abnormal behavior: agitation, delirium, aggression, loss of learned behaviors
Contralateral:
- Blindness with normal pupillary light reflexes
- Subtle decrease in skin/facial sensation
- Hemi-inattention syndrome

Normal gait
Circling, pacing towards lesion
±Postural reaction deficits in contralateral limbs
Normal or increased (contralateral) spinal reflexes

Brainstem Lesions

Altered mentation: depression, stupor, coma
Multiple cranial nerve deficits (CN3-CN12, ipsilateral)
Upper motor neuron tetraparesis or hemiparesis (ipsilateral)
Postural reaction deficits in ipsilateral limbs
Normal or increased (ipsilateral) spinal reflexes
Respiratory and cardiac abnormalities

Cerebellar Lesions

Normal mentation
Ipsilateral menace deficit ±
Intention tremor
Hypermetric gait, truncal ataxia with normal strength
Normal knuckling and hopping (hypermetric ipsilateral)
Normal spinal reflexes
Possible paradoxical vestibular syndrome

common neurologic examination abnormalities in patients with lesions of the pons and medulla.

Cerebellum

The cerebellum controls the rate, range, and force of movements. It serves to coordinate muscular activity, regulate fine movement, and modulate muscle tone. Lesions of the cerebellum result in a wide-based stance, ataxia (incoordination) with normal strength and normal postural reactions, and increased muscle tone (spasticity). The gait is hypermetric or exaggerated, with each limb being raised excessively during protraction and then returned more forcefully than normal to weight bearing. Cerebellar lesions may also result in a fine tremor of the head that becomes more pronounced during voluntary movement such as reaching for food (intention tremor). Central vestibular nuclei and pathways are located in the flocculonodular lobe of the cerebellum and in the caudal cerebellar peduncle so that lesions of these regions commonly produce vestibular signs including head tilt, ataxia, and nystagmus. Cerebellar lesions commonly cause paradoxical vestibular syndrome, where the head tilt is

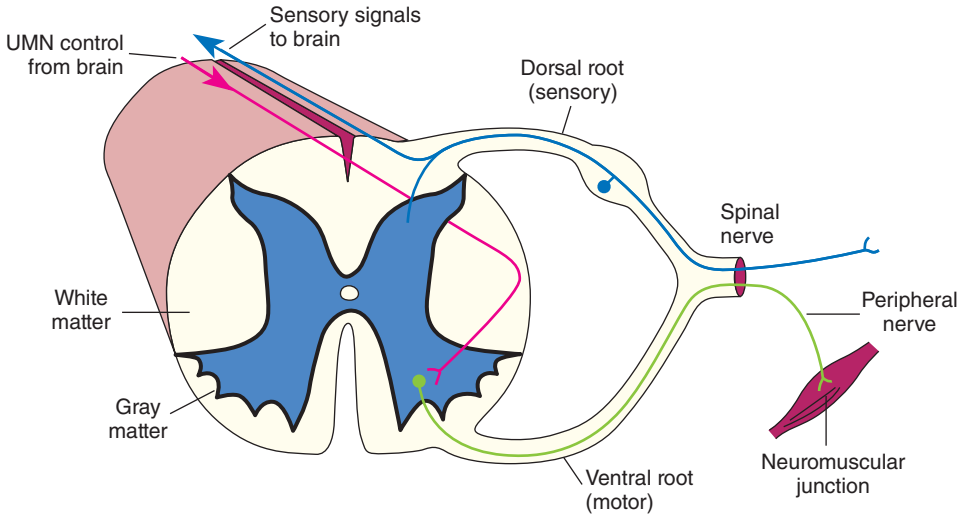

FIG 58.2
A single spinal cord segment.

directed towards the side opposite the lesion (see Vestibular disease, Chapter 63). Severe lesions of the rostral cerebellum may result in opisthotonus with rigid extension of all four limbs with flexed hips (decerebellate posture) (see the discussion of posture, p. 1043). Box 58.3 lists the clinical signs caused by lesions of the cerebellum. Causes of cerebellar dysfunction are discussed with other intracranial disorders in Chapter 60.

SPINAL CORD

The spinal cord resides entirely within the bony vertebral column. It is composed of a central H-shaped core of gray matter surrounded by white matter. Spinal cord gray matter contains the cell bodies of interneurons and lower motor neurons (LMNs). White matter is composed of nerve fibers organized into columns of ascending and descending long tracts. These long tracts transmit ascending sensory information (proprioception, touch, temperature, pressure, and pain) and descending motor signals between higher centers in the brain and spinal cord neurons.

The spinal cord can be functionally divided into segments, with each spinal cord segment giving rise to one pair of spinal nerves (left and right), each of which has a dorsal (sensory) and ventral (motor) root (Fig. 58.2). The cell bodies for the LMNs supplying the thoracic limbs are in the ventral gray matter within a thickened region of the cord called the *cervical intumescence* (segments C6-T2), whereas the LMNs supplying the pelvic limbs originate in the *lumbar intumescence* (segments L4-S3; Fig. 58.3).

Lower Motor Neuron Signs

The LMN is the efferent neuron that directly connects the central nervous system (CNS) to a muscle or gland (Fig. 58.4). Components of LMNs include the nerve cell bodies within the ventral gray matter, the axons leaving the spinal canal as ventral nerve roots and spinal nerves, and the peripheral nerves formed by the spinal nerves that terminate at the neuromuscular junction (NMJ) in the muscle to

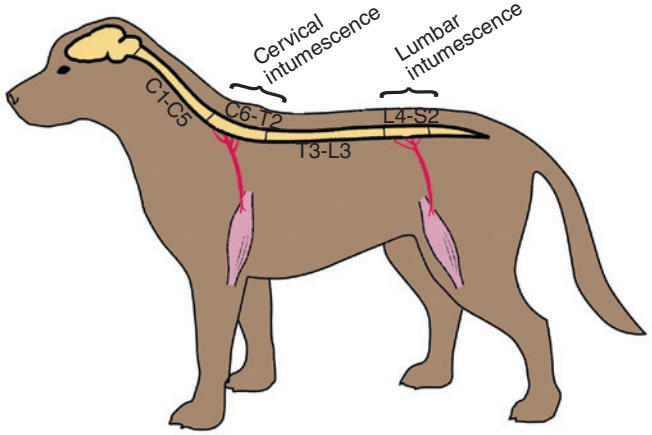

FIG 58.3
Spinal cord segments at the cervical intumescence (C6-T2) and the lumbar intumescence (L4-S3) give rise to the important peripheral nerves of the limbs.

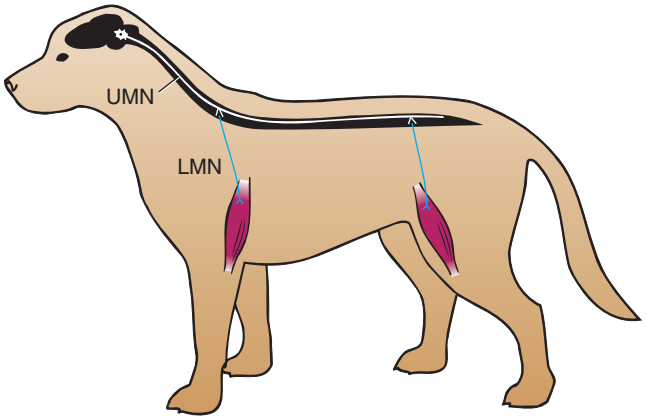

FIG 58.4
The upper motor neuron (UMN) and lower motor neuron (LMN) systems are responsible for mediating normal motor function.

produce contraction (see Fig. 58.2). Damage to any component of the LMN will result in the appearance of abnormalities called *LMN signs* in the muscles normally innervated by that particular LMN. LMN signs include flaccid paresis (weakness) or paralysis (loss of motor function), decreased or absent muscle tone, rapid muscle atrophy, and decreased or absent spinal reflexes (Table 58.1). Animals with LMN signs have a short-strided gait and usually normal postural reactions if their weight is supported. When there is severe damage to the sensory component of the LMN (peripheral nerve, spinal nerve, or dorsal nerve root), there may also be a loss of sensation in the skin and limb directly supplied by that LMN. Spinal cord lesions causing focal LMN signs are discussed in Chapter 65. Disorders affecting peripheral nerves and disorders causing diffuse LMN paralysis are discussed in Chapter 66.

Upper Motor Neuron Signs

Those motor systems originating in the brain to control the LMN are UMNs (see Fig. 58.4). UMNs are responsible for initiating and maintaining normal movement, regulating the muscle tone used to support the body against gravity, and inhibiting myotactic reflexes. Components of the UMN include ascending sensory tracts in the spinal cord and brainstem, nerve cell bodies in the cerebral cortex, basal nuclei, and brainstem as well as the descending motor tracts in the brainstem and spinal cord white matter, which relay information from the higher centers to the LMN. These pathways cross the midline in the rostral brainstem so that forebrain lesions result in contralateral deficits in the limbs, whereas UMN lesions of the spinal cord, pons, or medulla result in ipsilateral deficits in the limbs (Fig. 58.5). Damage to the UMN nuclei or tracts will cause loss of the ability to initiate movement and a release of the inhibitory effect of UMNs on all LMNs caudal to the level of injury. The resultant UMN signs in the limbs caudal to the site of the lesion include loss of voluntary movement (paralysis) or delayed limb movement when trying to walk or hop (UMN paresis), increased extensor muscle tone, and normal to increased spinal reflexes (see Table 58.1). Associated sensory signs such as ataxia (incoordination) and decreased sensation in the skin and limbs caudal to the lesion reflect interruption of the UMN sensory tracts responsible for mediating proprioception (position sense) and pain perception.

Spinal Cord Sensory Pathways

Sensory nerves that detect touch, temperature, and nociception (pain) are distributed to the surface of the body and limbs. There are also sensory nerves responsible for proprioception that originate in the skin, muscles, tendons, and joints. The nerve cell bodies of most of these sensory nerves are located in the ganglia of dorsal nerve roots entering the spinal cord (see Fig. 58.2). Sensory tracts responsible for mediating sensation and proprioception ascend the spinal

TABLE 58.1

Summary of Upper Motor Neuron and Lower Motor Neuron Signs

CHARACTERISTIC	UPPER MOTOR NEURON	LOWER MOTOR NEURON
Motor function	Spastic paresis to paralysis in all limbs caudal to lesion	Flaccid paresis or paralysis at site of lesion
Postural reactions (knuckling)	Often delayed	Normal unless severe lesion
Gait	Wide-based stance, ataxic, long strides, delayed limb protraction	Short strides, limbs maintained under center of gravity
Muscle tone	Normal or increased	Decreased
Muscle atrophy	Late and mild—disuse	Rapid and severe—neurogenic
Spinal reflexes	Normal or increased	Decreased or absent

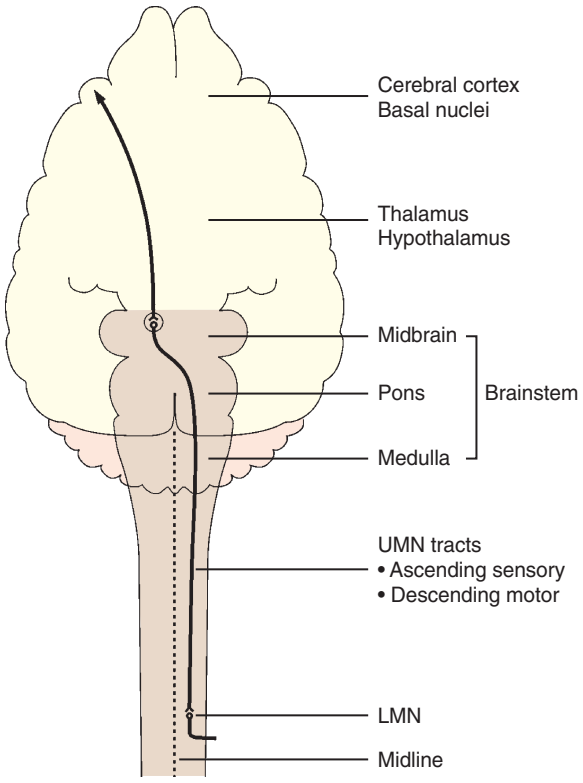

FIG 58.5
Ascending (sensory) and descending (motor) upper motor neuron pathways cross midline in the rostral brainstem.

cord and brainstem to the brain. Most of these tracts ascend the ipsilateral spinal cord and cross over in the rostral brainstem to reach the contralateral cerebrum (see Fig. 58.5). Patients with a unilateral forebrain lesion will typically experience hypalgesia (decreased sensation) in the limbs, trunk, and face on the opposite side. Damage to the sensory tracts in the spinal cord will disrupt the transmission of sensory and proprioceptive information to the brain (UMN), resulting in ataxia and loss of proprioception in all limbs caudal to the site of the lesion. With unilateral spinal cord lesions, the deficits will be ipsilateral. If UMN spinal cord lesions are severe, there may also be some loss of skin sensation caudal to the lesion. In addition to the sensory tracts responsible for relaying information to UMN centers regarding skin sensation and proprioception, there are multisynaptic, small-diameter, bilateral crossing tracts deep in the white matter of the spinal cord that project to the cerebral cortex and are involved in conscious perception of noxious stimuli (nociception, deep pain). The small diameter and deep location of these tracts make them very resistant to compressive injury, so loss of the ability to perceive a noxious stimulus (loss of deep pain perception) in the rear limbs of an animal with a compressive T3-L3 lesion usually indicates a very severe transverse spinal cord injury.

Loss of sensation caused by damage to spinal cord dorsal gray matter, dorsal nerve roots, or the sensory portion of a peripheral nerve allows a LMN lesion to be precisely localized by mapping where skin sensation has been lost. Compressive or irritative lesion of nerve roots or peripheral nerves will sometimes cause severe hyperesthesia (nerve pain) at the site.

Localizing Spinal Cord Lesions

After a neurologic examination, each limb should be characterized as normal or as having upper motor neuron (UMN) or LMN signs. This will allow localization of spinal cord lesions to one of four clinically important functional anatomic regions: spinal cord segments C1-C5, C6-T2, T3-L3, or L4-S3 (Box 58.4). Cervical (C1-C5) spinal cord lesions cause UMN signs in all limbs whereas C6-T2 lesions cause LMN signs in the forelimbs and UMN signs in the pelvic limbs. Animals with thoracolumbar (T3-L3) lesions have normal forelimbs and UMN signs in the pelvic limbs, and lumbosacral lesions cause LMN signs in the pelvic limbs.

Because the ascending and descending tracts to the rear limbs are located more superficially in the cord than the tracts supplying the forelimbs, it is common for dogs and cats with compressive lesions of the cervical (C1-C5) cord to have more pronounced UMN deficits in the rear limbs than in the forelimbs. In contrast, lesions such as hemorrhage, infarcts, or intramedullary neoplasms that preferentially affect the central regions of the spinal cord (*central cord syndrome*) cause unusual signs that can be explained by the location of ascending and descending spinal cord tracts. Lesions of the central spinal cord in the C1-C5 region spare the more superficially located UMN tracts to the pelvic limbs, resulting in UMN deficits only affecting the forelimbs with normal or only mildly affected (UMN) rear limbs. Central cord lesions in the C6-T2 region affect the centrally located LMNs in the intumescence, causing profound LMN deficits in the forelimbs with normal or only mild UMN deficits in the rear limbs.

BOX 58.4

NEUROMUSCULAR SYSTEM

Peripheral Nerves

The peripheral nervous system consists of 12 pairs of cranial nerves originating in the brainstem and 36 pairs of spinal nerves originating in the spinal cord. Nerve fibers from the spinal nerves in the cervical and lumbar intumescences form the peripheral nerves that innervate the muscles of the limbs. Spinal nerve or peripheral nerve lesions result in LMN motor signs in affected muscles and limbs and sometimes decreased, absent, or altered sensation. Box 58.5 lists the clinical signs caused by peripheral nerve lesions. Peripheral nerve disorders are discussed in Chapter 66.

Neuromuscular Junction

At the NMJ, electrical activity is transmitted from nerve axons to muscle fibers, resulting in muscular contraction. This process is mediated through the calcium-dependent release of the neurotransmitter acetylcholine (ACh) from the nerve terminal into the synaptic cleft. ACh diffuses across the synaptic cleft and binds to ACh receptors on the postsynaptic (muscle) membrane, inducing a conformational change and ion flux that result in muscular contraction. ACh

BOX 58.5

Signs Caused by Lesions in the Neuromuscular System

Peripheral Nerve Lesion: Signs Seen in Affected Limb/Muscle

Flaccid paresis/paralysis
Decreased to absent muscle tone
Rapid and severe muscle atrophy
Decreased or absent spinal reflexes
EMG suggests denervation
Skin sensation decreased or absent if sensory portion of nerve is affected
Abnormal proprioception/postural reactions if sensory portion of nerve is affected

Neuromuscular Junction Disorders: Signs Seen in All Limbs

Flaccid paresis/paralysis
Decreased to absent muscle tone
Decreased or absent spinal reflexes
EMG: decreased amplitude of muscle action potential
Normal postural reactions if able to move and weight is supported
Normal sensation
Myasthenia gravis (postsynaptic defect)
- Paresis, often exacerbated by exercise
- Normal postural reactions
- Normal muscle tone and size
- Normal spinal reflexes

Muscle atrophy, pain, or swelling ±
Normal postural reactions if weight is supported
Normal spinal reflexes
Normal skin sensation

EMG, Electromyography.

is then rapidly removed from the synapse by acetylcholinesterase (AChE), readying the synapse for the next nerve impulse. Disorders that interfere with ACh release or inactivation and disorders that alter postsynaptic cholinergic receptor function will adversely affect neuromuscular transmission. Presynaptic NMJ disorders causing decreased release of ACh result in flaccid tetraparesis and decreased spinal reflexes (see Box 58.5) similar to diffuse peripheral nerve disorders.

Myasthenia gravis (MG) is a postsynaptic disorder with reduction in the number of functional ACh receptors. The result is partial failure of NMJ transmission. Animals with MG have clinical signs that are more typical of a muscle disorder than an NMJ disorder, including exercise-induced weakness that improves with rest, normal muscle tone, and normal spinal reflexes (see Box 58.5). Disorders that interfere with AChE, the enzyme that normally inactivates ACh in the synapse, typically cause autonomic nervous system overstimulation and excessive muscle depolarization followed by neuromuscular weakness. Disorders of neuromuscular transmission are discussed in Chapter 66.

Muscle

Skeletal muscle functions to maintain body posture and produce movement. Generalized weakness (tetraparesis), a stiff and stilted gait, and exercise intolerance are common clinical features (see Box 58.5). Postural reactions and reflexes are typically normal. Some disorders cause muscle pain and muscle swelling, whereas others cause muscle atrophy and/or fibrosis. Muscle disorders are discussed in Chapter 67.

NEUROLOGIC CONTROL OF MICTURITION

Physiologic control of micturition is complex and integrated centrally. The pelvic nerve originates in sacral segments S1-S3 (in the L5-L6 vertebral bodies) and detects bladder fullness (stretching) and supplies parasympathetic innervation to the bladder, with stimulation causing detrusor muscle contraction, and bladder emptying. The striated skeletal muscle of the external urethral sphincter is under conscious and reflex control and is innervated by the pudendal nerve, also arising from sacral segments S1-S3. Sympathetic innervation to the bladder is supplied through the hypogastric nerves arising in the lumbar segments (L1-L4 segments in L1-3 vertebrae in dogs, L2-L5 segments in L2-4 vertebrae in cats). Sympathetic tone dominates during urine storage, causing detrusor muscle relaxation (β-adrenergic fibers) and contraction of the internal urethral sphincter (α-adrenergic fibers), allowing the bladder to distend with urine. As the bladder enlarges, sensory information from bladder wall stretch receptors is transmitted via the sensory portion of the pelvic nerve through ascending spinal cord pathways to the thalamus and cerebral cortex. When it is appropriate to void, impulses are sent from the cerebral cortex to the pons and then down the reticulospinal tract to the sacral spinal cord segments. Parasympathetic stimulation results in detrusor muscle contraction. There is normally simultaneous inhibition of α-adrenergic sympathetic tone in the internal urethral sphincter and somatic (pudendal) input to the external urethral sphincter, allowing urine to flow. Damage to any component of this complex system or the connection with UMN centers will result in disorders of micturition.

Sacral spinal cord, sacral nerve and nerve root lesions, and pelvic and pudendal nerve lesions result in urinary incontinence and a large bladder that is easily expressed and leaks continuously (LMN bladder). Perineal and bulbocavernosus reflexes are decreased or absent. The spinal nerves arising from the sacral spinal cord segments are most susceptible to compressive or traumatic injury at the lumbosacral junction.

Spinal cord lesions cranial to the sacral segments (cranial to the L5 vertebral body) may cause diminished voluntary control of urination and reflex hyperexcitability of the urethral sphincter. With relatively mild lesions a syndrome of detrusor-urethral dyssynergia may result, wherein

involuntary contraction of the urethral sphincter occurs during detrusor contraction, halting urine flow during voiding. UMN spinal cord lesions causing severe paresis or paralysis typically result in a bladder that is enlarged and very difficult or impossible to express manually (UMN bladder). Occasionally a reflex or automatic bladder will develop 5 to 10 days after acute UMN spinal cord injury, resulting in reflex detrusor contraction and spontaneous partial emptying of the bladder without cortical perception or voluntary control.

SCREENING NEUROLOGIC EXAMINATION

A screening neurologic examination takes only a few minutes (Box 58.6). Abnormalities of mentation, posture, and gait are initially evaluated. Postural reactions are then evaluated. If abnormalities are detected, evaluation of muscle tone, spinal reflexes, urinary tract function, and sensory perception aids in lesion localization. Finally, cranial nerves are evaluated, and if necessary, localization of a lesion within the brain is attempted.

MENTAL STATE

Owners should always be asked if they have noticed any changes in their pet's behavior, because subtle changes are often not apparent to the examiner. A decreased level of consciousness, such as depression or stupor (Table 58.2), may occur with a metabolic disturbance, systemic illness, or damage or disease affecting the cerebrum or brainstem. Coma almost always indicates a brainstem lesion. Delirium, confusion, or agitation suggests either cerebral cortical disease or a metabolic encephalopathy. Seizures occur with forebrain lesions or functional disturbances secondary to metabolic encephalopathies or intoxications. Aggression, compulsive pacing, loss of housebreaking, vocalizing, and head pressing can all be seen with a forebrain lesion. A behavioral syndrome in which animals with a structural unilateral forebrain lesion ignore all sensory input from the contralateral half of their environment has been called *hemiinattention syndrome.*

POSTURE

A normal upright posture is maintained through integration of multiple CNS pathways and spinal reflexes. Abnormal postures reflect a disruption of this normal integration. A wide-based stance is common in ataxic animals, particularly those with balance problems due to cerebellar or vestibular disease (Fig. 58.6). A continuous head tilt with resistance to

TABLE 58.2

Disorders of Consciousness

STATE	CHARACTERISTIC
Normal	Alert; responds appropriately to environmental stimuli
Depressed	Quiet or drowsy, responds to environmental stimuli; obtunded
Delirious	Alert; responds inappropriately to stimuli; agitated or confused
Stuporous	Unconscious, except when aroused by strong (often painful) stimuli
Comatose	A state of deep unconsciousness from which the animal cannot be aroused, even with noxious stimuli

FIG 58.6

straightening is usually associated with an abnormality of the vestibular system (Fig. 58.7; see Chapter 63). In recumbent animals, posture and other neurologic findings aid in lesion localization.

Schiff-Sherrington Posture

The Schiff-Sherrington posture is observed in dogs when an acute, severe, thoracic, or cranial lumbar spinal cord lesion (usually a fracture/luxation, infarction, or hemorrhage) interferes with the normal ascending inhibition of thoracic limb extensor motor neurons by border cells in the cranial lumbar spinal cord segments (mostly L2-L4). Forelimbs exhibit increased extensor tone with normal voluntary motion, strength, and proprioception (Fig. 58.8). The rear limbs are paralyzed, with normal to increased reflexes (UMN). This posture suggests acute severe spinal cord damage between the T3 and L1 spinal cord segments but does not have prognostic significance.

Decerebrate Rigidity

This posture is observed when there is a severe rostral brainstem (midbrain) lesion. Affected animals are stuporous or comatose, all limbs are rigidly extended, and there is dorsal extension of the head and neck (opisthotonus; Fig. 58.9, *A*).

FIG 58.7
Right-sided head tilt in an adult cat with right-sided peripheral vestibular disease caused by otitis media/interna.

FIG 58.8
Schiff-Sherrington posture in a 9-year-old Lhasa Apso caused by traumatic fracture and luxation of the spine at T11-T12, with damage to the spinal cord at that site. There was a loss of proprioception, loss of voluntary motion, and loss of deep pain in the rear limbs, with increased reflexes. The forelimbs were neurologically normal except for increased extensor tone.

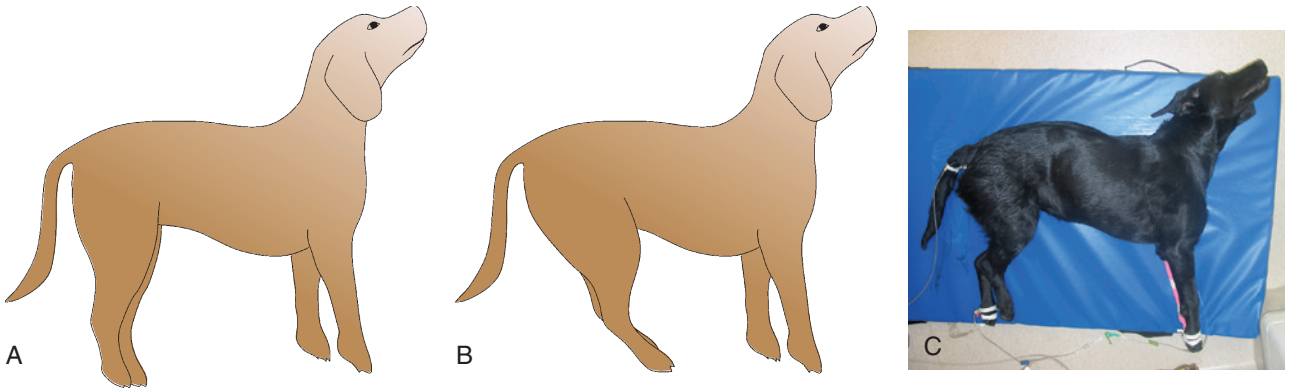

FIG 58.9
Abnormal postures. **(A)** Decerebrate rigidity. **(B)** Decerebellate rigidity. **(C)** Decerebellate rigidity in a 6-month-old Labrador Retriever with intracranial hemorrhage after warfarin intoxication.

Decerebellate Rigidity

The rostral portion of the cerebellum is responsible for inhibition of excessive extensor muscle tone. An acute lesion in this region can result in increased thoracic limb extensor muscle tone and opisthotonus. Mentation is normal, helping to differentiate this posture from decerebrate rigidity. The hips may be flexed forward as a result of increased iliopsoas muscle tone. This posturing can be episodic (see Fig. 58.9, *B* and *C*).

GAIT

Clinical evaluation of gait involves observation of the animal's movements during walking on a flat, nonslippery surface, with frequent turns and circling. If the animal is unable to walk unassisted, it should be supported with a harness or sling so that voluntary movement and gait can be better assessed. Each patient must be evaluated for paresis (weakness), ataxia, lameness, and circling.

Paresis/Paralysis

Paresis is defined as weakness or inability to support weight (LMN paresis) or inability to generate a normal gait (UMN paresis). *Paralysis* is the term used to describe the loss of all voluntary movement (Table 58.3). When animals are still ambulatory, the gait that results from LMN disease is markedly different from the gait that results from a UMN lesion. Animals with LMN disease are usually profoundly weak (paretic), the muscles in affected limbs are relatively flaccid, and they take small steps, attempting to maintain their feet under their center of gravity. Their short-strided, choppy gait is commonly mistaken for an orthopedic lameness, and they may tremble or collapse with minor exertion. Attempts to move quickly may result in a bunny-hopping gait or collapse. Unless they are paralyzed or have significant sensory nerve dysfunction, animals with LMN disease should have normal postural reactions as long as their body weight is supported during placing and hopping.

In contrast, animals with UMN lesions have a delay in the onset of protraction of their limbs (the swing phase of the gait) when trying to walk or hop, and they often have a longer-than-normal stride with a variable degree of spasticity or stiffness of the limbs (spastic paresis). Animals with UMN lesions have abnormal postural reactions and are ataxic as a result of disruption of the general proprioceptive (sensory) tracts that accompany the UMN tracts.

TABLE 58.3

Localizing Lesions Causing Paresis and Paralysis

Tetraparesis/Tetraplegia: Paresis or Paralysis of All Four Limbs	
Normal proprioception and spinal reflexes	Nonneurologic disorders *(cardiac disease, hypoglycemia, electrolyte abnormalities, hypoxemia)* Myasthenia gravis Generalized muscle disorders
LMN fore and rear	Generalized disorders of spinal cord ventral gray matter, ventral nerve roots, peripheral nerves or neuromuscular junction
LMN forelimbs, UMN rear limbs	C6-T2 spinal cord
UMN forelimbs, UMN rear limbs	C1-C5 or brainstem
Paraparesis/Paraplegia: Paresis or Paralysis of Rear Limbs	
Normal forelimbs, LMN rear limbs	L4-S3 spinal cord
Normal forelimbs, UMN rear limbs	T3-L3 spinal cord
Monoparesis/Monoplegia: Paresis or Paralysis of One Limb	
LMN	Lesion of the LMN directly innervating the affected limb *(motor neuron cell body in ventral spinal cord gray matter, ventral nerve roots, spinal nerves, peripheral nerves)*
Rear limb UMN	Ipsilateral T3-L3 spinal cord
Hemiparesis/Hemiplegia: Paresis or Paralysis of Both Limbs on One Side	
LMN fore, UMN rear	C6-T2 ipsilateral spinal cord
UMN fore, UMN rear	C1-C5 ipsilateral spinal cord; ipsilateral brainstem; contralateral forebrain lesion

LMN, Lower motor neuron; *UMN,* upper motor neuron.

Ataxia

Ataxia, or incoordination, is caused by lesions of the cerebellum, vestibular system, or the general proprioceptive (GP) sensory tracts in the spinal cord and caudal brainstem (Box 58.7). Animals with GP ataxia lose awareness of where their limbs are in space (Video 58.1). They have a wide-based stance, long strides, increased extensor tone in the affected limbs, excessive abduction of limbs during turning, exaggerated limb flexion, and a tendency to scuff or knuckle affected limbs while walking. When affected animals are walking, their limbs may cross, and the weight-bearing phase may be prolonged because of delayed protraction of affected limbs. Deficits are often most apparent when animals are walked in tight circles. Postural reactions are most obviously abnormal in animals with GP ataxia due to spinal cord or brainstem lesions.

Vestibular ataxia is manifested primarily as a loss of balance, reflected in a head tilt and a wide-based, crouched stance with a tendency to lean, drift, fall, or roll to the side (Video 58.2). Vestibular ataxia is often accompanied by an

BOX 58.7

Normal postural reactions
Intention tremor of the head

abnormal nystagmus (see Chapter 65). Cerebellar ataxia reflects an inability to control the rate, range, and force of movement (Video 58.3). Affected animals will have a wide-based stance, swaying of the body from side to side (truncal ataxia), and slightly delayed limb protraction followed by exaggerated (hypermetric) limb movements. There is marked overflexion of the limbs during protraction and then forceful return to weight bearing, creating a "bursty" effect to the movement. Animals with cerebellar ataxia have normal strength, increased muscle tone, and usually relatively normal postural reactions (Fig. 58.10). A fine head tremor may be present; when vestibular components of the cerebellum are affected, head tilt, nystagmus, and loss of balance may be evident (see Chapters 60 and 63).

Lameness

Animals are lame when normal movement causes discomfort. If all limbs are equally painful, they may develop a stiff, short-strided gait, as seen in animals with polyarthritis. Animals with lameness affecting one limb have a short weight-bearing phase in the affected limb and a longer-than-normal weight-bearing phase in the contralateral limb. In some cases the painful limb will be elevated or carried. Lameness affecting one limb is common in animals with orthopedic disease but can also be a prominent feature in animals with entrapment (pinching) of a spinal nerve or nerve root by a lateralized disk extrusion or nerve root tumor.

FIG 58.10

FIG 58.11
Tight circling and head tilt to the right in a 3-year-old Maltese with inflammatory disease affecting the right forebrain and brainstem.

Circling

Circling can be caused by lesions of the forebrain or the vestibular system. Dogs with unilateral forebrain lesions will usually walk or pace in wide circles toward the side of the lesion. Tight circling toward the side of the lesion is more often associated with vestibular disorders (Fig. 58.11). Most animals with vestibular disease also exhibit ataxia, loss of balance, head tilt, and nystagmus.

POSTURAL REACTIONS

The complex series of responses that maintain an animal in an upright position are called *postural reactions.* Postural

reaction testing is used to determine whether animals can recognize the position of their limbs in space (proprioception). Sensory receptors for proprioception originate in the muscles, tendons, and joints, and spinal cord proprioceptive tracts relay this sensory information to the cerebral cortex. Most proprioceptive tracts ascend the ipsilateral spinal cord and cross midline in the rostral brainstem (see Fig. 58.5). Abnormalities detected during the manipulations performed to test postural reactions do not provide precise localizing information but are sensitive indicators that suggest the presence of neurologic dysfunction somewhere along the neurologic pathway. A careful and systematic evaluation of postural reactions may permit the examiner to detect subtle deficits not observed during routine gait examination and to determine whether each limb is neurologically normal or abnormal. Postural reaction testing should include knuckling, hopping, wheelbarrowing, and hemiwalking (Fig. 58.12) (Video 58.4). When performed by an experienced clinician comparing the right and left limbs in an animal that has voluntary movement, hopping is the most sensitive and reliable postural reaction test. The animal is supported bearing weight on one limb, and its body is leaned and hopped laterally so that its center of gravity is no longer adequately supported by that limb. The normal response is to immediately lift the limb and replace it directly under its center of gravity. Any delay in this response is abnormal. In animals with significant weakness, it is important to support most of the body weight during postural reaction testing. Animals with neuromuscular disorders that still have normal sensation and the ability to voluntarily move their limbs will hop quickly (normal) as long as their weight is supported because their proprioception is normal. For the purpose of lesion localization, abnormalities of postural reaction testing are usually interpreted as UMN signs, which must then be confirmed with testing of muscle tone and spinal reflexes (see Box 58.4 and Table 58.1).

MUSCLE SIZE/TONE

Muscle atrophy and muscle tone should be assessed by careful palpation and movement of each limb through a range of motion. Muscle atrophy can occur slowly as a result of disuse or rapidly as a result of a lesion of the LMN supplying a muscle (neurogenic atrophy). If focal muscle atrophy is detected in a limb, this can be used to precisely localize lesions of the peripheral nerve, nerve roots, or spinal cord gray matter because the spinal cord segments and peripheral nerves responsible for innervating each of the individual limb muscles are well known. Muscle swelling or enlargement is a feature of some myopathies. Muscle tone is generally decreased in animals with significant lesions of the LMN, whereas extensor muscle tone is usually increased with UMN lesions (see Table 58.1). Extreme alterations in muscle tone can be seen in animals with Schiff-Sherrington syndrome and with decerebrate and decerebellar rigidity (see Figs. 58.8 and 58.9).

SPINAL REFLEXES

Spinal reflex evaluation helps classify a neurologic disorder as being UMN or LMN. Spinal reflexes and muscle tone will be diminished to absent in limbs affected by LMN disorders and normal to increased in UMN disease. Spinal limb reflexes are best assessed in a relaxed animal restrained in lateral recumbency. Each reflex is judged to be absent (0), decreased (+1), normal (+2), or increased (+3 or +4). LMN lesions severe enough to cause weakness and abnormal gait will reliably cause an absent or decreased reflex. UMN lesions cause an increased reflex that will not always be distinguishable from normal. In the absence of other neurologic deficits, an exaggerated reflex means little and can be observed in an excited or nervous animal. The most useful limb reflexes in dogs and cats include the patellar reflex, sciatic reflex, pelvic limb withdrawal (flexor) reflex, and thoracic limb withdrawal (flexor) reflex. Because other reflexes are found inconsistently in normal animals, they are not routinely evaluated. The spinal reflexes and the spinal cord segments responsible for mediating each reflex are listed in Table 58.4.

Patellar Reflex

With the animal restrained in lateral recumbency, the examiner evaluates the reflex in the upper (nonrecumbent) limb by holding the stifle in partial flexion and striking the patellar ligament with the flat surface of the reflex hammer (pleximeter), stretching the fibers of the quadriceps muscle (Fig. 58.13). The normal response is a reflex contraction of the quadriceps muscle. This is a monosynaptic myotactic (stretch) reflex, with both sensory and motor components contained in the femoral nerve and the L4, L5, and L6 spinal nerves, nerve roots, and spinal cord segments. A weak or absent patellar reflex indicates a lesion of the femoral nerve or the L4-6 spinal cord segments or nerve roots. A lesion cranial to the L4 spinal cord segment will typically cause an exaggerated reflex. Although this is the most reliable tendon reflex for evaluation, it is sometimes difficult to interpret the response. Occasionally a lesion of the sciatic nerve or the L6-S2 spinal cord segments will cause the patellar reflex to appear increased by decreasing tone in the muscles opposing stifle extension (pseudohyperreflexia). The patellar reflex is sometimes difficult to elicit in animals with significant orthopedic disease of the stifle. It is occasionally decreased or absent in normal dogs (especially large-breed puppies) and may be absent in some geriatric dogs, presumably due to an age-related neuropathy affecting the sensory side of the reflex arc. In tense patients, the reflex is sometimes decreased or absent in the upper limb but normal in the relaxed recumbent limb, making it important to check this reflex in both limbs in both recumbencies.

Pelvic Limb Withdrawal (Flexor) Reflex

The examiner squeezes a digit with enough pressure to elicit flexion of the hip, stifle, hock, and digits (Fig. 58.14, *A* and *B*). If manual pressure is inadequate, the examiner squeezes the base of a toenail with a pair of forceps. The pelvic limb withdrawal reflex is complex. Sensory input is through the

FIG 58.12
Postural reaction testing. **(Aa) (Ab)** Proprioception (knuckling) is evaluated by placing the dorsal surface of the animal's paw on the floor while the animal's weight is supported. The normal response is an immediate return to a normal position. **(B)** Forelimb hopping. The animal is supported under the abdomen, and one thoracic limb is lifted from the ground. The animal is leaned and moved laterally toward the limb being evaluated. The normal animal responds by quickly lifting and replacing the limb under its body as it moves laterally. **(C)** Pelvic limb hopping. The animal is supported under the chest, and one pelvic limb is lifted. The animal is leaned and moved laterally toward the limb being evaluated. The normal animal responds by quickly lifting and replacing its limb under the body as it moves laterally. **(D)** Hemiwalking. The front and rear limbs on one side are lifted, and forward and lateral walking movements are evaluated. **(E)** Wheelbarrowing. The animal is supported under the abdomen and moved forward. The head may be elevated to remove visual input and accentuate proprioceptive abnormalities, as shown here.

TABLE 58.4

Spinal Reflexes

REFLEX	STIMULUS	NORMAL RESPONSE	SPINAL CORD SEGMENTS
Thoracic limb withdrawal	Pinch foot of forelimb	Withdraw limb	C6, C7, C8, T1 (T2)
Patellar	Strike patellar ligament	Extend stifle	L4, L5, L6
Pelvic limb withdrawal	Pinch foot of rear limb	Withdraw limb	L6, L7, S1 (S2)
Sciatic	Strike sciatic nerve between greater trochanter and ischium	Flexion of stifle and hock	L6, L7, S1 (S2)
Cranial tibial	Strike belly of cranial tibial muscle just below proximal end of tibia	Flexion of hock	L6, L7 (S1)
Perineal	Stimulate perineum with pinch	Anal sphincter contraction, ventroflex tail	S1, S2, S3, pudendal nerve
Bulbourethral	Compress vulva or bulb of penis	Anal sphincter contraction	S1, S2, S3, pudendal nerve
Cutaneous trunci	Stimulate skin over dorsum just lateral to vertebral column	Twitch of the cutaneous trunci muscle	Response will be absent caudal to a severe spinal cord lesion Used to localize lesions between T3 and L3

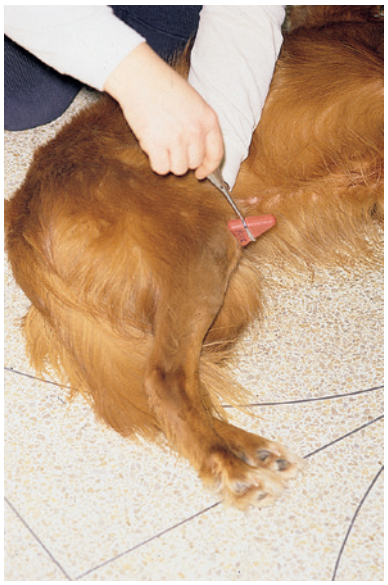

FIG 58.13
Patellar reflex. The straight patellar ligament is struck, resulting in a reflex "kick" extension of the stifle.

peroneal (dorsal, lateral) and tibial (ventral) branches of the sciatic nerve and the saphenous branch of the femoral nerve (medial). Motor output is through the sciatic nerve and its branches, the tibial nerve (digital flexion), and the peroneal nerve (tarsal flexion). Because the femoral nerve and the lumbar spinal nerves mediate hip flexion, this component of the reflex can occur when the medial toe is stimulated even if the sciatic nerve and its branches have been destroyed. A decreased pelvic limb withdrawal response indicates an LMN lesion affecting the sciatic nerve (or branches) or the L6-S1 spinal cord segments or nerve roots (and sometimes S2). A lesion cranial to L6 results in a normal to increased reflex response. The withdrawal response is a segmental reflex that is not dependent on the animal's conscious perception of the noxious stimulus. Functional transection of the spinal cord cranial to L6 will result in a normal to increased reflex (UMN) but no ability to feel the stimulus.

Sciatic Reflex

With the animal in lateral recumbency, the examiner palpates the notch formed by the greater trochanter of the femur and the ischial tuberosity. Using the tapered end of the pleximeter to tap in this notch, the examiner elicits a brief flexion of the hock (see Fig. 58.14, *C*). A normal sciatic reflex requires that the sciatic nerve, spinal cord segments L6-S1, and the peroneal nerve (branch of the sciatic nerve) be intact. The reflex will be decreased with lesions of those components and normal to increased with UMN lesions cranial to L6.

Thoracic Limb Withdrawal (Flexor) Reflex

The only reliable forelimb reflex is the withdrawal reflex. Because multiple nerves are involved, this reflex is used as a crude test of the entire brachial plexus (nerve roots and peripheral nerves) and cervical intumescence (C6-T2). The examiner squeezes a digit to elicit flexion of the shoulder, elbow, carpus, and digits (Fig. 58.15). Lesions involving the peripheral nerves, nerve roots, or spinal cord segments at that site will result in a decreased or absent reflex. Lesions above C6 in the spinal cord will cause a normal to increased (UMN) reflex response.

Crossed Extensor Reflex

When the withdrawal (flexor) reflexes are elicited in an animal in lateral recumbency, a reflex extension of the

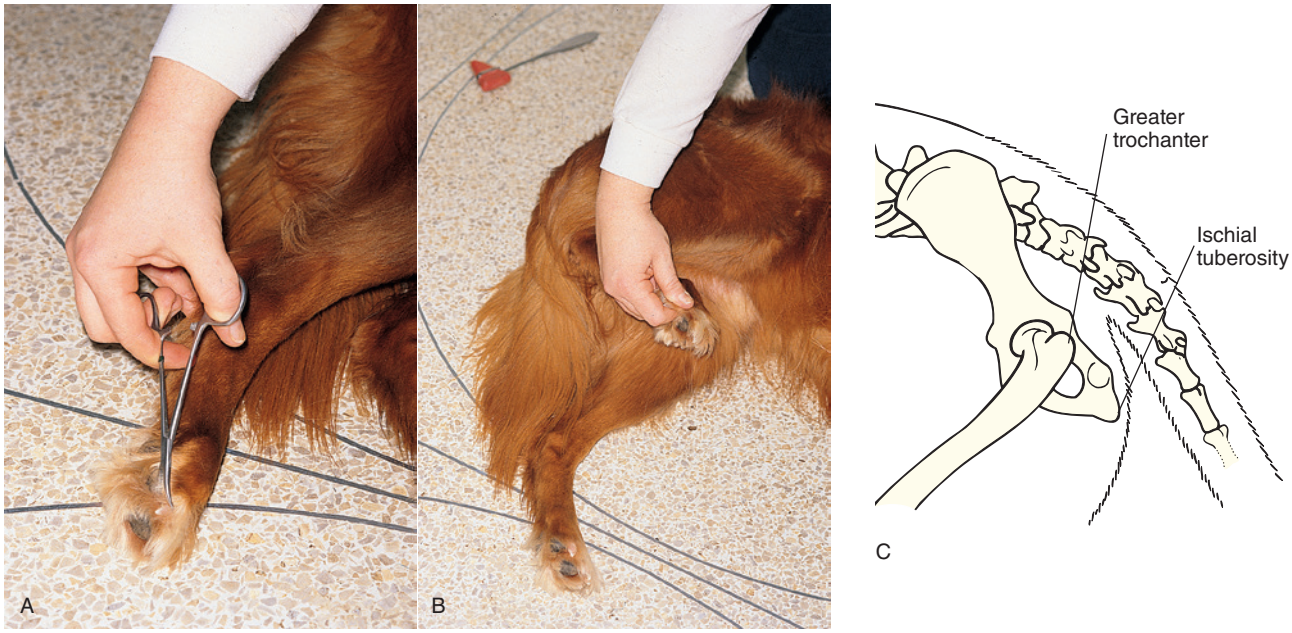

FIG 58.14
Assessing the sciatic nerve and spinal cord segments L6-S2. Pelvic limb withdrawal reflex: pinching the toe **(A)** results in limb flexion **(B).** Assess flexion in all of the joints of the limb. It may be necessary to apply a forceps to the nail base to provide adequate stimulation. **(C)** Sciatic reflex: striking the sciatic nerve in the notch between the greater trochanter of the femur and the ischial tuberosity results in limb flexion.

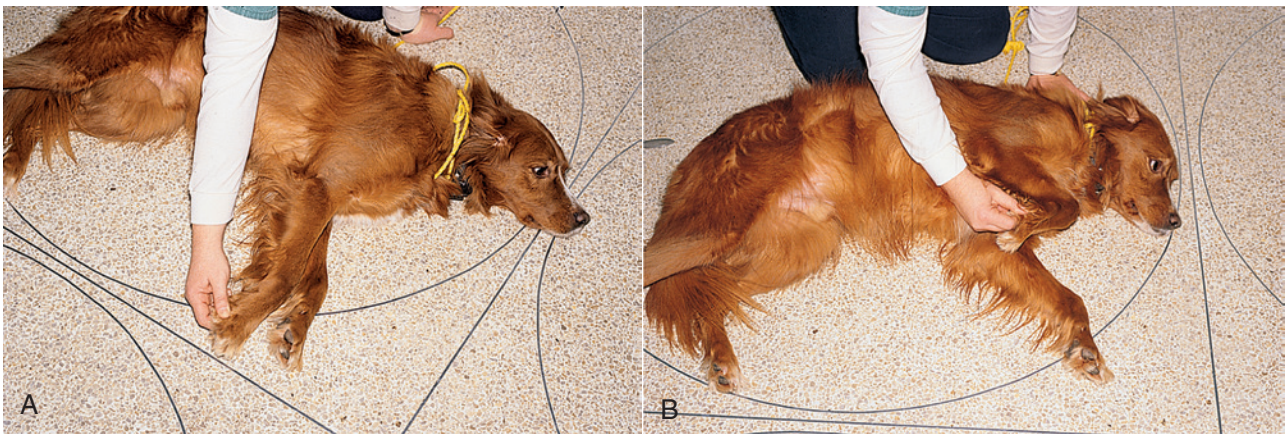

FIG 58.15

limb opposite the one being stimulated is termed a *crossed extensor reflex.* The presence of this reflex in a paralyzed animal or an animal that is not trying to rise or get away suggests that there is a UMN lesion to the limb being evaluated.

Perineal Reflex and Bulbourethral Reflex

The perineal and bulbocavernosus reflexes are used to assess the pudendal nerve (sensory and motor) and sacral spinal cord segments S1-S3. In the perineal reflex the perineal skin is pinched with a hemostat, causing the anal sphincter to contract and the tail to ventroflex (Fig. 58.16). The same response should occur during digital rectal examination. The bulbourethral reflex causes anal sphincter contraction in response to gently squeezing the bulb of the penis or the vulva. LMN damage to the pudendal nerve or the S1-S3 spinal cord segments will cause a loss of both of these reflexes, urinary incontinence (LMN bladder), loss of tone in the internal and external anal sphincters, and resultant anal dilation and fecal incontinence.

Cutaneous Trunci Reflex (Panniculus)

Pinching the skin of the dorsum causes a reflex contraction of the cutaneous trunci muscles bilaterally, producing a

FIG 58.16
Perineal reflex. Stimulate the perineal skin with a hemostat, causing the anal sphincter to contract and the tail to ventroflex.

twitch of the overlying skin. This reflex can be very useful in the evaluation of patients with a severe spinal cord lesion localized to the T3-L3 region. Affected patients will have UMN signs in the rear limbs and normal forelimbs, but unless they have a painful site, it can be difficult to localize the lesion more precisely. When skin along the dorsum is pinched, the stimulated sensory nerve from that site enters the spinal cord and afferent sensory information ascends the spinal cord in sensory tracts. If the spinal cord is intact between the site of stimulation and the C8-T1 segments, a synapse occurs bilaterally at the C8-T1 spinal cord segments, stimulating motor neurons of the lateral thoracic nerve, which causes the cutaneous trunci muscle to contract. In T3-L3 spinal cord lesions causing paralysis, the ascending pathway is often disrupted such that no panniculus reflex is elicited when the skin is pinched caudal to the level of the lesion, but stimulation of the skin cranial to the lesion elicits a response (Fig. 58.17). Testing is started at the level of the iliac wings, although in many normal animals the reflex cannot be elicited until stimulation is applied cranial to the midlumbar region. If a twitch occurs at the most caudal aspect, then the entire pathway is intact. If there is no response, systematic stimulation of the skin just lateral to each vertebral body should be performed, progressing anteriorly until a twitch is observed. Because the sensory nerves that supply the skin enter the spinal cord one or two vertebrae cranial to the dermatome stimulated, the cord lesion is predictably slightly cranial to the site where the panniculus reflex is lost. The cutaneous trunci reflex can be lost unilaterally when there is a lesion of the ipsilateral brachial plexus or C8-T1 spinal cord segments, ventral nerve roots, or spinal nerves. In rare cases this reflex cannot be elicited in a normal dog.

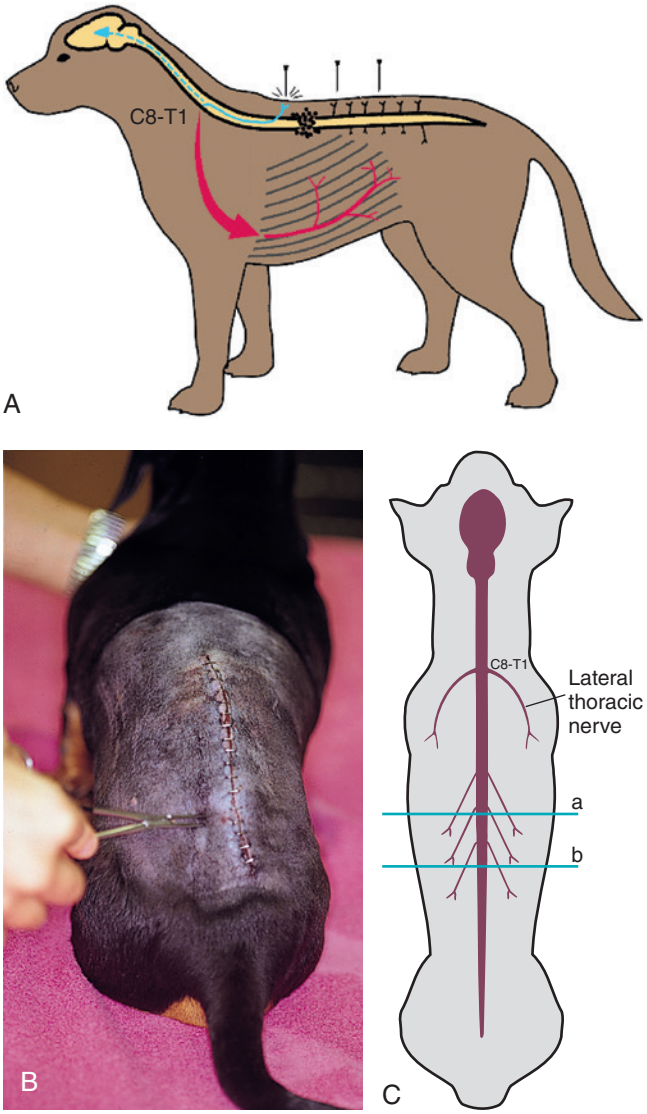

FIG 58.17
Cutaneous trunci reflex. **(A-B)** Pinch the dorsal skin with a hemostat just lateral to the spine. If the spinal cord is not injured between the site of stimulation and the C8-T1 spinal cord segments, this will lead to a bilateral twitch of the cutaneous trunci muscle. The reflex may be absent caudal to a severe spinal cord lesion. **(C)** The spinal sensory nerves course caudally, so the dermatomes for skin sensation lateral to the vertebral column are caudal to their own vertebral bodies. A spinal cord lesion at site *a* will therefore result in loss of the panniculus response caudal to site *b*.

SENSORY EVALUATION

Evaluation of an animal's ability to feel a noxious stimulus such as a pinch (nociception) can be helpful in localizing UMN and LMN lesions. When there is a severe transverse UMN spinal cord lesion in the T3-L3 region, the animal's ability to feel a painful stimulus (skin or toe pinch with fingers or hemostat) may be decreased in the pelvic limbs and in the skin of the trunk caudal to the lesion because the ascending sensory tracts are disrupted in the damaged spinal

cord. If minor stimulation in a paralyzed animal does not elicit a behavioral response such as turning the head, vocalizing, or trying to bite, then the animal's ability to perceive a more severe noxious stimulus such as a hemostat applied to the nail base (deep pain) should be tested. The spinal tracts that carry deep pain sensation are small, bilateral, and multisynaptic and located deep in the spinal cord white matter, so only a very severe bilateral spinal cord lesion will completely disrupt these tracts, making the ability to perceive deep pain an important prognostic indicator in animals with severe compressive T3-L3 spinal cord injury (Fig. 58.18). It is important to remember that withdrawal of the limb indicates only an intact reflex arc (peripheral nerve and spinal cord segments), whereas a behavioral response requires that the sensory spinal cord tracts ascending to the brain also be intact.

When LMN paralysis of a limb is evident, mapping the boundaries of normal and diminished sensation can aid in lesion localization to specific peripheral nerves, dorsal nerve roots, or spinal cord segments. The skin should be pinched with a hemostat and regions of local anesthesia or decreased sensation identified (Fig. 58.19). These results can be compared with established maps of cutaneous regions deriving sensory innervation from individual nerves (dermatomes), allowing the LMN neurologic defect to be precisely localized (see Chapters 65 and 66).

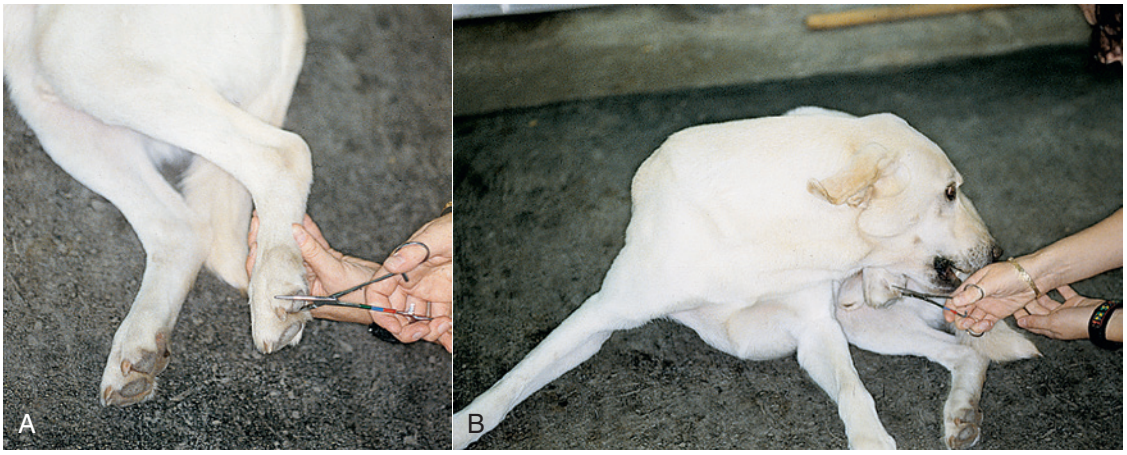

FIG 58.18
Evaluation of deep pain. Pinch the toe **(A)** to assess whether this elicits a behavioral response **(B).** The absence of deep pain sensation indicates the presence of severe spinal cord damage.

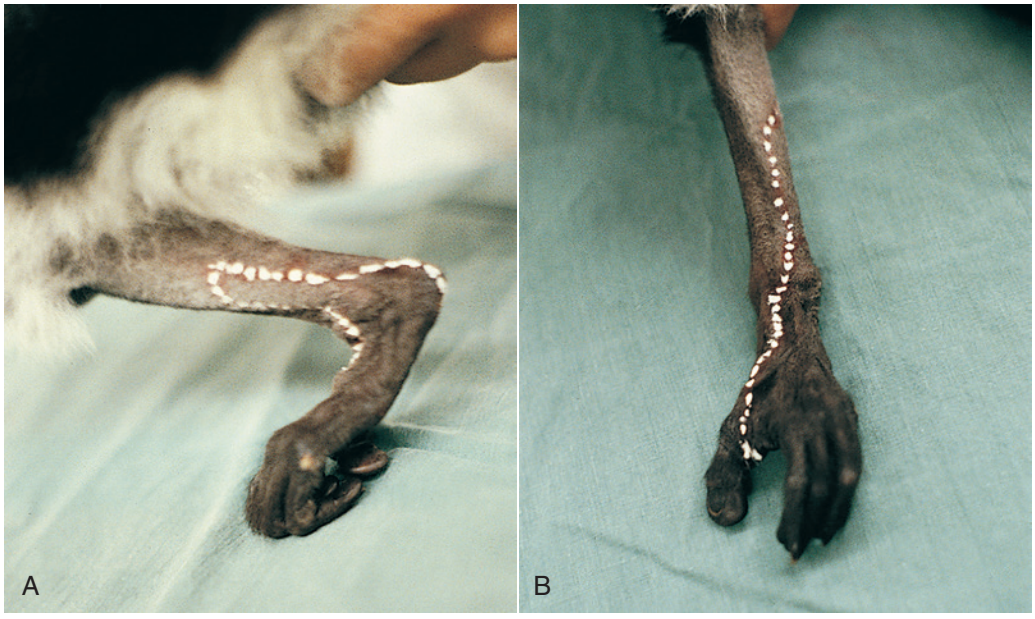

FIG 58.19

PAIN/HYPERPATHIA

The neck, spine, limbs, muscles, bones, and joints should be palpated and manipulated to detect painful areas or restricted mobility (Video 58.5). Pain is usually most intense directly over a lesion, making this part of the neurologic examination important in lesion localization. Traumatic and inflammatory conditions are most likely to be painful, whereas degenerative and congenital conditions are rarely painful. Neoplastic conditions causing distortion of tissues (meninges, nerve roots, or bone) may also cause discomfort.

The animal's posture and gait should be observed. Animals with neck pain maintain a low head carriage with their head and neck extended, and they are unwilling to turn their neck to look to the side; they will instead pivot their entire body. Animals with pain of the thoracic or lumbar spine stand with an arched back (Fig. 58.20). Animals with painful bones, joints, or muscles typically have a short-strided, stiff gait and are reluctant to exercise.

Neck pain is a sign commonly associated with compressive or inflammatory diseases of the cervical spinal cord, cervical spinal roots, or meninges. The neck should be gently manipulated in dorsal, lateral, and ventral flexion and resistance to movement or pain assessed. Deep palpation of the vertebrae and cervical spinal epaxial muscles may also be performed (Fig. 58.21). Anatomic structures that can cause neck pain include the meninges, nerve roots, facetal joints, bones, and muscles (Box 58.8). Neck pain has also been recognized as a clinical symptom of intracranial disease, particularly of forebrain mass lesions.

FIG 58.20

Continued

FIG 58.21, cont'd

Pain when pressure is applied to other regions of the vertebral column may help localize lesions caused by trauma, intervertebral disk disease, diskospondylitis, or neoplasia. Because animals with thoracolumbar spinal pain may also resist abdominal palpation, vertebral or spinal hyperpathia is often misinterpreted as abdominal pain. Cauda equina compression that is caused by a tumor, disk, or ligamentous proliferation typically causes pain in the lumbosacral region (see Chapter 65). This can be demonstrated in affected dogs by applying direct pressure over the lumbosacral junction or applying dorsal traction to the tail (see Fig. 65.20).

Muscular pain should be assessed by manipulating the limbs and palpating individual muscle groups. During palpation, it is important to attempt to differentiate pain that originates within the muscle from that due to bone or joint abnormalities. Muscle disorders that are associated with pain are primarily the inflammatory diseases, such as immune-mediated polymyositis, masticatory myositis, and infectious myositis caused by the protozoal organisms *Toxoplasma* and *Neospora*. Ischemic myopathy, as occurs in animals with thrombosis affecting the arterial blood supply to a muscle group, can also result in severe muscular cramping and pain on palpation.

URINARY TRACT FUNCTION

Severe lesions of the spinal cord are often associated with urinary tract dysfunction. Bladder function should be assessed on the basis of the owner's or clinician's observations of micturition, palpation of the bladder, and attempts to express urine. A flaccid, easily expressed bladder with absent or diminished perineal and bulbocavernosus reflexes and reduced anal tone are expected with lesions of the LMN (S1-S3 spinal cord segments, pudendal nerve, pelvic nerve). UMN lesions cranial to the sacral segments cause diminished voluntary control of urination and reflex hyperexcitability of the urethral sphincter. There can be incomplete voiding or detrusor-urethral dyssynergia. Severe UMN lesions will result in a tense, distended bladder that is difficult to express.

CRANIAL NERVES

Cranial nerve dysfunction may result from a disorder affecting a single nerve, a diffuse polyneuropathy affecting multiple nerves, or a cluster of abnormalities, as is commonly seen in animals with a disease affecting the middle and inner ear or brainstem. Animals with brainstem disease causing cranial nerve dysfunction usually have additional signs such as postural reaction deficits, hemiparesis, quadriparesis, or altered mentation.

Cranial nerve examination is not difficult. The cranial nerves most often affected can be evaluated quickly with a rapid regional neurologic examination (Table 58.5, Video 58.6). If findings yielded by the preliminary examination indicate the presence of an abnormality, a more thorough

examination of each individual cranial nerve can be undertaken (Table 58.6; also see Suggested Readings).

Evaluation of Menace Response, Vision, and Pupils

The optic nerve (CN2) is an important component of the afferent pathways for the menace response, vision, and the pupillary light reflex. To test the menace response, the examiner covers one of the animal's eyes and advances the hand in a menacing way toward the opposite eye, taking care to avoid touching the eyelid or whiskers or generating an air current that will stimulate the cornea, which is innervated by the sensory portion of the trigeminal nerve (CN5). (Fig. 58.22, *A*) It is a good idea to lightly stimulate the face before assessing the menace response to get the animal's attention and make certain there is an intact palpebral reflex (CN7) and the animal is able to blink. The menace response is a cortically mediated learned response and will not be present until 10 to 12 weeks of age in puppies and kittens. In addition to the menace response, vision can be assessed by observing the animal's response to its environment by making sudden movements and dropping cotton balls to see if the animal follows the movement. It may be necessary to set up a maze of objects to assess vision in each eye.

The parasympathetic axons of the oculomotor nerve (CN3) are responsible for pupil constriction. Pupil size should be examined at rest in a well-lit room and then in a dimly lit room and the two eyes compared. The examiner evaluates the ability of each pupil to constrict (parasympathetic function) and dilate (sympathetic function) by shining a bright light in one eye, then swinging the light into the other eye to observe the response, and then swinging it back again (Fig. 58.22, *B*). Loss of vision and pupillary abnormalities are discussed in Chapter 61.

Examine for Strabismus, Nystagmus, and Head Tilt

To check for strabismus and nystagmus, the examiner must determine whether the eyes are normally positioned in the orbits and whether there is any spontaneous nystagmus when the head is stationary. Spontaneous nystagmus at rest is always abnormal and indicates a central vestibular (medullary) lesion, a lesion of the vestibular portion of CN8, or a lesion of the cerebellum. A head tilt is common with a lesion in any of these locations. Abnormal eye position (strabismus) may occur when there is a vestibular disorder or damage to the innervation of the extraocular muscles (innervated by CN3, 4, 6) (Figs. 58.23 and 58.24). Oculomotor nerve (CN3) dysfunction can result in a ventrolateral strabismus and an inability to rotate the eye dorsally, ventrally, or medially. Lesions of the abducent (CN6) nerve cause a medial strabismus and an inability to look laterally, and lesions of the trochlear nerve (CN4) cause a dorsolateral rotation of the eye. Lesions of these nerves (CN3, 4, 6) often occur together, producing complete external ophthalmoplegia, usually due to a mass in the region of the paired cavernous sinuses on the floor of the calvarium (cavernous sinus syndrome).

Vestibular disorders may cause a ventral strabismus (eye drop) on the side of the lesion that is only evident during head and neck extension (positional strabismus). A quick assessment of the function of all these nerves can be accomplished by moving the head from side to side and eliciting the vestibulo-ocular reflex (Fig. 58.25). As the head is turned slowly to the right, the gaze of both eyes should slowly drift left before jerking to the right to resume a central position. The examiner assesses these normal vestibular eye movements (physiologic nystagmus, oculocephalic reflex) while moving the head in each direction.

In addition to moving the head from side to side to determine whether the eye movements are normal, the examiner should hold the animal's head still in each lateral position to determine whether an abnormal (positional) nystagmus develops. The head and neck should then be extended and held in that position while the eyes are evaluated for a ventral strabismus and development of nystagmus. When the head of a normal animal is held still in any position, there should be no nystagmus. In most animals with severe or acute central or peripheral vestibular lesions, a resting

(spontaneous) nystagmus will be detected. In less severe or compensated vestibular disorders the examiner will only be able to elicit a few beats of abnormal nystagmus when the animal's head is held in a certain position; this is called *positional nystagmus*, and it is abnormal. Positional nystagmus is most likely to become evident when the animal is suddenly placed in dorsal recumbency with the head and neck extended (Fig. 58.26). The direction of nystagmus is defined as the direction of the fast phase of eye movements.

Evaluation of Trigeminal (CN5) Nerves

The trigeminal nerve supplies sensory innervation to the skin of the ipsilateral face, the cornea, the mucosa of the nasal septum, the nasopharyngeal mucous membranes, and the teeth and gingiva of the upper and lower jaw while providing motor function to the muscles of mastication. Sensory function is tested by assessing the ipsilateral palpebral reflexes (sensory CN5, motor CN7) sensation in the skin of the face, and response to stimulation of the nasal septal mucosa (Fig. 58.27, *A, B, C*). The behavioral response is mediated by the contralateral forebrain so both sides should be carefully assessed. Occasionally decreased facial sensation (hypoalgesia) can be observed in animals with contralateral forebrain lesions. Motor function is assessed by evaluating the masticatory muscles for atrophy and testing the resistance of the jaw when opening the mouth. Bilateral trigeminal motor paralysis results in a dropped jaw and inability to close the mouth (Fig. 58.28). Loss of corneal sensation in

The sensory distribution of the trigeminal nerve (CN5) can be assessed by inducing the palpebral reflex **(A)**, pinching the skin of the maxilla **(B),** and by stimulating the nasal septal mucosa **(C)** with a hemostat.

FIG 58.28
Bilateral motor paralysis of the trigeminal nerve results in an inability of this 6-year-old Labrador Retriever to close its mouth.

dogs with trigeminal paralysis may decrease reflex release of tears and trophic factors, leading to keratitis (neurotrophic keratitis) and corneal ulceration in some dogs.

Evaluation of the Facial (CN7) Nerves

The facial nerve provides motor innervation to the muscles of the face and sensory innervation to the rostral two thirds of the tongue (for taste) and palate. Parasympathetic fibers innervate the lacrimal glands and the mandibular and sublingual salivary glands. Motor function is assessed by examining the face for symmetry and observing spontaneous blinking and ear movements, as well as by eliciting the palpebral reflex, the blink induced by the menace response, and the ability to twitch the face in response to a pinch (sensory CN5, motor CN7) (Fig. 58.29, *A, B, C*). Because the facial nerve courses through the middle ear before distribution to the muscles of the face, middle ear lesions can cause facial nerve dysfunction. The Schirmer tear test should be used to evaluate tear production in animals with facial paresis or paralysis.

Evaluation of the Glossopharyngeal (CN9), Vagus (CN10), and Hypoglossal (CN12) Nerves

The glossopharyngeal, vagus, and hypoglossal nerves are usually evaluated together as components of the gag reflex and normal eating and drinking. The glossopharyngeal nerve (CN9) provides motor innervation to the pharynx and palate and sensory innervation to the caudal third of the tongue and pharynx (providing the sense of taste). It also provides parasympathetic stimulation to the parotid and zygomatic salivary glands. The vagus nerve (CN10) provides motor and sensory innervation to the larynx, pharynx, and esophagus and sensory innervation to the thoracic and abdominal viscera. The parasympathetic portion of the

FIG 58.29
Motor function of the muscles of facial expression can be checked by inducing the palpebral reflex **(A)** and evaluating the ability of the lip to twitch in response to a pinch **(B)**. This dog **(C)** has right-sided facial paralysis causing a lip droop and inability to blink the right eye.

vagus provides motor innervation to most thoracic and abdominal viscera. The hypoglossal nerve (CN12) provides motor innervation to the tongue.

The swallowing or gag reflex (CN9 and CN10) can be evaluated by applying external pressure in the hyoid region to induce swallowing or by stimulating the pharynx with a finger to induce the gag reflex. It may be more practical to simply watch the animal eat and drink. The parasympathetic portion of CN10 can be tested by measuring the reflex bradycardia that normally occurs when digital pressure is applied to both eyeballs (oculocardiac reflex). The hypoglossal nerve (CN12) can be evaluated by inspecting the tongue for atrophy or asymmetry (Fig. 58.30) and observing tongue movement during eating and drinking or when licking food paste placed on the nose. Acute unilateral lesions of CN12 can result in deviation of the tongue to either direction, but chronic unilateral lesions result in ipsilateral atrophy and protrusion of the tongue towards the side of the lesion.

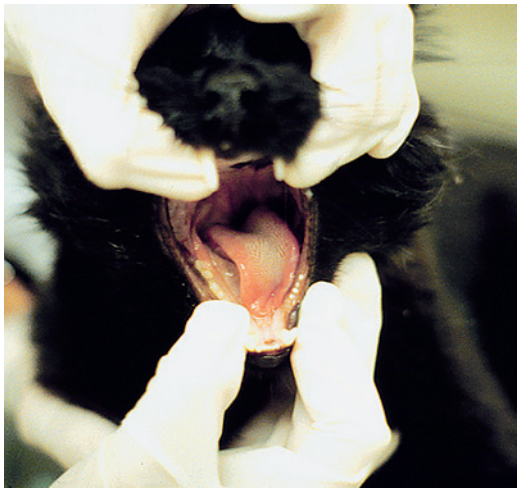

FIG 58.30
Deviation and atrophy of the tongue caused by left-sided hypoglossal nerve (CN12) paralysis.

LESION LOCALIZATION

After the neurologic examination is completed, an animal's mentation, cranial nerves, posture, gait, forelimbs, rear limbs, perineum, anus, and bladder can be characterized as normal or abnormal. If disease above the foramen magnum is present, clinical findings should allow a lesion to be localized to a specific region of the brain. In patients with spinal cord disease, determining whether the neurologic abnormality in each limb is UMN or LMN in origin allows localization to a region of the spinal cord or specific spinal cord segments (see Box 58.4). When LMN signs are present in a single limb, the lesion can often be even more precisely localized by determining the muscles affected and, if sensory nerves are also affected, by testing sensation in dermatomes. Focal hyperpathia may also help to precisely localize a lesion. Whenever possible, the clinician should be able to explain all detected neurologic abnormalities on the basis of a single lesion. Occasionally, however, this will be impossible because the animal has multiple foci of disease or a diffuse disorder.

DIAGNOSTIC APPROACH

Once a neurologic lesion has been localized, it is necessary to generate a list of likely differential diagnoses. This list should take into account the signalment, historical data, the neuroanatomic location of the lesion, and the nature of the onset and progression of neurologic signs. It is important to consider all possible mechanisms or causes of disease that can affect the nervous system (Box 58.9). Once a list of likely differential diagnoses has been developed, diagnostic tests can be performed to confirm or exclude each.

ANIMAL HISTORY

Patient age, gender, breed, and lifestyle may provide clues regarding the underlying disease. Young animals are most likely to be seen because of congenital or hereditary disorders; they are also at highest risk for intoxications and most infectious diseases. Older animals are more susceptible to neoplastic diseases and many of the known degenerative disorders. Certain breeds are predisposed to particular disorders, and there are many congenital and inherited disorders that have been seen in only one or a few breeds. Dogs engaging in particular competitive or working activities (e.g., hunting, herding, racing, jumping) may be at increased risk for specific activity-related injuries. Potential exposure to trauma, toxins, and infectious disorders should be ascertained through careful history taking.

BOX 58.9

DAMNIT-VP Scheme: Mechanisms of Disease

D	Degenerative
A	Anomalous
M	Metabolic, malformation
N	Neoplastic, nutritional
I	Infectious, inflammatory, immune, iatrogenic, idiopathic
T	Traumatic, toxic
V	Vascular
P	Parasitic

DISEASE ONSET AND PROGRESSION

Evaluation of the onset and progression of neurologic signs is of primary importance in prioritizing the list of differential diagnoses (Box 58.10). The signs may be peracute and nonprogressive, or they may become progressively more severe with time. In peracute disorders, the time of onset of the neurologic signs can be pinpointed exactly, with the animal going from being normal to abnormal within minutes or hours. Signs reach maximal intensity very rapidly and then remain static or improve over time. Examples include external trauma, internal trauma from intervertebral disk extrusion, vascular disorders such as infarcts or hemorrhage, and some rapid-acting intoxications such as strychnine. Rarely, animals with a typically slow progressive disorder (e.g., tumor) present with a peracute exacerbation of their signs as a result of hemorrhage or fracture at the site of the tumor. A thorough history will often reveal that these animals were not entirely normal before the acute deterioration.

Neurologic disorders with fairly rapid deterioration over days to weeks are classified as subacute and progressive. Infectious and noninfectious inflammatory diseases and some of the more rapidly progressive neoplasms (e.g., lymphomas, metastatic malignancies) usually fall into this category. Metabolic and nutritional disorders and some intoxications can also cause subacute progressive signs. Animals with chronic progressive signs that develop very slowly over many weeks or months are most likely to have neoplastic or degenerative disease.

BOX 58.10

Characterization of Disease Processes Based on Onset and Progression

Peracute (Minutes to Hours)

External trauma
Hemorrhage
Infarct
Internal trauma (disk extrusion, fracture)
Some intoxications

Subacute Progressive (Days to Weeks)

Infectious disease
Noninfectious inflammatory disease
Rapidly growing tumors (lymphoma, metastatic neoplasia)
Metabolic disorders
Some intoxications

Chronic Progressive (Months)

Most tumors
Degenerative disorders

CHAPTER 59

Diagnostic Tests for Nervous System and Neuromuscular Disorders

NEUROLOGIC EXAMINATION

A complete neurologic examination (Chapter 58) will enable the clinician to localize disease to a clinically relevant region of the nervous system. The neuroanatomic location of the lesion and the onset and progression of neurologic signs are important when developing a prioritized list of reasonable differential diagnoses. Once a list of likely differential diagnoses has been developed, diagnostic tests can be performed to confirm or exclude each.

SEARCH FOR SYSTEMIC ABNORMALITIES

Identification of concurrent systemic abnormalities may aid in the diagnosis of neoplastic, metabolic, or inflammatory disorders affecting the nervous system. A complete physical examination should be performed with particular attention to structures that have the potential to directly contact the nervous system such as eyes, ears, and bones of the spine and skull. Organs commonly affected by cancers with a high potential for nervous system metastasis such as skin, lymph nodes, mammary chain, prostate, and spleen should be carefully assessed whenever metastatic cancer to the nervous system is considered. A complete ophthalmologic evaluation including a funduscopic examination can identify abnormalities suggesting infectious or neoplastic disease.

Whenever metastatic neoplasia is being considered as a differential diagnosis for brain or spinal cord signs, a systemic cancer search should be performed, including thoracic and abdominal radiographs, abdominal ultrasound, and cytologic examination of fine-needle aspirates from lymph nodes and any cutaneous or internal masses. Imaging modalities and laboratory tests that allow diagnosis of specific nervous system disorders are limited, so identification and characterization of associated abnormalities in other tissues can facilitate diagnosis. More specific targeted diagnostic tests can then be performed to further evaluate animals with neurologic disease and thereby arrive at a specific diagnosis.

ROUTINE LABORATORY EVALUATION

Laboratory evaluation is used to search for a metabolic cause of encephalopathy in animals with seizures or other signs suggesting diffuse forebrain dysfunction, to characterize systemic disease, or to identify clinicopathologic abnormalities associated with some primary neurologic disorders. Routine testing including a complete blood count (CBC), serum biochemistry profile, and urinalysis is recommended in all patients with nervous system disease.

Hematologic findings are rarely specific, but a leukocytosis may suggest inflammatory disease. Dogs with acute canine distemper infection may be lymphopenic, and rarely inclusion bodies are identified within red blood cells (RBCs) and lymphocytes. Morulae are sometimes seen within neutrophils from dogs with granulocytic ehrlichiosis. Microcytosis with or without thrombocytopenia is common in dogs with portosystemic shunts. Rarely, atypical lymphocytes are identified in the blood from an animal with brain or spinal cord lymphoma.

A serum biochemical profile is most useful in identifying metabolic disorders causing neuropathies, encephalopathies, or seizures. A normal biochemistry profile can be used to eliminate diabetes mellitus, hypoglycemia, hypocalcemia, hypokalemia, uremia, and serum electrolyte disorders from the list of differential diagnoses. Serum creatine kinase is elevated in dogs and cats with muscle inflammation or necrosis. Urine specific gravity can be used to differentiate primary renal from prerenal azotemia. Ammonium biurate crystals are occasionally found in the urine of dogs and cats with portosystemic shunts (see Chapter 34).

Additional biochemical tests are frequently performed during the diagnostic evaluation of patients with neurologic disorders. Preprandial and postprandial bile acids are routinely measured to rule out hepatic encephalopathy in animals with forebrain signs and to monitor liver

function in animals being chronically treated with some anticonvulsants. Alternatively, provocative ammonia tolerance testing can be used to assess hepatic function in nonencephalopathic patients, and resting ammonia concentration can be measured in encephalopathic patients. Serum concentrations of anti-epileptic drugs are routinely monitored so that dosages can be adjusted to maximize efficacy and minimize toxicity (see Chapter 62). Several endocrine disorders can cause neurologic signs so specific testing is warranted whenever thyroid disease, adrenal gland dysfunction, or abnormalities of calcium or glucose metabolism could be responsible for an animal's neurologic signs.

IMMUNOLOGY, SEROLOGY, AND MICROBIOLOGY

A number of special diagnostic tests can be performed in patients with neurologic disorders when infectious or immune-mediated diagnoses are being considered. Clinicians should routinely perform bacterial culture of the cerebrospinal fluid (CSF), urine, and potentially blood in patients with inflammatory disease of the brain, spinal cord, or meninges. Concurrent systemic illness, potential for exposure, and vaccination status will determine what additional infectious disease testing is warranted. When lesions outside the CNS are identified (e.g., pneumonia, dermatitis), the most direct route to a diagnosis is usually by sampling those extraneural sites. Serum antibody or antigen tests are available for many of the infectious agents that can affect the CNS. An increased titer of a specific antibody in CSF relative to that in serum may be required to make a definitive diagnosis. Alternatively, immunohistochemical staining can be used to identify organisms in tissue (brain, spinal cord, muscle). In some cases, polymerase chain reaction (PCR) analysis is available for diagnosis of active infection by a specific organism.

Immune-mediated CNS disorders such as steroid-responsive meningitis-arteritis (SRMA), meningoencephalitis of unknown etiology (MUE), and granulomatous meningoencephalomyelitis (GME) are relatively common in dogs. Diagnosis requires finding typical clinical and clinicopathologic abnormalities and eliminating the possibility of infectious disorders, as previously discussed. Dogs with SRMA commonly have elevated serum and CSF immunoglobulin (IgA) levels, and some have concurrent immune-mediated polyarthritis that contributes to the diagnosis. In dogs with polyneuropathies, polymyositis, or apparent multisystemic immune-mediated disease, it may be useful to measure antinuclear antibody (ANA) titers to support a diagnosis of systemic lupus erythematosus (SLE). Most dogs with acquired myasthenia gravis have detectable circulating antibodies against acetylcholine receptors, and some dogs with masticatory muscle myositis have circulating serum antibodies directed against type 2M myofibers (see Chapter 67).

ROUTINE SYSTEMIC DIAGNOSTIC IMAGING

RADIOGRAPHS

Radiographs of the thorax are a useful screening test for metastatic neoplasia, some infectious disorders affecting the lung, and megaesophagus. Abdominal radiographs are useful for assessing liver size and organomegaly. Radiographs are noninvasive tests that should be performed routinely in animals with nervous system signs.

ULTRASOUND

Abdominal ultrasound is recommended to search for a primary tumor whenever metastatic neoplasia is considered as a possible cause of neurologic signs. Fine-needle aspirates of masses and enlarged organs should be submitted for cytologic evaluation. Ultrasound can also be used to identify portosystemic shunts in dogs and cats with forebrain signs.

DIAGNOSTIC IMAGING OF THE NERVOUS SYSTEM

SPINAL RADIOGRAPHS

Spinal radiographs are useful in the diagnosis of congenital malformations, fractures and luxations, disk disease, degenerative disease of the vertebrae or articular facets, diskospondylitis, and primary or metastatic vertebral neoplasia. Radiographs should be centered on the region of clinical interest established by the neurologic examination. General anesthesia is required to obtain lateral and ventrodorsal radiographs of sufficient quality to permit the detection of subtle abnormalities, but more obvious changes can often be identified with simple sedation. Radiographs are a useful first-line test but are not a very sensitive test for spinal disease. Vertebral bone lysis will not be detected radiographically until more than 50% of the cancellous bone is lost. Neoplasia affecting the soft tissues of the brain or spinal cord rarely causes abnormalities on plain radiographs.

MYELOGRAPHY

Myelography involves the intrathecal injection of a nonionic contrast medium followed by acquisition of lateral, ventrodorsal, and oblique radiographs to visualize the distribution of contrast material within the subarachnoid space. Historically, myelography has been most useful in identifying and localizing spinal cord compressive lesions such as herniated disks or tumors. During the last two decades, computed tomography (CT) and magnetic resonance imaging (MRI) have become more readily available and have largely replaced myelography for characterizing spinal lesions. Myelography is still a useful imaging study for patients with spinal cord disease when CT and MRI are unavailable.

CSF should always be collected before performing a myelogram, and it should be either analyzed or preserved for analysis. Injection of contrast will cause mild inflammation,

making diagnostic interpretation of CSF cytology difficult for at least 1 week after myelography.

Myelography can be technically difficult to perform and is associated with some risk of complications. The animal is anesthetized, CSF is collected for analysis, and survey radiographs are performed. Contrast material is introduced into the subarachnoid space at the atlanto-occipital (AO) or lumbar (L5/6) space. Lumbar injections are technically more difficult but associated with decreased risk of iatrogenic spinal cord trauma and improved delineation of thoracic and lumbar compressive spinal cord lesions, because the contrast material can be injected under increased pressure and forced around a site of severe compression. The techniques for cervical and lumbar myelography are described in detail elsewhere (see Suggested Readings).

Seizures occur in 10% to 20% of animals recovering from anesthesia after myelography and are most likely to occur in dogs larger than 29 kg requiring a large volume of contrast medium and when cisternal myelography is performed. These seizures can usually be controlled with diazepam (5-20 mg, administered intravenously). Neurologic deterioration occurs in some animals after myelography. Large-breed dogs with cervical spondylomyelopathy (Wobbler syndrome), dogs and cats with inflammatory CNS disease or extradural tumors, and dogs with degenerative myelopathy are most often affected. Fortunately this deterioration is usually transient.

A normal myelogram will show contrast material filling the subarachnoid space. This appears as a column of contrast agent on each side of the cord on ventrodorsal views and in the ventral and dorsal columns on lateral views (Fig. 59.1). In normal myelograms, a slight elevation and thinning of the ventral column of the contrast agent can be seen as it passes over each intervertebral disk space; however, a wide dorsal column remains, indicating that spinal cord compression is not present. Based on the features of the myelogram, a spinal cord lesion can be characterized as extradural compression, intradural extramedullary compression, or intramedullary swelling (Fig. 59.2). When available, the use of CT after myelography enhances visualization of small amounts of contrast in the subarachnoid space, allowing more precise lesion localization and diagnosis. This can be very helpful in determining location and laterality in the emergency evaluation of patients with acute nonmineralized disk extrusions. A much lower dose of contrast medium is required for CT myelography than for conventional myelograms (25% of contrast medium dose), decreasing the risk of myelogram-associated complications.

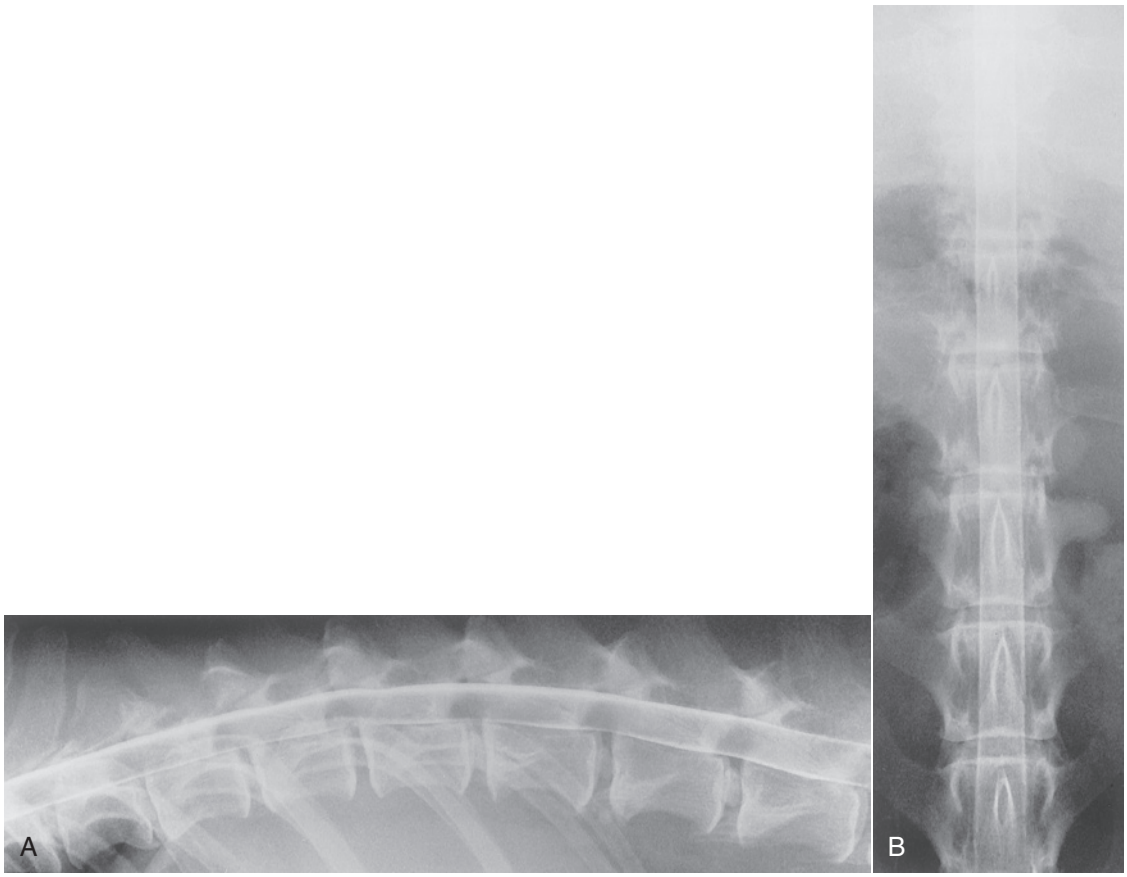

FIG 59.1
Lateral **(A)** and ventrodorsal **(B)** views of a normal myelogram of the thoracolumbar region in a dog. Multiple calcified intervertebral disks can be seen, but no spinal cord compression is evident. (Courtesy Dr. John Pharr, University of Saskatchewan.)

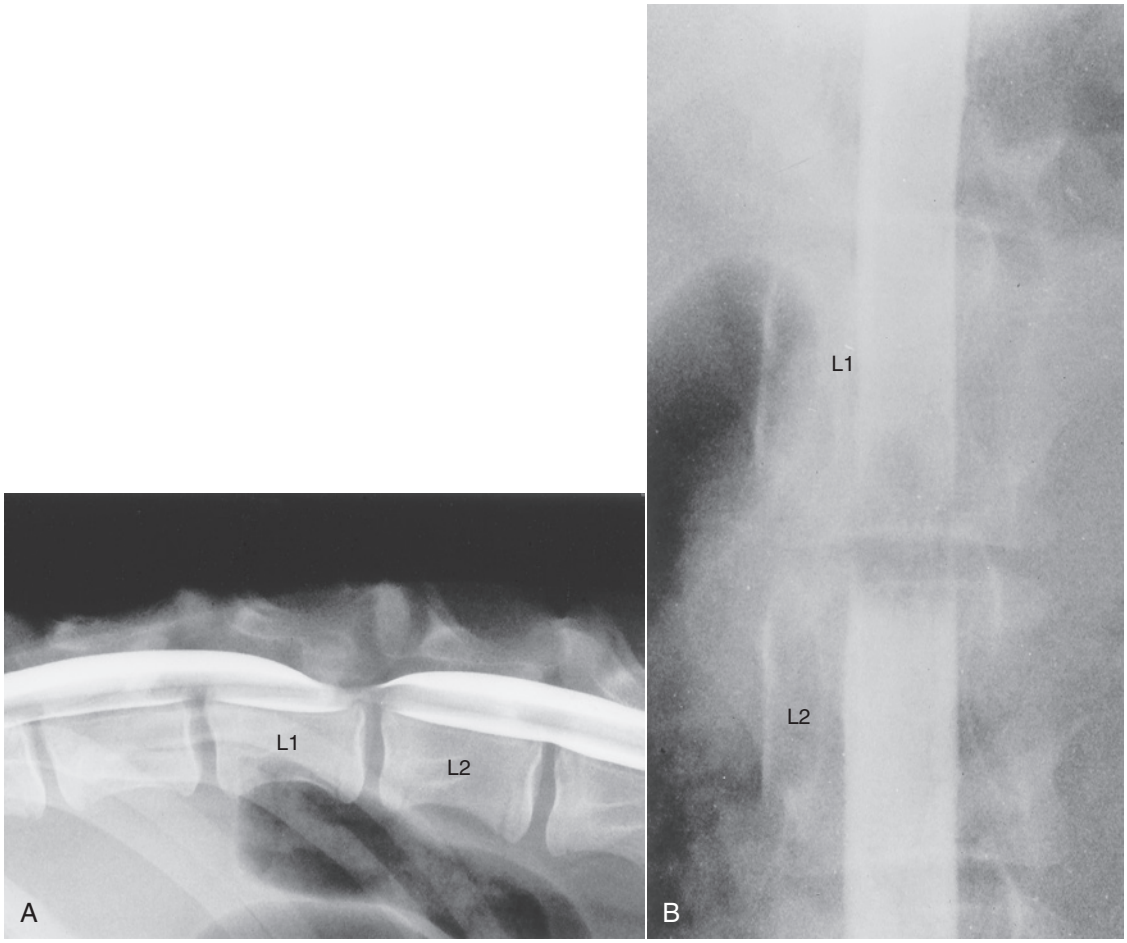

FIG 59.2
Lateral **(A)** and ventrodorsal **(B)** views of a myelogram in a 5-month-old German Shepherd Dog with a 3-week history of progressive ataxia. A dorsally located extradural compression of the spinal cord within the caudal portion of the L1 vertebra can be seen. At necropsy, the dog was found to have a single focal cartilaginous exostosis of the roof of the L1 vertebra.

COMPUTED TOMOGRAPHY

CT is most useful for identifying and characterizing bony abnormalities of the vertebral bodies and skull, particularly in patients with vertebral fractures/luxations, acute mineralized disk extrusions, vertebral tumors, bony lesions of cervical spondylomyelopathy, otitis media/interna, and fungal or neoplastic disease involving the nasal cavity or sinuses. Visualization and determining the laterality of nonmineralized disk extrusions using CT can be improved by administering nonionic water soluble iodinated contrast material into the subarachnoid space (CT-myelogram) or intravenously (CT-IV contrast). Although intraparenchymal detail of the brain and spinal cord is generally poor using CT alone, gross distortions and asymmetry can often be visualized. Precontrast and postcontrast images can be compared with highlight lesions that have increased vascularity or leaky vessels like many tumors or inflammatory lesions (Fig. 59.3)

During CT image acquisition an X-ray tube moves in a circular direction around the animal, and detectors measure X-rays projected through the animal. Images are reconstructed from this data, generating transverse and sagittal image slices and the potential for construction of images in other planes and 3-D volume renderings. This process is very rapid, resulting in very short scan times. CT scans are less expensive and more readily available than MRI, and can be performed under sedation rather than general anesthesia in stable patients.

MAGNETIC RESONANCE IMAGING

MRI, when available, is the imaging modality of choice for all lesions involving brain or spinal cord parenchyma, and peripheral nerves. MR images provide excellent soft tissue contrast resolution, displaying excellent neuroanatomical detail while providing insight into tissue composition and response to injury. The appearance of brain lesions using different MRI sequences not only localizes lesions precisely but helps distinguish inflammatory, neoplastic, and hemorrhagic lesions and infarcts. In animals with brain tumors,

anatomic location together with MRI characteristics can be used to predict tumor type in many cases (Figs. 59.4 and 59.5). Spinal MRI has been shown to be superior to CT and myelography in the imaging of dogs with cervical spondylomyelopathy, intervertebral disk herniation, synovial cysts, lumbosacral stenosis, spinal cord neoplasia, diskospondylitis, and vascular events such as bleeds, infarcts, and fibrocartilaginous emboli (Fig. 59.6). In addition to identifying sites of spinal cord compression, MRI allows evaluation of the response of neural tissues to compression, helping differentiate lesions causing acute clinical signs from older, more chronic lesions and scars.

MR images are generated by the effect of transiently applied radiofrequency currents on protons that are aligned by the strong magnetic field of the MRI scanner. When the radiofrequency pulse is halted, the protons realign and generate their own radiofrequency signal, which is measured by a coil. The combination of magnetic fields and radiofrequency pulses used to create an MRI image are called a pulse sequence. Different MRI sequences provide different information about tissues. The most common MR images used in veterinary neurology are T1-weighted and T2-weighted spin-echo images. Free fluid and most fluid within tissues (CSF, edema), appear black (low signal, hypointense compared with normal CNS parenchyma) on T1-weighted images and white (high signal, hyperintense compared with normal CNS parenchyma) on T2-weighted images.

Many tumors and inflammatory disorders result in increased fluid in tissues so have regions of increased T2-weighted signal intensity (bright regions). Wispy regions of high signal around lesions on T2-weighted images may represent edema. (Table 59.1) T1-weighted sequences are good for evaluating anatomy but are poor at detecting most lesions until MR imaging contrast material (gadolinium) is administered. In the regions where contrast leaks into the parenchyma due to a disrupted blood-brain barrier, there will be increased signal intensity (brightness on T1-contrast) representing the regions of the lesion that have a strong blood supply (see Fig. 59.4). In addition to the T1- and T2-weighted images obtained using routine spin-echo sequences, inversion recovery sequences can be used to suppress the high signal from fat using a short tau inversion recovery (STIR) sequence or the signal from free fluid using a fluid attenuated inversion recovery (FLAIR) sequence. Suppression of the signal from free fluid with a FLAIR sequence (making it hypointense) makes it possible to distinguish between cystic lesions and tissue edema within brain parenchyma and also improves visualization of subtle lesions adjacent to ventricular or subarachnoid CSF (see Table 59.1) It is important that MR images of the brain and spinal cord be evaluated and interpreted by specialists who are able to distinguish artifacts from actual lesions and are familiar with the rapidly expanding literature regarding the MRI characteristics of neurologic lesions. More details can be found in the recommended readings.

FIG 59.3
Computed tomography (CT) scan of the head of an 11-year-old Golden Retriever with a 5-month history of seizures and a progressive right head tilt. There is a large cystic, contrast-enhancing mass in the left cerebrum and cerebellum, most consistent with a cystic meningioma.

CEREBROSPINAL FLUID COLLECTION AND ANALYSIS

INDICATIONS

Analysis of CSF can be useful in the diagnostic evaluation of patients with CNS disease. Typical alterations in CSF

TABLE 59.1

cytology and protein concentration aid diagnosis in many conditions. Bacterial culture, PCR, and antibody determination in CSF can occasionally lead to a definitive diagnosis in patients with infectious CNS disease. CSF examination should be performed in most animals with certain or suspected brain or spinal cord disease in which a diagnosis is not readily apparent based on historical features, systemic abnormalities, and results of imaging. Analysis of CSF is most likely to contribute to diagnosis in dogs and cats with inflammatory CNS disease; patients with progressive forebrain signs and animals with fever and neck pain have the highest likelihood of CSF cytology being diagnostic.

CONTRAINDICATIONS

If proper technique is followed, the procedure for obtaining CSF is safe and simple. The animal is first placed under general anesthesia, and the puncture site is prepared in a sterile fashion. Spinal puncture should not be performed in

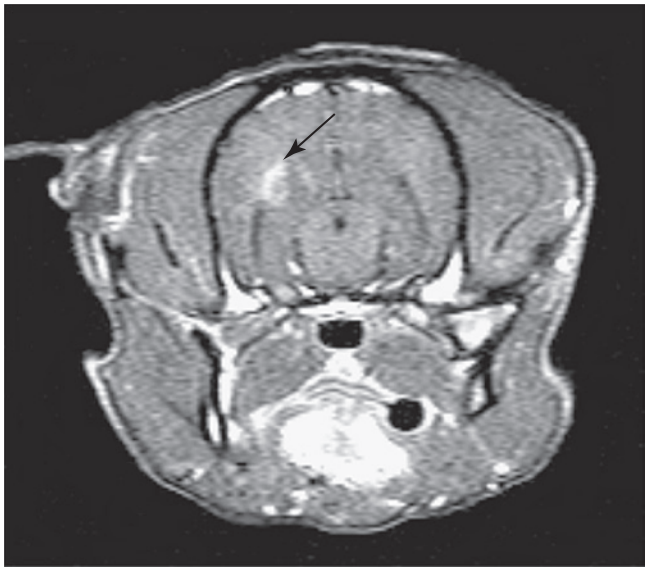

FIG 59.5
Magnetic resonance imaging (MRI) scan (transverse T1 image) of the brain of a 2-year-old Boston Terrier with a 2-week history of behavior change and difficulty walking. There is a 1-cm lesion within the right cerebrum that enhances with contrast *(arrow)*. This dog had granulomatous meningoencephalitis (GME) in his brain and cervical spinal cord.

BOX 59.1

Signs Suggesting Increased Intracranial Pressure

Depressed mentation or abnormal behavior
Constricted, dilated, or unresponsive pupils
Bradycardia
Increased arterial blood pressure
Altered breathing pattern

BOX 59.2

Treatment Steps to Decrease Intracranial Pressure

Oxygenate
Administer 20% mannitol: 1 g/kg, administered intravenously over 15 minutes
Furosemide: 1 mg/kg, administered intravenously
If anesthesia is necessary:
Rapid induction, intubate, and ventilate to maintain $Paco_2$ 30-40 mm Hg

an animal that is an obvious anesthetic risk or that has a severe coagulopathy. General anesthesia and collection of CSF should not be performed in any patient with suspected increased intracranial pressure (Box 59.1) without first taking steps to lower the intracranial pressure; this decreases the risk of brain herniation (Box 59.2).

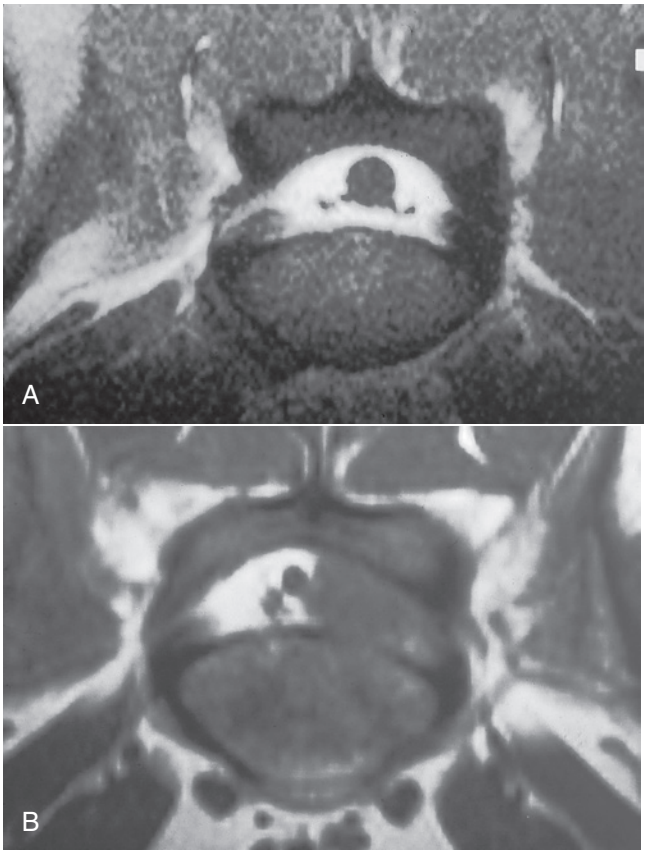

FIG 59.6
Magnetic resonance imaging (MRI) scans (transverse T1 images) of the caudal lumbar region of **(A)** a normal dog and **(B)** a Golden Retriever with prolapsed disk material within the vertebral canal. (Courtesy Dr. John Pharr, University of Saskatchewan.)

TECHNIQUE

In dogs and cats the most reliable source of CSF for analysis is the cerebellomedullary cistern (CMC), also termed the AO site. Lumbar CSF collection from the L5-L6 site may also be used, but it is more difficult to obtain a large volume of uncontaminated fluid from this site. CSF is produced by the choroid plexi within the ventricular system of the brain and flows from cranial to caudal, so when there is focal disease, CSF samples are most likely to be abnormal when collected caudal to the lesion. It is recommended to collect both lumbar and CMC CSF in animals with spinal cord disease.

Cisternal Puncture

With the animal under general anesthesia, clip and scrub the back of its neck between the ears from 2 cm rostral to the occipital protuberance to C2. If the clinician is right handed, the animal should be placed in right lateral recumbency with its neck flexed so that the median axis of the head is perpendicular to the spine. The nose should be elevated slightly so that its midline is parallel to the surface of the table. With the thumb and third finger of the left hand, the clinician should palpate the cranial edges of the wings of the atlas and

draw an imaginary line at their most cranial aspect. If that imaginary line is not perpendicular to the table, then padding should be placed under the animal's shoulder to bring the wings into alignment.

The examiner can then use the left index finger to palpate the external occipital protuberance and draw a second imaginary line caudally from that site along the dorsal midline. The needle should be inserted where the two imaginary lines intersect (Fig. 59.7) (Video 59.1).

A 1½ or 3-inch-long (3.75-7.5 cm) styletted spinal needle is then directed straight in through the skin (perpendicular to the spine) and into the underlying tissues, with the bevel directed cranially. The needle is advanced 1 to 2 mm at a time, and the stylette is removed so that the clinician can look for CSF. While the right hand is used to remove the stylette, the thumb and first finger of the left hand, which is rested against the spine for support, should grasp and stabilize the hub of the needle. A "pop" may be felt as the dorsal AO membrane and the dura mater and arachnoid mater are penetrated simultaneously (Fig. 59.8). This is not a reliable sign, however, and the level at which the subarachnoid space is reached varies greatly with the breed and individual animal. It is often very close to the skin surface in toy breeds and some cats.

If the needle strikes bone, it should be withdrawn, the patient position and landmarks reassessed, and the procedure repeated. If whole blood appears in the spinal needle, the needle should be withdrawn and the procedure repeated with another sterile needle. When CSF is observed, the fluid should be allowed to drip directly from the needle into a test tube. The clinician should check with the laboratory to determine the type of tube preferred for collection of CSF. Plastic tubes are preferred because cells may adhere to glass tubes. Grossly hemorrhagic CSF should be collected into a tube containing ethylenediaminetetraacetic acid (EDTA) to prevent clotting but samples for bacterial culture should be free of anticoagulant. The amount of CSF collected ranges from 0.5 to 3 mL depending on the size of the animal (no more than 1 mL/5 kg body weight). Simultaneous jugular vein compression may hasten flow but will transiently increase intracranial pressure. Blood in the CSF may be the result of the disease or the tap. If it is caused by the procedure, the amount of blood should decrease as the CSF drips from the needle. If this occurs, some of the less contaminated fluid should be collected in a second tube for cytologic evaluation. Mild CSF contamination with hemorrhage (<500 RBCs/μL) does not alter the CSF protein and leukocyte determinations.

Lumbar Puncture

The animal is placed in lateral recumbency with its trunk flexed. Foam cushions are placed between its limbs and beneath the lumbar region to achieve true lateral positioning. The spines of the lumbar vertebrae are palpated; the first dorsal spinous process that can be palpated cranial to the ilial crests is L6. Lumbar puncture should be performed at the L4-L5 or the L5-L6 space (ideal) in dogs and the L6-L7 space in cats. To access the L5-L6 space, a 3½-inch (8.75-cm) spinal needle is inserted on midline at the cranial edge of the dorsal spinal process of L6 and directed ventrally into the ligamentum flavum (Fig. 59.9). The needle is passed in a smooth motion through or alongside the caudal spinal cord and cauda equina into the ventral subarachnoid space. The animal's tail and pelvic limbs may twitch when the cord is penetrated. Because CSF flow is slower from this site and more likely to be contaminated by blood, cerebellomedullary collection is usually preferred for diagnostic purposes.

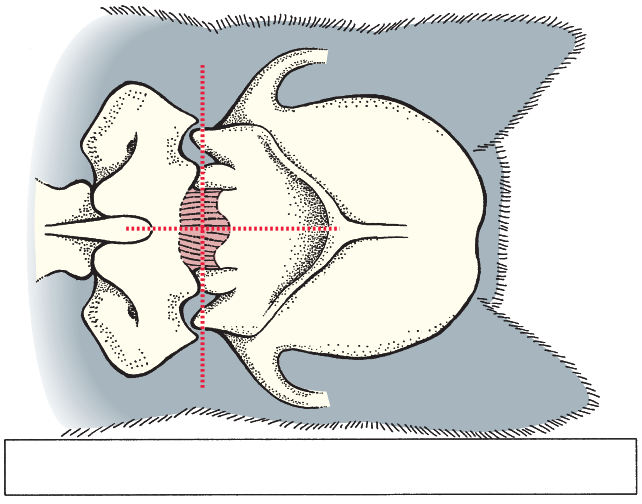

FIG 59.7
Landmarks for cerebrospinal fluid (CSF) collection at the cerebellomedullary cistern. The site of needle entry is at the intersection of the dorsal midline and the most cranial aspect of the wings of the atlas.

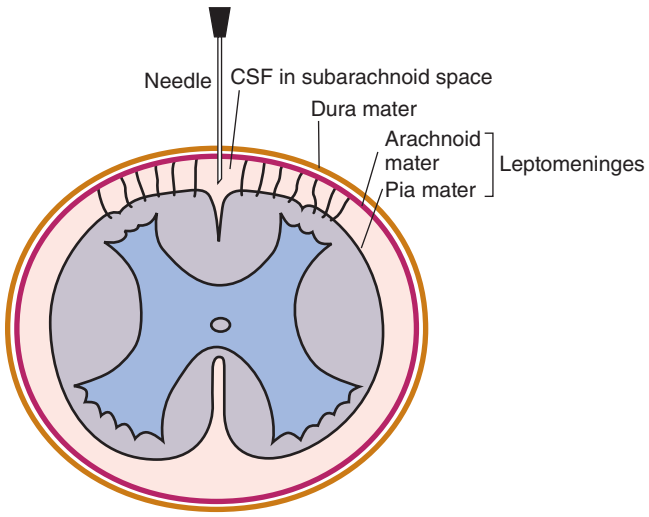

FIG 59.8

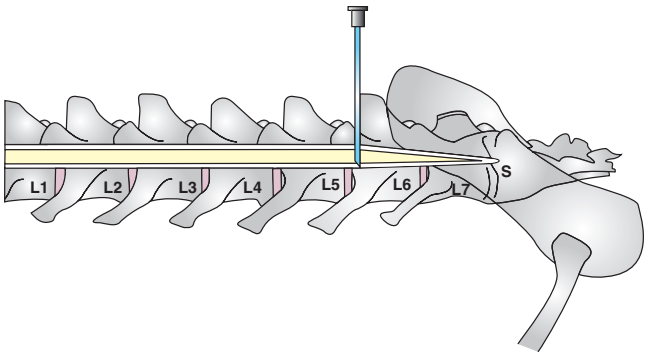

FIG 59.9
Landmarks for cerebrospinal fluid (CSF) collection from a lumbar site. The needle is inserted at the cranial edge of the dorsal spinal process of the L6 vertebra and directed into the ventral subarachnoid space. (From Taylor SM: *Small animal clinical techniques,* St Louis, 2010, Elsevier.)

ANALYSIS

Normal CSF is clear and colorless. A cell count should be performed and a cytologic preparation made for examination as soon as possible because white blood cells (WBCs) in the CSF deteriorate rapidly. If the sample must be stored for longer than 1 hour before analysis, the specimen should be refrigerated to slow cellular degeneration. Abnormal CSF with high protein and cell count can be refrigerated for up to 8 hours without changing diagnostic interpretation, but cellular degeneration is rapid in samples with normal protein concentration. The addition of autologous serum (10% by volume of the sample or 3 drops of serum/0.25 mL CSF) will preserve CSF so that cytologic analysis 24 to 48 hours after collection will yield reliable results, but a separate sample should be saved for protein analysis. Alternatively, hetastarch (6% hydroxyethyl starch in 0.9% NaCl [Abbott Laboratories, North Chicago, Ill]) can be added to CSF in equal volume (1:1) to preserve cytologic features without affecting the protein measurement (but diluting it by half) when CSF must be stored for longer than 1 hour before analysis.

Once the fluid is collected, a total cell count is performed and the concentration of RBCs and WBCs is determined. The normal range of values varies with each laboratory, but in general there should be fewer than 3 to 5 WBCs/μL. An increased number of CSF WBCs is referred to as *pleocytosis.* A pleocytosis should be further characterized by microscopic examination and differential cell count to determine the predominant leukocyte present. Cytologic analysis of CSF is necessary even if the WBC count is normal, because there may be abnormal cell types or organisms present.

A concentration procedure is usually required to obtain sufficient cells for cytologic assessment. Cytocentrifuge concentration of CSF is available in most institutions and commercial laboratories, and results are best if samples are processed within 60 minutes of collection or if samples are preserved as described earlier.

Most of the cells in the CSF of normal dogs and cats are small, well-differentiated lymphocytes (60%-70%). Minimally vacuolated large mononuclear phagocytes comprise most of the additional cells. Occasional neutrophils and eosinophils are present, but these cells should not normally make up more than 2% of the cell population. The typical CSF findings in some specific disorders in dogs and cats are summarized in Box 59.3. It is important to realize, however, that CSF cytologic findings must always be interpreted in relation to the signalment, history, and clinical findings.

If blood contamination is severe, it can influence the cytologic findings, but even grossly apparent iatrogenic contamination with peripheral blood will have only a minor impact on WBC count and protein analysis. To approximate the maximum effect blood contamination will have on the WBC count in CSF, 1 WBC/μL can be expected for every 500 RBCs/μL. Iatrogenic blood contamination can be distinguished from pathologic hemorrhage by the presence of platelets and/or the absence of cytologic evidence of erythrophagia or erythrocyte breakdown pigments in the sample.

The protein content of the collected CSF should be determined. The protein concentration in samples collected from the lumbar site (<40 mg protein/dL) is normally higher than the protein content of CSF collected from the CMC (<25 mg protein/dL). An increase in the CSF protein content can occur in diseases that disrupt the blood-brain barrier, cause local necrosis, interrupt normal CSF flow and absorption, or result in intrathecal globulin production. Whenever the CSF is cellular, it should be submitted for Gram staining and anaerobic and aerobic bacterial culture. If infectious disorders are considered likely (see discussion of meningitis, Chapter 64), specific culture techniques can be applied or, when available, PCR can be used to identify infectious agents in CSF. Antibody titers to a variety of infectious organisms can also be measured in CSF, but blood contamination and leakage of antibodies from the serum to the CSF can be problematic.

ELECTRODIAGNOSTIC TESTING

Electrophysiologic studies can be used to record electrical activity from muscle or neural tissue and aid in lesion localization and characterization. These tests are minimally invasive but usually require sedation or general anesthesia. Equipment costs and the experience needed to conduct the studies limit their use to academic and referral clinics.

ELECTROMYOGRAPHY

Normal muscle is electrically silent. As a needle is inserted into normal muscle, a short burst of electrical activity is elicited, which stops when the needle insertion is stopped. Severance, destruction, or demyelination of the peripheral nerve supplying the muscle results in the development of spontaneous fibrillations and positive sharp waves (i.e., denervation potentials) and prolonged insertional activity in affected muscles 5 to 7 days after denervation. These changes

BOX 59.3

Interpreting Cerebrospinal Fluid Cytology

Normal: Cell Count <5 White Blood Cells/μL; Protein <25 mg/dL

Normal Cell Count and Differential; Slightly Increased Protein
- Extradural spinal cord compression (disk, tumor, malformation, synovial cyst)
- Intramedullary spinal cord mass or dilation
- Brain neoplasia
- Degenerative myelopathy
- Fibrocartilaginous embolism
- Trauma
- Polyradiculoneuritis

Lymphocytic Pleocytosis (>50% lymphocytes)
- Viral meningitis/encephalitis (rabies, distemper)
- Necrotizing meningoencephalitis (Pugs, Malteses, Yorkshire Terriers, Chihuahuas)
- Feline polioencephalomyelitis
- Central nervous system lymphoma

Mixed Cell Pleocytosis (Lymphocytes, Mononuclear Phagocytes, Neutrophils, Plasma Cells)
- Canine granulomatous meningoencephalitis (GME)
- Meningoencephalitis of unknown etiology (MUE)
- Protozoal infection (neosporosis, toxoplasmosis)
- Rickettsial infection (ehrlichiosis, *Rocky Mountain spotted fever*)
- *Feline infectious peritonitis meningoencephalitis*
- *Lyme neuroborreliosis*
- *Fungal meningoencephalitis (blastomycosis, cryptococcosis, aspergillosis)*

Neutrophilic Pleocytosis
- Bacterial meningoencephalitis
- Fungal meningoencephalitis (blastomycosis, cryptococcosis, aspergillosis)
- Steroid-responsive meningitis arteritis
- Rocky Mountain spotted fever
- Feline infectious peritonitis meningoencephalitis
- Lyme neuroborreliosis
- Postmyelographic irritant meningitis

Eosinophilic Pleocytosis
- Steroid-responsive eosinophilic meningitis (especially Golden Retrievers)
- Parasite migration
- *Protozoal infection*
- *Fungal meningoencephalitis*
- *Neoplasia*

Italics signify unusual presentation.

may also be seen in some primary muscle disorders. Electromyography (EMG) is most useful to confirm a suspected diagnosis of a muscle or peripheral nerve disorder and to identify abnormal muscles for subsequent biopsy.

NERVE CONDUCTION VELOCITIES

The conduction velocity of motor nerves can be determined by stimulating a nerve at two separate sites and recording the time it takes for an evoked compound muscle action potential to occur in a target muscle. The motor nerve conduction velocity in the segment of nerve between the two stimulation sites can be determined by measuring the distance between the two sites and the difference in the time it takes for the evoked potentials to appear. Variations on this technique are used to determine conduction in motor nerve roots (F waves) and in sensory (or mixed motor/sensory) nerves. Slow conduction times are seen in demyelinating disorders, allowing the diagnosis of peripheral neuropathies. Nerves that have been injured or avulsed and that have degenerated (onset typically 4-5 days after injury) do not conduct an impulse, so nerve conduction velocity testing can also be used to diagnose and localize peripheral nerve injuries.

ELECTRORETINOGRAPHY

An electroretinogram (ERG) is a recording of the electrical response of the retina to a flashing light stimulus. It is an objective way to evaluate retinal function, assessing both rod and cone receptors. The ERG is most useful for evaluating blind animals in which the retina appears normal on ophthalmic examination (e.g., diagnosing sudden acquired retinal degeneration) or in which the retina cannot be visualized (e.g., determining whether animals with cataracts have concurrent retinal degeneration). The ERG is abnormal with degenerative disorders of the retina, but it is normal if the lesion causing visual dysfunction is located caudal to the retina (in the optic nerves, optic chiasm, optic tract, or cerebral cortex). The ERG can be performed under general anesthesia or under sedation if the patient is uncooperative.

BRAINSTEM AUDITORY EVOKED RESPONSE

The brainstem auditory evoked response (BAER) depicts the response of nervous tissues to an auditory stimulus (a click). The response is a series of waveforms representing activity beginning in the cochlea and being relayed up the auditory pathway in the brainstem. Lesions of the outer, middle, or inner ear; the peripheral vestibulocochlear nerve; and the brainstem caudal to the midbrain cause characteristic changes in the response, aiding in lesion localization. This test has been most widely used for detecting unilateral and bilateral congenital deafness in dogs.

ELECTROENCEPHALOGRAPHY

Electroencephalography provides a graphic record of the spontaneous electrical activity of the cerebral cortex. Results may help determine whether a cerebral disorder is focal or diffuse. Some dogs with epilepsy will have abnormal electroencephalograms (EEGs) between seizures.

BIOPSY OF MUSCLE AND NERVE

MUSCLE BIOPSY

Muscle biopsy specimens should be evaluated when there is clinical and electrophysiologic evidence of muscular disease. A biopsy may provide a definitive diagnosis or indicate the nature of the disease process. For best results, muscle that is affected should be biopsied, and in generalized disorders two different muscles should be sampled. For investigation of myopathic disorders, proximal limb muscles such as the vastus lateralis or triceps should be biopsied, whereas neuropathies are more evident in distal limb muscles such as the cranial tibial or extensor carpi radialis. Because complete histopathologic examination of muscle requires fresh-frozen tissue, most laboratories request that fresh muscle samples be wrapped in a saline-moistened gauze and shipped overnight under refrigeration. Whenever formalin-fixed samples are submitted, the sample should be attached to a splint, such as a tongue depressor, to prevent contraction during fixation. Routine histologic studies may reveal inflammatory or neoplastic changes and the etiologic agent if the disease is infectious.

When fresh-frozen tissue is evaluated using a full range of enzymatic and immunohistochemical techniques, many characteristics of the muscle can be determined. Based on enzymatic staining characteristics, muscle fibers can be classified according to type and the proportion and distribution of myofiber types described. Some myopathies result in a selective loss of one fiber type. Denervation with reinnervation, as occurs in many neuropathies, results in "type grouping," wherein the normal checkerboard pattern disappears and large clusters of fibers of the same type appear. Muscle fiber shape and size, the presence of degeneration or necrosis, the location of nuclei, the presence of vacuoles or inclusions, and the presence of cellular infiltrates are all evaluated. Immunostains are also available to identify some parasites *(Neospora)* and evaluate muscles for normal structural components. Muscle samples should be sent to a laboratory with a special interest and expertise in muscle disorders to ensure that optimal results are obtained and accurately interpreted. Clinicians should consult the laboratory that will process the biopsy to learn the proper technique of obtaining, preparing, and submitting specimens and the other procedures to be followed.

NERVE BIOPSY

It may be useful to obtain nerve biopsy specimens in an effort to evaluate peripheral nerve disorders. Nerves are biopsied by transecting approximately one third of the width of the nerve and removing fascicles about 1 cm in length, leaving most of the nerve trunk intact. It is important to biopsy nerves that are affected. The common peroneal nerve and the ulnar nerve are the mixed (i.e., motor and sensory) nerves most commonly biopsied. As with muscle biopsy specimens, nerve biopsy specimens require special handling to ensure that maximal information is obtained. Samples should be laid out on a piece of wooden tongue depressor and pinned at each end to keep them oriented longitudinally, but they should not be stretched. They should then be fixed in 2.5% glutaraldehyde or buffered 10% formalin for light microscopy. Fresh nerve samples can be frozen in liquid nitrogen and stored for biochemical analysis.

CHAPTER 60

Intracranial Disorders

GENERAL CONSIDERATIONS

When the neurologic examination suggests a lesion is located above the foramen magnum, a variety of disorders should be considered as differential diagnoses. Some disorders typically affect only one particular region of the brain (e.g., forebrain, cerebellum, or brainstem), whereas others can affect any location or multiple locations within the brain simultaneously. Localization of intracranial disease will help to determine a reasonable list of differential diagnoses and guide your diagnostic plan.

Altered mentation or seizures with a relatively normal gait are the most pronounced abnormalities in animals with forebrain disease, whereas dull mentation, proprioceptive ataxia, and multiple cranial nerve deficits suggest brainstem disease. Hypermetria and ataxia are common in cerebellar disorders, and lesions of the central vestibular system within the brainstem or cerebellum usually cause a head tilt, loss of balance, and nystagmus (see Chapter 63).

ABNORMAL MENTATION

Abnormal behavior, delirium, compulsive behavior, and seizures can be seen in dogs and cats with lesions of the cerebral cortex and with intoxications or metabolic encephalopathies. Disorders affecting the brainstem can also cause severe depression, stupor, and coma.

When presented with a dog or cat with abnormal mentation, the clinician must first ascertain whether the problem is purely behavioral, the result of systemic illness, or an indication of an intracranial lesion. The history obtained from the owner regarding the animal's normal behavior, systemic signs, and the circumstances preceding the onset of altered mentation may help identify a neurologic problem. Defined neurologic deficits confirm the existence of an abnormality within the nervous system. With some unilateral forebrain lesions, animals turn or circle toward the side of the lesion and ignore all sensory input (touch, seeing, hearing) on the side opposite the lesion (hemiinattention syndrome). Although their gait will usually be normal, animals with forebrain lesions may exhibit postural reaction deficits on the side opposite the lesion. Brainstem lesions more reliably cause altered consciousness, multiple cranial nerve deficits, and ipsilateral upper motor neuron (UMN) paresis, ataxia, and postural reaction deficits.

INTOXICATIONS

Intoxication with household toxins, insecticides, rodenticides, and prescription or illicit drugs must be considered in any dog or cat with an acute onset of abnormal mentation. Anxiety and delirium may precede severe depression, seizures, and other neurologic and systemic signs. Common toxic agents causing mentation changes and seizures in dogs and cats are discussed in Chapter 62. The clinical signs of intoxication are usually acute and severe, with rapid deterioration. A history of potential ingestion or exposure to a toxin and the finding of characteristic progressive clinical signs lead to the diagnosis. Treatment must be initiated to remove the toxin, prevent further absorption, and expedite its elimination. Intoxications resulting in seizures also require emergency treatment for seizures, as described for status epilepticus (see Box 62.7).

METABOLIC ENCEPHALOPATHIES

Animals with abnormal mentation, diminished consciousness, or seizures should always be evaluated for metabolic disturbances such as hepatic encephalopathy, hypoglycemia, severe uremia, electrolyte disturbances, and hyperosmolality (e.g., untreated diabetes mellitus). Severely depressed mentation can also be a manifestation of severe systemic illness, sepsis, hypoadrenocorticism, or hypothyroid myxedema coma. Detailed information on diagnosis and management of these metabolic disorders can be found elsewhere in this text.

HYPERMETRIA

A hypermetric gait, with each limb raised excessively during protraction and then returned more forcefully than normal to weight bearing, suggests that there has been a loss of the

normal cerebellar regulation of the rate, range, and force of movement. Animals with disease limited to the cerebellum are ataxic but strong, with normal postural reactions and spinal reflexes. They are unable to judge distances or control the range of movements and will make a series of jerking and bobbing movements (intention tremor) when attempting to perform precise movements. A fine tremor of the head and body may also be present at rest.

DIAGNOSTIC APPROACH TO ANIMALS WITH INTRACRANIAL DISEASE

Intracranial disorders that commonly cause neurologic signs include external trauma, vascular disorders (e.g., hemorrhage and infarction), congenital anomalies (e.g., hydrocephalus, lissencephaly, cerebellar hypoplasia), infectious and noninfectious inflammatory diseases (e.g., encephalitis), degenerative disorders, and primary or metastatic brain tumors (Box 60.1). Evaluation should always include a complete physical and neurologic examination as well as an ophthalmologic examination. When the cause of the neurologic signs is not readily apparent, animals should be screened for metabolic disorders and systemic manifestations of infectious or neoplastic disease using clinicopathologic tests, cytologic examination of aspirates from lymph nodes and masses, thoracic and abdominal radiographs, and abdominal ultrasound. Approximately 10% of dogs with intracranial neoplasia have abnormalities on these staging tests that make further diagnostic evaluation unnecessary. Advanced neuroimaging (computed tomography [CT] or magnetic resonance imaging [MRI]) and cerebrospinal fluid (CSF) collection and analysis will be required for diagnosis when disease is restricted to an intracranial site. MRI provides much better soft tissue resolution than CT and is the preferred imaging method whenever brain lesions are suspected, but CT is faster, less expensive, and more readily available in emergency situations, and it provides adequate images when bony lesions are present (Box 60.2).

BOX 60.1

Disorders Causing Intracranial Disease

- External trauma
- Vascular disorders
  - Hemorrhage
  - Infarcts
    - Ischemic infarcts—many causes
    - Feline ischemic encephalopathy (FIE)
    - Hippocampal necrosis
  - Hypertensive encephalopathy
- Congenital anomalies
  - Hydrocephalus
  - Lissencephaly
  - Cerebellar hypoplasia
  - Others
- Inflammatory disease
  - Infectious encephalitis
  - Meningoencephalitis of unknown etiology (MUE)
    - Granulomatous meningoencephalitis (GME)
    - Necrotizing meningoencephalitis
    - Leukoencephalitis
    - Others
- Degenerative disorders
  - Metabolic storage diseases
  - Spongy degeneration
  - Neuroaxonal dystrophy
  - Hereditary cerebellar ataxia
    - Cerebellar cortical degeneration
    - Spinocerebellar degeneration
    - Others
  - Many other disorders
- Neoplasia
  - Primary brain tumors
  - Tumors extending into brain (skull, nose, sinus, ear, eye)
  - Secondary brain tumors (metastatic from nonneural site)

INTRACRANIAL DISORDERS

HEAD TRAUMA

The outcome for animals with head trauma depends largely on the location and severity of the initial injury. Common causes of head injuries in dogs and cats include motor vehicle accidents and kicks and bites from larger animals. The initial trauma to the brain parenchyma is followed by secondary damage resulting from hemorrhage, ischemia, and edema. Because the brain is enclosed within the bones of the skull,

BOX 60.2

Diagnostic Approach to Animals With Suspected Intracranial Disease

1. Perform a complete history, physical examination, and neurologic assessment.
   - Focal or asymmetric deficits suggest intracranial disease.
2. Rule out metabolic encephalopathies.
   - Hematology, serum chemistry profile, urinalysis
   - Blood glucose: fasting, symptomatic, postprandial
   - Liver function test
3. Evaluate for systemic inflammatory or neoplastic disease.
   - Complete ophthalmic examination
   - Thoracic and abdominal radiographs
   - Abdominal ultrasound
   - Aspirates of lymph nodes (± spleen, liver, bone marrow, masses)
   - Serology when appropriate
4. Perform an intracranial examination.
   - Neuroimaging (computed tomography, magnetic resonance imaging)
   - Cerebrospinal fluid collection and analysis

as brain volume increases with edema or hemorrhage, there is an increase in intracranial pressure, leading to decreased cerebral perfusion and further brain damage.

Initial management of a patient with brain injury should focus on recognizing and treating systemic injuries and maintaining adequate circulation and respiration. Systemic hypotension decreases cerebral perfusion, so fluids should be administered to maintain blood volume (Box 60.3). Administration of synthetic colloids such as Pentaspan (10% Pentastarch in 0.9% NaCL [Bristol-Myers Squibb]) or administration of hypertonic saline solution (7.2%) allows rapid restoration of blood volume and pressure without the large volume of fluid required when crystalloids alone are administered. Oxygen should be administered by mask or via nasal or transtracheal catheter. If the animal is unconscious, immediate intubation and ventilation may be required. Hyperventilation reduces intracranial pressure but causes cerebral vasoconstriction and decreased cerebral perfusion, so it must be used with caution. Whenever possible, a $Paco_2$ of 30 to 35 mm Hg should be maintained. If seizures are evident, aggressive anticonvulsant therapy should be initiated as for status epilepticus (see Chapter 62) because seizure activity greatly increases intracranial pressure. Measures to lower intracranial pressure include elevating the head at a 30-degree angle from horizontal, administration of an osmotic diuretic such as intravenous mannitol (1 to 1.5 g/kg over 15 minutes) or hypertonic saline solution (4-5 mL/kg of 7.2% NaCl over 2-5 minutes), and administration of narcotic analgesic medications as required. Administration of high doses of methylprednisolone sodium succinate (SoluMedrol) during the first 6 hours after presentation has been shown to be beneficial in patients with spinal cord injury but may actually be detrimental in patients with serious brain injury.

Systemic and neurologic assessment should be repeated every 30 minutes. Although a scoring system (modified Glasgow Coma Scale) has been developed to allow grading and serial monitoring of neurologic status, it is only useful in dogs with such severe brainstem and cerebral injury that they are unlikely to recover.

BOX 60.3

Management of Intracranial Injury

All Patients

Establish patent airway, administer oxygen.
Examine, assess, and treat concurrent injuries.
Treat shock, maintain blood pressure (intravenous fluids, colloids).
- Isotonic crystalloids: ¼ of shock dose (90 mL/kg dog, 60 mL/kg cat), reassess q15min
- Pentaspan: ¼ of the 20 mL/kg shock dose
- Hypertonic saline: 4-5 mL/kg of 7.2% NaCl over 2-5 minutes

Maintain mean arterial blood pressure 80-120 mm Hg.
Monitor neurologic status every 30 minutes.

If Severe Initial Injury or Deterioration

Elevate head 30 degrees.
Treat seizures if present (see Box 62.7).
Administer hyperosmolar therapy.
- 20% mannitol: 1-1.5 g/kg, administered intravenously over 15 minutes (can repeat in 3 hours) ***or***
- Hypertonic saline: 4-5 mL/kg of 7.2% NaCl over 2-5 minutes

If intubated, maintain $Paco_2$ at 30-35 mm Hg.

VASCULAR ACCIDENTS

Vascular accidents, also called *strokes,* occasionally occur in the central nervous systems (CNS) of dogs and cats, and cause a peracute onset of neurologic abnormalities. Ischemic strokes result from occlusion of an intracranial blood vessel by a thrombus or embolus. Hemorrhagic strokes result from bleeding into the brain parenchyma.

Ischemic strokes occur when cells or clots enter the circulation from septic foci (endocarditis), primary or metastatic neoplasia, vasculitis, heartworm disease, or cardiac disease. Atherosclerosis, a common cause of thromboembolic stroke in humans, has also been associated with stroke due to intravascular clot formation in dogs with hypothyroidism, and less commonly in dogs with diabetes mellitus, hyperadrenocorticism, or hereditary hyperlipidemia. Chronic hypertension also promotes vascular changes predisposing to ischemic or hemorrhagic stroke. Animals with peracute neurologic signs should always have their blood pressure measured, and if they are hypertensive they should be evaluated for potential causes such as renal failure, hyperadrenocorticism (dogs), and hyperthyroidism (cats). Despite thorough investigations, an underlying cause is only identified in approximately half of all dogs with ischemic stroke.

Spontaneous intracranial hemorrhage can occur without an obvious underlying cause or can be the result of a coagulopathy, a bleeding primary or metastatic brain tumor (especially hemangiosarcoma), or hypertension. Screening for thrombocytopenia, inherited or acquired coagulopathies, disseminated intravascular coagulation, systemic neoplasia, and disorders associated with hypertension is indicated when intracranial bleeding is suspected.

In ischemic or hemorrhagic stroke, the abruptness with which neurologic deficits develop is highly suggestive of a vascular disorder. There may be some progression of signs due to edema in the first 24 to 72 hours, but most animals with nonfatal ischemic strokes begin to recover quickly. Hemorrhagic strokes are more likely than ischemic strokes to cause rapidly progressive neurologic deficits, increased intracranial pressure, and death.

Neurologic deficits reflect the location of the vascular insult, with forebrain and cerebellar strokes most common in dogs. In cats, forebrain and brainstem infarcts are more common. A predisposition for cerebellar infarcts is present in hypothyroid hyperlipidemic Labrador Retrievers and in Cavalier King Charles Spaniels. Results of physical

examination, clinicopathologic evaluation, and thoracic radiography may be unremarkable aside from the neurologic abnormalities or may reflect the underlying disease process. Systemic blood pressure should be measured and an ocular examination performed to search for hypertension-related hemorrhage or retinal detachment. Platelet numbers and coagulation should be assessed, and screening for systemic neoplasia is warranted. CT is an excellent imaging tool for identifying acute hemorrhagic stroke but is rarely diagnostic for ischemic disease. MRI can detect large ischemic strokes within 12 to 24 hours of the onset of signs and can distinguish hemorrhagic lesions from infarction. Although infarcts can be difficult to distinguish from inflammatory or neoplastic brain lesions, the conformity of a lesion to a wedge-shaped vascular territory with sharp demarcation from the surrounding normal brain and no mass effect is highly suggestive of an infarct. It is common for imaging to be normal or to show focal edema in animals with very small infarcts or vascular leaks. A more complete discussion of the imaging findings expected in animals with intracranial hemorrhage and ischemia can be found in the Suggested Readings.

Short-term aggressive therapy to lower intracranial pressure as described for head trauma (see Box 60.3) may be indicated in animals with suspected ischemic or hemorrhagic stroke. Underlying disorders such as hypertension and coagulopathy should be managed. Most mildly or moderately affected animals show dramatic improvement during the first 3 to 10 days after the onset of signs, although some never return to normal functional status.

HYPERTENSIVE ENCEPHALOPATHY

Hypertensive encephalopathy has been recognized in dogs and cats with an acute rise in blood pressure (increase >30 mm Hg from resting) or a sustained elevation in systolic arterial blood pressure (>180 mm Hg). Signs may result from vasogenic and interstitial cerebral edema caused by hyperperfusion. Clinical signs include altered mentation, anxiety, blindness, seizures, and occasionally vestibulocerebellar signs such as head tilt, loss of balance, and nystagmus. Signs usually rapidly resolve within hours to days of correcting the hypertension. Long-term treatment is usually required to prevent recurrence of signs.

FELINE ISCHEMIC ENCEPHALOPATHY

Feline ischemic encephalopathy (FIE) is a syndrome of acute cerebral cortical dysfunction caused by cerebral infarction in cats. The portion of the cortex supplied by the middle cerebral artery is most commonly affected. Most cases of FIE are diagnosed during the summer months in cats living in the northeastern United States with access to the outdoors. Cats with FIE are presented because of a peracute onset of asymmetric neurologic abnormalities including aggression, circling to the side of the lesion, and seizures. There may be a loss of proprioception and hyperactive reflexes (UMN signs) in the limbs opposite the side of the lesion, and the cat may be blind but have normal pupillary light reflexes (cortical blindness) on the side opposite the lesion. FIE should be suspected in any cat with a sudden onset of nonprogressive unilateral cerebral cortical dysfunction and no history of trauma or evidence of systemic illness or hypertension. The primary differential diagnosis is a vascular accident. Physical examination typically reveals no abnormalities other than the neurologic signs. Ophthalmologic examination, clinicopathologic evaluation, and blood pressure measurements are also normal. CSF is normal cytologically, with a normal or only slightly increased protein content, making inflammatory disease unlikely. MRI is the best method of documenting the infarcted region.

Cats with FIE that have died or been euthanized have extensive acute necrosis and edema of the cerebral cortex caused by acute infarction of the middle cerebral artery. Moreover, many cats show histopathologic features compatible with aberrant migration of *Cuterebra* fly larvae. The larvae apparently enter the brain through the nasal cavity and the cribriform plate, and once within the CNS they elaborate a toxic factor that causes neurologic damage and vasospasm, leading to brain infarction. Acutely, mannitol should be administered intravenously to decrease the edema associated with the vascular lesion (see Box 60.3). If seizures occur, anticonvulsants should be administered (see Box 64.7). Specific treatment of the migrating parasite is possible and may be warranted in young and middle-aged cats from endemic areas presenting with acute lateralizing cerebral cortical signs in the summer. Treatment is with diphenhydramine (4 mg/kg, administered intramuscularly), followed 2 hours later with dexamethasone (0.1 mg/kg, administered intravenously) and ivermectin (400 µg/kg, administered subcutaneously). This treatment is repeated 48 hours later. Most cats show marked improvement in 2 to 7 days whether or not the ivermectin treatment is initiated. Complete recovery occurs in approximately 50% of cats. Permanent neurologic sequelae may include aggressive behavior or recurrent seizures, often resulting in euthanasia.

FELINE HIPPOCAMPAL NECROSIS

Feline hippocampal necrosis (FHN) is a severe structural abnormality in the brain that has been associated with seizures in cats. It is uncertain whether this hippocampal pathology serves as a primary epileptogenic focus to cause seizures or if the FHN occurs secondary to ischemic damage during severe seizure activity. Most cats with FHN are presented because of a rapidly progressive cluster of seizures together with interictal abnormalities suggesting a forebrain lesion. Complex partial seizures with orofacial involvement are most common, including salivation, facial twitching, lip smacking, chewing, licking, and swallowing. Behavior changes that may persist between seizures include staring into space, disorientation, aggression, rapid running, hyperexcitablility, and fearfulness. MRI shows moderate T2 hyperintensity within the hippocampus and the piriform lobe that is often bilaterally symmetrical with signal alterations most apparent on fluid attenuated recovery sequences (FLAIR). Contrast enhancement is variable.

Early reports suggested that FHN had a poor prognosis, as all cats died or were euthanized when initial anticonvulsant therapy was ineffective, neurologic and behavioral abnormalities persisted, or recurrent seizures were difficult to control. There have, however, been reports of a few cats with FHN that gradually returned nearly to normal with few neurologic deficits and well-controlled seizures, suggesting that the long-term outcome can occasionally be good to excellent. There is some speculation that FHN could be a manifestation of autoimmune limbic encephalitis following reports that many cats with FHN experienced full remission (seizure-free) after antiepileptic, supportive, and corticosteroid treatment.

THIAMINE DEFICIENCY

Thiamine (vitamin B1) is a water-soluble vitamin that is important in normal carbohydrate metabolism and synthesis of neurotransmitters. Cats require more thiamine than dogs and can develop thiamine deficiency due to prolonged anorexia, maldigestion /malabsorption disorders, inadequate dietary intake, or ingestion of thiaminase in raw fish. Most cases of thiamine deficiency in dogs have been in groups of dogs eating raw fish. Thiamine deficiency results in a progressive encephalopathy and polioencephalomalacia of the oculomotor and vestibular nuclei and caudal colliculus. Neurologic signs may include impaired vision, mydriasis, ataxia, ventroflexion of the head and neck, vestibular signs, seizures, coma, and even death. Magnetic resonance (MR) imaging can be normal or can reveal bilaterally symmetrical hyperintense foci on T2-weighted and FLAIR (fluid attenuation recovery) in grey matter regions of the brainstem, cerebrum, and cerebellum. Supplementation with parenteral and oral thiamine, and changing the diet to include adequate thiamine will usually result in a rapid recovery and resolution of all neurologic signs, including seizures. Thiamine (12.5-30 mg/cat IM or SC q24h) is often administered to cats with undiagnosed progressive neurologic signs suggesting an intracranial lesion, particularly those with vestibular signs or seizures.

HYDROCEPHALUS

Hydrocephalus is a condition in which the cerebral ventricular system is enlarged secondary to obstruction of CSF flow toward its point of absorption into the systemic circulation via the arachnoid villi. Obstruction can occur secondary to inflammation, neoplasia, or prior hemorrhage, but most cases are congenital. Dog breeds at risk for congenital hydrocephalus include the Maltese, Yorkshire Terrier, English Bulldog, Chihuahua, Lhasa Apso, Pomeranian, Toy Poodle, Cairn Terrier, Boston Terrier, Pug, Chow Chow, and Pekingese. Cats are occasionally affected.

Many animals with congenital hydrocephalus have an obviously enlarged head, persistent fontanelles, and palpably open cranial sutures (Fig. 60.1). Care must be taken not to overinterpret these findings, however, because domed heads and small open fontanelles (<5 mm) are very common in some toy breeds. Although most dogs with large fontanelles

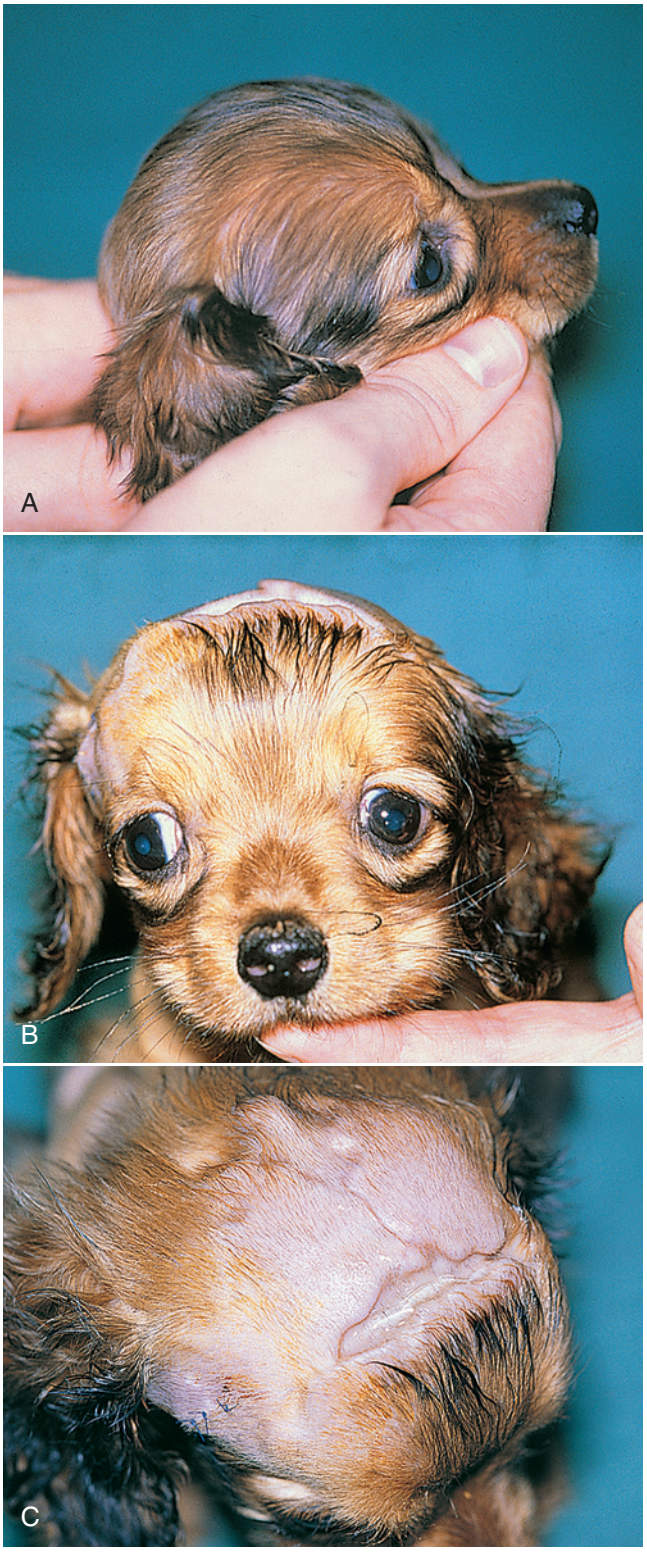

FIG 60.1
(A) and **(B)** Hydrocephalus in a Chihuahua puppy. Note the greatly enlarged, domed skull and the divergent strabismus. **(C)** The open skull sutures (fontanelles) are visible in this puppy after surgical drainage of the lateral ventricles with a ventriculoperitoneal shunt.

or fontanelles that remain open at 9 weeks of age do have some ventricular dilation, many will never develop clinical signs of hydrocephalus.

Animals with symptomatic hydrocephalus can be slow learners and may be difficult to housetrain. They may seem dull or depressed. They may have episodic or constant abnormal behavior, circling, and cortical blindness. Seizures may occur. Severely affected animals may exhibit tetraparesis, slow postural reactions, head tilt, or nystagmus. Some animals will develop a ventrolateral strabismus (see Fig. 60.1) due either to malformation of the orbit or brainstem dysfunction. Neurologic signs have an unpredictable course; deficits can progress over time, remain static, and even improve after 1 to 2 years of age. Signs can worsen coincident with other diseases or minor head trauma. About 30% of dogs with congenital hydrocephalus are not overtly symptomatic until 2 years of age.

Hydrocephalus is suspected on the basis of characteristic signs and physical examination findings in a young animal of a typical breed. If fontanelles are open, ultrasound examination of the brain can be performed through the openings, and this can determine the size of the lateral ventricles and confirm the diagnosis (Fig. 60.2). If the fontanelles are small or closed, ultrasound scanning is more difficult but may still be attempted through the temporal bone in young animals. Alternatively, CT or MRI can be performed to detect ventricular enlargement. Although historical studies have shown very little correlation between ventricular size and clinical signs, one report showed that ventricular enlargement (ventricle/brain [VB] ratio) was correlated with severity of clinical signs in small-breed dogs and that all asymptomatic puppies with a VB ratio of over 60% went on to develop neurologic signs related to their hydrocephalus.

Long-term medical management of animals with neurologic signs is directed at limiting CSF production and reducing intracranial pressure. Acetazolamide (10 mg/kg orally q8h), alone or in combination with oral furosemide (1 mg/kg/day) is the most commonly used drug therapy. Omeprazole may also decrease CSF production and aid control. Some animals improve with glucocorticoid treatment (prednisone, 0.5 mg/kg, administered orally daily, tapered weekly until 0.1 mg/kg q48h). Seizures may be controlled with antiepileptic drug therapy as described for epilepsy (see Chapter 62). The prognosis for a normal life is poor if neurologic signs are present. Surgical drainage and placement of a permanent ventriculoperitoneal shunt is an aggressive treatment option

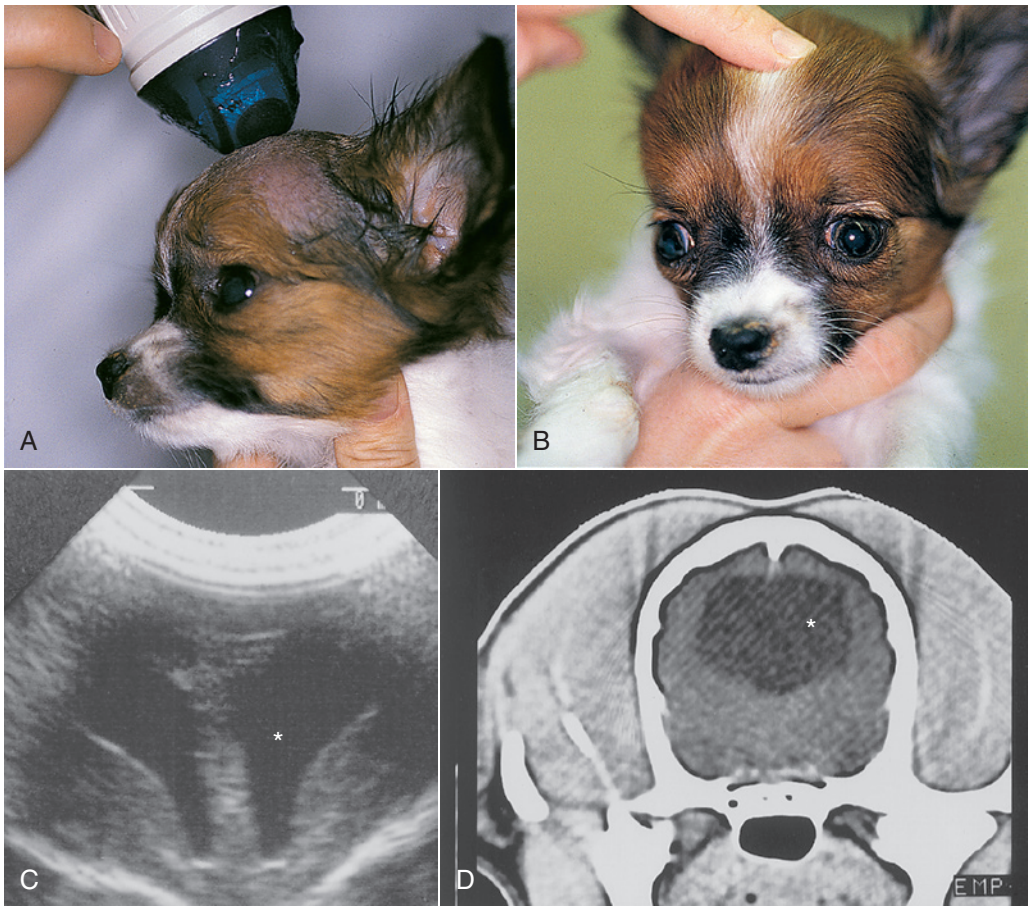

FIG 60.2

with many potential complications but is associated with a sustained positive outcome in greater than 50% of patients.

Acute, severe, and progressive neurologic signs occasionally occur in dogs and cats with hydrocephalus, probably as a result of a sudden increase in intracranial pressure. Therefore it is important to rapidly lower intracranial pressure in these animals, as described for animals with head trauma (see Box 60.3). If fontanelles are open, a ventricular tap can be performed and a small volume of CSF (0.1-0.2 mL/kg) removed.

LISSENCEPHALY

Lissencephaly is a rare condition in which the sulci and gyri fail to develop normally, resulting in a smooth cerebral cortex. Lissencephaly has been recognized primarily in the Lhasa Apso, Wire Fox Terrier, and Irish Setter. Behavioral abnormalities, seizures, and visual deficits are common. These animals are also very difficult to train and may not be housebroken. If seizures occur, they often are not prominent until the end of the first year of life. Definitive diagnosis requires MRI, brain biopsy, or necropsy.

CEREBELLAR HYPOPLASIA

Congenital hypoplasia of the cerebellum has been described in Chow Chows, Irish Setters, Wire Fox Terriers, and Siberian Huskies and sporadically in many breeds of dogs and in cats. Feline cerebellar hypoplasia is most often caused by naturally acquired in utero infection with panleukopenia virus (feline parvovirus) or when a pregnant queen is inoculated with modified-live panleukopenia virus vaccine. Clinical signs of cerebellar hypoplasia become noticeable when the animal first starts to walk, with hypermetria, ataxia, truncal sway, and tremor most apparent (*see* Video 58.3). Some cases are mild and others are very severe, making walking and eating difficult. Because signs do not progress, mildly affected animals can function as pets. Cerebellar hypoplasia that is not panleukopenia-related may actually reflect an early onset neurodegenerative disorder.

INFLAMMATORY DISEASE (ENCEPHALITIS)

Inflammatory disease (encephalitis) is an important differential diagnosis in all dogs and cats with progressive intracranial disease. Most of the infectious and noninfectious inflammatory disorders discussed in Chapter 66 have the potential to cause encephalitis, with neurologic signs reflecting the site and severity of the inflammation and parenchymal damage. A subacute onset with progression over a few days to weeks is typical of inflammatory disease. See Chapter 64 for more information regarding the clinical manifestations, diagnosis, and therapy for intracranial inflammatory disorders.

INHERITED DEGENERATIVE DISORDERS AFFECTING THE BRAIN

There are many inherited neurodegenerative disorders resulting from genetically programmed errors in cell metabolism and function. Some of these cause deficiencies of specific enzymes resulting in the accumulation of metabolites within cells (storage diseases), yet others alter cell function, neurotransmission, or brain development leading to degeneration. Signs of inherited neurodegeneration typically develop in young animals and are progressive, but some disorders are not evident until maturity. Some disorders cause widespread neuronal degeneration in the brain and spinal cord while others only cause focal degeneration of the cerebral cortex or cerebellum or spinocerebellar tracts. Diagnosis of these disorders is suspected when an animal of a susceptible breed develops a progressive symmetrical neurologic disorder with characteristic features as described in that breed. Identification of littermates or other related animals with similar signs raises the suspicion for an inherited neurodegenerative disorder and should prompt a search of the current veterinary literature and breed websites for descriptions of breed-specific diseases and available genetic tests. In many cases a presumptive diagnosis is only possible after doing extensive testing to rule out metabolic diseases, infectious and noninfectious inflammatory disorders, and neoplastic disease. Definitive diagnosis usually requires brain biopsy, but occasionally histopathologic examination of biopsy specimens from other affected organs or enzyme assays will provide a diagnosis. Genetic tests are increasingly available. Descriptions of the breed predispositions and clinical features of many inherited degenerative brain disorders can be found in the Suggested Readings, but this is a rapidly expanding field requiring constant updating. Two of the most common inherited neurodegenerative disorders recognized in multiple breeds of dogs are neuroaxonal dystrophy and the hereditary ataxia known as cerebellar cortical degeneration. No treatment is currently available for these conditions.

NEUROAXONAL DYSTROPHY

Neuroaxonal dystrophy is a slowly progressive degenerative disorder affecting sensory axons and nerve cell bodies throughout much of the CNS, with most severe lesions within the spinocerebellar tracts and the Purkinje cells of the cerebellum resulting in cerebellar ataxia. Young adult Rottweilers (typically 1-2 years old) are initially presented for a hypermetric gait and ataxia, and signs progress slowly over 2 to 4 years. Affected dogs develop an intention tremor, a constant fine tremor, spontaneous or positional nystagmus, and menace deficits. Postural reactions (knuckling and hopping) and strength remain normal. A similar disorder has been documented in young (2- to 4-month-old) Border Collies, Chihuahuas, Jack Russell Terriers, and Papillons, and tricolor kittens (5-6 weeks old). Diagnosis requires biopsy or postmortem, and there is no effective treatment.

CEREBELLAR CORTICAL DEGENERATION (ABIOTROPHY)

Historically called cerebellar abiotrophy based on the incorrect presumption that degeneration was secondary to the lack of a vital nutritive factor, the hereditary ataxia now known as cerebellar cortical degeneration is defined by postnatal

degeneration of cells within the cerebellar cortex. Clinical signs are usually rapidly progressive and include cerebellar ataxia, a hypermetric gait, limb spasticity, truncal sway, intention tremor, and sometimes spontaneous nystagmus. Rarely the degeneration occurs in neonates (Beagle), with signs evident at first ambulation and progressively worsening over weeks to months. In most breeds, clinical signs begin between 2 and 12 months of age and progress rapidly, but slow progression over several years has been described in Gordon Setters and Old English Sheepdogs. Scottish Terriers and Old English Sheepdogs occasionally have a late onset of signs at 3 to 8 years of age with slow progression. Testing to eliminate inflammatory and neoplastic disease is warranted. Imaging can be unremarkable or can reveal cerebellar atrophy. Genetic testing is available for a cerebellar cortical degeneration in few breeds. No treatment is effective.

NEOPLASIA

Primary brain tumors are common in dogs and cats, typically resulting in a gradual onset of slowly progressive neurologic signs. Signs may be more rapidly progressive when there are metastases to the brain parenchyma from an extraneural neoplasm or when an intracranial neoplasm bleeds. With the exception of brain lymphoma, which can occur at any age, most primary and metastatic brain tumors occur in middle-aged and older animals. The most commonly affected breeds include Golden Retrievers, Labrador Retrievers, mixed-breed dogs, and Boxers.

Brain tumors cause signs by destroying adjacent tissue, increasing intracranial pressure, or causing intraparenchymal hemorrhage or obstructive hydrocephalus. Seizures and mentation changes are the most common reason for presentation. Circling, ataxia, and head tilt are less common. As intracranial tumors enlarge, they may cause an increase in intracranial pressure with progressive loss of alertness and altered mentation; the owner may report that the dog or cat has recently become dull, depressed, and "old." Progressive subtle neurologic signs are sometimes present for weeks or months before the owner notices them.

Some animals with brain tumors are neurologically normal between seizures, but careful neurologic examination may reveal evidence of asymmetric neurologic dysfunction. Compulsive circling toward the side of the lesion and abnormal postural reactions, vision, and facial sensation on the side opposite the lesion are common with forebrain lesions, whereas positional nystagmus and subtle cranial nerve deficits are common with brainstem tumors.

Intracranial tumors may be primary (arising from the brain), or they may invade the brain from an adjacent site (e.g., skull, nose, sinus, ear, eye) or metastasize to the brain from a distant site. Secondary (metastatic) intracranial neoplasia occurs more often than primary neoplasia in dogs, with metastases from hemangiosarcoma, lymphoma, carcinomas, and melanoma being most common. A careful physical examination should be performed to identify potential sites of primary neoplasia that may have metastasized to the brain. Particular attention should be paid to the nose, lymph nodes, spleen, skin, mammary chain, and prostate gland. A complete blood count (CBC), serum biochemistry panel, and urinalysis should be performed to look for evidence of neoplasia or a paraneoplastic syndrome. Radiography of the thorax and abdomen and abdominal ultrasonography should be performed to search for a primary tumor or extraneural metastases. Also, most dogs and cats with intracranial neoplasia are older, and systemic evaluation for neoplasia has been reported to identify an unrelated extracranial neoplasm in up to 25% of cases, a finding that can have a major impact on prognosis and treatment decisions.

MRI is the most accurate advanced imaging modality for detection and characterization of intracranial tumors and differentiating tumors from inflammatory lesions. MRI can be used to characterize tumors as being intra-axial (parenchymal) versus extra-axial (surface), and can describe their location within the brain, degree of infiltration into surrounding tissues, shape, intensity compared with normal neural tissue on different MRI sequences, and contrast uptake. These imaging characteristics can be used to predict probable tumor type in approximately 70% of cases, but definitive diagnosis requires biopsy (Fig. 60.3).

Meningiomas are the most common intracranial tumors in dogs and cats, followed by an assortment of glial tumors in dogs and lymphoma in cats. Golden Retrievers are at increased risk for developing meningiomas, whereas brachycephalic breeds such as Boston Terriers and Boxers are especially predisposed to glial tumors. Because most intracranial tumors are poorly exfoliative, CSF collection and analysis rarely provide a definitive diagnosis. Identifying neoplastic cells in CSF is unusual except in patients with CNS lymphoma, carcinomatosis, and choroid plexus tumors. Dogs and cats with brain tumors may have normal CSF, normal CSF cytology with a slightly increased CSF protein content, or a mixed cell pleocytosis, complicating differentiation from inflammatory disorders based on CSF alone.

Treatment for brain tumors depends on the probable tumor type, tumor location, growth history, and neurologic signs. Once identified with CT or MRI, some small, superficially located, well-encapsulated, benign cerebral tumors; dorsal cerebellar tumors; and bony tumors of the skull are amenable to surgical removal by experienced neurosurgeons. In particular, there has been some success in removing feline cerebral meningiomas. Canine cerebral meningiomas are similarly superficially located and histologically benign, but they are not well encapsulated, making complete surgical removal more difficult. Median survival (MS) time after surgical removal of most primary brain tumors in dogs is approximately 140 to 150 days, with significant risk of mortality within the first 30 days after surgery. For meningiomas, MS times are longer (240 days with surgery alone, 1254 days using an ultrasonic surgical aspirator). Surgical removal of feline meningiomas has been associated with MS intervals of 22 to 27 months.

Radiotherapy is often used as an adjunct to surgery for resectable tumors and as the sole therapy for nonresectable primary (nonmetastatic) brain tumors in dogs. Many dogs

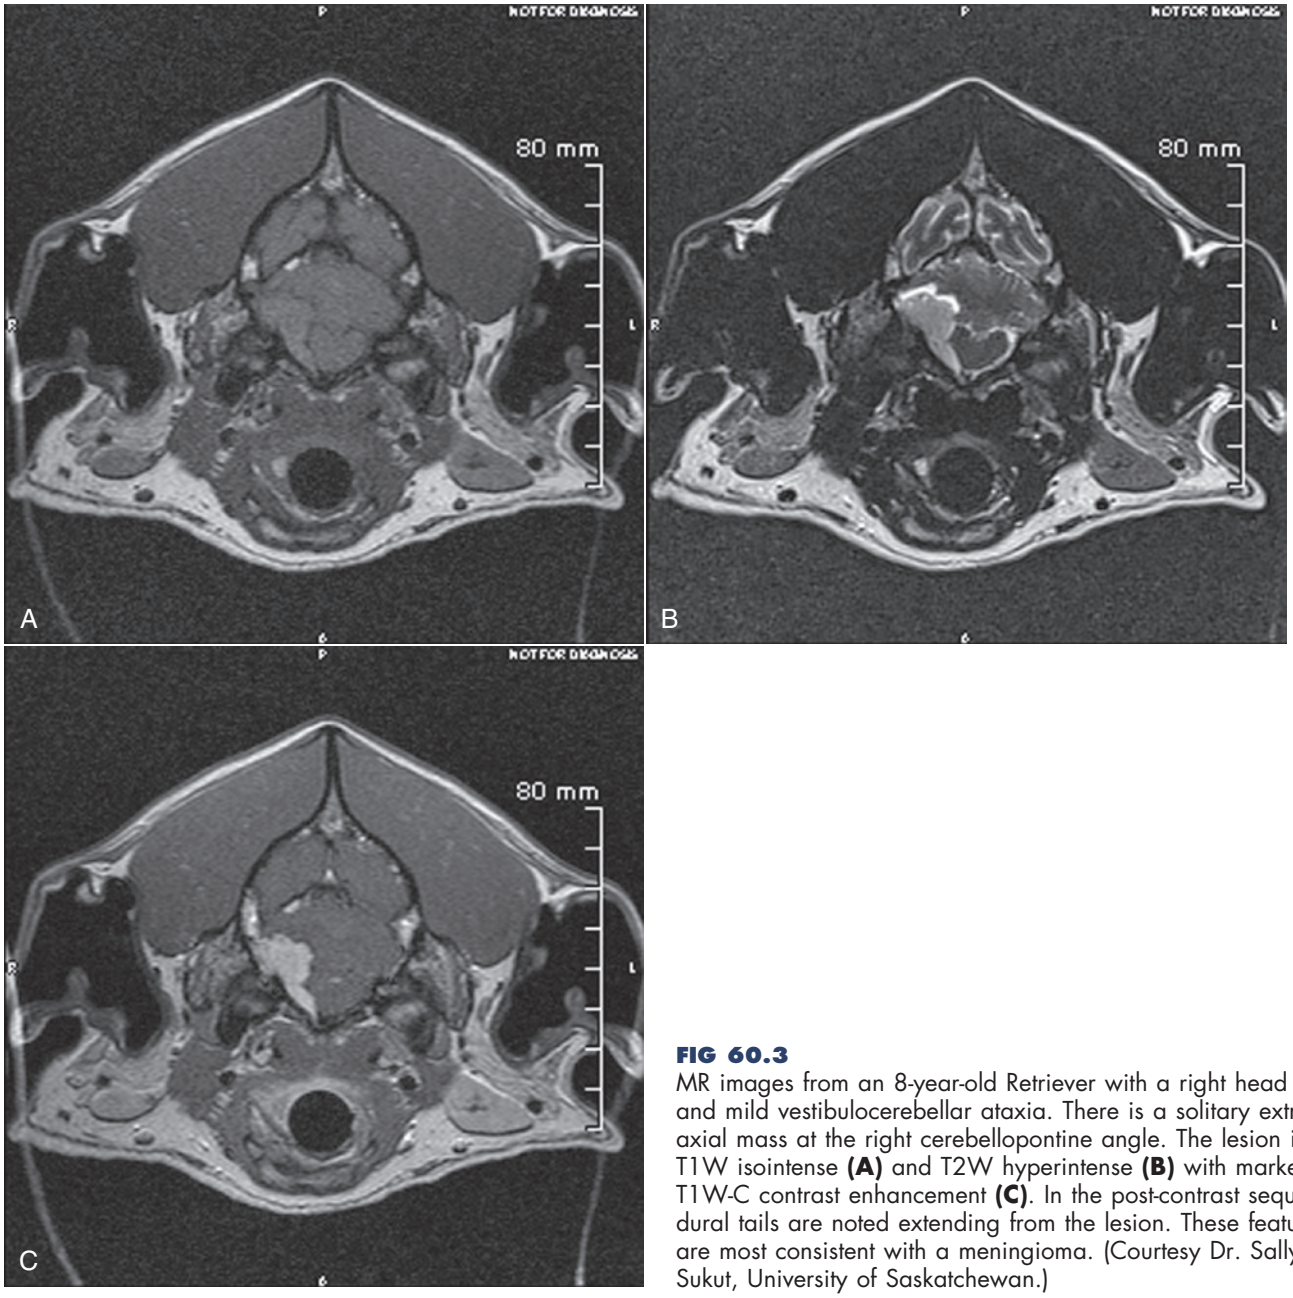

FIG 60.3
MR images from an 8-year-old Retriever with a right head tilt and mild vestibulocerebellar ataxia. There is a solitary extra-axial mass at the right cerebellopontine angle. The lesion is T1W isointense **(A)** and T2W hyperintense **(B)** with marked T1W-C contrast enhancement **(C)**. In the post-contrast sequence dural tails are noted extending from the lesion. These features are most consistent with a meningioma. (Courtesy Dr. Sally Sukut, University of Saskatchewan.)

that are stable neurologically before therapy show some clinical improvement. Dogs with brain masses causing neurologic signs (no specific diagnosis) have an MS time of approximately 2 years after radiotherapy, and MS of 14 to 30 months has been reported for canine meningioma when treated with surgery followed by radiation. An important drawback of conventional radiotherapy is that access to a referral center and multiple daily anesthesias are required to administer up to 20 fractionated doses of radiation. Stereotactic radiotherapy is a technique that uses a high dose of radiation delivered in a single (radiosurgery) or few fractions (stereotactic radiotherapy), decreasing the need for multiple anesthetics and hospital visits. Results and adverse effects reported with this technique are similar to those reported with conventional radiotherapy.

Supportive chemotherapy can be administered together with or instead of surgery and radiation. Glucocorticoid administration (prednisone 0.5-1 mg/kg/day, taper to q48h) may decrease edema surrounding the tumor and improve CSF absorption, decreasing neurologic signs and intracranial pressure. Chronic anticonvulsant therapy should be administered to control seizures. In the event of an acute exacerbation of tumor-related clinical signs, aggressive treatment to lower intracranial pressure is recommended, as outlined for head trauma (see Box 60.3). Specific chemotherapy for CNS lymphoma is possible, but most of the chemotherapeutic agents used for systemic therapy do not cross the blood-brain barrier. Cytosine arabinoside (Cytosar), lomustine (CCNU), and prednisone have some effect (see Chapter 79).

CHAPTER 61

Loss of Vision and Pupillary Abnormalities

GENERAL CONSIDERATIONS

Loss of vision or pupillary abnormalities may be detected during a physical examination for neurologic dysfunction or may be the primary reason for presentation. Owners rarely recognize a visual deficit until it is bilateral and complete, at which time the animal is brought in because of an apparently sudden onset of blindness. When an animal is evaluated for loss of vision, it is important to first determine whether there is actual blindness and to perform a complete ocular and neuroophthalmologic examination.

NEUROOPHTHALMOLOGIC EVALUATION

VISION

Vision should initially be assessed by observing the animal's response to the environment, including its ability to negotiate doorways and stairs and the attention it pays to rolling or falling silent objects such as cotton balls. If unilateral vision loss is suspected, the normal eye should be covered during testing. For vision to be present, the entire visual pathway must be intact. This includes the retina, optic nerve (which passes through the optic chiasm to the optic tract to synapse in the lateral geniculate nucleus [LGN] in the diencephalon), and axons projecting to the visual cortex in a band of fibers called the *optic radiation*. Most of the optic nerve axons cross in the optic chiasm (particularly those carrying information from the lateral visual field) and are continued in the contralateral optic tract, LGN, and optic radiations to the visual cortex (Fig. 61.1). The visual cortex must be functional for the animal to process and respond appropriately to visual cues.

MENACE RESPONSE

The menace response is a cortically mediated blink produced by a threatening gesture (Fig. 61.2). The sensory part of this response involves each of the components of the visual pathway (see Fig. 61.1). Normally the visual stimulus is directed at the nasal retina (i.e., the menacing gesture is in the lateral visual field coming from the side), and because almost all of the optic nerve axons that originate in the nasal retina cross in the optic chiasm, the menace response can be used to assess the visual cortex contralateral to the eye being menaced. The information interpreted in the visual cortex is forwarded to the motor cortex to initiate a blink response, requiring a functional facial nerve (CN7). The menace response is also coordinated in the cerebellum, with unilateral cerebellar lesions causing ipsilateral loss of the menace response but no loss of vision. The absence of a menace response could therefore be a result of ocular, retinal, or optic nerve disease; damage to the contralateral forebrain; an altered mental state; cerebellar disease; or an inability to blink (Box 61.1). The menace response is a learned response and may not be present in normal animals younger than 12 weeks of age.

PUPILLARY LIGHT REFLEX

The pupillary light reflex (PLR) should always be assessed whether or not an animal is able to see. A bright light is directed into the pupil, and the pupil is assessed for constriction (direct reflex). The opposite pupil should simultaneously constrict (consensual response). The sensory visual pathway is the same as that described for the menace response except that some optic tract axons synapse before the LGN in the pretectal nucleus located at the junction between the midbrain and the thalamus (Fig. 61.3). Most of the axons arising from this nucleus cross midline again and synapse in the parasympathetic (PSNS) component of the oculomotor nucleus ipsilateral to the eye being stimulated, inducing direct pupil constriction. Because some of the axons leaving the pretectal nucleus do not cross, there is also stimulation of the contralateral oculomotor nucleus, resulting in a somewhat weaker consensual pupillary response. The pupillary response to light can be minimal if the light used is not bright enough, if the animal is nervous and has high resting sympathetic tone, or if there is ocular disease (iris atrophy or greatly increased intraocular pressure) preventing pupillary constriction. The pupillary light response

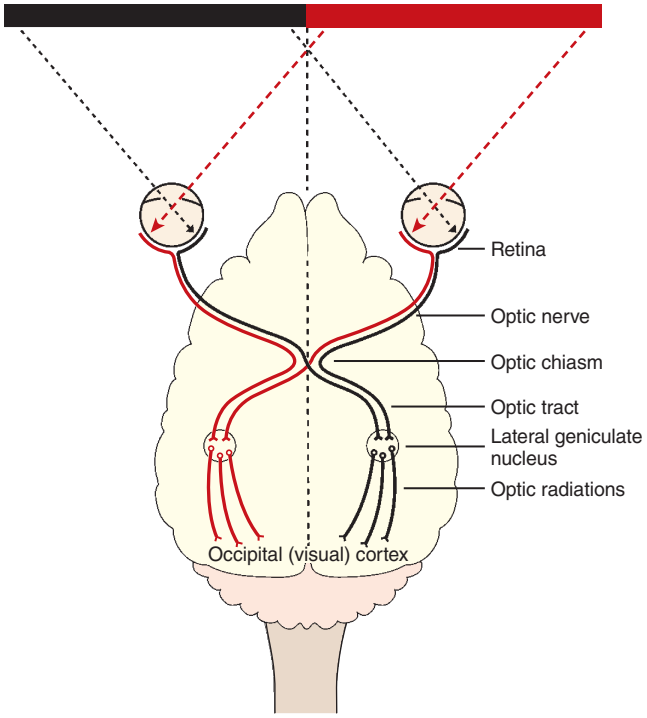

FIG 61.1
The visual pathways.

FIG 61.2
Menace response is evoked by making a threatening movement toward each eye in turn. The expected response is a blink. The stimulus is primarily directed toward the nasal retina, assessing the contralateral visual cortex.

requires fewer functional photoreceptors and optic nerve axons than vision, so partial lesions of the proximal visual pathways (retina, optic nerve, optic chiasm, optic tract) can sometimes cause loss of vision with normal PLRs, similar to lesions of the forebrain (Table 61.1).

BOX 61.1

Lesions Causing Loss of the Menace Response in Dogs and Cats

- Severe ocular disease
- Retinal disease
- Visual pathway lesion
  - Ipsilateral optic nerve
  - Optic chiasm
  - Contralateral optic tract, lateral geniculate nucleus, optic radiation
- Contralateral visual cortex (forebrain) lesion
- Altered mental status
  - Metabolic encephalopathy
  - Severe systemic illness
- Cerebellar disease
- Inability to blink (CN7)
- Immature reflex (<12 weeks of age)

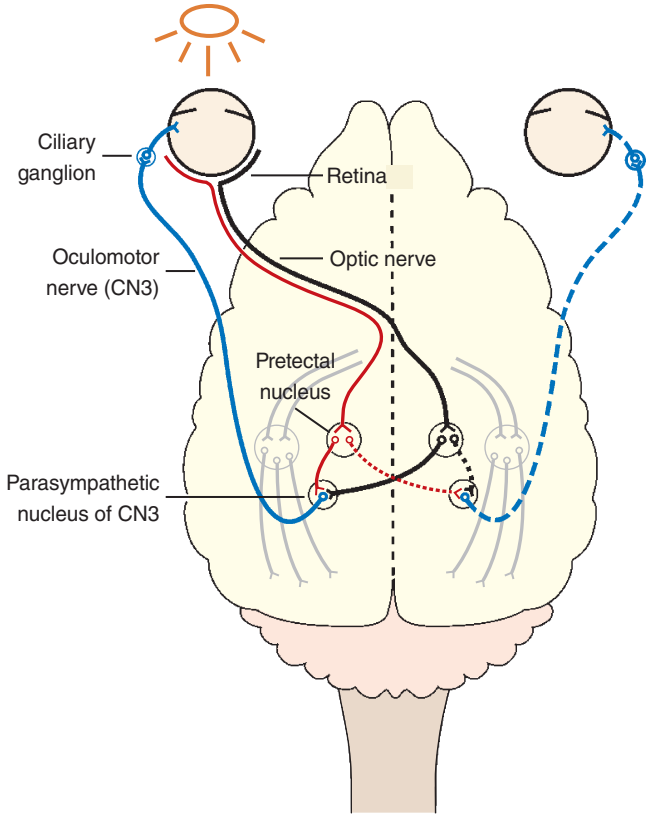

FIG 61.3
Pathway of the pupillary light reflex.

DAZZLE REFLEX

The dazzle response is the generation of a rapid blink when a very bright light is directed into the eye. The sensory visual pathway is as described for the PLR in that this is a subcortical ipsilateral reflex that does not require the visual cortex, but the motor pathway is mediated by the facial nerve (CN7) rather than the oculomotor nerve. A negative dazzle response

TABLE 61.1

Localization of Visual Pathway Lesions Based on Vision and Pupillary Light Reflexes

LOCATION OF COMPLETE LESION	VISION IN RIGHT EYE	VISION IN LEFT EYE	LIGHT IN RIGHT EYE	LIGHT IN LEFT EYE
Right retina/eye*	Absent	Normal	No response either eye	Both pupils constrict
Bilateral retina/eye*	Absent	Absent	No response either eye	No response either eye
Right optic nerve	Absent	Normal	No response either eye	Both pupils constrict
Bilateral optic nerves	Absent	Absent	No response either eye	No response either eye
Optic chiasm (bilateral)	Absent	Absent	No response either eye	No response either eye
Lesion caudal to optic chiasm *(right lateral geniculate nucleus, right optic radiation, or right visual cortex)*	Normal	Absent	Both pupils constrict	Both pupils constrict
Bilateral lesion caudal to optic chiasm	Absent	Absent	Both pupils constrict	Both pupils constrict
Right oculomotor nerve	Normal	Normal	Left pupil constricts; right pupil is dilated, no response	Left pupil constricts; right pupil dilated, no response

*Retinal or eye lesions must be very severe to cause loss of pupillary light reflexes.

in a blind eye implies a subcortical lesion affecting the retina or optic nerve. A positive dazzle response in a blind animal (with absent menace response) supports central (brain) disease.

PUPIL SIZE AND SYMMETRY

Pupil size and symmetry should be assessed in both room light and darkness to evaluate the pupils' ability to constrict (parasympathetic function) and dilate (sympathetic function). Pupil abnormalities causing dilation (mydriasis) or constriction (miosis) of only one pupil will result in unequal pupils (anisocoria). If the abnormal pupil is dilated and unable to constrict, the anisocoria will be most apparent in bright light. Anisocoria caused by a single miotic pupil, such as is seen in animals with Horner syndrome, will be most apparent in a darkened room as the normal pupil dilates but the affected pupil remains miotic. A complete ophthalmic examination should always be performed to ascertain whether pupillary abnormalities can be explained by non-neurologic abnormalities of the eye. Iris atrophy, iris hypoplasia, and glaucoma will cause mydriasis, whereas uveitis and painful conditions of the cornea commonly cause miosis. Hippus, a condition in which there are exaggerated oscillations of pupillary size in response to light, can be a nonspecific indication of central nervous system disease.

DISORDERS OF EYEBALL POSITION AND MOVEMENT

During the neurologic examination it is important to evaluate eye position and movement. The extraocular muscles are innervated by the oculomotor nerve (CN3), trochlear nerve (CN4), and abducent nerve (CN6), with lesions resulting in an abnormal eye position (strabismus) or failure of the eye to move appropriately when the head is moved during evaluation of the oculocephalic reflex (see Chapter 58). Strabismus can occur with lesions of individual nerves, swelling or fibrosis of extraocular muscles, or intracranial lesions (see Fig. 58.23). Simultaneous paralysis of all the extraocular muscles (external ophthalmoplegia) most often occurs when there is a mass in the region of the paired venous sinuses that lie on the floor of the calvarium adjacent to the pituitary gland in the mid-cranial vault (cavernous sinus syndrome). Mass lesions in this area also typically damage the PSNS fibers in the oculomotor nerve, causing internal ophthalmoplegia (a fixed midrange or mydriatic pupil with normal vision) and may also damage the ipsilateral ophthalmic and maxillary branches of the trigeminal nerve, causing diminished corneal and medial palpebral sensation and occasionally atrophy of the ipsilateral masticatory muscles.

LACRIMAL GLAND FUNCTION

The lacrimal gland and the lateral nasal gland are innervated by the parasympathetic portion of the facial nerve (CN7). Normal basal tear production is assessed by performing a Schirmer tear test, and function of the lateral nasal gland is assessed by examining the ipsilateral nostril for dryness. Lesions of the facial nerve can result in loss of the palpebral reflex because of an inability to blink, decreased basal tear production, and a dry nose. Sensory innervation of the cornea is provided by the trigeminal nerve (CN5), and corneal stimulation by touch, cold, wind, or other irritants normally results in a blink response and increased reflex tear production. Lesions of the ophthalmic branch of the trigeminal nerve (CN5) result in decreased reflex tear production and decreased blink frequency, which may lead to keratitis and corneal ulceration.

LOSS OF VISION

LESIONS OF THE RETINA, OPTIC DISK, AND OPTIC NERVE

Concurrent loss of vision and diminished or absent PLR indicate the presence of a lesion affecting both the visual and PLR pathways. Unilateral severe lesions of the retina, optic disk, or optic nerve before the optic chiasm result in impaired vision and loss of the direct PLR in the affected eye as well as a loss of the consensual PLR in the opposite eye when light is directed into the affected eye (see Table 61.1). The direct and consensual response should be normal (both pupils constrict) when light is directed in the unaffected eye. Ocular or optic nerve disease must be very severe to cause complete loss of PLRs. Whenever an animal is evaluated for blindness, the retina should be carefully examined to rule out disorders such as progressive retinal atrophy, retinal dysplasia, retinal detachment, retinal hemorrhage, and chorioretinitis (Fig. 61.4). Optic nerve atrophy secondary to glaucoma or trauma must also be eliminated as a cause of blindness and PLR loss.

Sudden Acquired Retinal Degeneration

Sudden acquired retinal degeneration syndrome (SARDS) is a syndrome causing sudden bilateral degeneration of retinal photoreceptors in dogs. Middle-aged and older dogs of any breed can be affected, with females and obese individuals predisposed. The primary presenting complaint is loss of vision, with complete blindness occurring over a period of hours to weeks and often overnight. Pupils are dilated and PLRs are sluggish in dogs examined shortly after vision loss and absent in dogs with advanced disease. Many affected dogs have concurrent polyuria, polydipsia, panting, weight gain, and lethargy with clinical, serum biochemical, and urinalysis findings typical of hyperadrenocorticism, but endocrine tests and advanced imaging of the pituitary and adrenal glands rarely (<20%) confirm that disorder. In the early stages of SARDS, both fundi appear normal, but with time a bilaterally symmetric retinal degeneration becomes apparent, with hyperreflectivity of the tapetal fundus and attenuation of retinal blood vessels. These retinal changes are indistinguishable from chronic retinal degeneration caused by other conditions. Early SARDS is differentiated from retrobulbar optic neuritis by its extinguished (flat-line) electroretinogram (ERG), demonstrating photoreceptor death. Pathogenesis of the disorder is uncertain. Systemic signs are usually transient and resolve without treatment, but the blindness is permanent.

Optic Neuritis

Inflammation of the optic nerves causes blindness and loss of PLRs. Funduscopic evaluation may reveal optic disk swelling and discoloration (red) with or without associated retinal detachment and hemorrhage. When optic neuritis occurs posterior to the globes (i.e., retrobulbar), the visible portion of the optic nerves will be normal. In dogs with blindness and loss of PLRs with a normal-appearing fundus, ERG is required to differentiate bilateral retrobulbar optic neuritis (normal ERG) from SARDS (flat-line ERG).

Optic neuritis is most commonly seen as an isolated idiopathic immune-mediated disorder affecting one or both optic nerves in dogs, but it may also be a manifestation of systemic infectious disease (Box 61.2), especially canine distemper, tick-borne diseases, fungal infections, and bacterial meningoencephalitis. Noninfectious disorders such as

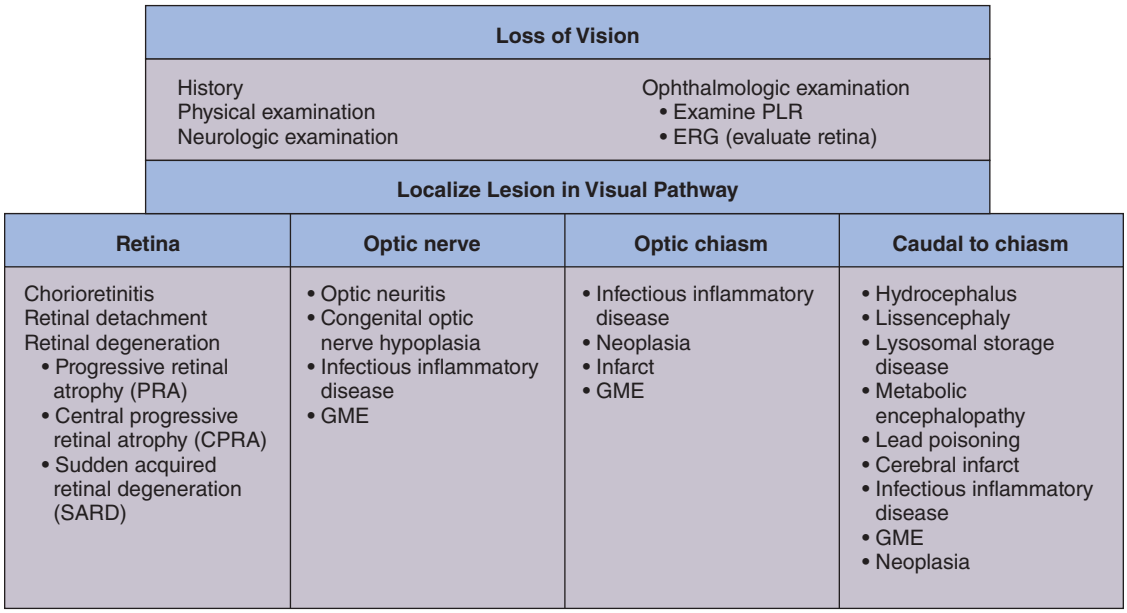

FIG 61.4
Diagnostic approach to a dog or cat with loss of vision. *ERG,* Electroretinogram; *GME,* granulomatous meningoencephalitis; *PLR,* pupillary light reflex.

BOX 61.2

Disorders Associated With Optic Neuritis

Infectious Disease
Systemic Fungal Infections
- Cryptococcosis
- Blastomycosis
- Systemic aspergillosis
- Coccidiodomycosis

Viral Diseases
- Canine distemper
- Feline infectious peritonitis
- Feline leukemia virus

Tick Borne Diseases
- Ehrlichiosis
- Lyme disease

Protozoal Infections
- Toxoplasmosis
- Neosporosis

Bacterial Disease
Noninfectious Inflammatory Disease
- Meningoencephalitis of unknown etiology
- Granulomatous meningoencephalitis
- Systemic lupus erythematosus
- Steroid-responsive meningitis arteritis

Neoplastic Disease
- Systemic neoplasia
- Optic nerve neoplasia
- Intracranial neoplasia

Idiopathic Immune-Mediated Optic Neuritis

granulomatous meningoencephalitis (GME), necrotizing meningoencephalitis (NME), and optic nerve neoplasia can also result in optic neuritis.

Diagnosis of idiopathic (immune-mediated) optic neuritis is made only after infectious and neoplastic disorders are ruled out during a thorough workup for systemic and intracranial disease, including a complete blood count (CBC), serum chemistry profile, urinalysis, heartworm antigen test, serologic screening for infectious diseases, thoracic radiography, abdominal ultrasound, and cerebrospinal fluid (CSF) collection and analysis. CSF should be normal in optic neuritis; inflammatory cytology suggests that the changes in the optic nerves are secondary to meningoencephalitis. Magnetic resonance imaging (MRI) can be used to look for mass lesions of the optic chiasm and will occasionally reveal hyperintensity of inflamed optic nerves on T2-weighted images in animals with optic neuritis. If test results fail to identify meningoencephalitis or a neoplastic cause, primary immune-mediated optic neuritis is tentatively diagnosed.

Treatment of idiopathic optic neuritis should be initiated with orally administered glucocorticoids (prednisone 2 mg/kg/day for 2 weeks). If a favorable response is seen (i.e., improved vision and PLRs), the dose of steroids should be decreased to 1 mg/kg/day for 3 weeks, gradually decreased to alternate-day therapy and then discontinued while monitoring carefully. If there is no initial response to steroid therapy, or if relapse occurs during prednisone tapering, then additional immunosuppressive drugs should be administered (cyclosporine, azathioprine). Lifelong treatment is occasionally required. When the response to initial treatment is rapid, complete, and long-lasting, then the prognosis for return of vision is excellent. Inadequately treated optic neuritis leads to irreversible optic nerve atrophy and permanent blindness. Even with appropriate therapy, many cases will progress or relapse.

Papilledema

Edema of the optic disk usually results from increased intracranial pressure caused by a cerebral tumor or inflammatory mass lesion, but may also occur secondary to tumors or inflammation of the optic nerves. Papilledema is recognized as an enlarged optic disk with indistinct or fluffy margins, kinking of blood vessels as they pass over the disk, and occasionally congestion or hemorrhage of the adjacent retina. Papilledema may be difficult to distinguish from optic neuritis on funduscopic evaluation, although patients with a significant forebrain lesion causing papilledema should have clinical evidence of forebrain disease (i.e., abnormal mentation, behavior change, seizures). Despite reports that papilledema does not affect vision, most patients with papilledema caused by increased intracranial pressure are cortically blind. In patients with no loss of vision and no abnormal neurologic findings, enlargement of the optic disk with indistinct margins may simply represent hypermyelination, a normal finding in some breeds of dogs, especially Boxers, German Shepherd dogs, and Golden Retrievers.

LESIONS OF THE OPTIC CHIASM

Lesions of the optic chiasm cause bilateral blindness, mydriasis, and loss of the direct and consensual PLRs; fundic examination and ERG will be normal. Neoplasia and other space-occupying masses can occur at this location, especially lymphoma (cats), pituitary macroadenomas, meningiomas, and primary nasal tumors extending into the brain (Fig. 61.5). Vascular lesions such as hemorrhage and infarction, infectious inflammatory granulomas, and GME can also affect the optic chiasm. Evaluation should include a search for evidence of extraneural infectious or neoplastic disease, followed by cranial MRI, CSF collection and analysis, and endocrinologic testing as warranted.

LESIONS CAUDAL TO THE OPTIC CHIASM

Lesions in the LGN, optic radiations, or visual cortex prevent interpretation of the image, resulting in visual deficits in the eye opposite the lesion despite normal PLRs, normal fundic examination, and normal ERG. This is called cortical blindness. Other clinical signs of forebrain disease (e.g., seizures, circling, altered mentation) are usually evident in animals with forebrain lesions severe enough to cause cortical blindness but are not always present. Intracranial causes of cortical blindness include trauma-induced hemorrhage, edema, vascular infarcts, GME, infectious encephalitis, intracranial

FIG 61.5
Neoplasm of the optic chiasm identified with magnetic resonance imaging in a 7-year-old Doberman Pinscher with an acute onset of bilateral blindness and loss of pupillary light reflexes but no other neurologic deficits.

neoplasia, congenital malformations (e.g., hydrocephalus, lissencephaly), and degenerative disorders (see Box 60.1). Animals with functional disturbances of the forebrain caused by metabolic encephalopathies, intoxications, hypoxia, or postictal cerebral edema may also present with cortical blindness that is often transient or intermittent. Diagnostic evaluation for cortical blindness should follow the guidelines outlined in Chapter 60 for evaluation of animals with suspected intracranial disease and should include thorough physical, ophthalmologic, and neurologic examinations; a laboratory database; screening thoracic and abdominal radiographs and abdominal ultrasound; CSF analysis; and cranial MRI evaluation.

HORNER SYNDROME

Lesions disrupting the sympathetic innervation to the eye result in Horner syndrome. This condition causes miosis (constriction of the affected pupil), drooping of the upper eyelid (ptosis), and an inward sinking of the eyeball (enophthalmos) as well as partial protrusion of the third eyelid (nictitating membrane) (Box 61.3; Fig. 61.6).

Horner syndrome can result from injury to the sympathetic innervation of the eye anywhere along its pathway (Box 61.4; Fig. 61.7). Lesions are classified as first order (central), second order (preganglionic), or third order (postganglionic) according to the level of the lesion along the sympathetic pathway.

First-order neurons originate in the hypothalamus and rostral midbrain and travel down the brainstem and cervical spinal cord to terminate at the preganglionic cell bodies in

FIG 61.6
Horner syndrome in a domestic short-haired cat with otitis media/interna.

BOX 61.3

Components of Horner Syndrome

Miosis
Enophthalmos
Ptosis
Prolapsed nictitans

BOX 61.4

Common Causes of Horner Syndrome

First-Order (Central) Causes (Rare)

Intracranial neoplasia, trauma, infarct, inflammatory disease
Cervical spinal cord lesion
- Intervertebral disk protrusion
- Neoplasm
- Fibrocartilaginous embolism
- Trauma
- Infectious inflammatory disease
- Granulomatous meningoencephalitis

Second-Order (Preganglionic) Causes

Spinal cord lesion T1-T3 (trauma, neoplasia, fibrocartilaginous embolism, inflammation)
Brachial plexus avulsion
T1-T3 spinal nerve root tumor
Cranial mediastinal mass
Cervical soft-tissue neoplasia, trauma
Skull base trauma

Third-Order (Postganglionic) Causes

Otitis media/interna
Neoplasia in middle ear
Retrobulbar injury, neoplasia
Idiopathic

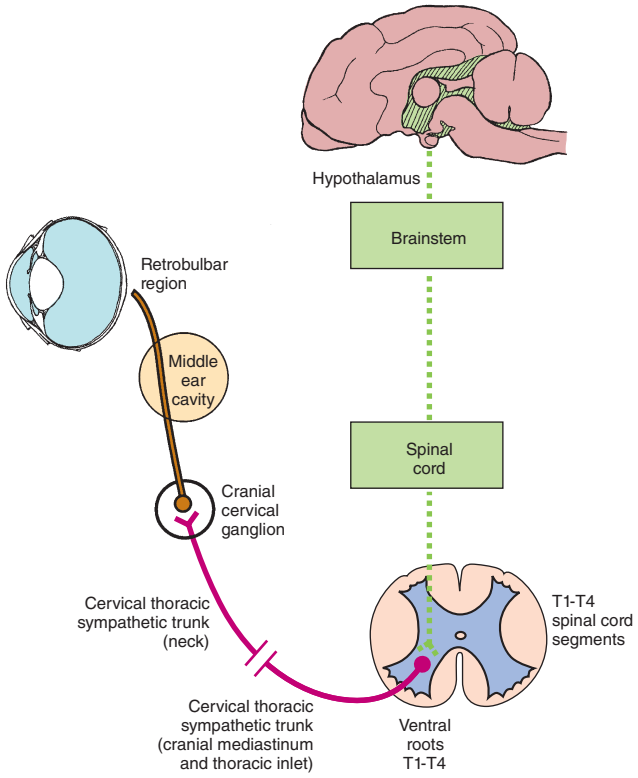

FIG 61.7
Sympathetic innervation to the eye. An injury anywhere along this pathway will result in Horner syndrome.

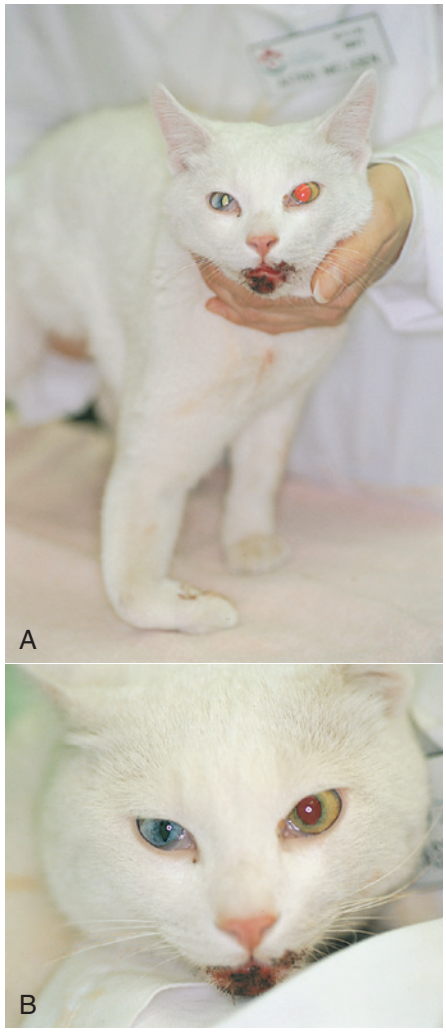

FIG 61.8
(A) and **(B)** Horner syndrome in a domestic short-haired cat with traumatic right brachial plexus avulsion.

the thoracic spinal cord. Upper motor neuron lesions in the brainstem or cervical spinal cord are a relatively rare cause of Horner syndrome but may occur secondary to trauma, infarction, neoplasia, or inflammatory disease. Ipsilateral hemiplegia and other concurrent neurologic abnormalities are expected in animals with first-order lesions (see Box 61.4).

The preganglionic cell bodies of second-order neurons are located in the lateral horn of the spinal cord gray matter at the level of the first three thoracic spinal cord segments (T1-T3). The second-order axons leave the spinal cord with the T1-T3 ventral nerve roots, but then leave the spinal nerves to form the thoracic sympathetic trunk, which courses cranially within the thorax. The sympathetic axons course cranially within the vagosympathetic trunk in the cervical region and synapse in the cranial cervical ganglion, ventral and medial to the tympanic bulla at the base of the skull. Injury to second-order neurons can occur when there is damage to the spinal cord at the cervical intumescence (C6-T2) caused by trauma, infarcts, neoplasia, or inflammatory disease. Affected animals will exhibit lower motor neuron (LMN) signs in the affected forelimb, upper motor neuron (UMN) signs in the ipsilateral rear limb, and Horner syndrome. In animals with brachial plexus avulsion, there will be complete LMN paralysis of the affected limb and an ipsilateral Horner syndrome that may be partial (miosis only) because of sparing of the T3 (and sometimes T2) nerve roots (Fig. 61.8). Horner syndrome can also occur when the second-order neurons are damaged by thoracic surgery, mediastinal masses (lymphoma or thymoma), bite wounds to the neck, strangulation injuries, invasive thyroid carcinoma, or errors made during thyroidectomy or surgery for cervical intervertebral disk disease. Physical and neurologic findings are often useful in localizing and determining the cause of preganglionic Horner syndrome.

Most dogs and cats with Horner syndrome have postganglionic (third-order) lesions. The postganglionic axons for ocular sympathetic innervation course rostrally through the tympanooccipital fissure into the middle ear and enter the cranial cavity with the glossopharyngeal nerve (CN9), leaving the cranial cavity via the orbital fissure for distribution to the smooth muscle of the orbit, the upper and lower eyelids, the third eyelid, and the iris muscles. Third-order Horner syndrome is common in patients with otitis media or neoplasia within the middle ear, often accompanied by evidence of peripheral vestibular (CN8) disturbance and

FIG 61.9
Dramatic muscle atrophy in a dog with masticatory muscle myositis has resulted in retraction of the globes into the orbits and protrusion of the third eyelid over most of the corneal surface.

sometimes facial nerve (CN7) paralysis. No underlying cause can be identified in most dogs with postganglionic Horner syndrome, and these cases have been called idiopathic Horner syndrome.

Pharmacologic testing has been recommended to help localize the cause of Horner syndrome in dogs and cats. When Horner syndrome has been present for at least 2 weeks, denervation hypersensitivity will occur in the affected eye secondary to the loss of sympathetic innervation. To localize Horner syndrome pharmacologically, a single drop of a very dilute concentration of a direct-acting sympathomimetic (0.1% phenylephrine: stock 10% solution diluted 1:100 with saline solution) is applied to both eyes. The pupil in the normal eye should not dilate with that dilute concentration. Dilation of the affected pupil will occur within 20 minutes in an animal with a postganglionic (third-order Horner syndrome) lesion. If neither pupil dilates within 20 minutes, repeat the test using a more concentrated adrenergic (1% phenylephrine) applied to the affected eye and then monitor pupil size every 2 minutes in both eyes. The time that it takes for the affected pupil to dilate to the same size as the unaffected pupil is the test endpoint. If dilation occurs within 20 minutes, the lesion is most likely postganglionic (third order). Dilation in 20 to 45 minutes has been reported in dogs with second-order lesions and 60 to 90 minutes in dogs with central lesions and dogs that have not had sympathetic denervation of the eye for at least 2 weeks. Although pharmacologic testing can be helpful in localizing the site of neuron injury in animals with Horner syndrome, results of pharmacologic testing can be equivocal and may not always contribute practical information regarding the cause or prognosis.

The diagnostic approach in an animal with Horner syndrome should include complete physical, ophthalmologic, neurologic, and otoscopic examinations. Neurologic findings can often help to locate the site of disruption of sympathetic innervation. Further tests should be recommended after lesion localization. Careful palpation of the soft tissues of the neck and radiographs of the thorax and the cervical and thoracic spine should be performed and advanced diagnostic imaging (MRI) should be considered if a first- or second-order lesion is suspected. When a postganglionic lesion is suspected, skull radiographs, CT, or MRI should be performed to evaluate the middle ear for signs of otitis media, neoplasia, or trauma. The most common causes of Horner syndrome in cats are middle ear disease and injury to the soft tissues of the neck. Dogs more frequently have brachial plexus avulsion, nerve root tumors of the brachial plexus, C6-T2 spinal cord injury, middle ear disease, and cervical soft tissue injuries or tumors. Most dogs with Horner syndrome (>50%) have no other neurologic abnormalities, and a cause for their Horner syndrome is not identified; these animals are classified as having idiopathic disease. Idiopathic postganglionic Horner syndrome is especially common in Golden Retrievers. The prognosis for resolution of idiopathic Horner syndrome is excellent as most cases resolve spontaneously within 4 to 6 months. Treatment is rarely required, but occasionally in dogs with bilateral disease vision is obscured by the prolapsed third eyelids and some periodic relief can be provided by administering topical phenylephrine (1%).

PROTRUSION OF THE THIRD EYELID

In dogs and cats the third eyelid may protrude over the corneal surface in the presence of corneal or conjunctival irritation, or space-occupying retroorbital disease. This may also occur if the animal experiences a decrease in periorbital mass as a result of dehydration, a loss of retrobulbar fat or muscle (Fig. 61.9), or a loss of volume within the eye (i.e., microphthalmos, phthisis bulbi).

Protrusion of the third eyelid is a conspicuous feature of both Horner syndrome (with miosis) and dysautonomia (with mydriasis). Systemic illness or tranquilization can also result in third eyelid protrusion in some dogs and cats. A peculiar syndrome of dramatic bilateral third eyelid protrusion with no obvious cause (i.e., Haw syndrome) has been observed in cats and occasionally in dogs. Affected cats are usually younger than 2 years of age and in good health otherwise, although digestive disturbances or heavy intestinal parasite loads have occasionally been documented. Instillation of sympathomimetic drops (phenylephrine 10%) causes the membrane to rapidly retract. The condition resolves spontaneously within several weeks or months.

CHAPTER 62

Seizures and Other Paroxysmal Events

SEIZURES

A seizure is the clinical manifestation of excessive or hypersynchronous abnormal electrical activity in the brain. The clinical features of seizures can be separated into four components: prodrome, aura, ictal period, and postictal period. The *prodrome* is the period of time (hours to days) before the seizure begins, when the owner may report unusual behavior such as restlessness or anxiety. The prodrome may be barely noticeable in some animals and distinct enough to enable owners to accurately predict seizure onset in others. The *aura* is the period of time immediately before the seizure when animals may exhibit stereotypical sensory or motor activity (pacing, licking, swallowing), autonomic patterns (salivation, vomiting, urination), or abnormal behavior (hiding, attention seeking, whining, or agitation) for seconds to minutes before seizure onset. The *ictus* is the seizure itself, when the animal exhibits a variety of signs that may include loss or derangement of consciousness, altered muscle tone or movements, paddling of the limbs, jaw chomping, salivation, and involuntary urination and defecation. This phase usually lasts only seconds to minutes. The *postictal period* immediately follows the seizure and reflects transiently abnormal brain function (seconds to several hours), during which time the animal may exhibit abnormal behavior, disorientation, somnolence, or actual neurologic deficits such as blindness, ataxia, weakness, or proprioceptive deficits. Identification of a postictal phase is highly suggestive that the preceding paroxysmal event was a seizure. Regardless of etiology, seizures can occur singly or in clusters, where two or more seizures occur within a 24-hour period. *Epilepsy* is a term used for any condition characterized by chronic recurrent seizures.

NONEPILEPTIC PAROXYSMAL EVENTS

Dogs and cats are occasionally affected by nonepileptic paroxysmal disorders during which they may experience altered behavior, collapse, abnormal movements, transient neurologic symptoms, or paralysis. Distinguishing these paroxysmal transient events from focal seizures can be challenging but important for diagnosis and treatment. Cardiac arrhythmias causing syncope; weakness caused by hypoglycemia, hypocortisolemia, or electrolyte disturbances; and myasthenia gravis can all cause transient neurologic signs. Nonepileptic neurologic disorders causing repeated paroxysms of neurologic signs in animals that are normal between episodes include acute vestibular "attacks" (see Chapter 63); paroxysmal dyskinesias (PDs); narcolepsy and cataplexy; and several inherited disorders of neurotransmission or function. Descriptions of the event and the animal's activity and demeanor immediately preceding, during, and after the event will often help distinguish these events from seizures (Box 62.1). Observing a videotaped episode will be helpful in the diagnosis of disorders that have a very characteristic appearance. Discussion of some of the important or common neurologic nonepileptic paroxysmal events that are often confused with seizures can be found at the end of this chapter.

SEIZURE DESCRIPTIONS

Most true seizures in dogs and cats are tonic-clonic, generalized-onset motor seizures in which the animal experiences a period of extremely increased extensor muscle tone (tonus), falls into lateral recumbency in opisthotonus with its legs extended, and then has periods of tonus alternating with periods of relaxation (clonus), resulting in rhythmic contractions of muscles manifested as paddling or jerking of the limbs and chewing movements. Animals typically lose consciousness during severe generalized seizures, although their eyes may remain open. Autonomic signs such as salivation, urination, defecation, and mydriasis are common.

Less common than generalized-onset, symmetric tonic-clonic seizures in dogs and cats are focal seizures (also called *partial seizures*) arising in part of one cerebral hemisphere, resulting in asymmetric signs initially. Focal seizures may progress to generalized motor seizures in some animals.

BOX 62.1

Paroxysmal Disorders Confused With Epileptic Seizures

- Syncope (reduced cerebral blood flow)
  - Cardiac arrhythmias
  - Hypotension
- Episodic weakness
  - Hypoglycemia
  - Low blood cortisol
  - Electrolyte disturbances
- Myasthenia gravis
- Acute vestibular "attacks"
- Sleep disorders
  - Narcolepsy
  - Cataplexy
- Movement disorders (dyskinesias)
- Exercise-induced weakness or collapse disorders
  - dynamin-associated Exercise-Induced Collapse (dEIC)
  - Border Collie collapse

Although it is often stated that partial motor seizures are associated with focal intracranial pathology, many dogs and cats with idiopathic epilepsy (IE) experience focal seizures with or without progression to generalized seizures. Focal motor seizure manifestations may include abnormal movements or postures such as turning of the head to one side, focal twitching, rhythmic contraction of limb or facial muscles, lip smacking, or chewing movements. Labrador Retrievers, Poodles, and occasionally other breeds may experience partial seizures that resemble episodes of staggering, loss of balance, confusion, trembling, or crawling without loss of consciousness. Circling, rapid running, and climbing activity is common in epileptic cats and may suggest temporal lobe involvement. Focal sensory seizures can cause tingling, pain, or visual hallucinations, resulting in tail chasing, limb chewing, compulsive digging, or "fly biting." It can be very difficult to distinguish sensory seizures from compulsive stereotypic behavior in dogs.

Repetitive episodes of autonomic signs may occur as unusual manifestations of a focal seizure disorder. Signs may include vomiting, diarrhea, apparent abdominal discomfort, drooling, repetitive swallowing or gulping, compulsive licking of the carpet or floor, or eating grass. Signs may last for hours rather than the seconds to minutes usually associated with epileptic seizures. Affected dogs are normal between episodes, and extensive gastrointestinal evaluations looking for a cause of their signs are typically negative. Many affected dogs have resolution of their episodes with chronic oral anticonvulsant therapy, supporting the suspicion that these are seizure events. A phenobarbital (PB)-responsive syndrome of drooling, retching, and dysphagia in dogs with painful enlargement of the mandibular salivary glands and salivary gland necrosis likely also represents a focal seizure with prominent autonomic signs.

Complex focal seizures, also known as *psychomotor seizures* or *automatisms,* are focal seizures with altered mentation. Animals may appear confused, disoriented, or unresponsive to owner commands while head pressing, pacing, aimlessly walking, circling, or staggering. Some complex focal seizures are associated with episodes of howling, unprovoked aggression, or extreme fearfulness. "Rage syndrome" or "episodic dyscontrol" in St. Bernards and Springer Spaniels may be a complex focal seizure disorder.

Reflex seizures are seizures that can be consistently provoked by specific stimuli or events. The most common precipitating factor in people is a flickering light, but certain sounds and eating have also been identified as triggers. Reflex focal, generalized, or myoclonic seizures in response to high-pitched repetitive sound stimuli have been well described in cats, characterizing a disorder called feline audiogenic reflex seizures. Wirehaired Dachshunds with Lafora disease have been reported to have myoclonic seizures triggered by auditory and visual stimuli.

SEIZURE CLASSIFICATION AND LOCALIZATION

Seizure disorders can be classified according to their cause as being idiopathic, intracranial, or extracranial in origin (Box 62.2). IE is the most common cause of recurrent seizures in dogs but is less common in cats. Animals with IE have no identifiable extracranial or intracranial cause for their seizures, are neurologically normal between seizures, and their seizures are presumed to be genetically based. Intracranial (structural) causes (e.g., anomaly, inflammation, neoplasia, infarct, trauma, scar) are responsible for seizures in approximately 35% of dogs and most cats with seizures (see Chapter 60). Extracranial causes of seizures such as ingestion of toxins or metabolic or endocrine derangements occur less frequently (see Box 62.2).

Seizure activity always indicates a functional or structural abnormality of the forebrain, particularly of the frontal or temporal lobes of the cerebrum. Metabolic and toxic disorders can cause functional alterations of the balance between inhibitory and excitatory neurotransmitters, leading to seizures. Defined localizing neurologic deficits are unlikely to be detected interictally (between seizures) in patients with extracranial causes of seizures. Animals with an intracranial lesion causing seizures typically exhibit multiple signs localizing disease to the forebrain, including behavior change, circling toward the side of the lesion, contralateral hemiparesis and postural reaction deficits, and contralateral vision loss and facial hypalgesia. Animals with small intracranial lesions will, however, sometimes be normal interictally, with no other identifiable neurologic deficits.

IE is a condition wherein the seizure threshold is decreased. This disorder has been shown to be inherited in a few dog breeds, and a familial basis for the condition is suspected in others. Affected animals are normal interictally, and extensive diagnostic evaluation, including histologic examination of the brain, is normal.

BOX 62.2

Common Disorders Resulting in Seizures

Extracranial Causes (Reactive Seizures)

Toxins
Metabolic diseases
- Hypoglycemia
- Liver disease
- Hypocalcemia
- Hyperlipoproteinemia
- Hyperviscosity
- Hypertension
- Electrolyte disturbances
- Hyperosmolality
- Severe uremia
- Hyperthyroidism (cats)
- Hypothyroidism (dogs)—predisposition to intracranial infarcts

Intracranial Lesions (Structural Epilepsy)

Congenital malformations
- Hydrocephalus
- Lissencephaly

Neoplasia
- Primary brain tumors
- Metastatic tumors

Inflammatory disease
- Infectious inflammatory diseases
- Meningoencephalitis of unknown etiology (dogs)
  - Granulomatous meningoencephalitis
  - Necrotizing meningoencephalitis
  - Necrotizing leukoencephalitis

Vascular disease
- Hemorrhage
- Infarct

Metabolic storage diseases
Degenerative conditions

Scar Tissue–Related Acquired Epilepsy

Idiopathic Epilepsy (Primary Epileptic Seizures)

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a patient with seizures includes IE, intracranial disease, scar tissue–related acquired epilepsy, and extracranial disorders (see Box 62.2).

IDIOPATHIC EPILEPSY

IE is the most common cause of seizures in the dog and is characterized by repeated episodes of seizures with no demonstrable cause. Affected dogs are normal between seizures. The diagnosis can be suspected clinically based on breed, age of onset, normal interictal neurologic examination, typical seizure recurrence pattern, and failure to progress to systemic or neurologic abnormalities over time, but the diagnosis remains uncertain unless diagnostic evaluation has eliminated metabolic and structural causes for seizures. IE has always been considered to be uncommon in cats, but most recent reports suggest that 20% to 50% of cats with recurrent seizures may have IE. Intracranial causes of seizures are, however, much more common in cats than in dogs, so an intracranial evaluation is still recommended in all cats with recurrent seizures.

A genetic basis for IE is strongly suspected or proven in German Shepherd dogs, Belgian Tervurens, Keeshonds, Beagles, Dachshunds, Labrador Retrievers, Golden Retrievers, Poodles, Border Collies, Shetland Sheepdogs, Irish Wolfhounds, Vizslas, Bernese Mountain Dogs, and English Springer Spaniels. Genetic factors are likely in other affected breeds as well, and IE is often called familial epilepsy.

The first observed seizure in dogs with IE usually occurs between 6 months and 3 years of age, although seizures are not observed until 5 years of age or older in some dogs. In most breeds it seems that the younger the age at the onset of a seizure disorder, the more difficult the disorder will be to control. Cats with IE typically experience their first seizure between 3 and 5 years of age.

The seizures in dogs and cats with IE are often generalized-onset, tonic-clonic, and associated with a loss of consciousness lasting from 1 to 2 minutes. However, dogs and cats with IE can have a variety of focal-onset seizures or a combination of focal-onset and generalized seizures. Some dog breeds, especially Labrador Retrievers and Miniature Poodles, very commonly experience a mild generalized type of seizure during which they maintain consciousness but exhibit staggering, loss of balance, confusion, a crouched posture or crawling stance, uncontrollable trembling, or muscular rigidity. In Retrievers, common triggers for these unusual seizures include exercise, excitement, or hyperventilation, prompting some diagnostic confusion with Exercise Induced Collapse (EIC, see page 1106). Many of these epileptic Labrador Retrievers experience a postictal phase, develop more classical generalized tonic-clonic seizures later in life, and respond to chronic oral anticonvulsant therapy, confirming that these paroxysmal events are seizures.

The frequency of seizures varies greatly between dogs and cats with IE, but seizures typically recur at regular intervals, with weeks or months intervening between seizures. As the animal ages, the frequency and severity of seizures may increase, especially in large-breed dogs. In some dogs, particularly large breeds, seizures can eventually occur in clusters in which multiple seizures occur during a 24-hour period. Cluster seizures are not seen in association with the first observed seizure in most dogs or cats with IE, so this presentation should prompt consideration of intracranial causes. The most common time for seizures to occur in dogs and cats with IE is when an affected animal is sleeping, drifting off to sleep, or waking up abruptly, but in some patients seizures seem to be provoked by specific stimuli such as certain sounds, excitement, hyperventilation, or exercise.

IE is the most likely diagnosis in a young adult, neurologically normal animal with a long history (>1 year) of a nonprogressive intermittent seizure disorder and a lengthy interictal period (>4 weeks). The diagnosis of IE is one of

exclusion; although it can be suspected based on typical signalment, seizure history, and unremarkable physical, neurologic, and ophthalmologic evaluations, diagnosis requires the exclusion of underlying metabolic and toxic causes through clinicopathologic testing and imaging. Intracranial evaluation, when performed, is normal (Fig. 62.1).

INTRACRANIAL DISEASE

Intracranial disease localized in the forebrain commonly causes seizures. Congenital disorders, inherited degenerative conditions, and many infectious causes of encephalitis are most often seen in young animals, whereas neoplasia is more common in dogs and cats older than 6 years of age. Most of the intracranial disorders discussed in Chapter 60 and the inflammatory disorders discussed in Chapter 64 can cause seizures (see Box 62.2). Focal or multifocal neurologic deficits identified interictally strongly suggest that structural forebrain pathology exists, but not all patients with intracranial disease will have an abnormal neurologic examination. Diagnosis requires careful physical, neurologic, and ophthalmologic examination; evaluation for concurrent systemic manifestations of infectious and neoplastic disorders; and often intracranial evaluation, including cerebrospinal fluid (CSF) analysis, and advanced diagnostic imaging (Fig. 62.2).

SCAR TISSUE–RELATED ACQUIRED EPILEPSY

Scar tissue in the brain after an inflammatory, traumatic, toxic, metabolic, or vascular insult can result in a seizure

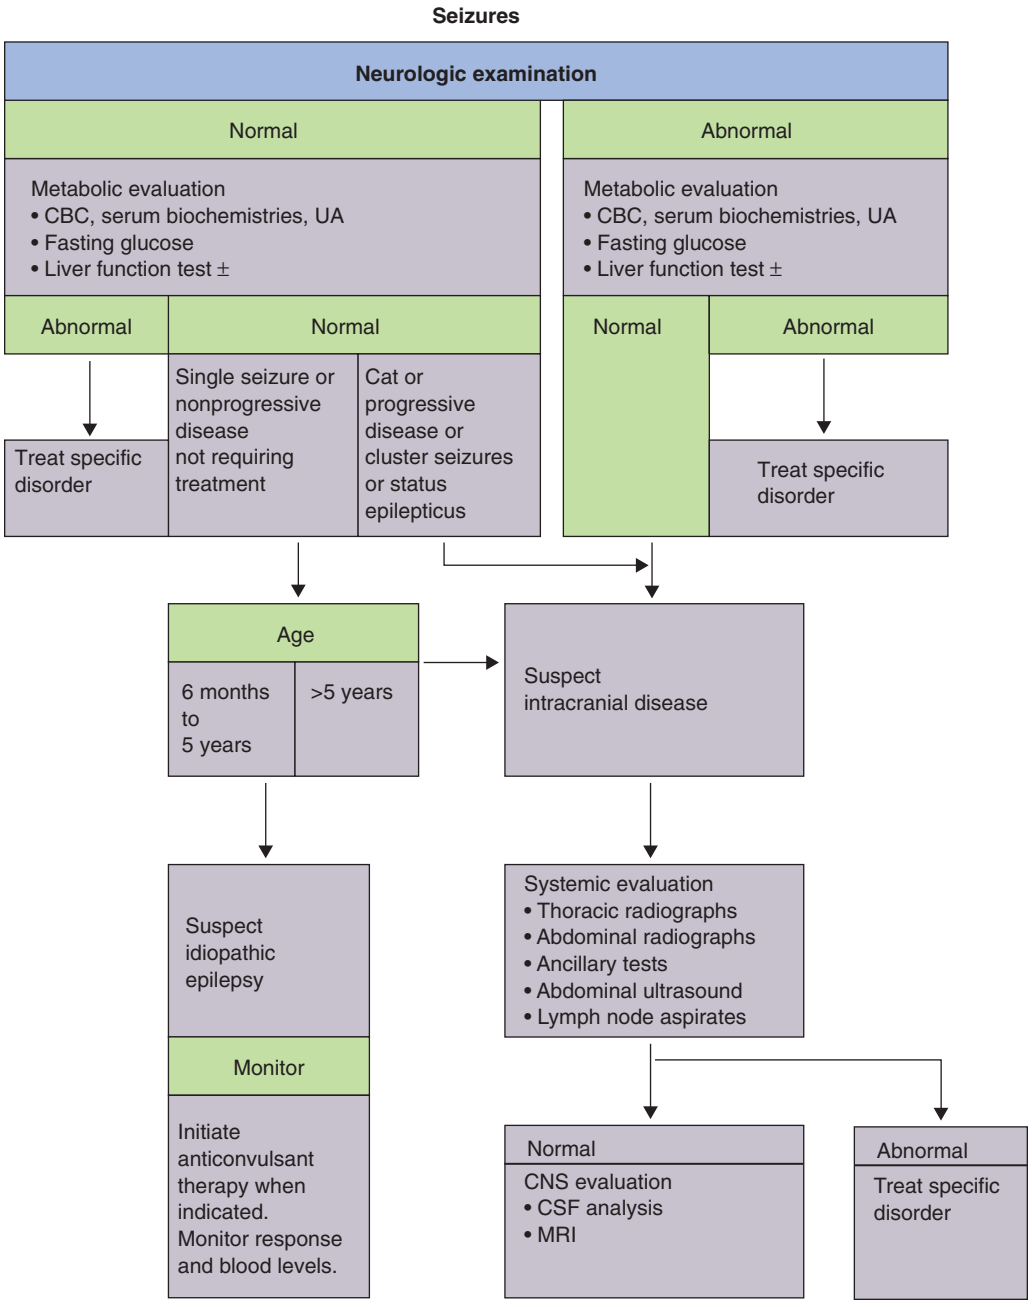

FIG 62.1 Diagnostic approach used in dogs or cats with seizures. *CBC,* Complete blood count; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *MRI,* magnetic resonance imaging; *UA,* urinalysis.

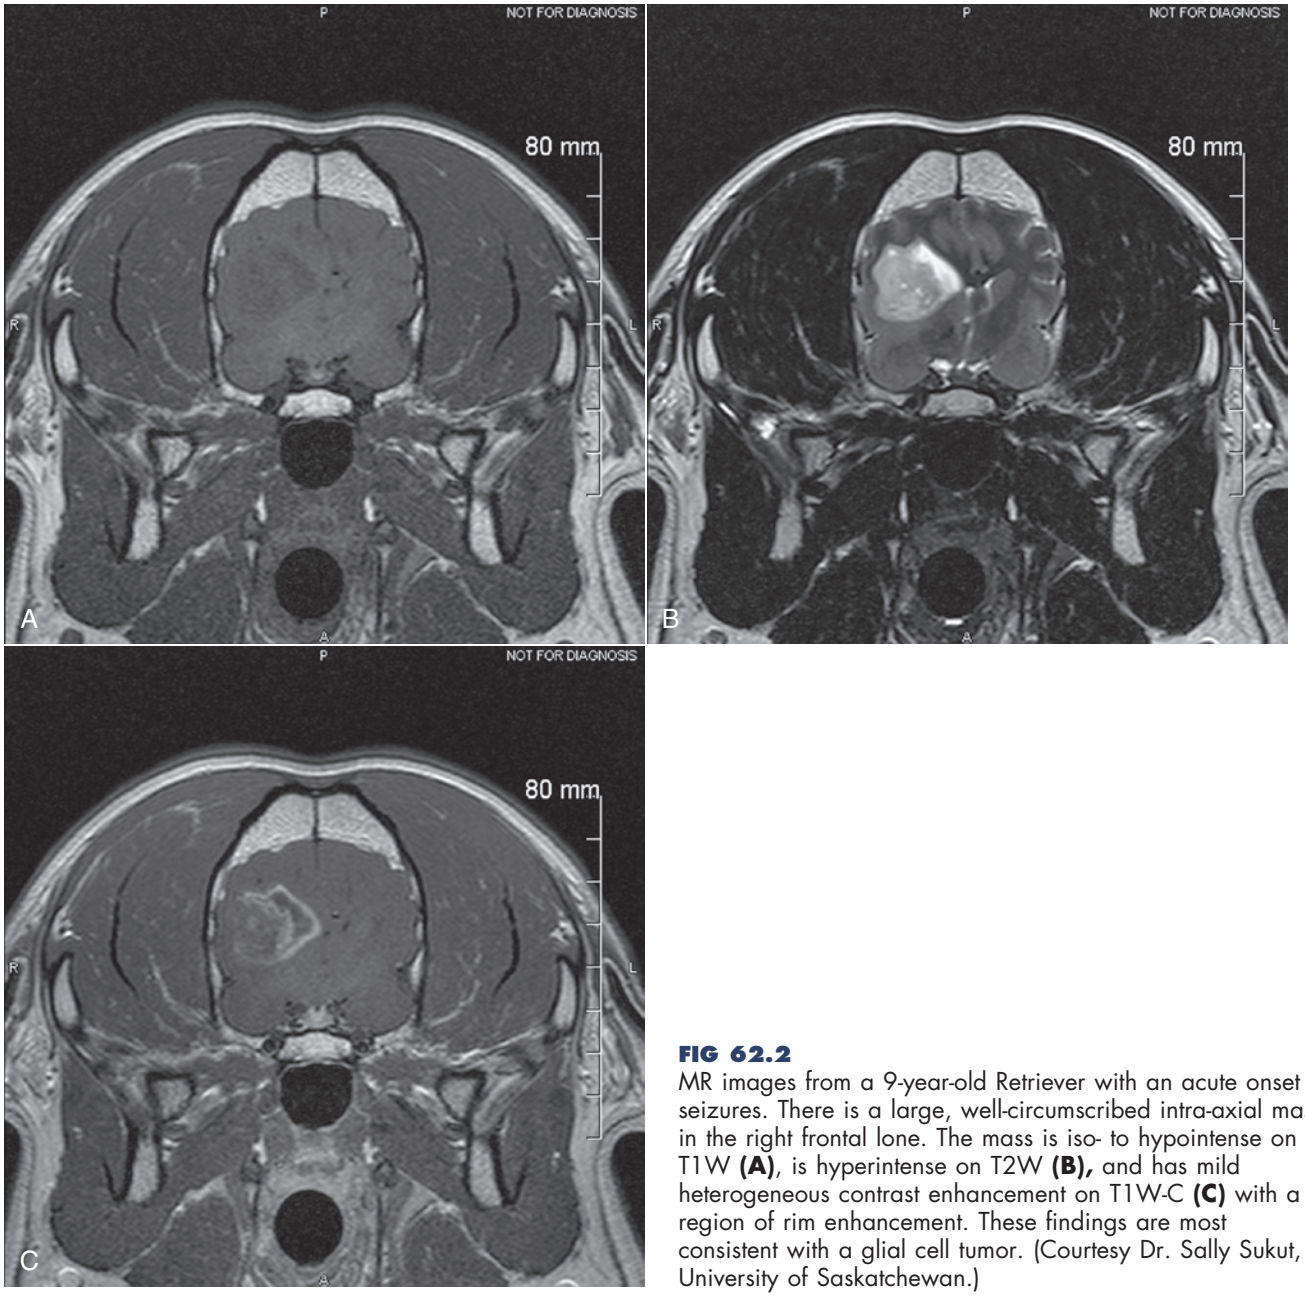

FIG 62.2
MR images from a 9-year-old Retriever with an acute onset of seizures. There is a large, well-circumscribed intra-axial mass in the right frontal lone. The mass is iso- to hypointense on T1W **(A)**, is hyperintense on T2W **(B),** and has mild heterogeneous contrast enhancement on T1W-C **(C)** with a region of rim enhancement. These findings are most consistent with a glial cell tumor. (Courtesy Dr. Sally Sukut, University of Saskatchewan.)

disorder. If a history of significant trauma or infection can be ascertained, that event usually precedes the onset of the seizure disorder by 6 months to 3 years. Findings from physical and neurologic examinations, clinicopathologic tests, and CSF analysis are normal. It is not usually possible to detect a structural abnormality using magnetic resonance imaging (MRI), and even necropsy will not reliably demonstrate a lesion. Treatment is the same as for IE (i.e., anticonvulsant therapy), but the prognosis for seizure control and lack of progression may be better for those with scar tissue–related acquired epilepsy than for those with IE.

EXTRACRANIAL DISEASE

Seizures with an extracranial cause are known as reactive seizures. Reactive seizures reflect a response by a normal brain to a transient metabolic or toxin-induced disturbance in cerebral function. Metabolic disorders including hypoglycemia, hepatic encephalopathy, hypocalcemia, and primary hyperlipoproteinemia commonly cause seizures in dogs and cats. Hyperviscosity syndromes (e.g., multiple myeloma, polycythemia), severe electrolyte disturbances (e.g., hypernatremia), hyperosmolality (e.g., untreated diabetes mellitus), heatstroke, severe hypertension, feline hyperthyroidism, and prolonged severe uremia also occasionally cause seizures (see Box 62.2). Hypothyroidism does not directly induce seizures in dogs but can cause atherosclerotic vascular changes that predispose to intracranial infarcts.

Systemic signs and physical and neurologic examination findings may increase suspicion of an extracranial cause of seizures. Many metabolic encephalopathies intermittently or

permanently alter consciousness, causing dull mentation, confusion, or delirium. Symmetrical signs including cortical blindness, diminished facial sensation, and impaired proprioceptive positioning can all be seen. All patients with seizures should be evaluated for an extracranial cause. Results of a complete blood count (CBC), serum biochemistry panel, and urinalysis often help establish the diagnosis. Hepatic encephalopathy resulting from portosystemic shunting can occasionally cause seizures in the absence of other clinical or clinicopathologic abnormalities, especially in cats, so evaluation of liver function is an important component of the initial evaluation for metabolic causes of seizures. More detailed information on the diagnosis and management of these metabolic disorders is contained elsewhere in this text. Common intoxications causing seizures are described in Box 62.3, and treatment of some common intoxications is outlined in Box 62.4.

DIAGNOSTIC EVALUATION

A complete and accurate history must be obtained in every animal presenting for a seizure. The owner's description is crucial to determining whether the observed paroxysmal event was actually a seizure. The relationship of seizures to daily activity (e.g., exercise, sleep, eating, excitement), seizure duration and frequency, and a description of any observed postictal abnormalities should be recorded. Recent systemic signs such as cough, vomiting, diarrhea, polyuria, polydipsia, and weight loss or weight gain could suggest a metabolic encephalopathy or systemic disease (infection, neoplasia) spread to the brain. Vaccination status, diet, potential exposure to infectious causes of encephalitis, access to drugs or toxins, and history of serious head injury should also be determined. When seizures have occurred intermittently over a prolonged period of time (weeks to months), the seizure pattern and frequency should be assessed. Owners should be asked whether they have noticed any changes in the animal's behavior, gait, vision, or sleep patterns, characteristics that might indicate a structural forebrain lesion. When IE or an inherited neurodegenerative disorder is considered likely, owners should be encouraged to contact the breeder to ascertain whether litter mates or other related dogs are affected.

Neurologic, physical, and ophthalmologic examinations should be performed in every animal presented for seizures. In the immediate postictal period, cerebral edema and altered cerebral metabolism can cause transient symmetric neurologic abnormalities such as blindness, altered consciousness, and postural reaction deficits, so these should not be overinterpreted. Neurologic abnormalities that persist beyond the postictal period suggest an intracranial cause for seizures requiring further evaluation. A complete physical examination with particular attention to lymph node and abdominal palpation as well as mammary gland and prostate examination should always be performed in dogs and cats with seizures to evaluate for primary neoplasia that could have spread to the brain. Ophthalmologic examination is often abnormal in infectious and neoplastic causes of seizures and can also reveal changes suggestive of hemorrhage, hypertension, or increased intracranial pressure.

Every animal evaluated for seizures should have a CBC, serum biochemistry panel, and urinalysis and blood pressure measurement performed. Additional testing may be recommended based on the age, breed, seizure pattern, and physical and neurologic examination findings. Blood glucose should be measured during any observed seizure, and whenever insulinoma is a possibility, random blood glucose measurement should be performed during the day to include samples after a 12-hour fast and 15 minutes after eating. Young dogs and cats with a seizure history, animals with initial laboratory results suggesting hepatic dysfunction, and all seizure patients that might potentially be treated with an antiepileptic drug (AED) metabolized by the liver should have their liver function evaluated with serum bile acids or ammonia testing (see Chapter 36). Thyroid function should be evaluated in mature dogs with an acute onset of seizures because of the association between hypothyroidism and intracranial infarcts. All cats with seizures should be screened for feline leukemia virus (FeLV) antigen and feline immunodeficiency virus (FIV) antibody.

The animal's signalment and history as well as the onset and progression of the seizure disorder allow ranking of likely differential diagnoses. Congenital structural disorders such as hydrocephalus and lissencephaly are likely causes of a seizure disorder in very young animals. Infectious causes of encephalitis typically cause rapidly progressive neurologic dysfunction rather than seizures alone. In aging animals, primary or metastatic cerebral neoplasia, vascular infarct or hemorrhage, and acquired metabolic disturbances are the most likely causes of seizures. Animals with IE nearly always have their first observed seizure between 6 months and 5 years of age, so it is not a likely diagnosis in a dog or cat with seizures that began late in life.

When the systemic, neurologic, and screening laboratory tests are all normal in an animal with seizures, recommendations for further testing are based on history and signalment. Dogs between 1 and 5 years of age presenting with a single generalized seizure, or a history of a few generalized seizures weeks or months apart, most likely have IE; further evaluation may not be required. The frequency and severity of the seizures should be monitored, and, when necessary, treatment initiated with an AED. IE is not likely if cluster seizures or status epilepticus occur during a dog's first presentation for seizures or if seizures have a rapidly progressive course, prompting recommendations for a full systemic and intracranial evaluation. IE is relatively uncommon in cats, so even when all routine screening tests and systemic evaluation are normal, intracranial evaluation should be recommended.

When a metabolic or systemic cause for seizures cannot be identified with initial screening, further testing, including intracranial evaluation, should be recommended in all cats with seizures, in dogs with interictal neurologic

BOX 62.3

Intoxications Resulting in Acute Neurologic Dysfunction

Strychnine

Common use: rat, mole, gopher, and coyote poison
Clinical findings: stiff extension of legs and body, erect ears, tetanic spasms induced by auditory stimuli
Diagnosis: history of access or ingestion, characteristic signs, chemical analysis of stomach contents
Treatment: vomiting (if no neurologic signs), gastric lavage, diazepam as needed, pentobarbital to effect; establish diuresis

Metaldehyde

Common use: snail, slug, and rat poison
Clinical findings: anxiety, hyperesthesia, tachycardia, hypersalivation, muscle fasciculations, and tremors; not worsened by auditory stimuli; nystagmus in cats; may convulse; depression; respiratory failure
Diagnosis: history of access or ingestion, characteristic signs, acetaldehyde odor on breath, analysis of stomach contents
Treatment: gastrointestinal decontamination: induce vomiting if mild signs, administer activated charcoal with sorbitol as cathartic, diazepam bolus or CRI, methocarbamol (55-220 mg/kg slow IV, repeat in 12 h if needed). Propofol or pentobarbital if needed to effect; establish diuresis.

Tremorgenic Mycotoxins

Common use: moldy dairy products, nuts, grains, compost, garbage
Clinical findings: vomiting, tremors, ataxia, seizures
Diagnosis: history of access or ingestion, characteristic signs, analysis of stomach contents
Treatment: gastrointestinal decontamination: induce vomiting if mild signs, administer activated charcoal with sorbitol as cathartic, diazepam bolus or CRI, methocarbamol (55-220 mg/kg slow IV, repeat in 12 h if needed). Propofol or pentobarbital if needed.

Chlorinated Hydrocarbons

Common use: agricultural products and insecticides; lipid-soluble products usually absorbed through skin
Clinical findings: apprehension, hypersensitivity, hypersalivation, exaggerated response to stimuli, muscle twitching of face and neck progressing to severe fasciculations and tremors; tonic-clonic seizures may occur
Diagnosis: history of access, characteristic signs, insecticide smell to haircoat, analysis of stomach contents
Treatment: wash with warm soapy water to prevent further exposure; if ingested (rare), gastric lavage and instill activated charcoal; pentobarbital to effect

Organophosphates and Carbamates

Common use: insecticides
Clinical findings: excessive salivation, lacrimation, diarrhea, vomiting, and miosis; twitching of facial and tongue muscles, progressing to extreme depression and tonic-clonic seizures
Diagnosis: history of exposure, characteristic signs, analysis of stomach contents, low serum acetylcholinesterase activity
Treatment: prevent further exposure; wash if topical exposure; gastric lavage and activated charcoal if ingested; atropine (0.2 mg/kg IV initially and 0.2 mg/kg SC as needed q6-8h); pralidoxime (20 mg/kg IM q12h) if within 48 hours of exposure or if was dermal exposure

Lead

Common use: ubiquitous in environment in linoleum, rug padding, old lead-based paints (before 1950s), putty and caulking material, roofing materials, batteries, grease, used motor oil, golf balls, fishing sinkers, pellets, and lead shot
Clinical findings: gastrointestinal signs of anorexia, abdominal pain, vomiting and diarrhea, and megaesophagus; neurologic signs of hysteria, aggression, nervousness, barking, tremors, seizures, blindness, hypermetria and nystagmus (cats), and dementia
Diagnosis: history of exposure, characteristic signs, CBC changes (basophilic stippling of RBCs, increase in nucleated RBCs); blood lead level (heparinized tube: >0.5 ppm [50 mg/dL], diagnostic; >0.25 ppm, suggestive); radiographs may reveal radiopaque material in gastrointestinal system
Treatment: emetics, gastric lavage, activated charcoal, enemas; surgery or endoscopy if lead in stomach; diazepam or pentobarbital as needed to stop seizures; specific to chelate lead and hasten excretion: calcium ethylenediaminetetraacetic acid (Ca EDTA) (25 mg/kg, IV or SC, q6h as 1% solution in dextrose for 2-5 days) or succimer (10 mg/kg PO q8h for 5 days, then q12h for 14 days; Chemet, Sandofi Pharm, NY)

Ethylene Glycol

Common use: automobile antifreeze, color film processing solutions
Clinical findings: ataxia, severe depression, polyuria-polydipsia, vomiting; seizures are rare
Diagnosis: history of exposure, characteristic signs, severe metabolic acidosis, calcium oxalate crystalluria; eventually, decreased urine production and acute renal failure. Diagnosis and treatment of this disorder are discussed in detail in Chapter 44.

CBC, Complete blood count; *CRI,* constant rate infusion; *IM,* intramuscular; *IV,* intravenous; *ppm,* parts per million; *RBC,* red blood cell; *SC,* subcutaneous.

BOX 62.4

Emergency Treatment of Intoxications

Prevent Further Absorption of Intoxicant

Remove intoxicant from skin and haircoat

If:
1. Toxin was cutaneously absorbed.

How:
1. Remove flea collar if that is source of toxin.
2. Wash animal in warm soapy water; rinse and repeat.
3. Flush with warm water for 10 minutes.

Induce emesis

If:
1. Ingestion of intoxicant occurred fewer than 3 hours before presentation.
2. Product ingested was not caustic, petroleum based, strong acid, or strong base.
3. Animal has a normal gag reflex and is not convulsing or very depressed (danger of aspiration).

How:
1. At home can recommend oral syrup of ipecac (6.6 mL/kg) or 3% hydrogen peroxide (1-2 mL/kg PO); 5 mL = 1 teaspoon.
2. Administer apomorphine subcutaneously (0.08 mg/kg) or in conjunctival sac (1 crushed tablet or 1 disk [6 mg]: rinse eye with saline solution after emesis).
3. Administer xylazine (cats: 0.44 mg/kg IM).

Vomiting is most successful if stomach is full: feed first, then induce vomiting.

Save vomitus for analysis.

Gastric lavage

If:
1. Ingestion of intoxicant occurred fewer than 3 hours before presentation.
2. Attempts to produce emesis were unsuccessful or emesis was not recommended.

How:
1. Induce anesthesia, place cuffed endotracheal tube, inflate cuff.
2. Place in right lateral recumbency, lower head relative to body.
3. Pass a large-bore stomach tube to level of stomach.
4. Use water (5-10 mL/kg body weight) for each washing; aspirate with syringe.
5. Repeat 10 times or until clear.

Save stomach contents for analysis.

Gastrointestinal adsorbents

How:
1. If gastric lavage has been performed, administer activated charcoal* slurry (1-3 g/kg) using a 20% slurry (1 g of activated charcoal/5 mL of water) or a commercially available 10% slurry into the empty stomach after the last lavage. Let this sit for 20 minutes, then administer a cathartic.
2. If gastric lavage was not necessary, administer slurry (dose as above) via stomach tube or orally or administer tablets of activated charcoal.

Cathartics

How:
1. Sodium or magnesium sulfate (250 mg/kg); can be administered 30 minutes after activated charcoal is administered.
2. Alternatively, the first dose of activated charcoal can contain sorbitol as a cathartic.

Diuresis

How:
1. Administer saline solution to effect diuresis.
2. Mannitol (20% solution, 1-2 g/kg IV) or furosemide (2-4 mg/kg IV) may be added to enhance diuresis if needed.

Administer Specific Antidotes

See Box 62.3.

Supportive and Symptomatic Care

*Repetitive dosing of activated charcoal can result in hypernatremia, so it should be used only with fluid support and patient monitoring.

abnormalities, in dogs older than 5 years of age when their first seizure is observed, and in dogs with multiple seizures that take place within a 1-month period. When neurologic or systemic signs are present that could be caused by infectious diseases endemic to the region, noninvasive and relatively inexpensive serologic testing may be beneficial. Thoracic and abdominal radiographs and abdominal ultrasound should be performed to look for systemic manifestations of infectious causes of seizures and for primary or metastatic neoplasia. If these tests are negative, advanced imaging of the brain with MRI is recommended; CSF collection and analysis may be warranted when inflammatory disorders are suspected based on finding multifocal neurologic deficits or lesions identified on MRI.

ANTIEPILEPTIC DRUG THERAPY

Chronic management of dogs and cats with seizures can be attempted using AEDs. Because this requires a large financial, emotional, and time commitment by owners, they should be involved in the decision to initiate treatment. Not every animal with seizures requires AED therapy, but there is some evidence that dogs treated early in the course of their seizure disorder may have better long-term control of their seizures compared with dogs that are allowed to have many seizures before treatment is initiated. Maintenance treatment with AEDs should be recommended in all dogs and cats with the following: (1) seizures caused by an identifiable structural intracranial lesion, (2) one or more episodes of cluster

seizures or status epilepticus, (3) seizures that occur more often than once every 12 weeks, (4) seizures that are becoming more frequent, (5) seizures with severe or unusual postictal signs, or (6) seizures that occur within 1 month of a traumatic brain injury (Box 62.5).

Complete control of seizures in dogs and cats with IE is rarely possible, but a decrease in the frequency and severity of seizures is a realistic goal that can be accomplished in 70% to 80% of animals. Owners should keep a log detailing the frequency and severity of seizures so the effects of the medication can be monitored. Adverse effects of the medication and plans for monitoring blood concentrations and dose adjustments should be discussed. Owners should be told to never alter the dose of medication without veterinary consultation and should understand that missing even a single dose could precipitate seizures. Emergency situations (e.g., status epilepticus) should be described to owners and specific recommendations for treatment and veterinary assistance provided.

A minimum database, including a CBC, serum biochemistry profile, and urinalysis, should always be obtained immediately before the start of AED therapy, and if one was not recently performed, a liver function test is also recommended. Whenever possible, animals should be initially treated with a single AED (monotherapy) to reduce possible drug interactions and adverse effects, optimize owner compliance, and decrease overall costs of drugs and monitoring.

Therapeutic drug monitoring is often used to determine the proper dose of an AED for a patient. A standard dose of the chosen oral AED is administered initially, and when steady-state serum concentrations have been achieved (based on 5 elimination half-lives) the trough (pre-pill) serum concentration of the AED should be measured. Once a stable dose has been identified that maintains the serum drug concentration within an optimal range, then a seizure log should be used to assess the effect of the AED on seizure frequency. An AED is considered effective if seizure frequency is reduced by at least 50%. If the initial drug administered is ineffective in spite of optimal serum drug concentrations, then another AED should be added or substituted (Box 62.6). See Table 62.1.

BOX 62.5

Indications for Initiating Chronic Anticonvulsant Therapy

1. Unresolvable intracranial disease causing seizures
2. Cluster seizures
3. At least one episode of status epilepticus
4. Interictal period less than 12 weeks
5. Increasing seizure frequency or severity
6. Unusual or severe postictal signs

ANTIEPILEPTIC DRUGS

PHENOBARBITAL

For decades, PB has been considered the drug of choice for initial and ongoing treatment of seizures in most dogs and cats. PB is a relatively safe, effective, and inexpensive AED. It has a high bioavailability and is rapidly absorbed, with peak plasma concentration 4 to 8 hours after oral administration in dogs and 1 to 2 hours in cats. PB is metabolized primarily by the liver. An appropriate starting dose is 2.5 to 3 mg/kg given orally twice a day, but autoinduction often

BOX 62.6

Guidelines for Chronic Oral Anticonvulsant Therapy in Dogs

1. Initiate treatment with PB (2.5-3 mg/kg PO q12h).
2. At least 10 days after initiating therapy, measure the trough (pre-pill) serum PB concentration. If the concentration is less than 25 µg/mL (107 µmol/L), increase the PB dose by 25% and reevaluate the serum concentration 2 weeks later. Repeat until the trough serum PB concentration is between 25 and 35 µg/mL (107-150 µmol/L), ideally near the middle of the range.
3. If seizures are adequately controlled, maintain dose and monitor serum PB concentration and liver enzymes/function once or twice a year.
4. If seizure control is inadequate despite adequate serum concentration of PB, add potassium bromide therapy (15 mg/kg PO q12h with food).
5. If necessary to control seizures, increase the dose of potassium bromide to 20 mg/kg PO q12h.
6. Measure the potassium bromide concentration in 3 to 4 months. It should be 1 to 2 mg/mL (10-20 mmol/L).

PB, Phenobarbital; *PO,* by mouth.

TABLE 62.1

AEDs for Treating Epilepsy in Dogs

DRUG	DOSAGE	THERAPEUTIC RANGE
Phenobarbital	2.5-3.0 mg/kg q12h	25-35 µg/mL
Potassium bromide		
Monotherapy	20 mg/kg q12h	2.5-3.0 mg/mL
with PB	15 mg/kg q12h	1.5-2.0 mg/mL
Levetiracetam	20 mg/kg q8h	variable
Zonisamide	5-10 mg/kg q12h	10-40 µg/mL
Monotherapy	5 mg/kg q12h	10-40 µg/mL
with PB	10 mg/kg q12h	10-40 ρg/mL
Gabapentin	10-20 mg/kg q8h	4-16 mg/L

necessitates subsequent increases in dose to maintain trough serum concentration in the therapeutic range. Cats may be more susceptible to the sedative effects of PB, so a lower dose (1-2 mg/kg twice daily) might be used to initiate therapy.

After 2 to 3 weeks of therapy, the fasted morning pre-pill (trough) blood PB concentration should be determined. This should be in the therapeutic range of 25 to 35 µg/mL (107-150 µmol/L) in dogs and 20 to 30 µg/mL (90-129 µmol/L) in cats. Many references allow a wider therapeutic range in dogs (15 to 35 µg/mL) but report that seizure control is improved at serum concentrations greater than 25 µg/mL. If the measured serum concentration is too low, the dose of PB should be increased by approximately 25% (see Box 62.6) and the trough serum concentration determined again 2 to 3 weeks later. If the serum concentration is still inadequate, the dose of PB should be increased in 25% increments every 2 to 3 weeks while the blood concentration is monitored. Once the measured blood concentration of PB is within the therapeutic range, the dog or cat should be observed by the owner for a long enough period of time (time required for two or three cycles of seizures), and, if control is acceptable, therapy is maintained at that dosage. Blood PB concentrations should be reevaluated routinely every 6 months, 2 weeks after any change in dosage, and whenever two or more seizures occur between scheduled PB evaluations. Serum separator tubes should not be used to collect serum for this purpose, because their use will underestimate the concentration of PB.

PB is well tolerated in most dogs and cats at therapeutic serum concentrations. Sedation and ataxia may be pronounced for the first 7 to 10 days of therapy or after an increase in dosage, but these adverse effects resolve with time (10-21 days) as the animal acquires a tolerance for the sedative effects of the drug. Transient (7 days) hyperexcitability occurs as an idiosyncratic effect in up to 40% of dogs and cats. The most common persistent adverse effects of PB include polyuria, polydipsia, and polyphagia. Owners should be advised to refrain from overfeeding dogs receiving PB, even though their pet may seem ravenous. Neutropenia or thrombocytopenia has been recognized in a few dogs within the first 6 months of starting PB, but in most cases these blood dyscrasias are immune-mediated and they resolve when the PB is discontinued. Acute idiosyncratic hepatotoxic reactions with rapid elevations of alanine aminotransferase (ALT) are rare, but should prompt immediate transition to an alternative AED. PB may also be a risk factor for the development of superficial necrolytic dermatitis in dogs.

The most life-threatening potential complication of chronic PB therapy is drug-induced hepatotoxicity. PB is a potent inducer of hepatic enzymes, and mild to moderate elevations in serum alkaline phosphatase (ALP) and alanine transaminase (ALT) activities are seen in virtually all dogs receiving PB; significant hepatotoxicity is uncommon. Significant chronic hepatotoxicity is most likely to occur when peak serum PB concentrations are at the high end of the therapeutic range (>35 µg/mL; >150 µmol/L). Clinical features of significant hepatotoxicity include anorexia, sedation, ascites, and occasionally icterus. Laboratory testing typically reveals a large increase in ALT compared with ALP, decreased serum albumin, abnormal bile acids, and an increasing PB concentration despite no increase in the administered dose. All animals receiving chronic PB therapy should be evaluated every 6 months to assess the effectiveness of their drug regimen, serum concentration of PB, liver enzyme activities, and serum albumin concentration. Liver function testing should be performed if ALT levels suddenly increase or if serum albumin levels start to decrease. When chronic hepatotoxicity is suspected, PB should be discontinued, the patient should be rapidly switched to an alternative AED, and supportive measures should be initiated for liver failure. The hepatotoxicity is occasionally reversible if discovered early.

PB increases the biotransformation of drugs metabolized by the liver, decreasing the systemic effects of many drugs administered concurrently. PB also increases the rate of thyroid hormone elimination, decreasing measured serum total and free T_4 and increasing serum thyroid-stimulating hormone concentrations, but this is rarely associated with clinical signs of hypothyroidism (see Chapter 48). PB administration does not alter endogenous ACTH concentrations, the response to exogenous ACTH, or results of low-dose dexamethasone suppression testing. Drugs that inhibit microsomal enzymes (e.g., chloramphenicol, tetracycline, cimetidine, ranitidine, enilconazole) may dramatically inhibit the hepatic metabolism of PB, resulting in increased serum concentrations of PB and potentially causing toxicity.

Seizures are controlled in 70% to 85% of dogs and most cats treated with PB monotherapy if serum PB concentrations are maintained within the target range. If seizures continue to occur at an unacceptable frequency or severity despite adequate serum concentrations, therapy with additional drugs must be considered.

POTASSIUM BROMIDE

The addition of potassium bromide (KBr) to already established PB therapy in dogs with poorly controlled seizures despite adequate serum concentrations of PB effectively decreases seizure numbers by 50% or more in 70% to 80% of dogs (see Box 62.6). KBr is also effective as a single agent and is considered by many to be the initial AED of choice in dogs with hepatic dysfunction and in large-breed dogs and working dogs that have unacceptable side effects from PB. The drug should not be administered to cats because it can cause severe progressive bronchitis in that species that can be fatal.

Bromide is excreted unchanged by the kidney. It is not metabolized by the liver and does not cause hepatotoxicity. KBr is typically administered as an inorganic salt dissolved in double distilled water to achieve a concentration of 200 to 250 mg/mL. Administration of the salt in gelatin capsules is also possible, but the concentrated drug in this form is more likely to cause gastric irritation and vomiting.

Dietary chloride should remain constant in dogs treated with KBr, because chloride competes with bromide for renal reabsorption. High chloride intake (e.g., chips, rawhide bones) increases renal excretion of KBr, decreasing serum concentrations and potentially leading to seizures. Alternatively, switching a dog to a lower-sodium diet can cause dramatically increased bromide concentrations and signs of toxicity.

An appropriate starting dose of KBr is 20 mg/kg orally twice daily for monotherapy and 15 mg/kg orally twice daily when used as an add-on drug to PB. KBr serum concentrations are usually measured 1 month after initiating therapy, when concentrations are expected to be approximately 50% of the level at steady-state and then 8 to 12 weeks later when a steady-state is achieved. The goal is to achieve a serum concentration of 2.5 to 3 mg/mL (25-30 mmol/L) of KBr when used as monotherapy and 1.5 to 2 mg/mL (15-20 mmol/L) when used together with PB. Serum PB concentrations should continue to be maintained in the midtherapeutic range in animals receiving KBr and PB.

When maintenance doses of KBr are administered, there is a long lag period between initiation of treatment and achieving steady-state serum concentrations. If KBr must be administered as the only anticonvulsant therapy in a dog with a severe or progressive seizure disorder or in a dog that must be switched from PB to KBr because of toxicity, it is possible to achieve therapeutic serum concentrations of KBr more rapidly using a loading-dose protocol. Oral loading can be accomplished by administering 50 mg/kg of KBr orally four times a day (every 6 hours) for 2 to 3 days with food, followed by administration of maintenance doses.

Adverse effects of KBr include polyuria, polydipsia, and polyphagia, but in many dogs these are less dramatic than the changes induced by PB therapy. Transient sedation, incoordination, anorexia, and constipation are most pronounced in the weeks after initiating treatment or after a dosage increase, particularly in dogs receiving concurrent PB. Reversible limb stiffness, lameness, and muscle weakness rarely occur unless serum bromide levels are excessive. Vomiting due to gastric irritation from the hyperosmolality of the drug is a very common complaint; this can be diminished by further splitting the daily dose (into four equal doses administered approximately every 6 hours) or by feeding a small amount of food with each dose. Pancreatitis occurs rarely. Bromide toxicity (bromism) can develop when serum concentrations are at or near the upper end of the recommended range. Signs include stupor or coma, blindness, ataxia, tetraparesis with normal or decreased spinal reflexes, dysphagia, and megaesophagus. If bromism occurs, it is managed by temporarily stopping the KBr and initiating diuresis with intravenous (IV) saline and furosemide, but if blood levels drop too low, seizures will occur. Serum biochemical abnormalities are not common in dogs treated with KBr monotherapy, but because some laboratory assays cannot distinguish bromide from chloride, there may be an artifactual increase in measured chloride.

ZONISAMIDE

Zonisamide (Zonegran [Elan]) is a sulfonamide-based AED that suppresses epileptic foci and blocks propagation of epileptic discharges. This drug is well absorbed, is hepatically metabolized, and has a relatively long half-life (15 hours) in dogs not concurrently receiving PB or other drugs that induce microsomal enzymes. Steady-state levels are achieved in 3 to 4 days. Zonisamide is effective as a sole agent, and as an add-on drug that improves seizure control in 70% to 90% of dogs with seizures poorly controlled by other drugs. Mild adverse effects reported include sedation, ataxia, vomiting, inappetence, and decreased tear production. Rarely, hepatotoxicity and renal tubular acidosis have been reported. Patients with a history of sulfa drug hypersensitivity should not be prescribed zonisamide. The initial starting dose is 5 mg/kg twice daily in dogs not receiving PB and 10 mg/kg twice daily in dogs receiving concurrent PB. A serum concentration of 10 to 40 μg/mL is reported to be therapeutic. Zonisamide can also be administered to cats; an appropriate starting dose is 5 to 10 mg/kg once daily or 5 mg/kg twice daily.

LEVETIRACETAM

Levetiracetam (Keppra) is an effective anticonvulsant that is very well tolerated, with minimal side effects. The drug is well absorbed and rapidly metabolized, with an elimination half-life of 3 to 4 hours in dogs not taking PB and 1.7 hours in dogs taking PB, but seizure control is more prolonged than the half-life would suggest. Most of the drug is excreted unchanged in the urine, and the remainder is metabolized by hydrolysis in multiple organs, with no significant hepatic metabolism. Levetiracetam decreases seizure frequency by over 50% in many epileptic dogs and cats when used as an add-on drug. Levetiracetam has also been used effectively as monotherapy in some dogs and cats. A starting dose of 20 mg/kg q8h is recommended in dogs and cats, although much higher doses can be administered to dogs without toxicity and may be required to achieve seizure control, especially when used in conjunction with PB. Therapeutic monitoring is not usually recommended with levetiracetam because the drug has a wide margin of safety and there is little correlation between serum concentrations and seizure control. Adverse effects include minimal sedation, salivation, vomiting, and decreased appetite in a few dogs and cats. Administering an injectable formulation of levetiracetam (30-60 mg/kg) as a slow IV bolus over 5 minutes has been used with some success in the treatment of cluster seizures and status epilepticus in dogs.

GABAPENTIN

Gabapentin (Neurontin [Parke-Davis]) is a structural analog of γ-aminobutyric acid (GABA) that readily crosses the blood-brain barrier but does not bind to GABA receptors as its mechanism of action, instead inhibiting flow through neuronal voltage-gated calcium channels. This drug is most commonly used to treat neuropathic pain in dogs and cats but has some utility as an AED. Gabepentin is rapidly

absorbed and renally excreted, with some hepatic metabolism. The elimination half-life in dogs is very short (3-4 hours), requiring dosing every 6 to 8 hours. Gabapentin improves seizure control in more than 50% of dogs when added to PB or KBr. Starting doses of 10 to 20 mg/kg q8h have been recommended in dogs, but the dose can be increased gradually as needed (up to 80 mg/kg q8h) as long as excessive sedation does not occur, which is the only reported adverse effect. Serum concentrations are rarely monitored, but the suspected therapeutic range for dogs is 4 to 16 mg/L. An oral dose of 5 to 10 mg/kg every 8 to 12 hours has been recommended and used with limited success in cats.

FELBAMATE

Felbamate (Felbatol [Wallace]) can be an effective AED in dogs when used alone or as an add-on drug in dogs refractory to AED therapy with PB and KBr. After urinary excretion of 70% of the orally administered dose, felbamate is metabolized by hepatic microsomal P450 enzymes. The recommended starting dose is 15 mg/kg q8h. Felbamate appears to have a wide margin of safety, and the daily dose can be increased in 15-mg/kg increments until the seizures are adequately controlled, with reports of dosages as high as 70 mg/kg q8h without significant toxicity. Trough serum concentrations between 25 and 100 mg/L may be therapeutic, but the target range is not well established in dogs. Felbamate is an unusual AED in that it does not cause sedation. Potential side effects include nervousness and keratoconjunctivitis sicca. Mild reversible thrombocytopenia and leukopenia have also been reported. The potential for aplastic anemia and fatal hepatopathy has limited the use of felbamate in human patients, but anemia has not been reported in dogs. Approximately 30% of dogs treated with felbamate as an add-on drug with PB do develop hepatotoxicity, however, so monitoring of CBCs, biochemistry panels, and liver function tests is recommended every 3 months during treatment.

PREGABALIN

Pregabalin (Lyrica [Pfizer]) is a structural analog of GABA. The mean elimination half-life in dogs is approximately 7 hours. This AED is renally excreted and has few drug interactions. Efficacy as an add-on AED has been promising in dogs. The initial recommended dose is 4 mg/kg orally every 8 to 12 hours. Adverse effects are limited to sedation and ataxia.

DIAZEPAM

Diazepam (Valium [Roche]) is of limited use as a chronic oral AED in dogs because of its expense, its very short half-life, physical dependence, and the rapid development of tolerance to its anticonvulsant effects. Oral diazepam (0.5-2.0 mg/kg q8-12h) has been shown to be of some benefit for the long-term management of seizures in cats because it has a long elimination half-life in that species and a functional tolerance to its anticonvulsant effect does not seem to be a problem in cats. Diazepam is eliminated by hepatic metabolism, and the only common adverse effect is sedation, although idiosyncratic severe, life-threatening hepatotoxicity has been documented in a few cats receiving daily oral diazepam for 5 to 11 days. This potentially fatal reaction warrants close owner observation of appetite and attitude and periodic monitoring of liver enzymes in all cats treated with oral diazepam. PB is a better choice for chronic AED therapy in cats.

Diazepam also has a place in the emergency management of seizures and in the at-home treatment of dogs with IE experiencing cluster seizures. In dogs with a recognizable preictal phase or an aura preceding the seizure, an injectable preparation of diazepam (5 mg/mL) can be administered rectally (2 mg/kg) by the owner at the onset of these premonitory signs. Alternatively, this dose can be administered just after each observed seizure, with a maximum of three doses in 24 hours (each dose separated by at least 10 minutes). At-home rectal administration of diazepam decreases the occurrence of cluster seizures and the development of status epilepticus as well as dramatically decreasing the need for owners to seek expensive emergency treatment for their epileptic dogs. Diazepam dispensed for at-home rectal administration should be stored in a glass vial because plastic will adsorb the drug, decreasing its effectiveness. For administration, the drug can be drawn into a syringe and injected through a 1-inch plastic teat cannula or rubber catheter directly into the rectum.

ALTERNATIVE THERAPIES

Approximately 20% to 25% of dogs treated for epilepsy using standard AED therapy are never well controlled, despite attempts at therapeutic drug monitoring and appropriate dose adjustments. It is important to evaluate poorly controlled animals for underlying metabolic or intracranial disease that could be specifically treated. Alternative treatments should also be considered in these animals, including hypoallergenic diets, acupuncture, surgical division of the corpus callosum, and vagus nerve stimulation.

EMERGENCY THERAPY FOR DOGS AND CATS IN STATUS EPILEPTICUS

Status epilepticus is a series of seizures or continuous seizure activity lasting for 5 minutes or longer without periods of intervening consciousness. Status epilepticus increases arterial blood pressure, body temperature, heart rate, cerebral blood flow, and cerebral oxygen consumption. It also decreases blood pH (because of lactic acidosis) and may decrease effective ventilation. As seizures continue, metabolic deterioration, increased intracranial pressure, acidosis, hyperthermia, and cardiac dysrhythmias are common, leading to progressive cerebral ischemia and neuronal death. Permanent neurologic damage can result, and mortality rates

of up to 25% are reported in dogs with IE during an episode of status epilepticus.

Status epilepticus is always a medical emergency. The most common reasons for a known idiopathic epileptic patient to present in status epilepticus include poor chronic seizure control of cluster seizures and abrupt withdrawal of AED medications (missed doses). Nonepileptics may present in status epilepticus as a result of various metabolic, toxic, and intracranial disorders. History and physical examination findings help determine the cause of status epilepticus in an individual patient. Diagnostic testing for metabolic causes of seizures (especially hypoglycemia, hypocalcemia, electrolyte disturbances) should always be performed and specific treatment initiated when warranted. When intoxication is suspected, treatment should be directed at reducing further absorption of the toxin, increasing toxin excretion, and controlling the neurologic manifestation of seizures (see Box 62.4).

The goals of treatment are to stabilize the animal, stop the seizure activity, protect the brain from further damage, and allow recovery from the systemic effects of prolonged seizure activity. Oxygen is administered, as well as fluid therapy and supportive care, to minimize systemic effects. Diazepam is administered (intravenously or rectally) to stop the seizures. If this is effective but seizures recur then diazepam can be administered as a continuous rate infusion (CRI). An intravenous bolus of levetiracetam can also be effective. A longer-acting drug, usually PB, should be administered to prevent seizure recurrence. Distribution of PB to the central nervous system may take up to 30 minutes, so if the seizures were not stopped by diazepam or levetiracetam administration more aggressive treatment will usually be required. This involves a propofol or pentobarbital infusion to stop seizure activity. Mannitol or hypertonic saline is also recommended (as for head trauma, see Box 62.2) to decrease the brain edema secondary to prolonged seizure activity. Details regarding the treatment of status epilepticus are outlined in Box 62.7.

BOX 62.7

Status Epilepticus Treatment in Dogs and Cats

1. If possible, insert an IV catheter.
2. Administer diazepam 2 mg/kg rectally if no IV access. If IV access is possible, administer 1 mg/kg intravenously. Repeat every 2 minutes if ineffective or if seizures recur. Administer maximum of four doses if necessary. If patient responds to diazepam administration but seizures recur, *consider a diazepam CRI* (1 mg/kg/h) in 0.9% saline or in D_5W. Continue the CRI for at least 6 hours; if no seizures occur, can then taper by 25%/h.
3. Administer a loading dose of PB to prevent further seizures (6 mg/kg slow IV or IM twice, 10 minutes apart). This will take 20 to 30 minutes for maximum effect. Repeat 6-mg/kg dose IM q6h until oral dosing can be performed.
4. If seizures have not responded to diazepam or to the initial dose of PB, it will be necessary to stop the seizures using either:
   Sodium pentobarbital (3-15 mg/kg slow IV to effect), giving 25% of the dose at a time as a bolus until seizures stop and dog is anesthetized.
   Repeat as needed (q4-8h) to maintain anesthesia or place on CRI: (2-5 mg/kg/h to effect) in saline. *Continue CRI for at least 6-12 h before tapering.*
   or
   Propofol (4-6 mg/kg slow IV over 2 minutes), giving 25% of the calculated dose every 30 seconds until seizures stop and dog is anesthetized.
   Maintain on CRI (0.10-0.25 mg/kg/min; 6-15 mg/kg/h).
   Maintain anesthesia for 6-12 h, then taper CRI by 25% every 2-4 h to recover.
5. Maintain a patent airway and monitor respirations. Intubate and ventilate if necessary.
6. Initiate IV fluids (maintenance rate).
7. Assess body temperature. If >41.4° C (>105° F), cool with cool water enemas.
8. If hyperthermic or if seizure activity was prolonged (>15 minutes), administer:
   Mannitol: 1 g/kg IV over 15 minutes
   and/or
   Hypertonic saline solution (4 mL/kg of 7.2% HSS over 5 minutes)

CRI, Constant rate infusion; *IM,* intramuscular; *IV,* intravenous; *PB,* phenobarbital.

PAROXYSMAL EVENTS THAT ARE NOT SEIZURES

PAROXYSMAL DYSKINESIAS

PDs are a heterogenous group of inherited disorders that result in involuntary movements or postures in fully conscious individuals. These movement disorders have only occasionally been described in dogs and cats, and they may be very difficult to distinguish from focal seizures or stereotypical behavior disorders. Signs consist primarily of episodic, unpredictable, rhythmic, involuntary contractions of a group of skeletal muscles causing limb hyperextension or hyperflexion; head bobbing; or the adoption of abnormal postures. Episodes occur spontaneously or may be initiated by a trigger such as a sudden movement, sustained exercise, excitement, stress, or fatigue. Episodes start and end abruptly, and last several minutes to a few hours. PDs are familial and are all thought to be caused by genetic mutations that disrupt brain metabolism, blood-brain barrier glucose transport, or neurotransmitter production or release. Causative mutations have been identified in many human PD disorders and in a few canine disorders. Most PD disorders in dogs appear to be inherited as an autosomal recessive trait.

It can be challenging to differentiate PDs from focal seizures. Affected dogs maintain consciousness and normal mentation during episodes and have no associated neurologic abnormalities. Interictal and intraictal EEGs (when

performed) do not exhibit epileptic activity. There are generally no premonitory or postictal abnormalities, no autonomic signs associated with the episode, and no apparent response to AED medications. Episodes typically recur throughout the dog's lifetime, and there is no progression to a generalized seizure disorder or other neurologic signs. Movement disorders that may be dyskinesias have been reported in Norwich Terriers, Cavalier King Charles Spaniels, Malteses, Soft-Coated Wheaten Terriers, Chinooks, Border Terriers, Scottish Terriers, Labrador Retrievers, and Jack Russell Terriers.

Head bobbing. Canine idiopathic head tremor (IHT) is a poorly understood breed-specific tremor condition. Intermittent paroxysmal vertical (up and down nodding) or lateral (side-to-side head shaking) rhythmic head movements have been described in Boxers, English Bulldogs, and Doberman Pinschers. Typical age of onset is approximately 2 years. Episodes are most likely to occur when the dogs are at rest and last from a few seconds to several hours. Mentation is normal, and many affected dogs can be distracted out of an episode. Episodes may decrease in frequency or disappear as dogs mature. This head-bobbing disorder is thought to be a dyskinesia, but this is controversial because isolated head tremor has not been described as a PD in people.

Scotty cramp is a disorder in which affected Scottish Terriers develop paroxysmal dramatic gait abnormalities and collapse in association with stress, excitement, or exercise. The first episode of collapse occurs from 6 weeks to 18 months of age (most at 6 months). During exercise the forelimbs abduct and become stiff, followed by arching of the spine and pelvic limb stiffness resulting in falling or somersaults. Signs are evident for less than 10 minutes and then resolve. A similar disorder has been seen in Cairn Terriers, West Highland White Terriers, and Norwich Terriers. A few dogs have a milder phenotype, with the cramping limited to the pelvic limbs causing skipping and bunny hopping but no falling. No lesions are identified on imaging or postmortem examination. Episodes can be induced by administering drugs that are serotonin antagonists and prevented by administering serotonin agonists, suggesting that signs may be related to a relative CNS deficiency of the inhibitory neurotransmitter 5-hydroxytryptamine (serotonin) but brain serotonin concentrations are normal. The condition may improve with time and appropriate lifestyle changes. Many affected dogs respond favorably to fluoxetine (Prozac), a selective serotonin reuptake inhibitor (SSRI).

Episodic falling in Cavalier King Charles Spaniels is a PD disorder in which affected dogs between 3 and 7 months of age (occasionally 2-3 years) develop a peculiar gait and collapse during exercise. Dogs are normal when not exercising, but exercise induces progressive hypertonicity in the thoracic and pelvic limbs resulting in a bounding gait with stiff legs, bunny hopping, arching of the spine, a lowered head, and collapse with no loss of consciousness. Triggers include exercise, excitement, and stress. This was the first genetically mapped PD in dogs, and a genetic test is available. The autosomal recessive genetic mutation disrupts axonal, a CNS neurotransmission. Treatment with the benzodiazepine clonazepam (0.5 mg/kg q8h) can result in remission of signs, but tolerance to the drug commonly develops. Some dogs respond to acetazolamide.

Canine epileptoid cramping syndrome in Border Terriers is now more correctly called paroxysmal gluten-sensitive dyskinesia (PGSD). Signs become evident when dogs are 3 months to 6 years, with a median age of onset of 3 years. Exercise and movement are not recognized as triggers, but stress may be a trigger in some dogs. Episodes last minutes to hours and often occur in clusters of four to five episodes separated by several months. During episodes, there are abnormal contractions of limb muscles and muscles in the neck and back causing dogs to fall over. Many owners of affected dogs report that they can predict episodes as affected dogs exhibit staring or attention-getting behavior. Also mild to severe gastrointestinal signs such as vomiting, diarrhea, or borborygmi are common before, during, or after an episode. Reported response to AED therapy is variable. A recent study showed marked clinical improvement when an exclusively gluten-free diet is fed.

Soft-Coated Wheaton Paroxysmal Dyskinesia. A PD described in Soft-Coated Wheaton Terriers affects male and female dogs with a median age of onset of 2 years. Neurologic examination between episodes is unremarkable. Stress, exercise, and loud noises may serve as triggers for episodes that last several minutes to 4 hours. Typical episodes consist of pronounced flexion or extension of hind legs with varying degrees of truncal dystonia. Signs can alternate between the two rear limbs, or both hind limbs can be lifted off the ground simultaneously. Postmortem examination and MRI are normal. Recently the causative genetic mutation has been identified. Signs tend to worsen with age, and many affected dogs are euthanized.

EXERCISE-INDUCED COLLAPSE DISORDERS

Disorders that cause paroxysmal episodes of weakness or collapse with strenuous exercise are often confused with partial seizures. Dynamin-associated exercise-induced collapse (dEIC) causes reversible rear leg weakness and collapse after strenuous exercise in affected Labrador Retrievers and a few other breeds. Border Collie collapse (BCC) causes altered mentation and an abnormal gait in affected dogs after strenuous exercise. Other systemic and neuromuscular disorders causing exercise intolerance or weakness are discussed in Chapter 67.

Dynamin-associated exercise-induced collapse (dEIC) is an autosomal recessive CNS disorder common in Labrador Retrievers and occasionally identified in Chesapeake Bay Retrievers, Curly-Coated Retrievers, and Boykin Spaniels. The causative mutation has also been rarely identified in Pembroke Welsh Corgis, Bouvier des Flanders, German Wirehaired Pointers, Old English Sheepdogs, and Cocker Spaniels. Dogs are susceptible to collapse when they are homozygous for the causative mutation in dynamin-1, a protein required for repackaging of brain and spinal cord

neurotransmitters during exercise, excitement, and the hyperthermia associated with exercise. This disorder is the most common reason for exercise-induced weakness or collapse in Labrador Retrievers that seem otherwise normal and healthy.

Affected dogs are normal at rest and with moderate exercise, but prolonged (>10 minutes) strenuous exercise with excitement induces weakness and then collapse. Some affected dogs collapse whenever they are exercised strenuously; other dogs only exhibit collapse sporadically. Most affected (homozygous) Labradors will have their first episode of collapse when they are 7 months to 2 years old.

Typically during dEIC-related collapse, the rear limbs become weak and unable to support weight and dogs will continue to run while dragging their back legs (Fig. 62.3). Dogs develop a wide-based, long, loose stride rather than the short, stiff strides typically associated with muscle weakness. In some dogs the rear limb collapse progresses to forelimb weakness and occasionally to a total inability to move. Signs often become more pronounced in the first few minutes after exercise is terminated. Muscles of the rear limbs are relatively flaccid during collapse, and there is loss of the patellar reflex during collapse and for a short time during recovery. A few dogs appear to have a loss of balance and may fall over, particularly as they recover from collapse. Dogs are not painful or stiff during the collapse or upon recovery. Affected dogs may be extremely hyperthermic during collapse (> 41.5° C [106.7° F]) but not different from unaffected dogs performing the same exercise. A few dogs have died during or immediately after an episode of exercise-induced collapse, presumably due to hyperthermia or failure to ventilate adequately, so an affected dog's exercise should always be stopped immediately and cooling attempted at the first hint of incoordination or weakness.

FIG 62.3
A young Labrador Retriever with dynamin-associated exercise-induced collapse (dEIC) walks with a crouched rear limb gait after 10 minutes of retrieving exercise.

This disorder is very common in Labrador Retrievers, with initial genetic screening (2010) revealing that more than 30% of dogs in this breed had at least one copy of the causative mutation and that approximately 5% of all Labrador Retrievers were homozygous and susceptible to collapse. Labrador Retrievers with episodes of collapse that occur with exercise should, however, always have a full evaluation to rule out other causes of collapse that could be confused with dEIC (see Chapter 67). Dogs with dEIC have unremarkable physical and neurologic examinations during exercise, and no associated laboratory abnormalities. Episodes of collapse caused by dEIC always occur during prolonged strenuous exercise, are most likely to occur in hot weather, start with primarily pelvic limb signs, and are associated with normal mentation. Diagnosis is made by observing typical episodes of collapse, eliminating other causes of exercise intolerance, and demonstrating that the dog is homozygous for the DNM1 mutation.

Border Collie collapse (BCC) is an episodic neurologic disorder in Border Collies and related breeds. It is most common in dogs used for working stock but has also been seen in dogs training for agility or flyball competitions and in dogs repetitively retrieving a ball. Affected dogs are normal at rest, but they may become abnormal after 5 to 15 minutes of strenuous activity, particularly in warm weather. Affected dogs abruptly lose focus on the task being performed and are dull, dazed, or confused during episodes. They may wander aimlessly or walk compulsively. They are ataxic in all limbs and have increased extensor tone and scuffing and knuckling of the pelvic limbs or all limbs. They may develop truncal sway and stagger or fall to the side. A few dogs exhibit squinting eyelids and rapid blinking during each episode. Dogs are abnormal for 5 to 30 minutes, but then recover completely with no residual lameness or muscle stiffness or discomfort. Body temperatures are very high during an episode (often > 41.7° C [>107° F]), but not higher than unaffected dogs performing the same exercise. Cardiac, metabolic, and neurologic evaluations are normal, and muscle biopsies are normal. Chronic oral treatment with PB has not been effective at preventing episodes, and EEGs in a few affected dogs between and during episodes have not revealed epileptiform activity. Genetic studies are under way. Australian Kelpies, Australian Shepherds, Shetland Sheepdogs, Bearded Collies, and Whippets may be affected by a similar or identical disorder. Affected dogs can still live fairly normal lives, but they may have to have their participation in trigger activities limited, especially in warm weather. If they do have an episode, then attempts should be made to cool their body temperature to speed recovery.

SLEEP DISORDERS

Narcolepsy is a disorder characterized by abnormalities in the sleep/wake cycle related to an imbalance in central nervous system neurotransmitters important in maintaining normal sleep patterns. This disorder is inherited in Doberman Pinschers, Labrador Retrievers, Miniature Poodles, and Dachshunds, and occurs sporadically in other breeds.

Genetic testing is available for Labradors and Dobermans, where the disorder is inherited as an autosomal trait. The predominant sign in dogs and cats is cataplexy, characterized by an abrupt paroxysmal loss of muscle tone without loss of consciousness frequently induced by excitement such as eating or playing. Episodes occur abruptly and last from a few seconds to 30 minutes or more. Animals with narcolepsy may also exhibit excessive sleepiness during the day, prolonged deep sleep, and "sleep attacks" where they abruptly transition from an active and alert state to REM sleep with closed eyelids, loss of consciousness, and twitching. Treatment is generally focused on reducing cataplexic attacks using tricyclic antidepressants such as imipramine (0.4-1.0 mg/kg orally q8-12h) or serotonin reuptake inhibitors like Fluoxetine (1 mg/kg orally q24h). Stimulants can also be administered to decrease daytime drowsiness.

CHAPTER 63

Head Tilt

GENERAL CONSIDERATIONS

Head tilt is a common neurologic abnormality in dogs and cats. It indicates a lesion of the vestibular system, which consists of central and peripheral parts.

The peripheral vestibular system includes sensory receptors for vestibular input located in the membranous labyrinth of the inner ear within the petrous temporal bone of the skull and the vestibular portion of the vestibulocochlear nerve (CN8), which carries information from these receptors to the vestibular nuclei in the brainstem and cerebellum. The central vestibular structures include vestibular nuclei and pathways located within the brainstem (medulla oblongata), caudal cerebellar peduncles, and flocculonodular lobe of the cerebellum (Fig. 63.1). Abnormalities involving the central or peripheral vestibular system typically cause head tilt, loss of balance, tight circling, falling, rolling, ataxia, and spontaneous nystagmus.

NYSTAGMUS

Nystagmus is defined as an involuntary rhythmic oscillation of the eyeballs. In the jerk nystagmus typical of vestibular disease, eye movements have a slow phase in one direction and a rapid recovery phase in the opposite direction. *Jerk nystagmus direction* is described as the direction of the fast phase, despite the fact that the slow phase is typically directed toward the abnormal side. Abnormal jerk nystagmus results from disturbed vestibular input to the neurons innervating the extraocular eye muscles. Nystagmus characterized by small oscillatory movements of the eyeballs with no slow or fast phase is termed *pendular nystagmus* and is commonly observed as an incidental finding in Siamese, Birman, and Himalayan cats secondary to a congenital visual pathway abnormality.

In a normal animal, rotation of the head will result in a jerk nystagmus with the slow phase in the direction opposite the head rotation, followed by a fast phase in the direction of head rotation. This *physiologic nystagmus,* elicited during assessment of the *oculocephalic reflex,* only occurs while the head is moving. Nystagmus that occurs when the head is held motionless is called *spontaneous nystagmus* or *resting nystagmus,* and this is always abnormal. Some animals with compensated vestibular disease (either central or peripheral) do not have detectable spontaneous nystagmus but develop *positional nystagmus* when their head is held in an unusual position or they are rolled over on their back (see Fig. 58.26), making this manipulation an important part of the neurologic examination. Spontaneous or positional nystagmus in a patient with peripheral vestibular disease is always either horizontal or rotary, and although the intensity of nystagmus may change when the head is held in different positions, the direction of the fast phase will not. The nystagmus in animals with central vestibular diseases can be horizontal, rotary, or vertical, and may change direction as the position of the head is changed.

LOCALIZATION OF LESIONS

Head tilt indicates vestibular dysfunction. The first step in evaluating a patient with a head tilt should always be an attempt to localize disease to either the central or peripheral components of the vestibular system (Box 63.1). The clinician can usually accomplish this goal with a careful physical and neurologic examination.

Severe problems of balance resulting in ataxia, incoordination, falling, and rolling are prominent in animals with either central or peripheral vestibular disease. The head tilt (ear pointed toward the ground) is typically on the same side as the lesion as it reflects loss of anti-gravity muscle tone on that side. Tight circling toward the affected side is common. Ipsilateral ventral or ventrolateral strabismus may be seen when the nose is elevated (Fig. 63.2). Spontaneous or positional jerk nystagmus typically has its fast phase (compensatory phase) toward the side opposite the lesion and slow phase (pathologic phase) toward the side with diminished function (see Video 58.2). Vomiting, salivation, and other signs of motion sickness are often apparent. None of these features helps distinguish central from peripheral vestibular disease.

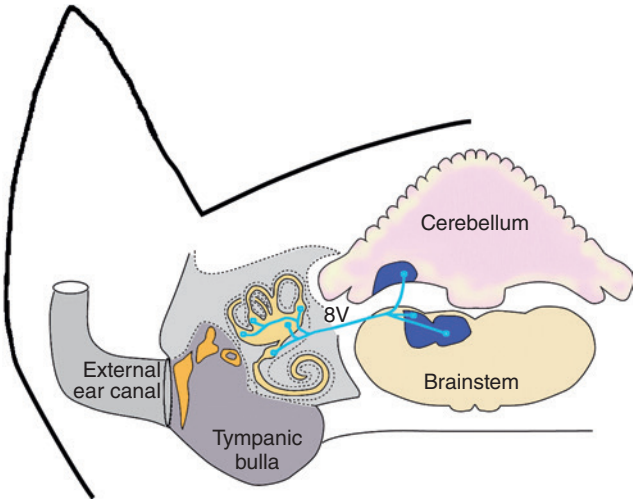

FIG 63.1
Anatomy of the central and peripheral vestibular system. Sensory receptors for vestibular input are located in the membranous labyrinth of the inner ear. Input from these receptors enters the brain via the vestibular portion of CN8 (8V), and fibers terminate in central vestibular nuclei in the brainstem and cerebellum.

PERIPHERAL VESTIBULAR DISEASE

Animals with peripheral vestibular disease should have normal mentation and consciousness. They have normal strength and postural reactions, although these tests may be difficult to assess because affected animals have impaired balance and a tendency to fall and roll. Spontaneous and positional nystagmus is horizontal or rotary or alternates between the two in animals with peripheral vestibular disease and will not change fast-phase direction when the animal is held in multiple positions or examined repeatedly during the day. Damage to inner ear receptors or the axons of CN8 occasionally results in concurrent deafness.

Peripheral vestibular lesions often involve the middle and inner ear. Middle ear lesions localized within the tympanic bulla typically produce head tilt and pathologic horizontal or rotary nystagmus. Disorders that affect both the middle and inner ear usually have more pronounced signs of vestibular ataxia, falling, circling, rolling, and positional strabismus. Damage to the axons of the facial nerve (CN7) within the inner ear and the sympathetic innervation to the eye within the middle or inner ear can result in facial nerve paralysis and Horner syndrome in animals with peripheral vestibular dysfunction (Fig. 63.3).

Animals with bilateral peripheral vestibular disease do not usually have a head tilt or pathologic nystagmus. They typically exhibit a wide-based crouched stance, loss of balance when turning or leaning to either side, and wide swinging excursions of the head from side to side. Sometimes the ability to elicit normal physiologic nystagmus (oculocephalic reflex) during head movement is lost. When the animal is held suspended by the pelvis and lowered toward the ground, an affected animal may curl its head and neck toward the sternum instead of raising its head and extending the thoracic limbs toward the floor for weight bearing. The diagnostic approach for bilateral peripheral vestibular disease is the same as that used in dogs and cats with unilateral peripheral vestibular disease.

BOX 63.1

Vestibular Disease Clinical Findings

Central and Peripheral Vestibular Disease

Incoordination, loss of balance, disoriented
Head tilt toward lesion
Circling/falling/rolling toward the side of the lesion
±Ventral strabismus on side of lesion
Vomiting, salivation
Spontaneous or positional nystagmus (fast-phase, away from lesion)

Peripheral Vestibular Disease

Nystagmus, when present, is horizontal or rotary
No change in nystagmus direction
Postural reactions and proprioception normal
With middle/inner ear disease, may see concurrent CN7 deficit and/or Horner syndrome
No other cranial nerve deficits

Central Vestibular Disease

Occasionally indistinguishable from peripheral disease
Findings that confirm disease as central:
- Vertical nystagmus
- Nystagmus that changes direction with head position
- Abnormal postural reactions on side of lesion
- Multiple cranial nerve deficits
- May be depressed, stuporous, comatose

Paradoxical Vestibular Syndrome (Cerebellar Lesion)

Head tilt and circling away from side of lesion
Fast-phase nystagmus toward the lesion
Horizontal, rotary, or vertical nystagmus
Abnormal postural reactions on side of lesion
±Multiple cranial nerve deficits on side of lesion
±Hypermetria, truncal sway, and head tremor

CENTRAL VESTIBULAR DISEASE

Certain clinical findings only occur with central vestibular dysfunction, but a central lesion cannot be excluded (especially early in the course of disease) simply because these localizing signs are not evident. With time and progression, however, most animals with central vestibular disease manifest signs indicating brainstem involvement. Vertical nystagmus and upper motor neuron (UMN) limb deficits are the most consistent signs that vestibular disease is central. Although spontaneous nystagmus can be in any direction, a vertical nystagmus or a nystagmus that changes fast-phase direction with different head positions strongly suggests central vestibular disease (brainstem or cerebellum).

FIG 63.2
Mild head tilt (**A**) and positional ventrolateral strabismus (**B**) in a young Border Collie with hypermetria, loss of balance, and intermittent positional vertical nystagmus. Necropsy revealed cerebellar and brainstem compression secondary to progressive hydrocephalus and hydromyelia.

UMN paresis and postural reaction deficits (abnormal knuckling, hopping) commonly develop on the side of a brainstem lesion because the UMN pathways to the limbs are damaged; affected animals may lose the ability to walk. If the animal is recumbent, extensor tone is decreased in the limbs on the side of the lesion and increased in limbs on the opposite side, creating a tendency to roll toward the side of the lesion. The presence of multiple cranial nerve abnormalities other than facial nerve paralysis and Horner syndrome in an animal with vestibular signs usually indicates central (i.e., brainstem) disease. Neoplasms or granulomas located at the cerebellomedullary angle commonly result in simultaneous

FIG 63.3
Adult cat with peripheral vestibular disease and Horner syndrome on the left side caused by otitis media-interna.

dysfunction of the vestibular (CN8), facial (CN7), and trigeminal (CN5) nerves, so the trigeminal nerve (i.e., facial and nasal sensation) should always be assessed carefully in animals with vestibular signs.

PARADOXICAL (CENTRAL) VESTIBULAR SYNDROME

A head tilt to one direction with hypermetria or postural reaction deficits affecting the limbs on the opposite side (contralateral limbs) is called *paradoxical vestibular syndrome* and usually indicates a lesion involving the caudal cerebellar peduncle or the flocculonodular lobe of the cerebellum on the side of the body opposite the head tilt. Postural reaction deficits in the limbs, when present, always indicate ipsilateral central disease, and are therefore the most reliable clinical feature allowing lesion localization (right vs. left). Other signs of cerebellar dysfunction (e.g., ipsilateral hypermetria, truncal sway, head tremor) are often seen. Paradoxical vestibular syndrome suggests central vestibular dysfunction originating in the cerebellum, so diagnostic evaluation is the same as that for other intracranial disorders (see Chapter 60).

DISORDERS CAUSING PERIPHERAL VESTIBULAR DISEASE

Peripheral vestibular disease is much more common in dogs and cats than central disease and generally carries a better prognosis. The most common disorders causing peripheral vestibular signs are infection, polyps, or neoplasia affecting the middle and inner ear and transient idiopathic vestibular syndromes. Peripheral vestibular disease can also occur as a congenital problem, as a result of trauma, and rarely as a result of aminoglycoside-induced receptor degeneration (Box 63.2). Peripheral vestibular signs with or without facial nerve paralysis have also been seen in hypothyroid-associated polyneuropathy in dogs.

BOX 63.2

Disorders Causing Head Tilt

Peripheral Vestibular Disease

Otitis media-interna
Neoplasia in middle ear
Feline nasopharyngeal polyps in middle ear
Geriatric canine vestibular disease
Feline idiopathic vestibular syndrome
Trauma
Congenital vestibular syndromes
Aminoglycoside ototoxicity
Chemical ototoxicity
Hypothyroid neuropathy

Central Vestibular Disease

Trauma or hemorrhage
Infectious disorders
Granulomatous meningoencephalitis (dogs)
Necrotizing leukoencephalitis (dogs)
Primary or metastatic neoplasia
Vascular infarct
Thiamine deficiency
Neurodegenerative disorders
Metronidazole intoxication

Diagnostic evaluation of patients with peripheral vestibular signs should include external palpation of the bullae for asymmetry or pain. If ototoxic drugs or treatments have been administered, these should be discontinued and improvement monitored over 24 to 48 hours. Systemic evaluation for inflammatory, neoplastic, or metabolic disease (including hypothyroidism in dogs) should be considered. Radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) of the tympanic bullae (middle ear) should be evaluated. CT and MRI are much more sensitive for detection of subtle abnormalities than radiography. When warranted based on the results of otoscopic examination or imaging, a myringotomy can be used to collect a sample from the middle ear for cytologic analysis and culture.

OTITIS MEDIA-INTERNA

Otitis media-interna (OM-OI) is one of the most common causes of peripheral vestibular signs in dogs and cats. Concurrent facial nerve paralysis or Horner syndrome affecting the same side is sometimes apparent (Figs. 63.3 and 63.4). All dogs and cats with peripheral vestibular disease should be evaluated for ear disease. Most animals develop OM-OI as an extension of obvious otitis externa, and many have a tympanic membrane that appears abnormal or ruptured. Otoscopic diagnosis of OM-OI can, however, be difficult when chronic otitis externa results in stenosis or hyperplasia of the external ear canal, making visualization of the tympanic membrane and sampling of the middle ear cavity impossible. Rarely, animals with OM-OI will have a normal

FIG 63.4
(A) Adult Cocker Spaniel with left peripheral vestibular disease caused by otitis media-interna. **(B)** Radiograph reveals thickening of the left bulla wall, with an increase in density within the bulla. Osteotomy of the ventral bulla revealed bilateral otitis media-interna.

otoscopic examination and an intact tympanum at the time of diagnosis, necessitating further testing.

Bulla radiographs, CT, or MRI may reveal fluid or soft tissue accumulations with the bullae as well as secondary reactive or remodeling changes. When performing a radiographic bulla series, rostrocaudal open-mouth radiograph and oblique views taken under general anesthesia are most often diagnostic (see Figs. 66.7 and 63.4). CT and MRI are more sensitive than radiography for evaluating the bullae in patients with OM-OI. Typical MRI findings include hyperintense material within the tympanic bulla on T2-weighted images, isointense material within the tympanic bulla on T1-weighted images, and gadolinium ring enhancement along the inner margin of the tympanic bulla. Animals with inner ear disease may also have loss of the normally visible intralabyrinthine fluid signal and contrast enhancement in the petrous portion of the temporal bone. While the animal

is sedated or anesthetized for imaging, a culture should be obtained from the external ear canal, and the ear canal and the tympanic membrane should be carefully examined using an otoscope or a small endoscope. If imaging suggests fluid is present within the middle ear, a sample of that fluid should be collected for cytologic analysis and culture. If the tympanic membrane is ruptured, the sample can be obtained directly under visualization. If the tympanic membrane appears to be intact, a myringotomy can be performed after the external ear canal is cleansed by flushing with warm 0.9% saline until the flush fluid obtained is clear and any excess fluid suctioned away. Using a 22-gauge, 3.5-inch spinal needle attached to a 6-mL syringe, the clinician punctures the ventral tympanic membrane just caudal to the malleus at the 6 o'clock position and gently aspirates fluid from the middle ear into the syringe. If fluid is not obtained, 0.5 to 1 mL of sterile saline can be instilled, then aspiration can be repeated. After the diagnostic sample is obtained, the middle ear should be flushed repeatedly with sterile saline to remove exudate from the bulla.

Medical treatment of dogs and cats with bacterial OM-OI consists of a 6- to 8-week course of systemic antibiotics, with the choice of antibiotic based on culture and sensitivity results. Pending culture results, antibiotic treatment can be initiated using a broad-spectrum antibiotic such as a first-generation cephalosporin (e.g., oral [PO] cephalexin, 22 mg/kg q8h), a combination of amoxicillin and clavulanic acid (Clavamox, 12.5-25 mg/kg PO q8h), or enrofloxacin (5 mg/kg PO q12h). Identification and treatment of factors predisposing to otitis externa and topical or systemic antiinflammatory therapy are also important. If conservative treatment does not resolve the infection or if there is radiographic evidence of chronic bone changes in the bulla, ventral bulla osteotomy or total ear canal ablation procedures should be performed, followed by a course of antibiotic therapy. Early recognition of OM-OI and prompt initiation of appropriate therapy result in a good prognosis for recovery. When facial nerve paralysis is present, it may be permanent despite treatment. Failure to aggressively treat OM-OI can result in ascent of the infection up the nerves into the brainstem, resulting in neurologic deterioration, central vestibular signs, and sometimes death.

GERIATRIC CANINE VESTIBULAR DISEASE

Geriatric canine vestibular disease (i.e., old dog vestibular disease), an idiopathic syndrome, is the most common cause of acute unilateral peripheral vestibular dysfunction in older dogs, with a mean age of onset of 12.5 years. The disorder is characterized by the very sudden onset of head tilt, loss of balance, and ataxia with a horizontal or rotatory nystagmus (Fig. 63.5; see Video 58.2). Clinical signs are often very severe, with inability to stand, rolling and falling toward the lesion, and vomiting. Proprioception and postural reactions are normal, although they may be difficult to assess. Facial paresis and Horner syndrome are not present, and no other neurologic abnormalities are observed.

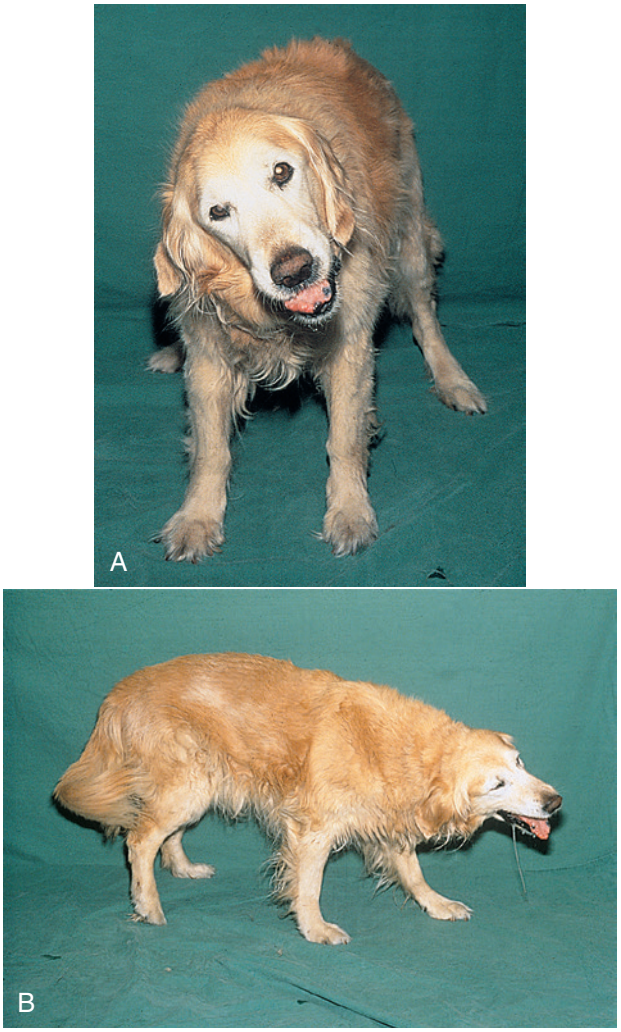

FIG 63.5
Twelve-year-old Golden Retriever with **(A)** head and **(B)** body tilt caused by geriatric canine vestibular disease.

Any older dog with a peracute onset of unilateral peripheral vestibular disease but no other neurologic abnormalities should be suspected to have geriatric canine vestibular disease. A careful physical examination, neurologic examination, and otoscopic examination should be performed. Further extensive diagnostic testing is often delayed for a few days while the dog is supported and monitored for improvement.

Diagnosis of geriatric canine vestibular disease is based on signalment, neurologic findings, exclusion of other causes of peripheral vestibular dysfunction, and alleviation of clinical signs with time. The spontaneous nystagmus usually resolves within a few days and is replaced by a transient positional nystagmus in the same direction. The ataxia gradually abates by 1 to 2 weeks, as does the head tilt. Occasionally the head tilt is permanent.

The prognosis for recovery is excellent; no therapy is recommended. When vomiting is severe, H_1 histaminergic receptor antagonists (subcutaneous [SC] diphenhydramine, 2-4 mg/kg q8h), M_1 cholinergic receptor antagonists

(chlorpromazine, 1-2 mg/kg PO q8h), or vestibulosedative drugs (meclizine, 1-2 mg/kg PO q24h) can be administered for 2 to 3 days to alleviate the emesis associated with motion sickness. Recurrent attacks are unusual but may occur on the same or opposite side. A similar acute nonprogressive course of peripheral vestibular signs has been reported occasionally in nongeriatric dogs and should be evaluated as a mononeuropathy (see Chapter 66).

FELINE IDIOPATHIC VESTIBULAR SYNDROME

Feline idiopathic vestibular syndrome is an acute nonprogressive disorder similar to the idiopathic geriatric vestibular syndrome that occurs in dogs, but it affects cats of any age. The disease may be more prevalent in the summer and early fall and in certain geographic locations, particularly the northeastern and mid-Atlantic United States, suggesting a possible role for an infectious or parasitic cause. This syndrome is characterized by peracute onset of peripheral vestibular signs (e.g., severe loss of balance, disorientation, falling and rolling, head tilt, spontaneous nystagmus), with no abnormalities of proprioception or in other cranial nerves. The diagnosis is based on clinical signs and the absence of ear problems or other disease. If radiographs, CT, or MRI of the tympanic bullae are obtained, the findings are normal, as are the results of cerebrospinal fluid (CSF) analysis. Spontaneous improvement is usually seen within 2 to 3 days, with a complete return to normal within 2 to 3 weeks.

NEOPLASIA

Tumors involving the inner and middle ear may damage peripheral vestibular structures and result in peripheral vestibular dysfunction. Tumors can arise from regional soft tissues, the osseous bulla, or the external ear canal. The most common primary aural tumors causing vestibular dysfunction are squamous cell carcinoma, ceruminous gland adenoma/adenocarcinoma, sebaceous adenoma/adenocarcinoma, and lymphoma. Less commonly, tumors of CN8 (e.g., neurofibroma, neurofibrosarcoma) or tumors of the osseous bulla (osteosarcoma, fibrosarcoma, chondrosarcoma) result in peripheral vestibular dysfunction.

Aural neoplasia may be evident on otoscopic examination, with aspiration or biopsy providing the diagnosis. When otoscopic examination is unremarkable but middle and inner ear disease is suspected, imaging is recommended. Soft-tissue density within the bullae and associated bone lysis suggests tumor. Advanced imaging with CT or MRI is necessary to provide additional detail regarding the extent of tumor if cytoreductive surgery or radiation therapy are to be considered. Diagnosis can be confirmed by biopsy. The invasive nature of tumors in the middle and inner ear makes total resection difficult. Radiotherapy or chemotherapy may be beneficial in some animals (see Chapters 75 and 76).

NASOPHARYNGEAL POLYPS

Nasopharyngeal inflammatory polyps originate at the base of the Eustachian tube in kittens and young adult cats and grow passively into the nasopharynx, nose, or middle ear. Most affected cats exhibit stertorous breathing or nasal discharge as a result of respiratory obstruction by these polyps, but cats with polyps in the middle and inner ear can be presented with peripheral vestibular signs and sometimes Horner syndrome and facial nerve paralysis. Otoscopic examination is often normal, although bulging of the tympanic membrane or extension of a polyp into the external ear canal is possible. A diagnosis of multiple nasopharyngeal polyps should be suspected when a young cat is presented with concurrent peripheral vestibular dysfunction and nasopharyngeal obstruction. Skull radiographs or CT reveal soft tissue within the bullae and thickening of the bone but no bone lysis. Traction polypectomy of pharyngeal or external ear canal polyps is usually successful, but polyps in the tympanic cavity must usually be removed surgically via ventral bulla osteotomy/ear canal ablation. The prognosis is excellent for cure if all abnormal tissue is removed, particularly when followed by a 2- to 4-week course of prednisolone (see Chapter 15).

TRAUMA

Trauma to the petrous temporal bone damaging the middle and inner ear will result in peripheral vestibular signs, often accompanied by Horner syndrome and facial nerve paralysis. Facial abrasions, bruises, and fractures may be evident on initial examination. Hemorrhage in the external ear canal may be evident on an otoscopic examination. Radiographs or advanced imaging will reveal the extent of the problem. Supportive treatment for head trauma and possible posttraumatic infection should be initiated. Vestibular signs usually resolve with time, whereas facial paralysis and Horner syndrome may persist.

CONGENITAL VESTIBULAR SYNDROMES

Purebred dogs and cats that show peripheral vestibular signs before 3 months of age are likely to have a congenital vestibular disorder. Congenital unilateral peripheral vestibular syndromes have been recognized in the German Shepherd dog, Doberman Pinscher, Akita, English Cocker Spaniel, Beagle, Smooth Fox Terrier, and Tibetan Terrier, as well as in Siamese, Burmese, and Tonkinese cats. Clinical signs may be present at birth or develop during the first few months of life. Head tilt, circling, and ataxia may initially be severe, but, with time, compensation is common, and many affected animals make acceptable pets. The diagnosis is based on the early onset of signs and exclusion of other disorders. If ancillary tests such as radiography and CSF analysis are performed, findings are normal. Deafness may accompany the vestibular signs, particularly in the Doberman Pinscher, Akita, and Siamese cat.

AMINOGLYCOSIDE OTOTOXICITY

Rarely aminoglycoside antibiotics cause degeneration within the vestibular and auditory systems of dogs and cats. This ototoxicity is usually associated with systemic administration of high doses or prolonged use (>14 days) of these antibiotics, particularly in animals with impaired renal function.

Degeneration within the vestibular system may result in unilateral or bilateral peripheral vestibular signs and loss of hearing. In most cases, the vestibular signs resolve if therapy is discontinued immediately, but deafness may persist.

CHEMICAL OTOTOXICITY

Many drugs and chemicals are potentially toxic to the inner ear. If the integrity of the tympanic membrane is in doubt, topical otic products containing chlorhexidine, dioctyl-sulfo succinate (DOSS), or aminoglycosides should not be used. Warm saline or 2.5% acetic acid solutions should be used for flushing ears. Whenever vestibular dysfunction becomes evident immediately after instilling a substance in an ear canal, the product should be removed and the ear canal flushed with copious quantities of saline. Vestibular signs will usually resolve within a few days or weeks, but deafness, if it occurs, may persist.

HYPOTHYROIDISM

Peripheral vestibular dysfunction has occasionally been reported in association with hypothyroidism in adult dogs. Concurrent facial nerve paralysis may be seen, and a few dogs exhibit weakness, suggesting a more generalized polyneuropathy. Other systemic signs of hypothyroidism, such as weight gain, poor haircoat, and lethargy, may or may not be present. Clinicopathologic testing may show abnormalities suggestive of hypothyroidism (e.g., mild anemia, hypercholesterolemia). The diagnosis is established through thyroid function testing (see Chapter 48). The response to replacement thyroid hormone is variable, but improvement typically occurs within 2 months if hypothyroidism was the cause.

DISORDERS CAUSING CENTRAL VESTIBULAR DISEASE

Central vestibular disease is much less common in dogs and cats than peripheral vestibular disease and generally carries a poor prognosis. Central vestibular disease can be caused by any inflammatory, neoplastic, vascular, or traumatic disorders affecting the brainstem or vestibular portion of the cerebellum (see Box 63.2).

A standard workup for intracranial disease is performed in animals that have central vestibular signs. Complete physical, neurologic, and ophthalmologic examinations are essential to look for evidence of disease elsewhere in the body. Clinicopathologic testing, thoracic and abdominal radiographs, and abdominal ultrasound are warranted to search for neoplastic or infectious inflammatory systemic disease. When systemic evaluation does not provide a diagnosis, brain MRI should be performed. MRI abnormalities are identified in almost every patient with evidence of central vestibular dysfunction. When inflammatory disease is suspected, CSF collection and analysis should also be considered. (See Chapter 60 for a more thorough discussion of the diagnostic approach taken in animals with intracranial disease.)

INFLAMMATORY DISEASES

Most of the infectious and noninfectious inflammatory diseases discussed in Chapter 64 can cause central vestibular signs. In particular, granulomatous meningoencephalitis, canine distemper, necrotizing leukoencephalitis, Rocky Mountain spotted fever, and feline infectious peritonitis (cats) seem to have a predilection for this region of the brain. Adult-onset neosporosis and steroid-responsive tremor syndrome also commonly affect the cerebellum, resulting in central vestibular signs. See Chapter 64 for a discussion of the diagnosis and treatment of intracranial inflammatory disorders.

THIAMINE DEFICIENCY

Thiamine deficiency can occur due to prolonged anorexia, maldigestion/malabsorption disorders, inadequate dietary intake, or ingestion of thiaminase in raw fish. Cats are much more susceptible than dogs, developing a rapidly progressive encephalopathy with neurologic signs suggesting diffuse vestibular dysfunction including vestibular ataxia, circling, and wide excursions of the head and neck. Other signs can include blindness, mydriasis, ventroflexion of the head and neck, seizures, coma, and even death. Magnetic resonance (MR) imaging can be normal or can reveal bilaterally symmetrical hyperintense foci on T2-weighted and FLAIR (fluid attenuation recovery) in grey matter regions of the brainstem, cerebrum, and cerebellum. Supplementation with parenteral and oral thiamine and changing the diet to include adequate thiamine will usually result in a rapid recovery and resolution of all neurologic signs, including seizures. Thiamine (12.5-30 mg/cat IM or SC q24h) is often administered to cats with undiagnosed neurologic signs suggesting an intracranial lesion, particularly those with vestibular signs or seizures (see Chapter 60).

INTRACRANIAL NEOPLASIA

Intracranial tumors such as meningiomas and choroid plexus tumors have a tendency to develop in the cerebellopontomedullary (caudal fossa) region, making central vestibular signs common. Central vestibular signs may result from any intracranial tumor that causes compression or invasion of vestibular nuclei, increased intracranial pressure, early brain herniation, or obstructive hydrocephalus. Presumptive diagnosis is usually made with MRI, but definitive histologic diagnosis requires biopsy. Prognosis is dependent on tumor histologic type, neuroanatomic location, and severity of the neurologic signs. Cytoreductive surgery and radiotherapy may be treatment options. Palliative treatment with glucocorticoids (prednisone, 0.5-1 mg/kg/day PO) may temporarily improve clinical signs.

CEREBROVASCULAR DISEASE

Ischemic infarcts have been increasingly recognized as a cause of acute-onset, nonprogressive central vestibular signs, often affecting the vestibulocerebellum and resulting in paradoxical vestibular signs. In dogs, thrombotic occlusion of the rostral cerebellar artery is especially common, resulting in

peracute to acute onset of nonprogressive neurologic deficits including vestibular ataxia, loss of balance, and hypermetria. Approximately 50% of affected dogs have a head tilt or spontaneous nystagmus. Proprioceptive deficits are relatively uncommon (<25%), occurring either as a result of brainstem compression by the edematous cerebellum or secondary to infarction of collateral arterial branches supplying the pons and medulla. Infarcts or hemorrhage primarily involving the brainstem would be expected to cause more significant UMN paresis, postural reaction deficits, altered mentation, cranial nerve deficits, and potentially death.

Whenever infarcts are suspected based on the neurologic findings and acute non-progressive course, the animal should be evaluated for underlying hypertension, hypothyroidism, hyperadrenocorticism, and cardiac or renal disease as well as for systemic inflammatory or neoplastic disease (see Chapter 60). Cerebellar infarction associated with atherosclerotic vascular disease has been recognized in dogs, especially in Labrador Retrievers with occult hypothyroidism, so evaluation of thyroid function is always warranted when a dog is suspected to have had a cerebrovascular infarct. Spaniels and Spaniel-crosses may be predisposed to cerebellar infarctions without evidence of an underlying cause. Chiari-like malformations, which are common in Cavalier King Charles Spaniels, may cause flow disturbances in the cerebellar vasculature, predisposing to rostral cerebellar infarction. Chapter 60 discusses diagnostic evaluation (including MRI) and treatment of cerebrovascular infarcts.

ACUTE VESTIBULAR ATTACKS

Peracute onset of loss of balance, nystagmus, and severe ataxia that lasts only 1 to 30 minutes is occasionally seen in dogs. Head tilt may be mild or absent, and consciousness is maintained. Neurologic examination during an episode does not reveal postural reaction deficits or cranial nerve abnormalities; a few dogs have had vertical nystagmus, suggesting central vestibular or cerebellar disease. Dogs completely recover within minutes to a few hours, with no residual neurologic abnormalities and no obvious postictal signs. Some affected dogs have gone on to develop brain (especially cerebellar) infarcts weeks or months later, which suggests that these events could be transient ischemic attacks (TIAs). Hypertension has been associated with recurrent vestibular paroxysms in dogs, presumably by predisposing to TIAs. Dogs with a history of these acute vestibular attacks should have a careful physical and neurologic examination performed, as well as systemic screening tests for inflammatory or neoplastic disease, disorders of coagulation, and hypertension. An otoscopic examination should also be performed to rule out early OM-OI causing episodic peripheral vestibular dysfunction. Advanced diagnostic imaging (MRI) to evaluate the middle ear and brain may be warranted in dogs with recurrent TIA-like episodes, but imaging in dogs with small transient vascular lesions is often unrewarding (see Chapter 60). Clinically it can be difficult to differentiate acute vestibular attacks (presumed TIAs) from focal seizures. When postictal signs are noted or there is progression over time to recognizable generalized epileptic seizures, vestibular paroxysms are thought to be a manifestation of a seizure disorder (see Chapter 62).

NEURODEGENERATIVE DISORDERS

Numerous lysosomal storage diseases, neuroaxonal dystrophy, neonatal ataxia in Coton de Tulear dogs, and several other inherited neurodegenerative disorders in dogs and cats cause progressive cerebellovestibular signs including ataxia and incoordination. Diagnosis of these disorders is suspected when a young animal of a susceptible breed develops a progressive symmetrical neurologic disorder with characteristic features as described in that breed. (See Chapter 60 for a discussion of the diagnostic approach to these patients.)

METRONIDAZOLE TOXICITY

Central vestibular or vestibulocerebellar signs have been reported in dogs after administration of metronidazole (Flagyl [Pharmacia and Searle]). Signs of metronidazole toxicity are most likely to develop when the drug is administered orally at high doses (usually >60 mg/kg/day) for 3 to 14 days, but individual animal susceptibilities to the toxic effects are variable. Initial signs include anorexia and vomiting, with rapid progression to ataxia and vertical nystagmus. The ataxia may be very severe, making walking impossible and resulting in a characteristic "bucking" gait. Seizures and head tilt occasionally occur. Treatment consists of stopping the medication and providing supportive care. The prognosis is good for recovery, but complete recovery may take 2 weeks. Diazepam (0.5 mg/kg once intravenously and then orally q8h for 3 days) has been shown to dramatically speed recovery. Metronidazole toxicity has also been reported in cats, but forebrain signs including seizures and altered mentation usually predominate in this species.

CHAPTER 64

Encephalitis, Myelitis, and Meningitis

GENERAL CONSIDERATIONS

Bacterial, viral, protozoal, mycotic, rickettsial, and parasitic pathogens are all recognized as etiologic agents of infectious inflammatory central nervous system (CNS) disease in dogs and cats. More common than the known infectious meningitis and encephalitis disorders in dogs are a group of CNS disorders that have no known identifiable cause but are presumed to have an immunologic basis. Some of these disorders, such as steroid-responsive meningitis arteritis (SRMA) and eosinophilic meningoencephalitis, have very characteristic clinical and laboratory features and are recognizable as specific disorders. Some of the other noninfectious inflammatory disorders are collectively known as *meningoencephalitis of unknown etiology* (MUE), with distinctions between the individual disorders less defined and often presumptive unless brain biopsies or postmortem examinations are available.

The clinical signs of CNS inflammation vary and depend on both anatomic location and severity of inflammation. Cervical pain and rigidity are common in dogs with meningitis of any etiology, causing a reluctance to walk, an arched spine, and resistance to passive manipulation of the head and neck (Fig. 64.1). Fever may occur with any disorder causing severe meningitis. Inflammation of the spinal cord (myelitis) will cause associated upper motor neuron (UMN) or lower motor neuron (LMN) deficits in the limbs, depending on the spinal cord region involved. Animals with inflammation in the brain (encephalitis) can experience vestibular dysfunction, seizures, hypermetria, or disorders of consciousness reflecting the distribution of intracranial lesions.

Diagnosis of inflammatory CNS disease involves a process of confirming the presence of inflammation, performing appropriate tests to look for infectious causes, and looking for characteristic lesions via diagnostic imaging. A thorough physical and ophthalmologic examination and searching for systemic abnormalities using laboratory tests and imaging should always be performed. Dogs and cats with bacterial meningitis/meningoencephalitis usually have an infected site from which the infection has spread to the CNS. Animals with viral, protozoal, fungal, or rickettsial meningitis/meningoencephalitis may have involvement of other organs (e.g., lung, liver, muscle, eye), which may aid in diagnosis. Cerebrospinal fluid (CSF) analysis is necessary to confirm a suspected diagnosis of CNS inflammatory disease. Analysis of the cells found in the CSF, together with the clinical and neurologic findings, may aid in determining the etiology of the inflammation in an individual case (see Box 59.3). Analysis of CSF protein, CSF culture, immunohistochemistry on CSF cytology, measurement of serum and CSF antibody titers for likely infectious agents, and CSF polymerase chain reaction (PCR) analysis may also be of diagnostic value. These results, together with other ancillary diagnostic tests, may allow diagnosis of a specific disorder and the initiation of prompt appropriate treatment (Table 64.1).

NECK PAIN

Neck pain is a sign commonly associated with compressive or inflammatory diseases of the cervical spinal cord. Animals with neck pain typically have a guarded horizontal neck carriage and are unwilling to turn their neck to look to the side; they will instead pivot the entire body. As part of every routine neurologic examination, the presence or absence of cervical hyperesthesia should be assessed by deep palpation of the vertebrae and cervical spinal epaxial muscles and by resistance to flexion, hyperextension, and lateral flexion of the neck (see Fig. 58.21). The spinal cord itself does not have pain receptors, so cervical pain is related to inflammation or compression of or traction on surrounding tissues or structures. Anatomic structures that can cause neck pain include the meninges, nerve roots, joints, bones, and muscles. Neck pain has also been recognized as a clinical symptom of increased intracranial pressure, particularly as a result of forebrain mass lesions (Box 64.1; see also Box 58.8).

The diagnostic approach to the patient with neck pain is fairly standardized. First, confirm and localize the site of painfulness using physical and neurologic examination, and then look for the cause of pain. Clinicopathologic testing

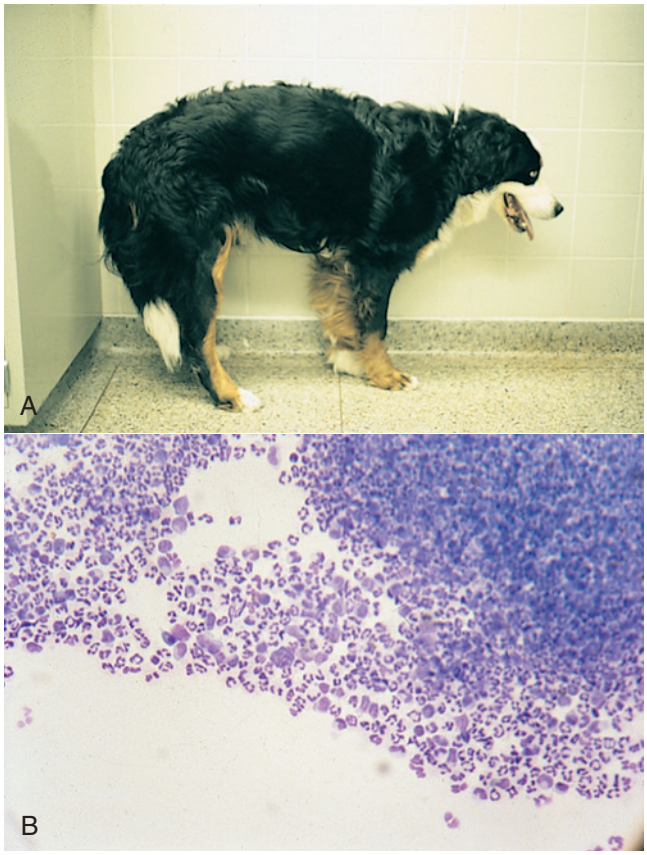

FIG 64.1
(A) Pain causes this young Bernese Mountain dog with steroid-responsive meningitis arteritis to stand with an arched spine and be reluctant to walk. **(B)** Cerebrospinal fluid from this dog is inflammatory, with a dramatic neutrophilic pleocytosis. BOX 64.1

Causes of Neck Pain in the Dog

MUSCLE: Myositis (immune, infectious), muscle injury
BONE: Fracture/luxation, diskospondylitis, vertebral osteomyelitis, neoplasia
JOINT (facetal joints): Polyarthritis (immune, infectious), degenerative joint disease (osteoarthritis)
NERVE ROOT: Neoplasia, compression (by disk, tumor, fibrous tissue, perineural cysts)
MENINGES: Neoplasia, inflammation (immune, infectious), compression/traction (synovial cysts, disk prolapse, atlanto-axial instability, cervical spondylomyelopathy, syringomyelia)
BRAIN: Mass lesion (neoplasia, inflammatory)

TABLE 64.1

Ancillary Tests in Diagnosis of Infectious Inflammatory Central Nervous System Disease

DISORDER SUSPECTED	ANCILLARY DIAGNOSTICS
Acute distemper (D)	Conjunctival scrapings Ophthalmic exam Thoracic radiographs Skin biopsy immunohistochemistry RT-PCR on blood, CSF CSF antibody titer
Bacterial (D, C)	Ear/throat/eye exam Thoracic radiographs Cardiac and abdominal ultrasound Spinal radiographs or CT Skull CT or MRI Blood/urine cultures CSF culture
Toxoplasmosis (D, C)	Ophthalmic exam ALT, AST, CK activities CSF, serum titers PCR on CSF, aqueous humor, blood, tissues
Neosporosis (D)	AST, CK activities CSF, serum titers Muscle immunohistochemistry PCR on CSF
Feline infectious peritonitis (C)	Ophthalmic exam Serum globulin Abdominal palpation/ultrasound Coronavirus antibody in CSF, serum Coronavirus immunohistochemistry on tissues Coronavirus PCR on CSF, affected tissues
Cryptococcosis (D, C)	Ophthalmic exam Thoracic radiographs Skull/brain MRI Nasal swab cytology Lymph node aspirates Test for capsular antigen in serum, CSF CSF culture
Rocky Mountain spotted fever (D)	Thoracic radiographs CBC, platelet count Serum globulin Skin biopsy: IFA Serum titer (demonstrate rise)
Ehrlichiosis (D)	CBC, platelet count Serum titer Ophthalmic examination

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *C,* cat; *CBC,* complete blood count; *CK,* creatine kinase; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *D,* dog; *IFA,* immunofluorescent antibody analysis; *MRI,* magnetic resonance imaging; *PCR,* polymerase chain reaction; *RT-PCR,* reverse transcriptase–polymerase chain reaction.

(complete blood count [CBC], chemistry including creatine kinase [CK] and urinalysis) and survey spinal radiographs are warranted in most cases. When these tests are negative, advanced imaging (computed tomography [CT], magnetic resonance imaging [MRI]), and synovial fluid and CSF collection and analysis are usually recommended.

NONINFECTIOUS INFLAMMATORY DISORDERS

STEROID-RESPONSIVE MENINGITIS-ARTERITIS

SRMA is one of the most common forms of meningitis diagnosed in most veterinary hospitals. An immunologic cause is suspected, resulting in vasculitis/arteritis affecting the meningeal vessels throughout the entire length of the spinal cord and brainstem. This disorder has also been called *aseptic meningitis, steroid-responsive suppurative meningitis, necrotizing vasculitis, juvenile polyarteritis,* and *Beagle pain syndrome.* Affected dogs are usually juveniles or young adults (6-18 months of age), but middle-aged and older dogs are occasionally affected. Large-breed dogs are most commonly affected. SRMA may be seen as a breed-associated syndrome in Beagles, Bernese Mountain dogs, Boxers, German Shorthaired Pointers, Bassett Hounds, and Nova Scotia Duck Tolling Retrievers.

Clinical signs of SRMA include fever (50%-90%), reluctance to move, neck pain, and vertebral pain that may wax and wane early in the course of disease. Affected dogs are alert and systemically normal, with a common owner complaint being that the dog will not eat or drink unless the bowl is raised to head level. Neurologic deficits (e.g., paresis, paralysis, ataxia) are very uncommon but can develop in chronically affected or inadequately treated dogs as a result of concurrent myelitis, spinal cord hemorrhage, or infarction. Signs of intracranial extension of inflammation are rare. The vast majority of dogs with SRMA are presented for neck pain and fever but have a normal neurologic examination.

Laboratory changes typically include a neutrophilic leukocytosis with or without a left shift. Hypoalbuminemia and hyperglobulinemia suggest systemic inflammation. Cervical radiographs are often performed to look for evidence of diskospondylitis and are normal. Spinal fluid analysis shows a neutrophilic pleocytosis (often >100 cells/μL; >75% neutrophils) and an increased protein concentration. Early in the course of the disease, when neck pain is intermittent, CSF may be normal or minimally inflammatory. Within 24 hours of administration of a single dose of prednisone, CSF may be normal or show a predominance of mononuclear cells; therefore CSF should always be collected for diagnosis when a dog is symptomatic before initiating therapy. High immunoglobulin (Ig)A concentrations are found in the CSF and serum of most dogs (>90%) with SRMA, aiding diagnosis, but this finding lacks specificity. Some dogs with SRMA have concurrent immune-mediated polyarthritis (IMPA). Bacterial cultures of the CSF and blood are negative. To date, no etiologic agent has been identified.

Treatment with glucocorticoids consistently and rapidly alleviates the signs of fever and cervical pain. Dogs not treated early in the course of the disease occasionally develop neurologic deficits associated with spinal cord infarction and meningeal fibrosis; treatment may not resolve the resultant neurologic signs in these dogs. Glucocorticoids should be administered initially at immunosuppressive dosages and then tapered to alternate-day therapy and decreasing dosages over a period of 4 to 6 months (Box 64.2). Dogs that do not respond completely to prednisone and dogs that relapse during prednisone tapering may benefit from the addition of oral (PO) azathioprine (Imuran [Burroughs Wellcome], 2.2 mg/kg PO q24h) to their treatment for 8 to 16 weeks. The prognosis for survival and complete resolution is excellent, with 60% to 80% of dogs with acute signs recovering with treatment and never relapsing. Older dogs and Beagles, Bernese Mountain dogs, Nova Scotia Duck Tolling Retrievers, and German Shorthaired Pointers with breed-associated SRMA may have disease that is more difficult to control, so treatment with prednisone and azathioprine from the outset and a more prolonged schedule for tapering of prednisone dose may be warranted. Lifelong treatment is rarely required.

CANINE MENINGOENCEPHALITIS OF UNKNOWN ETIOLOGY

Nonsuppurative meningoencephalitis of unknown cause is a frequent finding in dogs. Unsuccessful systematic efforts to identify infectious causes, particularly viral and protozoal agents, have resulted in the conclusion that these disorders are likely to have an immune-mediated or hereditary pathogenesis. Although attempts are made to differentiate three distinct disorders—granulomatous meningoencephalitis (GME), necrotizing meningoencephalitis (NME), and necrotizing leukoencephalitis (NLE)—based on clinical and laboratory features, imaging characteristics, and breed predisposition, a definitive diagnosis cannot be obtained without

BOX 64.2

Treatment Recommendations for Steroid-Responsive Meningitis Arteritis

1. Prednisone 2 mg/kg q12h orally for 2 days
2. Prednisone 2 mg/kg q24h orally for 14 days
3. Assess clinical response.

If clinical signs have resolved, the dose of prednisone is gradually tapered:
1 mg/kg q24h for 4-6 weeks
1 mg/kg q48h for 4-6 weeks
0.5 mg/kg q48h for 8 weeks

If clinical signs are present or if they recur during tapering, return to step 2 and add azathioprine (2 mg/kg/day) to treatment for 8-16 weeks. Continue prednisone, tapering after signs resolve.

histopathology. Assessments of treatment efficacy are therefore almost always based on only a presumptive diagnosis.

GRANULOMATOUS MENINGOENCEPHALITIS

GME is an idiopathic inflammatory disorder of the CNS that occurs primarily in young adult dogs of small breeds, with Poodles, toy breeds, Pekingese, and Terriers most commonly affected. Large-breed dogs are occasionally affected. Most dogs with GME are 2 to 6 years of age, although the disease may affect older dogs or dogs as young as 6 months. Females may be predisposed. Cats are not affected.

There are three distinct forms of GME. The *ocular* form is the least common and results in optic neuritis with an acute onset of blindness and dilated nonresponsive pupils (see Chapter 61). Fundiscopic examination may reveal a hyperemic, edematous optic disk or hemorrhage. Dogs with ocular GME may concurrently or later develop disseminated GME. The *focal* form of GME induces clinical signs suggestive of a single enlarging space-occupying mass with neurologic signs that progress slowly over 4 to 6 months, similar to a tumor. Focal GME most often affects the caudal cranial fossa, resulting in vestibulocerebellar signs or the cerebrum causing forebrain signs including seizures. The *disseminated* form of GME causes rapidly progressive signs of multifocal or disseminated disease affecting the cerebrum, brainstem, cerebellum, cervical spinal cord, or meninges. Affected dogs may be febrile, and neck pain is common.

Clinical signs reflect the location and nature of the lesion. About 20% of affected dogs exhibit seizures, circling, or behavior change. Other common features may include brainstem signs such as nystagmus, head tilt, loss of balance, and cranial nerve deficits. Cervical pain occurs in up to 10% of dogs with GME, suggesting meningeal inflammation, focal spinal cord involvement, or increased intracranial pressure. Spinal cord infiltration occurs in approximately 10% of cases. Some dogs (50%) with the disseminated form of GME have a fever and peripheral neutrophilia but no other evidence of systemic disease. The disseminated form of the disease has an acute to subacute progression over days to weeks to months, with 25% of the cases dead within 1 week and most dead within 21 days. The focal form is more insidious, with slow progression over 4 to 6 months.

The diagnostic approach to patients with progressive intracranial or spinal cord disease should include careful systemic evaluation for infectious or neoplastic disease. Screening laboratory tests, thoracic radiographs, abdominal ultrasound, lymph node aspirates, and ophthalmic examination should all be performed. If these tests are unremarkable then advanced imaging is recommended. Focal GME may be identified on MRI as a single space-occupying mass lesion with irregular margins, hyperintensity of T2-weighted images and FLAIR, variable intensity of T1-weighted images (usually isointense or hypointense), and variable contrast enhancement. Disseminated GME usually causes multiple poorly defined lesions of the parenchyma and meninges. CT is not as sensitive as MRI at identifying the parenchymal lesions of GME, but contrast enhancement is common, reflecting inflammation. Imaging results not conclusive for neoplasia should prompt collection and analysis of CSF.

CSF analysis from dogs with GME typically reveals an increase in protein concentration and a mild to marked mononuclear pleocytosis. Small lymphocytes, monocytes, and occasional plasma cells predominate (Fig. 64.2). Anaplastic mononuclear cells with abundant lacy cytoplasm are sometimes present. Neutrophils are seen in two thirds of the samples, usually making up less than 20% of the cells. A single sample of CSF may be normal in 10% to 15% of cases. CSF electrophoresis typically shows evidence of blood-brain barrier disruption, and chronically affected dogs have dramatically increased intrathecal production of gamma globulins. Evaluation for infectious causes of meningoencephalomyelitis through bacterial culture and appropriate serum and CSF titers (Neospora, Toxoplasma, tick-borne diseases, West Nile virus) and antigen tests or PCR should always precede a presumptive diagnosis of GME. Definitive diagnosis requires biopsy or necropsy for histologic examination, but this is rarely performed. A tentative diagnosis is

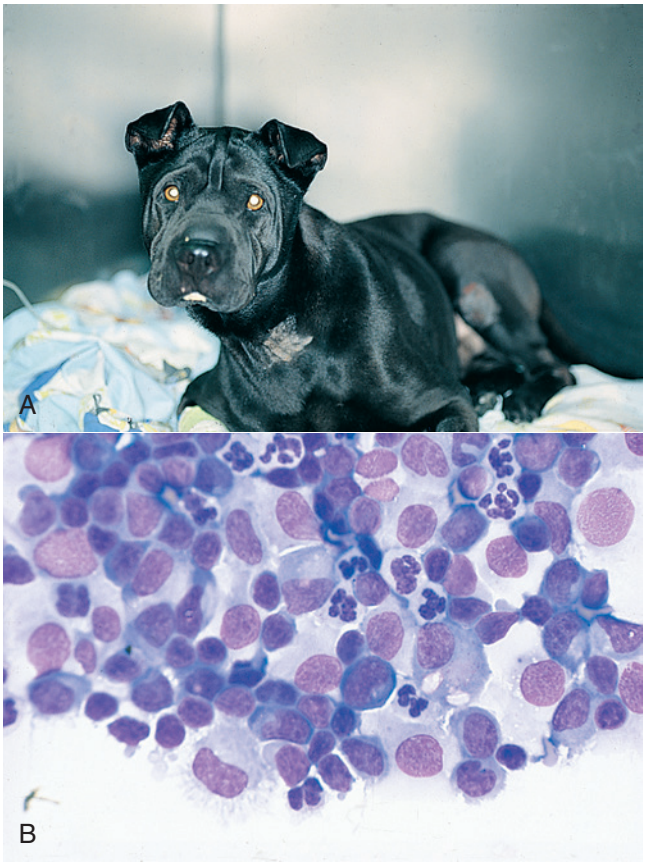

FIG 64.2
(A) Young Chinese Shar-Pei with incoordination, depression, vertical nystagmus, and a slight head tilt resulting from disseminated granulomatous meningoencephalomyelitis. **(B)** Cerebrospinal fluid from this dog has increased cellularity—primarily lymphocytes, monocytes, plasma cells, and neutrophils.

made antemortem based on the typical MRI and CSF findings and elimination of infectious and neoplastic diseases on the list of likely differentials.

Glucocorticoids can temporarily halt or reverse the progression of clinical signs in dogs with GME, particularly in animals with slowly progressive signs associated with focal disease. Clinical signs often recur quickly, with the median survival time highly variable (7-114 days) depending on type and location of disease. More prolonged improvement in clinical signs and survival can be seen when more aggressive chemotherapy protocols are used, with median survival times longer than 12 months expected when dogs with focal disease are treated with combinations of immunosuppressive drugs. Recommended drugs and protocols are outlined in Box 64.3.

Comparative efficacy between protocols is difficult to assess because of disease and patient variability and the failure to obtain a definitive pretreatment diagnosis. Dogs with GME or MUE in the author's hospital are usually treated with a combination of prednisone, 4 cycles of cytosine arabinoside, and either cyclosporine or azathioprine. Although most dogs improve with treatment, the prognosis for permanent recovery is poor. Dogs with forebrain signs have a significantly longer survival than dogs with multifocal or brainstem signs, but dogs with seizures or MRI evidence of cerebral edema have limited survival. Some treatment protocols recommend monitoring of MRI images and CSF cytology before tapering drug doses, but that is rarely performed. Radiation therapy has been reported to benefit some dogs with focal intracranial masses resulting from GME, and results are similar to chemotherapy.

BOX 64.3

Chemotherapy Options for Presumed Granulomatous Meningoencephalitis

Prednisone

1 mg/kg PO q12h for 2 weeks, then 1 mg/kg PO q24h for 4 weeks, then 1 mg/kg q48h
Slowly taper to lower dose (0.5 mg/kg PO q48h) when used in combination drug protocol

Cytosine Arabinoside (Cytosar [Pfizer])

50 mg/m^2 body surface area SC q12h on 2 consecutive days every 21 days for 3-4 cycles
Alternatively administer on 2 consecutive days every 21 days for 4 cycles, then every 28 days for 4 cycles, every 35 days for 4 cycles, every 42 days for 4 cycles

Procarbazine (Matulane [Sigma-Tau Pharmaceuticals])

25-50 mg/m^2 body surface area PO q24h for 30 days, then q48h

Cyclosporine (Neoral [Novartis])

6 mg/kg PO q12h (trough target 200-400 ng/mL)

Azathioprine (Imuran [Roxane Laboratories])

2 mg/kg PO q24h for 30 days, then q48h

Leflunomide (Arava [Aventis Pharma])

2-4 mg/kg PO q24h

Mycophenolate Mofetil (CellCept [Roche])

20 mg/kg PO q12h for 30 days, then 10 mg/kg PO q12h

PO, By mouth; *SC,* subcutaneous.

NECROTIZING MENINGOENCEPHALITIS

NME is a breed-specific idiopathic inflammatory condition affecting the brain of Pugs (Pug encephalitis) and Maltese Terriers. It has also been seen sporadically in the West Highland White Terrier, Chihuahua, Pekingese, Shih Tzu, Papillon, Coton du Tulear, and Lhasa Apso. Affected dogs first show clinical signs between 9 months and 7 years of age, with a mean age of onset about 18 months in Pugs and 29 months in other breeds. Female Pugs may be predisposed.

Most dogs with NME are presented with an acute onset of seizures and neurologic signs referable to the cerebrum and meninges. They may have difficulty walking or may be weak or lack coordination. Circling, head pressing, behavior change, cortical blindness, and neck pain are common. Neurologic deterioration is rapid, and without treatment most dogs develop uncontrollable seizures or become recumbent, unable to walk, and comatose within 5 to 7 days.

A few dogs (especially Pugs) occasionally present with a more slowly progressive form of NME. They are presented with a single generalized or partial motor seizure, but they are neurologically normal after that seizure. Seizures then recur at varying intervals from a few days to a few weeks, followed by the gradual development of other neurologic signs referable to the cerebral cortex. Survival times with this more slowly progressive manifestation of NME are typically fewer than 6 months.

A diagnosis of NME should be suspected on the basis of signalment and characteristic clinical, clinicopathologic, and imaging features. Hematologic and serum biochemistry findings are unremarkable, and testing for metabolic encephalopathies is negative. Imaging studies are consistently abnormal, with CT and MRI showing focal cavitations filled with high-protein fluid within the brain parenchyma. Hyperintense (T2W) infiltrative lesions are typically in the white matter of the cerebral hemispheres just lateral to the ventricles and at the junction between cerebral gray and white matter, resulting in loss of the normal sharp demarcation on MRI. CSF analysis reveals a high protein concentration and an increased nucleated cell count, with the predominant cell type being the small lymphocyte, with a few larger mononuclear cells. Even in typical cases, testing should be performed to eliminate an infectious etiology (Toxoplasma, Neospora, canine distemper). Definitive diagnosis requires autopsy or brain biopsy. NME is distinguished from GME by finding characteristic necrotic lesions and cavitations in cerebral white or grey matter.

No specific treatment has been shown to consistently alter the course of this disease, but long-term remission has been achieved in a few dogs using treatment protocols as outlined for GME (see Box 64.3). Treatment with antiepileptic doses of phenobarbital may decrease the severity and frequency of seizures. The prognosis for long-term improvement and survival must be considered poor.

NECROTIZING LEUKOENCEPHALITIS

NLE is a breed-specific idiopathic multifocal necrotizing, nonsuppurative encephalitis affecting the brains of Yorkshire Terriers, French Bulldogs, and occasionally Maltese Terriers. Dogs first show clinical signs between 1 and 10 years of age, with a mean age of onset around 4.5 years. Males and females are affected equally.

Lesions predominate in the white matter ("leuko-") of the cerebrum, thalamus, and brainstem. Signs may include altered mentation, seizures, visual deficits, head tilt, nystagmus, cranial nerve abnormalities, and proprioceptive deficits. Neurologic deterioration is rapid, and within 5 to 7 days most dogs are recumbent or dead. A diagnosis of NLE should be suspected on the basis of signalment and characteristic rapidly progressive cortical and brainstem signs. MRI studies show multiple asymmetric hyperintense (T2W) lesions and cystic areas of necrosis restricted to the white matter of the cerebrum, thalamus, and brainstem. CSF analysis reveals a mild to moderate increase in protein and a mixed inflammatory pleocytosis consisting of macrophages, monocytes, lymphocytes, and plasma cells. Treatment as for GME is recommended, but the prognosis for recovery is poor.

CANINE STEROID-RESPONSIVE TREMOR SYNDROME

An acute-onset whole-body tremor disorder is most commonly recognized in small white dogs such as Maltese and West Highland White Terriers and Bichon Frise, leading to the name "little white shaker syndrome." Although this disorder is most common in young adult dogs of the small white breeds, it can occur in any breed and in dogs of any coat color. Cairn Terriers and Miniature Pinschers are also predisposed. Affected dogs are presented for evaluation of tremors and incoordination. Tremors can range from mild to incapacitating and tend to worsen with exercise, stress, and excitement. In most dogs, signs are restricted to tremor, but occasionally vestibular or cerebellar ataxia, nystagmus, or loss of menace response can accompany the tremor.

Diagnosis should be suspected based on signalment, history, and clinical signs. Lack of access to tremorgenic toxins and failure to progress to more severe signs like seizures make intoxication unlikely. Normal metabolic testing (glucose, liver function) and normal mentation are expected. MR imaging is usually normal. CSF can be normal, but most often there is a slight increase in protein and a lymphocytic pleocytosis. Testing for infectious causes of CNS inflammation, including neosporosis, canine distemper, West Nile virus, and tick-borne pathogens, should be performed where appropriate, and treatment for 1 to 2 weeks with clindamycin or doxycycline may be considered. Signs usually persist until prednisone therapy is initiated (1-2 mg/kg PO q12h for 14 days). Tremors usually improve or resolve within the first week or two after initiating therapy. Once the tremors have resolved, the prednisone dose can be tapered gradually over 3 to 6 months to the lowest effective dose (usually 0.25 mg/kg q48h) and then can usually be discontinued. If the tremors return, immunosuppressive prednisone therapy is reinitiated, with more gradual tapering. Some dogs require additional immunosuppressive treatment with cyclosporine or azathioprine to taper the prednisone dose to acceptable levels and prevent relapses. The prognosis is good for recovery, but occasionally dogs will require lifelong continuous or intermittent therapy. Histologically, some affected dogs have had a mild nonsuppurative meningoencephalitis with perivascular cuffing that is most severe in the cerebellum.

CANINE EOSINOPHILIC MENINGITIS/ MENINGOENCEPHALITIS

Eosinophilic meningitis and meningoencephalitis occur uncommonly in dogs. Eosinophilic inflammation can be the response to migrating helminths, protozoal or fungal infection, or rarely viral infection of the CNS. There is also a primary allergic or immune-mediated disorder of dogs characterized by eosinophilic inflammation of the CNS and known as *idiopathic eosinophilic meningoencephalitis* (EME). This idiopathic disorder is most common in young (8-month to 3-year-old) large-breed dogs, particularly Golden Retrievers and Rottweilers. Neurologic signs of EME reflect cerebral cortical involvement and include behavior change, circling, and pacing. Ataxia and proprioceptive deficits are uncommon. Some dogs (10%-20%) also manifest systemic signs of diarrhea, vomiting, and abdominal pain. Peripheral eosinophilia is uncommon. MRI can be normal or reveal focal or multifocal patchy regions of T2 hyperintensity with variable contrast enhancement. CSF analysis reveals increased cellularity, with 20% to 99% eosinophils (often >80%). It is important to rule out or treat parasitic and infectious disease before initiating treatment for EME. If testing is negative for heartworm disease, fungal and protozoal pathogens, and *Baylisascaris* (serology), broad-spectrum deworming with fenbendazole and ivermectin is recommended, followed by 2 to 4 weeks of oral clindamycin and immunosuppressive doses of prednisone. Some dogs recover without treatment. Most dogs (75%) have a good response to treatment and can be weaned off oral prednisone after 3 to 4 months.

FELINE POLIOENCEPHALITIS

A nonsuppurative encephalomyelitis with no etiologic agent identified (viral non-FIP encephalitis) occasionally causes progressive seizures or brainstem and spinal cord signs in young adult cats. Affected cats range from 3 months to 6 years of age, but most are younger than 2 years. Affected animals have a subacute to chronic course with neurologic signs progressing over 3 to 5 weeks. Ataxia, paresis, and proprioceptive deficits affecting the pelvic limbs or the pelvic and thoracic limbs are common. When inflammation

extends to the nerve roots, LMN signs of hyporeflexia and muscle atrophy are apparent. Seizures, circling, behavior change, blindness, intention tremor, and nystagmus are observed in some cats.

Clinicopathologic findings are normal in most affected cats. CSF analysis is normal or reveals a mild increase in mononuclear cells and slightly increased protein concentration. Definitive diagnosis can only be confirmed at necropsy. Lesions are confined to the CNS and include meningitis, neuronal degeneration, and variable lymphohistiocytic perivascular infiltrates with characteristics suggesting a viral etiology. Routine testing for a wide variety of infectious agents has been negative. The prognosis is poor, although reports exist of spontaneous recovery from a clinically similar disorder in a few cats.

INFECTIOUS INFLAMMATORY DISORDERS

FELINE IMMUNODEFICIENCY VIRUS ENCEPHALOPATHY

Neurologic abnormalities associated with feline immunodeficiency virus (FIV) encephalopathy in cats include behavioral and mood changes, altered sleep patterns, depression, persistent staring, inappropriate elimination, seizures, twitching of the face and tongue, and occasionally paresis. A presumptive diagnosis of FIV encephalopathy is made on the basis of suggestive clinical signs and positive FIV serology, but because FIV-infected cats have increased susceptibility to numerous neoplastic and infectious causes of encephalitis, it is important to carefully exclude other neurologic diseases. CSF analysis reveals an increase in lymphocytes and normal or only slightly increased CSF protein concentration. FIV antibodies can be demonstrated in the CSF of most affected cats. Care must be taken to keep from contaminating the CSF with blood during collection, because serum antibody titers are higher than those in the CSF. Culture of freshly collected CSF may yield the virus. Administration of the reverse transcriptase inhibitor Zidovudine (AZT: 5 mg/kg PO q12h) may reduce the severity of neurologic impairment in some cats.

BACTERIAL MENINGOENCEPHALOMYELITIS

Bacterial infection of the CNS is uncommon in dogs and cats. It may result from direct extension of infection from an extraneural site such as the middle/inner ear, eye, retrobulbar space, sinus, or nose or because of a penetrating injury to the skull or a migrating foreign body. Hematogenous dissemination from extracranial infected foci occurs less frequently, except in neonates with omphalophlebitis and dogs and cats with severe immunodeficiency or overwhelming sepsis. Dogs with highly vascular septic pleuritis, prostatitis, endocarditis, pyelonephritis, osteomyelitis, and diskospondylitis may be at risk. Bacterial meningitis and meningoencephalomyelitis in dogs and cats, unlike in humans, are not caused by microorganisms having a specific predilection for the nervous system. Bacterial infections of the CNS are instead associated with the wide variety of organisms infecting extraneural sites.

Clinical signs of bacterial infection of the CNS commonly include pyrexia, neck pain, and severe systemic illness. Many affected animals either have an obvious site of infection adjacent to the CNS or they are bacteremic and systemically severely ill at the time of presentation. Rarely, affected animals are systemically normal. Neurologic abnormalities in dogs and cats with bacterial infections of the CNS reflect the location of damaged parenchyma and may include seizures, coma, blindness, nystagmus, head tilt, cranial nerve deficits, severe neck pain and progressive paresis, or paralysis. The clinical course is usually rapidly progressive and frequently fatal. Shock, hypotension, and disseminated intravascular coagulation are common, and routine laboratory tests may reflect the underlying inflammatory process. Advanced imaging typically reveals the site of original infection and confirms inflammation of the meninges and brain parenchyma. Spinal epidural empyema and abscessation are rarely identified.

CSF analysis may reveal an increased protein concentration and a severe neutrophilic pleocytosis in acute and severe cases but less pronounced changes or normal CSF in chronic low-grade cases. Neutrophils in the CSF only occasionally appear toxic or degenerate, and intracellular bacteria are rarely seen (Fig. 64.3). Treatment with antibiotics before CSF is collected may lower the CSF cell count and result in a predominance of mononuclear cells. The rate of organism recovery by CSF culture can be improved by inoculation of CSF into broth enrichment media, but fewer than 40% of dogs with bacterial meningitis will have positive CSF cultures. Because it is so difficult to document and characterize infection within the CNS, it is very important to evaluate the patient systemically whenever bacterial meningitis is suspected. Diagnostic evaluation should include blood and urine bacterial cultures, ophthalmologic and otic examinations, abdominal and cardiac ultrasound examinations, screening radiographs or CT of the spine and thorax, as well as CSF cytologic analysis and CSF anaerobic and aerobic bacterial culture. MR imaging of the affected region should also be considered. The presence of systemic bacterial illness or identification of an extraneural focus of infection in a dog or cat with neurologic signs and inflammatory CSF should prompt immediate treatment for suspected bacterial CNS infection. If the focus of underlying infection can be determined, that site should be cultured. Therapy is usually initiated before culture results are available.

Bacterial meningitis can be a life-threatening infection requiring rapid and aggressive treatment. Appropriate therapy of CNS infections is based on identifying the causative organism and selecting an effective antimicrobial agent that will reach high concentrations in the CSF and CNS tissues. Enrofloxacin, marbofloxacin, third-generation cephalosporins (e.g., ceftriaxone, cefotaxime), and the second-generation cephalosporin cefuroxime are good choices for

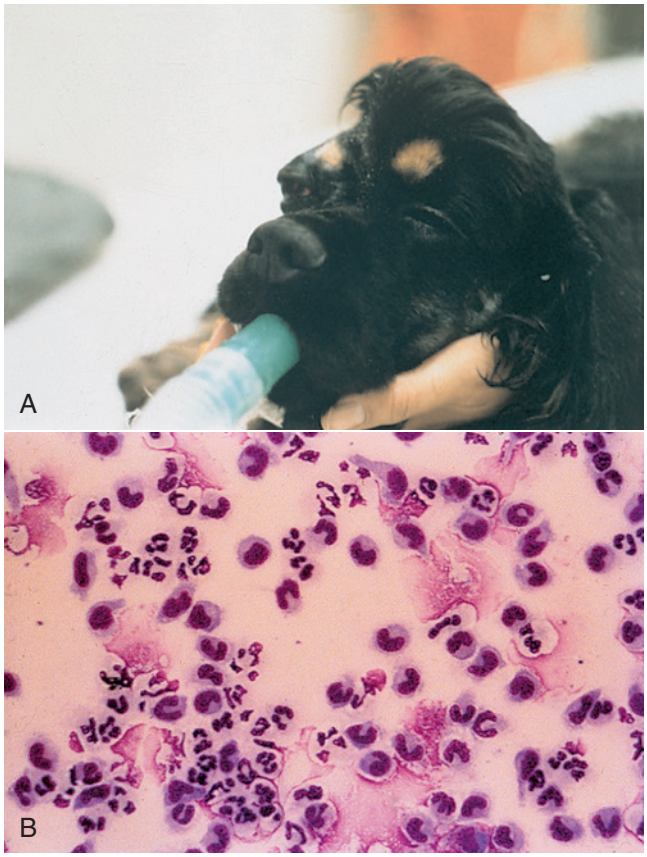

FIG 64.3
(A) This 4-year-old Cocker Spaniel with a chronic retrobulbar abscess developed fever and severe depression. **(B)** Cerebrospinal fluid from the dog revealed septic inflammation. Postmortem examination confirmed communication between the retrobulbar abscess and central nervous system.

gram-negative infections, and metronidazole can be used for anaerobic infections. Doxycycline, trimethoprim-sulfa, and chloramphenicol may also reach therapeutic concentrations in the CNS. While inflammation persists, ampicillin and amoxicillin with clavulanic acid are also effective and may be the best choice for gram-positive infections. Initial treatment with a combination of intravenous (IV) ampicillin (22 mg/kg IV q6h), enrofloxacin (2.5 mg/kg IV q12h), and metronidazole (15 mg/kg IV × 1, then 7.5 mg/kg IV q8h) may be warranted if the infectious agent is unknown. Whenever possible, antibiotics should be administered intravenously for 3 to 5 days to achieve high CSF concentrations, and then oral therapy should be continued for 4 to 8 weeks after recovery. Concurrent IV fluids and systemic support are important, and anticonvulsants should be administered to patients having seizures (see discussion of status epilepticus in Chapter 62). Antiinflammatory drugs or glucocorticoids (dexamethasone, 0.2 mg/kg IV q12h) are sometimes administered for the first 2 days of antibiotic treatment to minimize the inflammatory consequences of antibiotic-induced bacterial lysis. When imaging reveals significant spinal cord compression by an epidural abscess, surgery may be required.

The response to antibiotic therapy is variable, and relapses are common, particularly if the underlying source of the bacterial infection cannot be resolved. The prognosis should be considered guarded in most cases, because even with appropriate therapy many animals die. An exception may be otogenic intracranial infections in dogs and cats, where a good success rate after treatment with surgical drainage and antibiotics has been reported.

CANINE DISTEMPER VIRUS

Canine distemper virus (CDV) is a paramyxovirus that affects the CNS of dogs. Widespread vaccination has substantially decreased the incidence of clinically apparent CDV infections in many regions, but outbreaks still occur among unvaccinated dogs and sporadically in vaccinated dogs. Clinical signs vary depending on virulence of the virus strain, environmental conditions, and host age and immune status. Most CDV infections are probably subclinical or are associated with mild signs of upper respiratory tract infection that resolve without therapy. Young, immunocompromised, and unvaccinated dogs are most likely to develop severe generalized distemper.

Progressive generalized infection with CDV most commonly affects unvaccinated puppies between 12 and 16 weeks of age. The first sign of infection is a mild serous to mucopurulent ocular and nasal discharge followed by a dry cough and sometimes tonsillitis. The cough becomes moist and productive as pneumonia develops. Affected dogs are depressed, inappetent, and often febrile. Diarrhea develops in some puppies and may be mild or severe. Hyperkeratosis of the footpads and nose, pustular dermatitis affecting the unhaired skin on the ventral abdomen, and severe moist otitis externa may also be seen. Neurologic signs typically begin 1 to 3 weeks after recovery from the initial systemic illness and may include forebrain, vestibulocerebellar, brainstem, or spinal cord signs. Some of the most common neurologic signs reported include dementia, disorientation, altered mentation, seizures, circling, head tilt, nystagmus, cranial nerve deficits, hypermetria, tetraparesis, and ataxia. Seizures can be of any type, depending on the region of the forebrain that is affected, but "chewing gum" seizures caused by polioencephalomalacia of the temporal lobes are commonly described. Myoclonus, a repetitive rhythmic contraction of a group of muscles resulting in repetitive flexion of a limb or contractions of the muscles of mastication, is often referred to as *distemper chorea* and is very common in dogs with distemper encephalomyelitis. Anterior uveitis, optic neuritis, or chorioretinitis may be detected during an ophthalmologic examination in some infected dogs. Dogs surviving mild CDV infection before eruption of their permanent teeth will often have irregular dental surfaces and brown discoloration of their teeth subsequent to virus-induced enamel hypoplasia. Older animals occasionally develop chronic encephalomyelitis months to years after prior CDV infection and recovery (old dog encephalitis),

with neurologic abnormalities that include progressive tetraparesis or vestibular dysfunction in the absence of systemic signs.

CDV is diagnosed on the basis of history, physical examination, and laboratory findings. In most young dogs a history of mild to severe gastrointestinal and respiratory illness precedes the onset of neurologic signs. Results of a CBC may be normal or may reveal a persistent lymphopenia; distemper inclusions can sometimes be found in the circulating lymphocytes and erythrocytes. Optic neuritis, chorioretinitis, and retinal detachment are occasionally seen.

Early in an infection (first 3 weeks), immunofluorescent or immunohistochemical techniques using anti-CDV antibodies may reveal CDV in cytologic smears prepared from conjunctival, tonsilar, or nasal epithelium. Virus may be detected past these initial stages in epithelial cells and macrophages obtained from the lower respiratory tract by tracheal wash or in histologic samples of the skin, footpads, and CNS; thus immunohistochemical techniques can be applied to biopsy or necropsy specimens for diagnosis. Biopsy of the haired skin of the dorsal neck can be used for antemortem immunohistochemical testing to confirm acute and subacute infection with CDV. Reverse transcriptase–polymerase chain reaction (RT-PCR) can also be used as a sensitive and specific test to detect CDV RNA in whole blood, buffy coat preparations, CSF, and tissues of affected dogs.

MRI findings include poorly demarcated focal or multifocal hyperintense lesions on T2W in the forebrain, brainstem, cerebellum, or spinal cord. Distemper meningoencephalitis characteristically causes an increase in protein concentration and a mild lymphocytic pleocytosis in the CSF; occasionally the CSF is normal or more indicative of an inflammatory process (increased neutrophils). Increased protein concentration in the CSF has been identified primarily as anti-CDV antibody. Measured CDV antibody titer in the CSF may be increased relative to the serum titer.

Treatment of acute CDV meningoencephalomyelitis is supportive, nonspecific, and frequently unrewarding. Progressive neurologic dysfunction usually necessitates euthanasia. Anticonvulsant therapy has been recommended to control seizures. Antiinflammatory doses of glucocorticoids (predisone 0.5 mg/kg q12h PO for 10 days, then taper) may be used to control other neurologic signs in the absence of systemic disease, but their beneficial effects are not well documented.

Prevention of CDV infection through routine vaccination is usually very effective. CDV can, however, develop with exposure after stress, illness, or immunosuppression, even in a currently vaccinated dog. Meningoencephalitis that was presumed to be vaccine-induced distemper was reported in a few immunosuppressed puppies 7 to 14 days after vaccination with modified-live virus–canine distemper vaccines (MLV-CDV). Although this was likely a historical problem with particular batches of vaccines produced using old technology, vaccination of immunosuppressed neonates, particularly those with a known or suspected parvoviral infection, should be avoided.

RABIES

Rabies virus infection in dogs and cats is almost always the result of a bite from an infected animal with rabies virus in its saliva. Most dogs and cats are infected through contact with wildlife vectors (e.g., skunks, raccoons, foxes, bats). Although the prevalence of wildlife rabies has been increasing, cases of rabies in pet dogs and cats have been decreasing thanks to routine vaccination protocols. The incubation period from the time of the bite to the onset of clinical signs is extremely variable (1 week to 8 months), with average incubation 3 to 8 weeks. Once neurologic signs develop, the disease is rapidly progressive, with death occurring within 7 days in most animals.

Rabies can have a wide range of clinical signs, which makes it difficult to differentiate from other acute progressive encephalomyelitis syndromes. Because of its public health significance, rabies should be on the list of differential diagnoses considered in every animal with rapidly progressing neurologic dysfunction, and precautions should be taken to minimize human exposure. Rabies infection has classically been divided into two major types: furious and paralytic. Dogs and cats typically undergo an early prodromal phase lasting 2 to 3 days during which they may be apprehensive or nervous and may lick or chew at the site of inoculation. This can be followed by a furious or psychotic phase (1-7 days) in which animals are increasingly irritable and excitable, often snapping at imaginary objects and biting at their cage or surroundings. They become uncoordinated and may exhibit generalized seizures progressing to death. Animals that develop the paralytic or dumb type of rabies develop generalized LMN paralysis progressing from the site of inoculation to involve the entire CNS within a few (range, 1-10) days. Cranial nerve paralysis may be the first sign seen (especially if the bite was on the face). Difficulty swallowing, excessive drooling, hoarse vocalization, diminished facial sensation, and dropped jaw occur, usually progressing to respiratory paralysis and death.

Any inadequately vaccinated animal with an acute, rapidly progressive course of neurologic disease should be suspected of having rabies. Ancillary testing should be performed with caution, minimizing exposure of personnel. CSF analysis reveals increased mononuclear cells and protein concentration, as might be expected with any viral encephalomyelitis. Rabies antibody may be increased in CSF compared with serum. Biopsies obtained from the dorsal skin at the nape of the neck or the maxillary sensory vibrissae may be positive for rabies virus antigen, but although positive results are reliable, negative results are not. Definitive diagnosis of rabies encephalitis is through postmortem demonstration of rabies virus antigen by immunohistochemical techniques in the brain tissue (thalamus, pons, medulla) of an infected animal. Because of the risk associated with inadvertent human exposure, it is recommended that all inadequately vaccinated animals euthanized or dying with progressive neurologic dysfunction of unknown origin undergo postmortem evaluation, and persons performing these examinations should be advised to take precautions to prevent rabies exposure.

Fortunately, vaccinations have been extremely effective in reducing the prevalence of rabies in pet dogs and cats, and in decreasing the incidence of rabies infection in humans. Inactivated products and recombinant vaccines are available and are relatively safe and effective when used as directed. Dogs and cats should receive their first rabies vaccine after 12 weeks of age and then again at 1 year of age. Subsequent boosters are administered every 1 to 3 years, depending on the vaccine used and local public health regulations. Rarely, soft tissue sarcomas have developed in cats at the site of rabies virus prophylactic inoculation. Postvaccinal polyradiculoneuritis causing an ascending LMN tetraparesis has also been reported occasionally in dogs and cats.

FELINE INFECTIOUS PERITONITIS

Progressive neurologic signs occur in approximately 30% of cats affected with the dry form of feline infectious peritonitis (FIP). Neurologic FIP is the most common single cause of inflammatory brain disease and the most common cause of progressive spinal cord signs in cats. Neural FIP is most common in male cats younger than 2 years of age from multi-cat households.

The most common neurologic signs of FIP include seizures, behavior change, vestibular dysfunction, tremors, hypermetria, cranial nerve deficits, and UMN paresis. Most affected cats have a fever and systemic signs such as anorexia and weight loss. Concurrent anterior uveitis, iritis, keratic precipitates, and chorioretinitis are common and should raise suspicion of this disease. Careful abdominal palpation will reveal organ distortion caused by concurrent granulomas in the abdominal viscera in over 50% of cats with CNS FIP.

Typically, the CBC is inflammatory, and serum globulin concentrations may be very high. Results of serum tests for anticoronavirus antibodies are variable. MRI typically reveals inflammation of the ventricular lining and meninges, secondary hydrocephalus, and occasionally focal or multifocal granulomatous lesions in the brain or spinal cord parenchyma. CSF analysis reveals a marked neutrophilic or pyogranulomatous pleocytosis (>100 cells/μL; >70% neutrophils) and an increase in CSF protein concentration (>200 mg/dL) in most cases, but occasionally CSF will be normal or only slightly inflammatory. Coronavirus can sometimes be detected in the CSF and other affected tissues using RT-PCR. The prognosis for cats with CNS FIP is very poor. Some palliation may be achieved with immunosuppressive and antiinflammatory medications (see Chapter 96 for more information on FIP).

TOXOPLASMOSIS

Toxoplasma gondii infections can be acquired transplacentally, through ingestion of raw meat containing encysted organisms, or through ingestion of food or water contaminated by cat feces containing oocysts. Most infections are asymptomatic. Transplacentally infected kittens may develop acute fulminating signs of liver, lung, CNS, and ocular involvement. Disease in older animals results from reactivation of a chronic encysted infection. Infection is evident in the lung, CNS, muscle, liver, pancreas, heart, and eye in cats. In dogs, lung, CNS, and muscle infections predominate, but ocular infections may also occur.

CNS toxoplasmosis can cause a variety of signs, including behavioral change, blindness, seizures, circling, tremors, ataxia, paresis, and paralysis. Muscle pain and weakness caused by *Toxoplasma* myositis is discussed in Chapter 67.

Routine laboratory work may be normal in dogs and cats with CNS toxoplasmosis, or a neutrophilic leukocytosis and eosinophilia may be seen. Serum globulins may be increased. Liver enzymes are increased when there is hepatic infection, and CK is increased in animals with myositis. CSF analysis typically reveals increased protein concentration and a mild to moderately increased nucleated cell count. Lymphocytes and monocytes usually predominate, but occasionally the pleocytosis is neutrophilic or eosinophilic. The CSF concentration of antibodies directed against *T. gondii* may be increased relative to serum concentration, suggesting local production of specific antibodies. Rarely, CSF cytologic examination reveals *T. gondii* organisms within host cells, allowing a definitive diagnosis of toxoplasmosis.

Antemortem diagnosis of CNS toxoplasmosis may be difficult because *T. gondii*-specific antibodies and antigen can be detected in the serum of normal cats. If other organ systems are involved, finding organisms in samples from affected extraneural tissues allows definitive diagnosis. In patients with myositis, immunohistochemistry can be used to identify organisms in muscle biopsies. A fourfold rise in IgG titer in two serum samples taken 3 weeks apart or a single elevated IgM titer in a patient with neurologic signs supports a diagnosis of toxoplasmosis, but antibody titers are negative in some animals with severe disease (see Chapter 98). Identification of *T. gondii*-specific IgM antibody and organism DNA (by PCR) in CSF or aqueous humor of symptomatic animals suggests *T. gondii* meningoencephalomyelitis.

Recommended treatment for meningoencephalomyelitis caused by toxoplasmosis in dogs and cats consists of clindamycin hydrochloride (10 mg/kg PO q8h or 15 mg/kg PO q12h for at least 4-8 weeks). This drug has been shown to cross the blood-brain barrier and has been used with success in a limited number of animals. Trimethoprim-sulfadiazine (15 mg/kg PO q12h) can be used as an alternate anti-*Toxoplasma* drug, especially in combination with pyrimethamine (1 mg/kg/day), but if this is used for long-term treatment, folic acid supplementation should be considered; there may be some toxicity in cats. Azithromycin (10 mg/kg PO q24h) has been used successfully in some cats. Regardless of therapy, prognosis for recovery is grave in animals with profound neurologic dysfunction. Affected cats should be routinely tested for concurrent feline leukemia virus (FeLV) and FIV infections. Neurologic, ocular, and muscular manifestations of toxoplasmosis are not usually associated with patent infection and oocyte shedding in cats, so isolation of affected animals is not necessary.

NEOSPOROSIS

Neospora caninum is a protozoan parasite that causes neuromuscular and CNS disease in dogs. Clinical disease in naturally infected cats has not been reported. Domestic dogs and coyotes are definitive hosts, shedding oocysts in their stool after ingestion of *N. caninum* cysts in muscle from intermediate hosts (primarily deer and cattle). The predominant route of transmission is transplacental, causing acute symptomatic infection in some puppies and subclinical infection leading to encystment in neural and muscle tissues in others.

Congenitally infected puppies 6 weeks to 6 months of age typically develop rear limb weakness, loss of patellar reflexes, quadriceps muscle atrophy, and finally LMN paralysis of the rear limbs as a result of inflammation of the muscles and nerve roots (Fig. 64.4). Multiple puppies from a litter may be affected. If treatment is not initiated promptly, severe denervation atrophy of the muscles and myositis leads to irreversible fibrous contracture of the quadriceps and gracilis muscles fixing the rear limbs in rigid extension (Fig. 64.5). Most affected puppies are bright and alert and otherwise normal. Rarely, untreated dogs develop similar progressive signs involving the forelimbs or even brain signs.

Serum CK may be mildly to moderately increased in affected puppies. Serology can be used to support the diagnosis of neosporosis, but negative results are common in acute disease. Organisms can sometimes be detected using immunohistochemical stains in areas of lymphoplasmacytic inflammation in muscle biopsies. CSF may be normal or there may be a mild mixed inflammatory pleocytosis. A presumptive diagnosis of pediatric neosporosis is usually made based on the characteristic signs of rear limb weakness, quadriceps muscle weakness and atrophy, and loss of the patellar reflex. Treatment is initiated while test results are still pending. Clindamycin hydrochloride 10 mg/kg q8h is administered for 4 to 12 weeks. Rapidly progressive signs, delayed treatment, and pelvic limb hyperextension are associated with a poor prognosis for recovery.

Disease in older animals usually results from reactivation of a chronic encysted infection acquired congenitally or through ingestion of tissue cysts. These dogs commonly have signs of CNS involvement, with progressive cerebellar signs of hypermetria, cerebellar ataxia, and intention tremor most common. Paraparesis, tetraparesis, seizures, vestibular signs, and cranial nerve abnormalities have all been reported, and some dogs have concurrent myositis. Most affected dogs are systemically normal, but occasionally systemic neosporosis will occur, causing fever, pneumonia, hepatitis, pancreatitis, esophagitis, or pyogranulomatous dermatitis.

Hematologic and biochemical findings vary and depend on the organ systems involved. In dogs with myositis, serum CK and aspartate aminotransferase (AST) activities may be increased. Some puppies with clinically evident neosporosis will have negative serology, but most affected adult dogs have positive titers. Adult dogs with CNS neosporosis may have normal CSF or may have mild increases in protein concentration and leukocyte count, with monocytes, lymphocytes, and neutrophils predominating and rarely eosinophils. Inflammatory CSF should always prompt serologic and CSF testing for a variety of infectious agents including *Neospora* before initiating treatment for a presumed noninfectious inflammatory disorder. *Neospora*-specific antibodies or organism DNA (PCR) may be detected in the CSF from adult dogs with neosporosis. Immunocytochemical staining can be used to identify *Neospora* and differentiate it from *Toxoplasma* in muscle biopsies from dogs with myositis. When there is a high clinical suspicion for neosporosis because of typical signs in a young dog, treatment should be initiated promptly instead of waiting for test results.

Treatment with clindamycin hydrochloride (10 mg/kg PO q8h or 15 mg/kg PO q12h for at least 4-8 weeks) is most

FIG 64.4
Ten-week-old Irish Wolfhound puppy with crouched rear limb stance, quadriceps muscle weakness, and atrophy and patellar areflexia caused by *Neospora caninum* myositis and lumbar radiculoneuritis. This dog recovered after clindamycin treatment.

FIG 64.5
Young Labrador Retriever with rigid extension of the rear limbs caused by pediatric neosporosis.

effective in puppies and dogs without severe neurologic signs. Multifocal signs, rapid progression of signs, pelvic limb rigid hyperextension, and delayed treatment are all associated with a poor prognosis for recovery.

LYME DISEASE

Lyme neuroborreliosis resulting from CNS infection by the spirochete *Borrelia burgdorferi* has been well documented in people, but there are few reports of dogs with neurologic signs convincingly caused by Lyme disease. Most affected dogs have had concurrent polyarthritis, lymphadenopathy, and fever. Reported signs of neurologic system involvement include aggression, other behavior changes, and seizures. CSF may be normal or only slightly inflammatory, and there may be an increase in anti–*B. burgdorferi* antibody in the CSF compared with serum. Although it is rare, Lyme neuroborreliosis should be considered in the differential diagnosis of disease involving the CNS in dogs from endemic regions. Early antibiotic treatment may be effective, but it is important to select an effective antibiotic capable of reaching high concentrations in the CSF. Subcutaneous (SC) or IV ceftriaxone (25 mg/kg q24h for 14-30 days), oral doxycycline (10 mg/kg PO q12h for 30 days), and oral amoxicillin (20 mg/kg PO q8h for 30 days) have all been recommended.

MYCOTIC INFECTIONS

Disseminated systemic mycotic infections may occasionally involve the CNS and eyes. Clinical findings depend on the fungus involved and typically include fever, weight loss, severe respiratory or gastrointestinal signs, lymphadenopathy, or lameness in patients with neurologic and ocular signs. The most common neurologic signs are depressed mentation, behavior change, seizures, circling, and paresis. Ocular examination may reveal uveitis, chorioretinitis, retinal detachment, or optic neuritis. Typical abnormalities on CSF analysis include a neutrophilic pleocytosis and increased protein content. Diagnosis usually relies on finding the organism in extraneural infected tissues. Therapy may be attempted, but the prognosis is poor when the nervous system is involved. Fluconazole (5 mg/kg PO q12h for 3-4 months) or voriconazole (6 mg/kg PO q24h) may be the most effective antifungal drugs for most CNS or ocular fungal infections.

It is uncommon for systemic mycoses to present with neurologic signs alone. The exception is infection caused by the encapsulated yeasts *Cryptococcus neoformans* and *Cryptococcus gatti*. These organisms have a predilection for the CNS in the dog and cat. Infection occurs via inhalation, and CNS infection occurs by extension from the nose through the cribriform plate and via hematogenous dissemination. Cats are often presented for signs of nasal and sinus infection that progresses to neurologic, ocular, and sometimes cutaneous involvement. Dogs are more often presented for neurologic signs without clinical signs related to systemic infection. Neurologic signs seen in both species include mentation change, blindness, seizures, vestibular signs, paresis, ataxia, and neck or spinal pain.

MRI in most dogs and some cats with CNS *Cryptococcus* reveals focal or multifocal ill-defined contrast enhancing inflammatory parenchymal lesions and meningeal enhancement. A few cats have normal MRI images, and others have multifocal parenchymal mass lesions that enhance only peripherally, representing accumulations of fungal organisms and capsular material without much inflammation—gelatinous pseudocysts.

In most dogs and cats with cryptococcal meningoencephalitis, CSF analysis reveals increased protein concentration and cell counts. A neutrophilic pleocytosis is most common, but mononuclear cells and eosinophils have been reported. Organisms can be visualized in the CSF in up to 60% of cases. Fungal culture of the CSF should be considered in animals with inflammatory CSF in which no organisms are visible. Cytologic examination of nasal exudate, draining tracts, enlarged lymph nodes, and granulomas located extraneurally usually yields the diagnosis. The organism is readily visible using Gram stain, India ink, or Wright stain. Detection of capsular antigen in the CSF or serum of affected animals using cryptococcal antigen latex agglutination serology (CALAS) is a sensitive and specific test in dogs and cats. Treatment of CNS cryptococcal infection is usually attempted using amphotericin B or fluconazole, both of which penetrate the CNS. Mortality is high during the first few weeks of treatment. Long-term survival is possible but may require intermittent or continuous lifelong therapy. Prognosis is related to the extent and severity of neurologic involvement (see Chapter 97 for more information).

RICKETTSIAL DISEASES

A number of tick-borne rickettsial diseases can cause neurologic abnormalities in dogs. Rocky Mountain spotted fever (RMSF), caused by infection with *Rickettsia rickettsii,* is the most likely to cause severe neurologic signs, but infection with *Ehrlichia canis, Anaplasma phagocytophilum,* and *Ehrlichia ewingii* have also been reported to cause neurologic signs in dogs. Neurologic signs with each of these diseases may be associated with vasculitis and include depression, altered mentation, neck or spinal pain, paresis, ataxia, tremors, vestibular signs, and seizures. Neurologic abnormalities have not been recognized in dogs without concurrent systemic disease. Signs of systemic disease depend on the organism involved and the degree of involvement of other organ systems but may include fever, anorexia, depression, vomiting, oculonasal discharge, cough, dyspnea, lameness, and lymphadenopathy.

Although the number of cases reported is small, neutrophils seem to predominate in the CSF of dogs with RMSF, whereas lymphocytes or neutrophils predominate in ehrlichiosis; CSF is normal in some dogs with each disease. In some dogs with acute *A. phagocytophilum* and *E. ewingii* infections, neutrophils in the blood, synovial fluid, or CSF may contain morulae. Serologic testing or PCR (blood or CSF) is essential to confirm the diagnosis of rickettsial infection and differentiate between these diseases. Treatment with doxycycline (5-10 mg/kg PO or IV q12h) is effective in most

cases. Short-term treatment with corticosteroids may also be warranted. Dramatic clinical improvement should be expected within 24 to 48 hours of initiating treatment. The presence of neurologic signs may slow recovery, and in some cases the neurologic damage is irreversible (see Chapter 97 for more information on rickettsial diseases).

PARASITIC MENINGITIS, MYELITIS, AND ENCEPHALITIS

Meningitis and meningoencephalitis caused by aberrant parasite migration have been reported in the dog and cat. In these diseases, migration and growth of parasites can result in extensive damage to the neural parenchyma. An eosinophilic CSF pleocytosis should prompt consideration of parasitic migration through the CNS, although several more common neurologic disorders should also be considered, including intracranial neoplasia, toxoplasmosis, neosporosis, GME, and idiopathic EME. Diagnostic evaluation of animals with eosinophilic CSF should include a fundic examination, CBC, serum biochemistry profile, urinalysis, serum and CSF titers for *Toxoplasma* and *Neospora,* thoracic and abdominal radiographs, abdominal ultrasound, fecal flotation, and heartworm antigen testing. CT and MRI may document necrosis along the path of parasite migration within the CNS. Definitive diagnosis of parasitic CNS disease requires pathologic demonstration of the parasite in the CNS. Empirical treatment with ivermectin should be considered if parasite migration is likely (200-300 µg/kg PO or SC every 2 weeks for 3 treatments). Antiinflammatory treatment with prednisone may also be indicated.

CHAPTER 65

Disorders of the Spinal Cord

GENERAL CONSIDERATIONS

Spinal cord disorders can be caused by anomalies, degeneration, neoplasia, inflammatory conditions, external trauma, internal trauma from disk extrusion, hemorrhage, or infarction (Box 65.1). Clinical signs depend on lesion location and severity and frequently include focal or generalized pain, paresis, ataxia, paralysis, and occasionally an inability to urinate. Examination of the signalment, history, onset, and progression of the disease can provide valuable information necessary for establishing a likely cause. Neoplasia and type II intervertebral disk (IVD) protrusion occur most commonly in middle-aged and older dogs. Congenital malformations are present at birth, generally do not progress, and are often breed-associated. Type I disk extrusions primarily occur in chondrodystrophic small breeds of dogs, whereas Cavalier King Charles Spaniels are predisposed to Chiari-like malformations and syringomyelia. External trauma, traumatic IVD extrusions, vascular disorders (hemorrhage or infarction), and most type I IVD extrusions are associated with peracute or acute nonprogressive signs of spinal cord dysfunction (see Box 65.1). Infectious and noninfectious inflammatory disorders typically have a subacute and progressive course, whereas tumors and degenerative processes are most often slowly progressive.

LOCALIZING SPINAL CORD LESIONS

Once a complete neurologic examination has been performed and gait, postural reactions, proprioception, strength, muscle tone, spinal reflexes, and painfulness have all been assessed, it is possible to identify the location of a spinal cord lesion. Functionally, the spinal cord can be divided into four regions: the cranial cervical spinal cord (C1-C5), cervical intumescence (C6-T2), thoracolumbar region (T3-L3), and lumbar intumescence (L4-S3). Signs allowing localization of spinal cord lesion to each site are listed in Table 65.1.

C1-C5 LESIONS

Lesions of the cranial cervical spinal cord cause upper motor neuron (UMN) paresis in all four limbs. Because the spinal cord pathways to the rear limbs are longer and more superficially located in the cord than those to the forelimbs, rear limb UMN deficits are almost always worse than forelimb deficits in patients with mild compressive lesions of the C1-C5 spinal cord segments. Most lesions of the C1-C5 spinal cord cause a classical UMN gait in all four limbs, including a long-strided ataxic gait, postural reaction deficits, decreased proprioception (slow knuckling, toe scuffing), increased extensor muscle tone, and normal to increased spinal reflexes in all four limbs. Animals with C1-C5 lesions often exhibit overextension of their thoracic limbs as they move, resulting in an overreaching or floating forelimb gait that should not be confused with the hypermetria associated with cerebellar disease, where each limb is overflexed on protraction. Unilateral lesions of the cervical cord cause hemiparesis and UMN signs affecting the ipsilateral rear limbs and forelimbs. Cervical lesions are rarely severe enough to cause loss of deep pain sensation; such a severe injury would be expected to cause complete respiratory paralysis and rapid death. Central cord lesions (e.g., intramedullary neoplasia, infarcts, hydromyelia) in the C1-C5 region occasionally cause severe UMN deficits in the forelimbs but nearly normal rear limbs (central cord syndrome) because the more superficially located white matter tracts to the rear limbs are spared, whereas the more centrally located ascending and descending tracts to the forelimbs are affected.

C6-T2 LESIONS

Spinal cord lesions between segments C6 and T2 result in paresis of all four limbs and GP ataxia in the rear limbs. The C6-T2 spinal cord segments contain the cell bodies of the nerves of the brachial plexus, so lower motor neuron (LMN) signs of weakness, a short-strided "choppy" gait, rapid muscle atrophy, and hyporeflexia predominate in the forelimbs. The ascending and descending spinal cord tracts to the pelvic limbs pass through this region, so C6-T2 lesions cause UMN deficits in the rear limbs including ataxia, a long stride, loss

BOX 65.1

Common Spinal Cord Disorders

Acute (Minutes to Hours)

External trauma
Hemorrhage/vascular infarction
Type I intervertebral disk extrusion
Traumatic disk extrusion
Fibrocartilaginous embolism
Atlantoaxial subluxation*

Subacute Progressive (Days to Weeks)

Infectious meningoencephalomyelitis
Noninfectious inflammatory disease
  Granulomatous meningoencephalitis (GME), others
  Aseptic meningitis (usually painful, normal neurologic exam)
Diskospondylitis (usually painful, normal neurologic exam)
Type I intervertebral disk extrusion*
Rapidly growing tumors (lymphoma, metastatic neoplasia)

Chronic Progressive (Months)

Neoplasia
Spinal articular cysts
Spinal arachnoid diverticula
Type II intervertebral disk protrusion
Degenerative myelopathy
Cauda equina syndrome
Cervical spondylomyelopathy

Progressive in Young Animals

Neuronal abiotrophies and degenerations
Metabolic storage diseases
Atlantoaxial instability
Syringomyelia/hydromyelia

Congenital (Constant)

Spina bifida
Caudal dysgenesis of Manx cats
Spinal dysraphism

**Atypical onset/progression for this disorder.*

TABLE 65.1

Neurologic Findings in Dogs and Cats With Spinal Cord Lesions

SITE OF LESION	THORACIC LIMBS	PELVIC LIMBS
C1-C5	UMN	UMN
C6-T2	LMN	UMN
T3-L3	Normal	UMN
L4-S3	Normal	LMN

LMN, Lower motor neuron signs; *UMN,* upper motor neuron signs.

of proprioception, delayed postural reactions, increased extensor muscle tone, and normal to increased reflexes. When C6-T2 lesions are unilateral, ipsilateral forelimbs and rear limbs will be affected. Horner syndrome may be seen if the T1-T2 spinal cord segments or nerve roots are involved (see Chapter 61), and the ipsilateral cutaneous trunci reflex may be lost if the C8-T1 spinal cord segments or nerve roots are damaged. Because the phrenic nerve originates at C5-C7, a severe lesion in this region could also cause diaphragmatic paralysis. When C6-T2 lesions affect only the central cord, the superficially located long tracts to the rear limbs are spared, so the forelimb LMN signs may be much more pronounced than the rear limb UMN signs.

T3-L3 LESIONS

Spinal cord lesions between segments T3 and L3 cause UMN paresis and ataxia affecting the rear limbs (see Table 65.1), but forelimbs are normal. Examination of the rear limbs reveals a long uncoordinated stride, loss of proprioception, delayed postural reactions, increased extensor muscle tone, and normal to increased reflexes. As compressive spinal cord lesions in this region become more severe, a predictable worsening of neurologic deficits (Fig. 65.1) and gait deterioration follow. With severe focal lesions in this region, there may be a loss of superficial sensation and the cutaneous trunci reflex caudal to the lesion site. Identification of the spinal location caudal to which the cutaneous trunci reflex (panniculus) disappears and demonstration of a focal site of hyperpathia (painfulness) can greatly assist in the localization of severe T3-L3 spinal cord lesions.

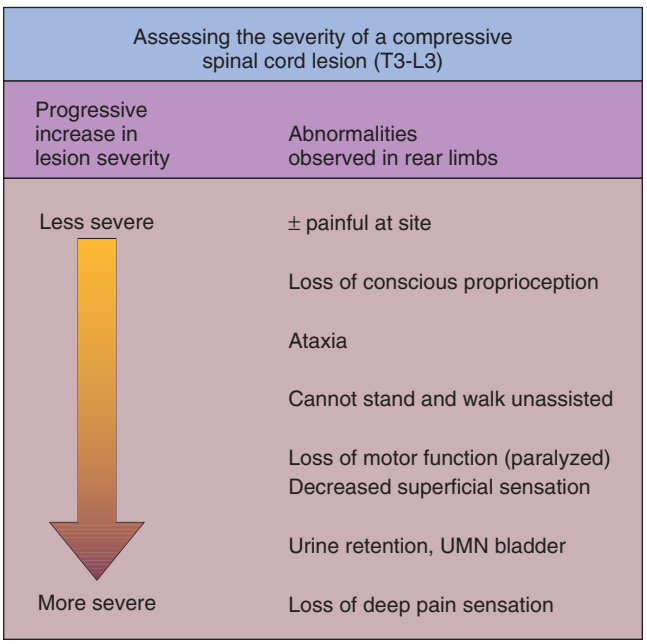

FIG 65.1
Assessing severity of a compressive lesion of the T3-L3 spinal cord.

L4-S3 LESIONS

Lesions affecting the lumbar intumescence cause LMN signs in the rear limbs. Severe weakness, muscle atrophy, and loss of reflexes are apparent in the rear limbs, whereas the forelimbs are normal. Animals that can still walk exhibit a weak, short-strided rear limb gait. Bladder dysfunction and paresis or paralysis of the anal sphincter and tail are also common with severe lesions affecting the sacral cord segments. Lesions that compress the lumbar, sacral, and caudal nerve roots as they extend caudally from the end of the spinal cord within the vertebral canal (cauda equina) typically cause pain at the site and, when severe, cause LMN dysfunction as well.

DIAGNOSTIC APPROACH

Lesions should be localized to a spinal cord region on the basis of the neurologic examination. It is important to recognize that spinal cord segments do not correlate directly with vertebral location in the dog and cat (Table 65.2; Fig. 65.2). The C6-T2 spinal cord segments of the cervical intumescence are located within vertebrae C4-T2. The L4-S3 spinal cord segments of the lumbar intumescence are located within vertebrae L3-L5 in dogs and L3-L6 in cats. The spinal cord is shorter than the vertebral canal, with the caudal segments ending at approximately the L6 vertebra in dogs and the L7 vertebra in cats. The nerve roots arising from the L7, sacral, and caudal spinal cord segments (cauda equina) course caudally within the vertebral canal to their site of exit immediately caudal to the vertebra of the same number and are susceptible to compressive damage in the lumbosacral region (see discussion of cauda equina syndrome).

Once spinal cord lesions are localized to the proper regional spinal cord segments and vertebrae, imaging and further diagnostic testing will usually be necessary to establish a diagnosis. Radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) of the vertebral bodies that house the affected spinal cord segments may be useful. Vertebral radiographs can be used to identify vertebral

malformations, subluxation caused by trauma, diskospondylitis, vertebral fractures, intervertebral disk disease (IVDD), and lytic vertebral neoplasms. CT is a good imaging modality for all of these same lesions affecting bone and for identification and localization of calcified IVD extrusions. Myelography can be used to localize compressive spinal cord lesions either alone or with CT. MR imaging is the best tool for evaluating the spinal cord as it allows identification of compressive, expansive, or infiltrative lesions within the spinal canal and allows assessment of spinal cord parenchyma. Cerebrospinal fluid (CSF) analysis can be performed to look for evidence of neoplasia or inflammation. When infectious or neoplastic disorders are considered as differentials for a myelopathy, systemic screening tests such as thoracic and abdominal radiographs, abdominal ultrasound, lymph node aspirates, complete ophthalmic examination, infectious disease serology, and tissue biopsies should be considered to help determine the diagnosis. Rarely, surgical exploration or biopsy of the spinal cord at the affected site will be required to achieve a diagnosis, gauge prognosis, and recommend treatment.

PERACUTE OR ACUTE SPINAL CORD DYSFUNCTION

TRAUMA

Traumatic injuries to the spinal canal are common, with fractures and luxations of the spine and traumatic disk extrusion being the most frequent consequences. Severe spinal cord bruising and edema can occur secondary to trauma, even without disruption of the bony spinal canal.

Clinical Features

Clinical signs associated with spinal trauma are acute and generally nonprogressive. Animals are usually in pain, and other evidence of trauma (e.g., shock, lacerations, abrasions, fractures) may be present. Neurologic findings depend on lesion location and severity. Neurologic examination should determine the location and extent of the spinal injury. Excessive manipulation or rotation of the animal should be avoided until the vertebral column is determined to be stable.

Diagnosis

A diagnosis of trauma is readily made on the basis of the history and physical examination findings. A thorough and rapid physical examination is important to determine whether the animal has life-threatening nonneurologic injuries that should be addressed immediately. Concurrent problems may include shock, pneumothorax, pulmonary contusions, diaphragmatic rupture, ruptured biliary system, ruptured bladder, orthopedic injuries, and head trauma. Concern that the animal may have vertebral column instability warrants use of a stretcher or board to restrain, examine, and transport the dog or cat in lateral recumbency.

The neurologic examination can be performed with the animal in lateral recumbency but will be limited to evaluation of mental status, cranial nerves, posture, muscle tone, voluntary movement, spinal reflexes, the cutaneous trunci reflex, and pain perception. Dogs with severe thoracic spinal cord lesions may exhibit the Schiff-Sherrington posture (see Fig. 58.8). The most important prognostic indicator after spinal trauma is the presence or absence of nociception or deep pain sensation. If deep pain is absent caudal to a traumatic thoracolumbar spinal cord lesion, the prognosis for functional recovery is poor, and, regardless of treatment, about 20% of dogs will develop ascending descending myelomalacia (see p. 1142) in the hours or days after injury.

The neurologic examination allows determination of the neuroanatomic site of the lesion. Survey radiographs or CT can then be used to more specifically localize the lesion, assess the degree of vertebral damage and displacement, and aid in prognosis. Manipulation or twisting of unstable areas of the spine must be avoided during imaging. If the animal is recumbent or restrained on a board, lateral and cross-table ventrodorsal radiographs allow assessment for the presence or absence of fractures or an unstable vertebral column. CT is a much more accurate means to assess vertebral damage than radiography, whereas MRI is superior for evaluating spinal cord parenchyma.

The *entire* spine should be assessed. Most spinal fractures and luxations occur at the junction of mobile and immobile regions of the spine, such as the lumbosacral junction or the thoracolumbar, cervicothoracic, atlantoaxial, or atlantooccipital regions. Multiple fractures occur in some 10% of trauma patients and are easily missed. Neurologic signs caused by LMN lesions at an intumescence can mask UMN lesions located more cranially in the spinal cord, so imaging and clinical evaluation of all spinal regions are important. When lesions identified using imaging do not correspond completely with clinical neuroanatomic localization, further investigation is required.

Various classification schemes exist to determine the stability of vertebral injuries and the need for surgery. The vertebral body can be divided into three compartments and each assessed using radiographs or CT for damage (Fig. 65.3). When two of the three compartments are damaged or displaced, the fracture is considered unstable. Unstable fractures generally require surgical intervention or splinting, whereas stable fractures without significant ongoing spinal cord compression can usually be managed conservatively. Splints are most effective when deep pain sensation is present, ventral and middle compartments are intact, and associated soft tissue injuries are minimal. Most dogs with cervical or lumbosacral injury are managed nonsurgically unless the patient deteriorates neurologically or remains in a great deal of pain 72 hours after injury, which suggests nerve root entrapment. Surgery is preferred for unstable thoracic and lumbar spinal injuries.

Treatment

Primary treatment of animals with acute spinal injury involves evaluation for and treatment of other life-threatening

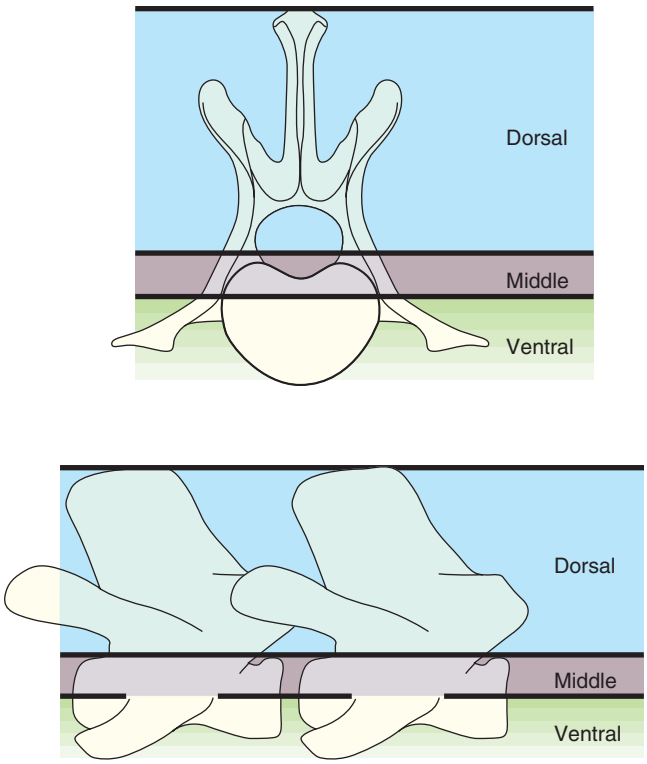

FIG 65.3
Illustration of the three-compartment model for radiographic evaluation of spinal fractures. Dorsal compartment includes articular facets, laminae, pedicles, spinous processes, and supporting ligaments. Middle compartment contains the dorsal longitudinal ligament, dorsal annulus, and the floor of the spinal canal. Ventral compartment consists of the remainder of the vertebral body and the annulus, nucleus pulposus, and ventral longitudinal ligament. When two or three of the compartments are damaged or displaced, surgical stabilization is indicated.

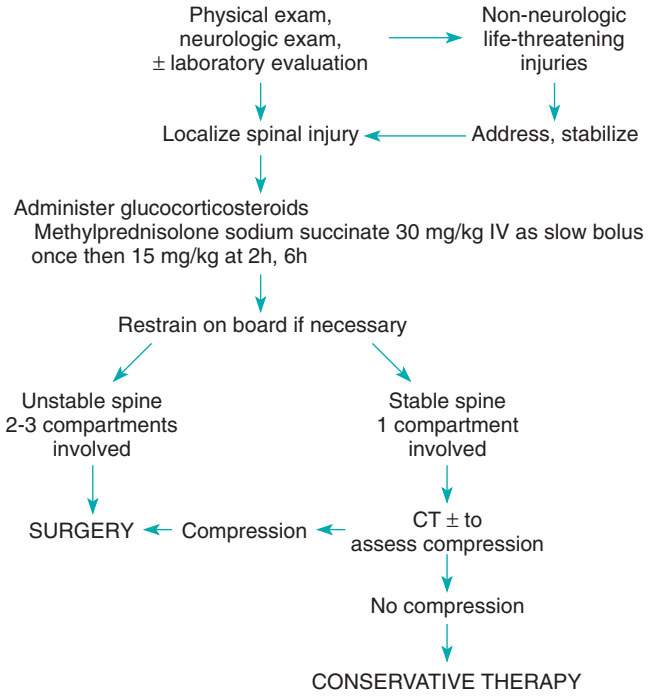

FIG 65.4
Algorithm for management of acute spinal trauma.

injuries and maintenance of patient blood pressure, perfusion, and oxygenation. There is weak experimental evidence that intravenous (IV) administration of methylprednisolone sodium succinate (MPSS), a highly soluble corticosteroid with neuroprotective effects exerted primarily by its actions as a free-radical scavenger, within 8 hours of trauma may be beneficial (Fig. 65.4). Unfortunately, a few dogs treated according to this protocol suffer from serious gastrointestinal complications. Adverse effects should be monitored and may be decreased by concurrent administration of an H_2-receptor blocker (oral [PO] or IV ranitidine, 2 mg/kg q8h; or famotidine, 0.5 mg/kg PO or IV q24h), a proton pump inhibitor (omeprazole, 0.7-1.5 mg/kg/day) or a synthetic prostaglandin E_1 analog (misoprostol, 2-5 µg/kg PO q8h), and a mucosal protectant (sucralfate, 0.25-1 g PO q8h; see Chapter 28).

Intensive nursing care is critically important in dogs and cats managed conservatively or surgically. Narcotic analgesics may be administered as needed (Table 65.3). Thickly padded, clean, dry cages and frequent turning of the patient will help prevent pressure sores. All impaired limbs should be moved repeatedly through a full range of motion many times each day. Maintenance of an indwelling urinary catheter ensures a dry animal but may increase the risk of urinary tract infection, particularly when kept in place for longer than 3 days. When long-term care is necessary, the bladder should be gently expressed or catheterized and emptied four to six times daily and urinary tract infections treated as they occur. In animals with UMN bladders (see Chapter 58) or those with urethral spasm, medical therapy (phenoxybenzamine, 0.25-0.5 mg/kg PO q8h, and diazepam, 0.5 mg/kg q8h) may help relax the urethral sphincter, making bladder expression easier and less traumatic. When an animal starts to regain voluntary motion in the limbs, physical therapy is increased; hydrotherapy or swimming stimulates voluntary movement, improves circulation to the limbs, and cleans the skin.

TABLE 65.3

Narcotic Analgesics Used to Treat Spinal Pain in Dogs

DRUG	DOSAGE
Oxymorphone	0.05 mg/kg IM
Morphine	0.3-2.2 mg/kg, SC or IM
Butorphanol	0.4-0.8 mg/kg SC
Buprenorphine	0.02-0.06 mg/kg, IM or SC

IM, Intramuscular; *SC,* subcutaneous.

Prognosis

Prognosis for recovery depends on the site and severity of injury. Unstable cervical vertebral fractures are associated with very high mortality at the time of trauma and also in the perioperative period. Prognosis for recovery is good if affected animals do not die acutely from respiratory dysfunction. Animals with thoracic and lumbar spinal cord injury and intact voluntary motion have a good prognosis for return of full function. Animals that are paralyzed but retain deep pain and normal bladder function have a fair prognosis for recovery, although they may have residual neurologic deficits. Animals presenting after spinal trauma with no deep pain sensation rarely recover. Lesions of the white matter producing strictly UMN signs may have a better prognosis for full recovery than lesions affecting clinically important LMNs at the cervical or lumbar intumescence. In any animal with paralysis caused by a spinal cord injury, if no signs of improvement are evident by 21 days after injury, the prognosis for recovery is poor.

HEMORRHAGE/INFARCTION

Nontraumatic hemorrhage into the spinal canal causing acute neurologic deficits and sometimes pain (i.e., hyperesthesia) has been recognized in young dogs with hemophilia A, dogs of any age with von Willebrand disease, dogs and cats with acquired bleeding disorders (i.e., warfarin intoxication, thrombocytopenia, disseminated intravascular coagulation), dogs with vascular anomalies (i.e., aneurysms, arteriovenous fistulas), and dogs and cats with primary or metastatic spinal neoplasia that bleeds (i.e., lymphoma, hemangiosarcoma). Signs occur acutely and are minimally progressive, with neurologic signs reflecting the site and severity of spinal cord damage or compression. Bleeding into the subarachnoid space can cause inflammation (meningitis) and pain. Antemortem diagnosis usually requires advanced diagnostic imaging (i.e., MRI), although identification of a systemic bleeding disorder or neoplasia can suggest the diagnosis. Treatment should be initiated to resolve the cause of bleeding, and surgical decompression of the spinal cord will rarely be required.

Spinal cord infarction by a blood clot is a rare cause of peracute neurologic dysfunction in dogs and cats. Signs are referable to the site and severity of the vascular compromise. Blood stasis, endothelial irregularity, hypercoagulability, and impaired fibrinolysis are all known predisposing factors for thromboembolism (see Chapter 12). Cardiomyopathy, hyperadrenocorticism, protein-losing nephropathy, immune-mediated hemolytic anemia, heartworm disease, vasculitis, and disseminated intravascular coagulation have all been associated with an increased risk of systemic thrombosis and can occasionally result in regional spinal cord infarction. Treatment consists of general supportive care and anticoagulant medications to decrease the risk of further infarction, but antemortem definitive diagnosis is difficult and prognosis for recovery is poor.

ACUTE INTERVERTEBRAL DISK EXTRUSION

The intervertebral disks are composed of an outer fibrous layer (annulus fibrosus) and a gelatinous center (nucleus pulposus). With normal aging the nucleus is gradually replaced by fibrocartilage. In some dogs, particularly the chondrodystrophoid breeds, the nucleus matrix degenerates, dehydrates, and mineralizes, making these dogs prone to acute disk rupture. Acute extrusion of mineralized nucleus pulposus into the spinal canal through the dorsal annulus causing bruising or compression of the spinal cord is classified as a Hansen type I IVD extrusion (Fig. 65.5). This type

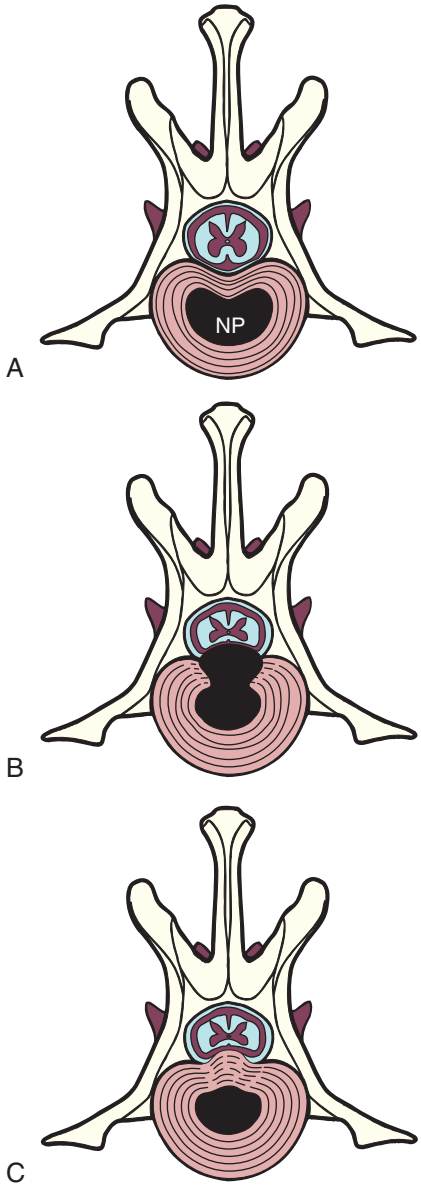

FIG 65.5
(A) Normal relationship between the intervertebral disk and spinal cord. **(B)** Hansen type I disk extrusion, wherein the NP herniated into the vertebral canal through a ruptured annulus fibrosus. **(C)** Hansen type II disk protrusion, with bulging of the thickened annulus into the vertebral canal. *NP,* Nucleus pulposus.

of disk injury is most common in small-breed dogs like the Dachshund, Toy Poodle, Pekingese, Beagle, Welsh Corgi, Lhasa Apso, Shih Tzu, Chihuahua, and Cocker Spaniel, with a peak incidence between 3 and 6 years of age. Dachshunds are the breed most often presented for thoracolumbar IVD extrusions, whereas cervical IVD extrusions are most common in Beagles. Acute type I IVD extrusions also occasionally occur in middle-aged and older large-breed dogs, particularly in Basset Hounds, Labrador Retrievers, Dalmatians, Shar Peis, Border Collies, Rottweilers, Doberman Pinschers with caudal cervical spondylomyelopathy (CSM), and German Shepherd dogs. Intervertebral disk extrusion is a rare cause of clinically evident spinal cord compression in the cat, occurring in older cats (mean age, 9.8 years) and typically affecting the lower thoracic and lumbar regions (most commonly, L4/L5).

Clinical Features

Pain is a prominent feature in most dogs with acute IVD extrusion. The extruded material compresses the highly innervated nerve roots and meninges, causing pain. Some dogs with acute IVD extrusion are presented with spinal pain and no accompanying neurologic deficits. Others suffer concussive or compressive injury to the spinal cord from the disk extrusion and are presented with varying degrees of spinal cord injury. Clinical signs depend on the location of the spinal injury, severity of cord bruising, and degree of spinal cord compression.

Cervical disk extrusions (C1-C5) most commonly cause neck pain without associated neurologic deficits, even when large masses of disk material extrude into the spinal canal. This is because the vertebral canal in the cervical region has a very wide diameter with space around the cord, making significant spinal cord compression uncommon. Affected dogs guard their neck from movement and may vocalize when they shift position. Many affected dogs will exhibit root signature—limping on one forelimb and holding it up when standing (Fig. 65.6) in response to muscle spasm. If significant spinal cord compression does occur in the cervical region, UMN signs will be seen in all four legs.

Acute disk extrusion in the thoracolumbar (T3-L3) region also causes pain, but there is less room in the vertebral canal around the spinal cord in this region, so T3-L3 disk extrusions often cause significant spinal cord compression as well as back pain. Mildly affected dogs may be neurologically normal but stand with an arched back and exhibit pain on movement, spinal palpation, or being picked up. The severity of neurologic signs can be related to the force of disk extrusion and the extent of cord bruising, but in most cases there will be a typical progression of UMN signs in the pelvic limbs as the degree of T3-L3 spinal cord compression worsens (see Fig. 65.1). Proprioception is lost first, then the ability to rise and walk, then the ability to voluntarily move the rear legs, then bladder control, followed by the ability to feel deep pain. Most IVD extrusions in the T3-L3 region occur at the T11/12, T12/13, T13/L1, and L1/2 sites. Cranial thoracic IVD extrusions are relatively uncommon owing to dorsal stabilization by the intercapital ligaments, but they do occasionally occur, particularly in German Shepherd dogs and Cocker Spaniels. Disk extrusion in the lower lumbar region between the L3/4 and L6/7 disks is less common (10%-15% of dogs) than T3-L3 extrusions, damaging the spinal cord at the lumbar intumescence and resulting in LMN signs. The neurologic signs that occur with spinal cord compression by type I IVD extrusions are usually symmetric, although lateralized disk extrusions can result in asymmetric signs.

FIG 65.6
Adult Beagle with neck and shoulder pain secondary to cervical intervertebral disk prolapse. Lifting of the limb has been referred to as *root signature*.

Diagnostic Approach

Acute IVD extrusion should be suspected as the cause of neurologic dysfunction based upon the signalment, history, physical examination, and neurologic findings. Neurologic examination and detection of a specific area of spinal pain are used to localize the lesion to a particular region of the spinal cord. Animals with IVD extrusion should have no systemic signs of illness (e.g., fever, weight loss) and no specific neurologic abnormalities suggesting intracranial disease. Acute neurologic dysfunction caused by IVD extrusion must be distinguished from fracture/luxation, hemorrhage, or fibrocartilaginous embolism (FCE) through clinical findings and testing.

The amount of workup recommended at the time of presentation will vary. When the diagnosis is fairly certain based upon signalment and history, and clinical findings and neurologic assessment suggest that nonsurgical treatment is warranted, medical management can be recommended without further testing or definitive diagnosis. When clinical findings, history, or signalment make acute IVD extrusion a less likely diagnosis, screening radiographs or CT are indicated. Spinal radiographs can be taken in an awake animal

to look for characteristic features of disk disease and to rule out other diseases (e.g., diskospondylitis, lytic vertebral tumor, fracture, atlantoaxial luxation).

Radiographic observation of calcified disks confirms the presence of generalized IVDD, but, unless there is dorsal displacement of mineralized disk material into the spinal canal, this does not necessarily implicate the disk extrusion as the cause of neurologic dysfunction. Radiographic changes consistent with extrusion of a disk in the thoracolumbar region include a narrowed or wedged disk space, a small or cloudy intervertebral foramen ("horse's head"), narrowing of the facetal joints, and a calcified density in the spinal canal above the involved disk (Figs. 65.7 and 65.8). Many dogs with disk extrusion have multiple abnormal sites, however, and radiographs cannot determine which is the active site causing the current problem. Myelography or advanced diagnostic imaging (i.e., CT, MRI) will be required to definitively localize the site of an extruded disk causing spinal cord compression in animals in which surgical treatment is being considered.

Myelography was once the standard imaging modality for diagnosing and localizing acute disk extrusion in dogs, but this has largely been replaced with the less invasive and more diagnostic CT and MRI (Fig. 65.9). Myelography is a good test to demonstrate the site of disk extrusion but does not (without concurrent CT) reliably determine whether more of the disk material is located on the left or right side of the cord—important information for surgical planning. Collection and analysis of CSF should always be recommended before proceeding with a myelogram, because inflammatory CNS disorders (granulomatous meningoencephalitis [GME], others) can be clinically very similar to disk extrusion and can be very difficult to diagnose once CSF has been altered by instilling myelographic contrast material into the subarachnoid space (see discussion of myelography, Chapter 59).

CT can be used as an adjunct to myelography or as the sole diagnostic procedure to demonstrate spinal cord compression by an extruded disk and to eliminate other bone-related reasons for spinal cord signs (fracture, luxation, vertebral lysis). CT is very quick, can often be performed under sedation instead of general anesthesia, and has diagnostic accuracy similar to myelography for diagnosis and localization of calcified extruded disks. CT myelography may be necessary to determine lateralization of IVD herniation when the extruded disk is not calcified or severe spinal cord swelling is present.

MRI is the best diagnostic method for localizing the site and the side of extruded disks with nearly 100% accuracy (Fig. 65.10). MRI also allows evaluation of the cord parenchyma for injury and edema, which may be associated with prognosis for recovery in patients with loss of deep pain sensation. However, MRI is slower than CT, less readily available, and more expensive, requiring general anesthesia.

Treatment Recommendations

Treatment recommendations for dogs with acute IVD extrusion are based on location of the spinal cord injury and severity of signs noted at the time of presentation (Tables 65.4 and 65.5). Treatment options are conservative (medical) and surgical. Surgery should be recommended when decompression will significantly increase the likelihood, speed, and completeness of recovery.

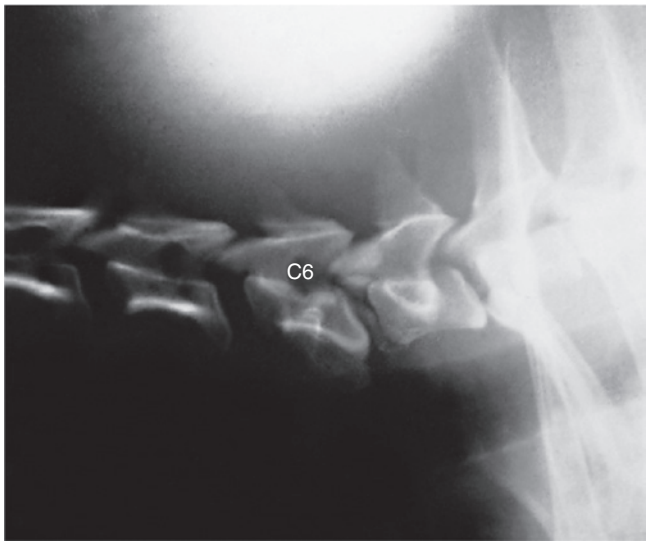

FIG 65.7
Lateral radiograph of the cervical vertebral column of an adult dog showing acute intervertebral disk prolapse at the C6-C7 site. The intervertebral space is narrowed, and a calcified density can be seen in the spinal canal above the disk space.

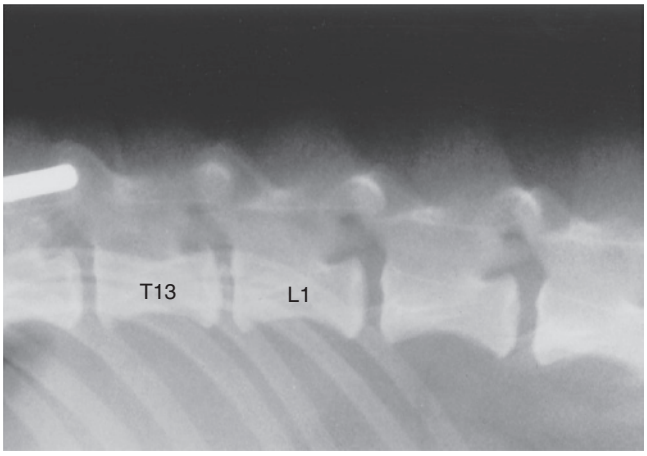

FIG 65.8
Lateral plain radiograph of vertebral column of a 4-year-old Pekingese with acute intervertebral disk prolapse. The intervertebral space between T13 and L1 is narrowed, the intervertebral foramen ("horse's head") is small, and a calcified density can be seen in the spinal canal above the T13-L1 disk space.

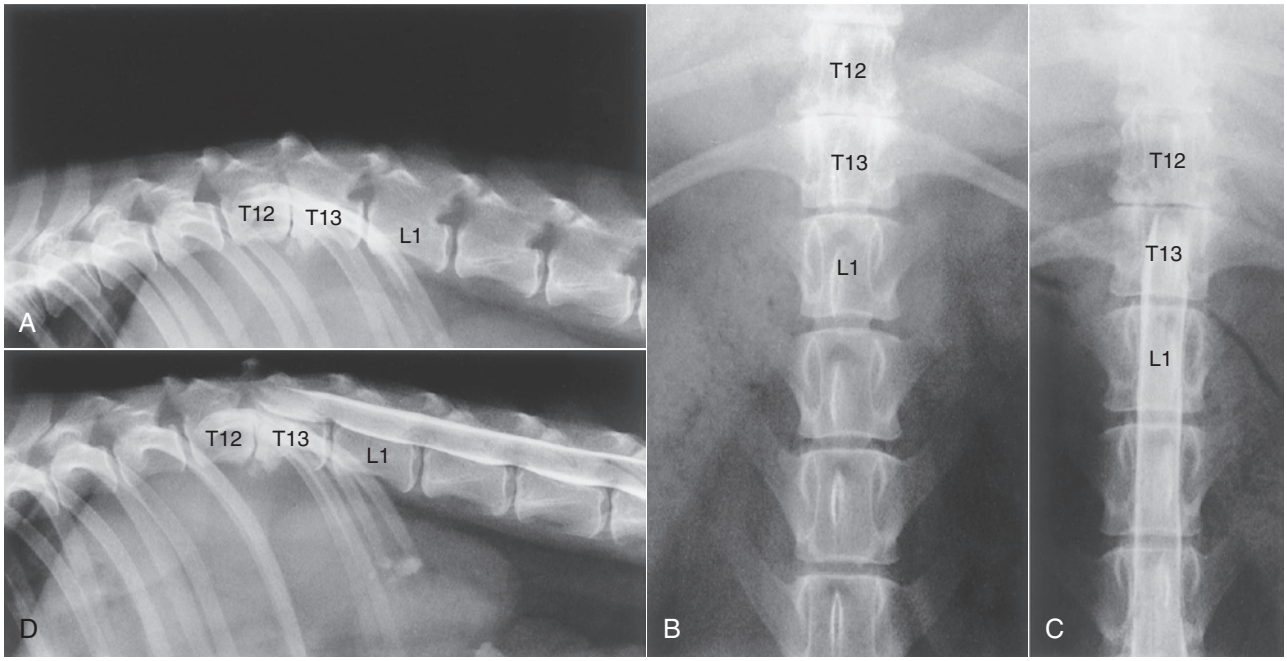

FIG 65.9
Lateral **(A)** and ventrodorsal **(B)** plain radiographs of the vertebral column of an 8-year-old Miniature Schnauzer with acute paralysis after a chronic history of intermittent back pain. Marked collapse of the intervertebral space at T12-T13, a small intervertebral foramen, and clouding of the foramen is evident. The T13-L1 space is also slightly narrowed. **(C)** and **(D)** Myelography confirms the presence of a significant extradural mass at T12-T13 located ventrally and on the right, causing considerable cord compression and displacement. A minimal extradural mass effect also exists at T13-L1, without significant compression. Surgery confirmed spinal cord compression by the disk material at T12-T13.

TABLE 65.4

Classification of Dysfunction and Treatment Recommendations: Canine Cervical Disk Extrusion

GRADE	CLINICAL FINDINGS	TREATMENT
1	Single episode of pain Normal neurologic exam	Cage rest ± analgesics
2	Intractable pain or recurrent pain	Surgical decompression
3	Neurologic deficits ± pain	Surgical decompression

TABLE 65.5

Classification of Dysfunction and Treatment Recommendations: Canine Thoracolumbar Disk Extrusion

CLINICAL FINDINGS	TREATMENT
Single episode of pain Normal neurologic exam	Cage rest ± analgesics
Intractable pain *or* Recurrent pain *or* Deterioration in neurologic status	Surgical decompression
Ataxia, proprioceptive deficits Paraparesis, able to stand and walk	Cage rest ± analgesics
Severe paraparesis, unable to stand and walk	Surgical decompression
Paralyzed	Surgical decompression

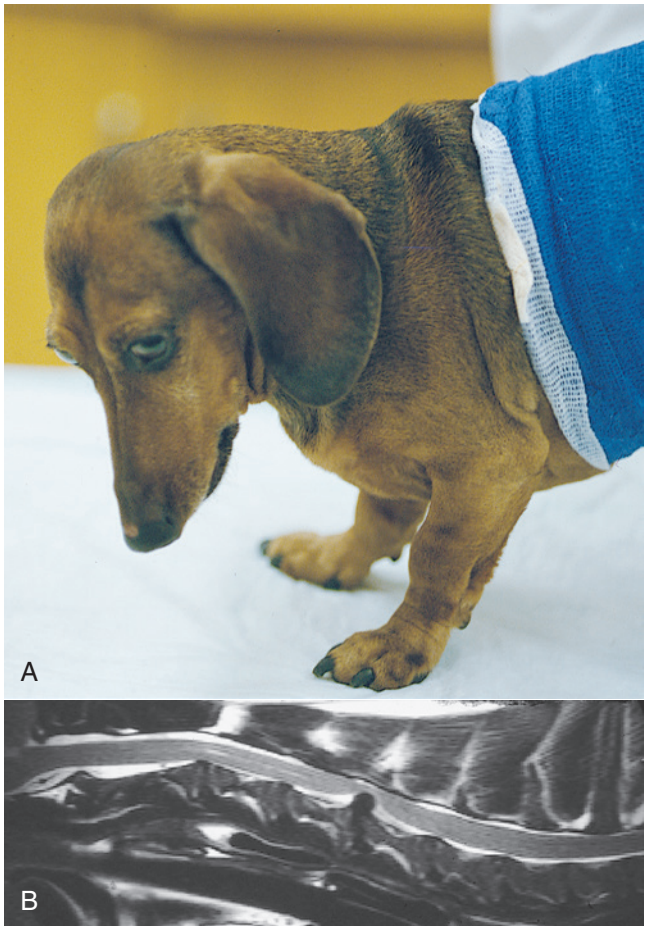

FIG 65.10
(A) This 7-year-old Dachshund had a 3-week history of severe neck pain and mild proprioceptive deficits in the left rear limb. **(B)** Magnetic resonance imaging revealed prolapse of the C3-C4 intervertebral disk, with significant spinal cord compression at that site.

Medical Management

Strict cage rest is the most important part of medical management and must be maintained for a minimum of 4 weeks to allow the annulus to repair. Animals should be kept in a small kennel crate or in the owner's arms at all times except when walked outside with a harness to urinate and defecate. Nonsteroidal antiinflammatory drugs (NSAIDs) or narcotic analgesics (see Table 65.3) can be administered for the first 3 to 5 days if strict confinement is likely to be enforced. Muscle relaxants (methocarbamol, 15-20 mg/kg PO q8h) may help to decrease painful muscle spasms in dogs with cervical disk extrusions, and gabapentin (10-20 mg/kg PO q8h) is sometimes administered when nerve root pain is suspected. Although many veterinarians routinely treat IVD extrusion dogs with glucocorticoids to decrease pain, there is no evidence that this improves the long-term outcome, and there is a high risk of gastrointestinal adverse effects even if low doses are used (prednisone, 0.1-0.2 mg/kg PO bid). Glucocorticoids and NSAIDs should never be administered concurrently. Animals being treated medically must be evaluated frequently for deterioration in neurologic status. After 4 weeks of strict crate confinement, 3 weeks of house confinement with no jumping or running and leash exercise only should be recommended, followed by a gradual increase in monitored exercise and (if necessary) a weight reduction program. Food and water dishes should be elevated and a chest harness should be used instead of a collar in dogs recovering from cervical disk extrusion.

Cervical Disk Extrusion

Approximately 15% of dogs with IVD extrusion have a cervical disk, with the cranial cervical sites (especially C2-3) most frequently affected in small-breed dogs. Dogs with a first episode of acute neck pain and no neurologic deficits are usually managed conservatively with strict cage confinement and analgesics. Most dogs respond at least transiently to conservative medical management, but a few will have intractable pain or recurrent episodes of pain days or weeks later. Dogs with cervical pain that does not resolve with 1 or 2 weeks of conservative management, dogs with severe pain that cannot be controlled short term, dogs with recurrent episodes of neck pain, and dogs that develop even mild UMN paresis or ataxia indicating cervical spinal cord compression should be treated surgically (see Table 65.4). Because the spinal canal is so much larger than the spinal cord in the cervical region, any neurologic evidence of spinal cord compression suggests there is a large amount of disk material within the spinal canal, so recovery will be more complete and rapid if surgery is performed.

When surgery is recommended for cervical IVD extrusion, imaging must be performed to precisely locate the lesion, and surgical decompression is performed using a ventral slot procedure. A small rectangular window of bone is removed from the ventral aspect of the vertebral bodies adjacent to the extruded disk, and the disk material is removed from the spinal canal. Most dogs are in a great deal less pain within 24 to 36 hours after decompressive surgery, and resolution of neurologic deficits usually occurs gradually over 1 to 4 weeks. Exercise should be restricted for 2 weeks, followed by physiotherapy to enhance recovery. The prognosis for full recovery in dogs with neck pain alone or neck pain plus moderately severe tetraparesis is 80% to 90% at 4 weeks. Dogs with paralysis are more likely to have residual deficits, but roughly 80% of these dogs will become ambulatory.

Thoracolumbar Disk Extrusions

Nearly 70% of type I IVD extrusions occur in the T3-L3 region of the spine. Medical management is recommended when there is pain only with no neurologic deficits or when there are mild rear limb neurologic deficits but the dog has good voluntary motion bilaterally and is still able to rise and walk unassisted (see Table 65.5). Dogs should be monitored closely during medical management, because neurologic deterioration or failure to improve within 5 to 7 days should prompt recommendations for surgical intervention. Dogs with thoracolumbar IVD extrusions occasionally have

uncontrollable pain or recurrent episodes of pain that should also prompt a recommendation for surgery.

Surgical treatment is recommended for all patients with thoracolumbar IVD extrusion that are unable to walk at the time of presentation because their rate of recovery will be faster after decompression than after nonsurgical treatment, and the likelihood that they will have residual neurologic deficits is decreased. Surgery may also be recommended in fully ambulatory dogs with less severe spinal cord compression if the owners do not wish to attempt medical treatment or if the neurologic signs or pain do not rapidly resolve with medical therapy.

Whenever surgical treatment is anticipated, preoperative imaging is essential to identify the affected interspace and determine which side to decompress to gain access to disk material. Decompression is usually accomplished through a hemilaminectomy, and disk material is removed from the spinal canal. In addition to surgical decompression, many surgeons recommend concurrent fenestration of the affected site and adjacent high-risk sites (T11-L3) to help decrease the likelihood of subsequent herniations.

Postsurgically, animals must be kept clean and confined. Padded bedding and frequent turning can prevent pressure sores. Complete bladder emptying at least four times daily by manual expression, an indwelling catheter, or intermittent aseptic catheterization is necessary in dogs that have lost bladder function. In dogs with UMN bladders, medical treatment with phenoxybenzamine and diazepam can lower sphincter pressure, facilitating manual expression and attempts by the animal to void. Massage of the limbs and passive physiotherapy, including limb abduction, may help prevent neurogenic atrophy and muscle fibrosis and may lead to a more complete recovery. Towel walking of paraparetic dogs can improve attitude and promote early use of the affected limbs. Once the skin incision has healed, swimming may be instituted to encourage movement. In dogs with a prolonged anticipated recovery period, use of a paraplegic cart can provide a stimulus for recovery (Fig. 65.11). Improvement in neurologic function usually occurs within 1 week of surgery. No improvement after 28 days signals that the prognosis for recovery is poor.

More than 95% of dogs with deep pain perception at the time of evaluation recover fully after effective decompression, with most becoming ambulatory within 14 days after surgery (Table 65.6). Dogs with loss of deep pain perception (grade 5) are very unlikely to recover without surgical intervention, but with rapid decompression (within 12-72 hours), approximately 60% of small-breed dogs and 25% of large-breed dogs will make a functional recovery. If deep pain does not return within 4 weeks, the prognosis for recovery is very poor.

Acute, forceful, IVD extrusions sometimes cause considerable intramedullary hemorrhage and edema as well as spinal cord compression. In approximately 10% of dogs with

FIG 65.11
A paraplegic cart can provide a stimulus for recovery and improve mobility and attitude in paralyzed dogs recovering from thoracolumbar disk surgery.

TABLE 65.6

Results of Treatment for Thoracolumbar Disk Disease

NEUROLOGIC GRADE	CONSERVATIVE % SUCCESS	CONSERVATIVE RECOVERY TIME (WEEKS)	DECOMPRESSION % SUCCESS	DECOMPRESSION RECOVERY TIME (WEEKS)
1 No deficits	>95%	3	>95%	<2
2 Paresis (walking)	84%	6	95%	<2
3 Paresis (not walking)	84%	6	95%	<2
4 Paraplegia	81%	9-12	95%	1-4
5 No deep pain	<10%	—	64%	5-10

thoracolumbar IVD extrusion presenting with complete paralysis and loss of deep pain perception, focal spinal cord damage and swelling result in spinal cord ischemia and progressive myelomalacia of the cord cranial and caudal to the original lesion (i.e., *ascending descending myelomalacia, progressive hemorrhagic malacia*). This condition usually develops within 5 days of the original disk extrusion. Myelomalacia should be suspected when the line demarcating the presence of the cutaneous trunci reflex moves cranially or the patellar and withdrawal reflexes are lost (LMN signs) in the rear limbs of a dog that had UMN paralysis in the rear limbs when first evaluated. Most affected dogs are also very anxious and experience a great deal of pain. When ascending descending myelomalacia is recognized, euthanasia should be recommended; no chance for recovery exists, and most affected dogs will die within a few days of respiratory paralysis.

TRAUMATIC DISK EXTRUSIONS

Exercise or trauma-induced peracute disk extrusions (*Hansen's type III disk extrusion, acute noncompressive nucleus pulposus extrusion: ANNPE*) occur occasionally in dogs without preexisting degenerative disk disease. The sudden explosive rupture of the annulus in these dogs usually occurs during running or jumping or in association with a fall or motor vehicle accident. This results in an acute nucleus pulposus extrusion with neurologic signs caused by spinal cord bruising, hemorrhage, and edema. Predisposed breeds include Border Collies, Labrador Retrievers, Staffordshire Bull Terriers, Sighthounds, and other large-breed athletic dogs. The onset of signs is peracute and associated initially with discomfort, but within 12 to 24 hours there is no site of pain on spinal palpation. Neurologic signs reflect the location and severity of the spinal injury. Asymmetry is common. Spinal radiographs do not reveal evidence of chronic disk degeneration or mineralization, but mild IVD space narrowing is often evident at the site of disk extrusion. Advanced imaging typically reveals a focal area of T2 weighted (T2W) intramedullary spinal cord hyperintensity overlying an IVD space, a reduced volume of the T2W hyperintense nucleus pulposus signal at that site, mild narrowing of the associated disk space, and a variable amount of extradural material in the canal at that site with little or no spinal cord compression. The pathology in these dogs is related to cord bruising and hemorrhage from the force of the disk extrusion without significant spinal cord compression, so surgical decompression is not warranted. Traumatic disk extrusion in older dogs and chondrodystrophic dogs will occasionally (<30%) result in moderate to severe spinal cord compression by extruded disk material requiring surgical decompression so imaging should always be recommended. The recommended treatment for noncompressive traumatic disk extrusion is supportive care and physical therapy. Most dogs that have deep pain sensation will regain the ability to walk within 1 to 4 weeks, but some residual paresis is common. Urinary or fecal incontinence, when present, may take longer to recover from or may be permanent.

FIBROCARTILAGINOUS EMBOLISM

Acute infarction and ischemic necrosis of the spinal cord parenchyma occur when fibrocartilage presumably from the nucleus pulposus of the IVD is embolized into the very small arteries and veins supplying the spinal cord parenchyma and leptomeninges. This causes peracute nonprogressive signs of spinal cord dysfunction affecting any region of the spinal cord and results in paresis or paralysis. The cause of this disorder is unknown. It is most common in medium-sized and large-breed dogs. It has also been described in small-breed dogs, especially the Miniature Schnauzer, and in a few cats. Most affected dogs are young or middle-aged, with the majority of cases between 3 and 7 years of age. A few dogs younger than 1 year of age have been recognized with FCE, especially Irish Wolfhounds. No gender predilection exists.

Clinical Features

The onset of neurologic signs is very sudden. In about half of all cases, FCE occurs immediately after minor trauma or during exertion. Neurologic examination reflects a focal spinal cord lesion, and the deficits observed depend on the region of spinal cord affected and severity of cord involvement. The thoracolumbar cord (causing UMN signs in the rear limbs) and the lumbosacral intumescence (causing LMN signs in the rear limbs) are most often affected. The cervical cord is affected less frequently (10%), but it may be the site most often affected in small-breed dogs. Neurologic dysfunction may be mild or severe. Asymmetry is common, with the right and left sides affected to different degrees. Dogs may cry out as though in pain at the onset of signs, and dogs evaluated within 2 to 6 hours of onset sometimes exhibit focal spinal hyperpathia (i.e., painfulness); however, this resolves quickly, and most affected dogs do not exhibit pain by the time they are brought to a veterinarian, even on manipulation of their spine. The lack of pain and the asymmetry are very helpful in differentiating FCE from other disorders that cause peracute nonprogressive neurologic dysfunction, such as acute type I IVD extrusion and fracture/luxation. FCE typically causes peracute nonprogressive signs, but up to 30% of affected dogs can have some worsening of neurologic signs within minutes to hours of onset.

Diagnosis

FCE is suspected on the basis of signalment, history, and recognition of peracute, nonprogressive, nonpainful spinal cord dysfunction. Spinal radiographs are normal but assist in ruling out diskospondylitis, fractures, lytic vertebral neoplasia, and IVDD. CSF is usually normal, although an increase in protein (especially albumin) concentration may be observed in some (50%) cases, and neutrophil numbers may be slightly increased within the CSF in the first 24 hours after the onset of clinical signs. Myelography or spinal CT may be performed to rule out compressive lesions of the spinal cord for which emergency surgery might be indicated, such as fractures, disk extrusion, and neoplasia. MRI may reveal focal edema and T2W hyperintensity within the spinal

FIG 65.12
This adult Border Collie had an acute onset of lameness, flaccid paresis, decreased sensation, and hyporeflexia in the left rear limb while retrieving a Frisbee. The limb was not painful, and radiographs, cerebrospinal fluid analysis, and myelogram were all normal. A presumptive diagnosis of fibrocartilaginous embolism (FCE) involving the lumbar and sacral spinal cord segments on the left side was made. This dog recovered uneventfully within a 3-week period.

cord parenchyma in severely affected dogs, but mild lesions will not be evident. The location of spinal cord hyperintensity over a vertebral body rather than centered over a disk space helps differentiate FCE from traumatic disk based on MRI. The diagnosis of FCE is typically made on the basis of clinical findings and exclusion of acute compressive spinal cord disorders (Fig. 65.12).

Treatment

Treatment for FCE consists of nonspecific supportive measures, nursing care, and physiotherapy. Most affected dogs are large breeds, making this type of management difficult. In animals brought to the clinician during the first 6 hours of paralysis, it may be reasonable to treat aggressively with one dose of methylprednisolone sodium succinate, as is sometimes recommended for the initial treatment of acute spinal cord trauma, but there is no evidence that this treatment affects outcome (see Fig. 65.4). Cage rest is not required—in fact, early intervention with physiotherapy may help speed recovery. Most clinical improvement takes place within the first 7 to 10 days after the onset of neurologic signs, although it may take 6 to 8 weeks for a complete return to function. If no improvement is seen within 21 days, it is unlikely that the dog or cat will improve.

Prognosis

Recovery depends on the extent and location of spinal cord injury. Most affected dogs (85%) walk within 21 days, but permanent neurologic deficits are common. The prognosis is best for recovery in dogs and cats with UMN signs and intact deep pain sensation. Animals with LMN signs caused by damage at the brachial or lumbosacral intumescence (C6-T2 or L4-S3) are less likely to fully recover. Animals that have lost the ability to perceive painful stimuli in the affected limbs are unlikely to recover the ability to ambulate without assistance.

ATLANTOAXIAL INSTABILITY

Although some dogs with congenital atlantoaxial instability will be presented acutely for neck pain and tetraparesis, many affected dogs have slowly progressive waxing and waning tetraparesis due to repeated cervical spinal cord injury. This condition will be discussed with progressive spinal cord disorders affecting young animals. Traumatic fracture of the dens leading to subluxation can occur in any dog or cat and will result in acute UMN dysfunction in all limbs. Management should be as described for acute spinal trauma.

NEOPLASIA

Neoplasms usually cause neurologic signs by compressing or infiltrating the spinal cord parenchyma. Neoplastic conditions will be discussed in this chapter with chronic progressive spinal cord diseases. It is important to realize, however, that primary or metastatic neoplasia can cause acute nonprogressive neurologic signs as a result of intraparenchymal hemorrhage or lysis of vertebral bones, leading to fracture.

PROGRESSIVE SPINAL CORD DYSFUNCTION

Damage to the spinal cord that progresses over a few days to weeks (subacute) is most often caused by inflammatory (infectious or immune) processes or some type of neoplasia. Degenerative disorders and most cancers generally cause more slowly progressive spinal cord dysfunction. In all patients with progressive spinal cord dysfunction, complete patient evaluation, including systemic evaluation for extraneural disease, should be recommended. The lesion should be localized and ancillary tests performed to reach a diagnosis and determine appropriate treatment.

SUBACUTE PROGRESSIVE DISORDERS

Infectious Inflammatory Disease

Most of the infectious inflammatory diseases discussed in Chapter 64 can result in myelitis (i.e., spinal cord inflammation), leading to progressive neurologic signs suggesting multifocal or focal spinal cord damage. Canine distemper, Rocky Mountain spotted fever, and neosporosis in dogs and feline infectious peritonitis in cats are the infectious disorders most likely to cause spinal cord signs. Systemic evaluation will sometimes reveal the specific diagnosis. MR imaging can help to localize and characterize lesions. CSF analysis is used to confirm that inflammatory disease is present and to test for infectious agents. Additional

diagnostic testing is often necessary to identify an etiology (see Chapter 64).

Noninfectious Inflammatory Disease

Some of the noninfectious inflammatory diseases discussed in Chapter 64 can cause progressive spinal cord signs. Dogs with steroid responsive meningitis-arteritis (SRMA) are typically presented for cervical pain and fever with no neurologic deficits. Neurologic deficits are common with meningoencephalitis of unknown etiology (MUE) or focal or disseminated GME affecting the spinal cord. CSF analysis is necessary to confirm inflammatory myelitis, and additional tests are required to rule out infectious etiologies. See Chapter 64 for more information.

Diskospondylitis

Diskospondylitis is an infection of the intervertebral disks and adjacent cartilaginous vertebral end plates by bacterial or fungal organisms. Hematogenous spread of infection from infected foci in the body is implicated as the cause in most cases, but extension of infection from an infected local site and migration of foreign bodies (grass awns or porcupine quills) to the site occasionally occur. Numerous causative organisms have been isolated, with the most common being *Staphylococcus* spp., *Streptococcus* spp., and *Escherichia coli*. *Brucella canis* is less common but should be tested for because of human health implications. *Actinomyces* spp. are commonly implicated in L2-L4 diskospondylitis caused by migration of inhaled grass awns.

Diskospondylitis occurs most often in young and middle-aged medium- to large-breed dogs. German Shepherd dogs, Labrador Retrievers, Boxers, Rottweilers, and Great Danes may have an increased prevalence of this disorder. Diskospondylitis has also been recognized in juvenile dogs (<6 months), especially after spinal trauma or recovering from parvovirus infection. Diskospondylitis is very rarely diagnosed in cats. Males are affected more often than females in both species.

Clinical Features

Spinal pain is the most common initial clinical sign of diskospondylitis. Palpation of the affected region of the spine usually allows lesion localization. Systemic signs such as fever, anorexia, depression, and weight loss occur in 30% of affected dogs, but hematologic inflammatory changes are rarely observed unless there is concurrent endocarditis or some other systemic infection. Secondary (i.e., reactive) polyarthritis may occur (see Chapter 69), resulting in a generally stiff, stilted gait in some dogs.

Neurologic deficits occur in less than 50% of dogs and cats with diskospondylitis. In chronic or untreated cases, neurologic dysfunction can result from spinal cord compression by proliferating inflammatory tissue, pathologic fracture of lytic vertebrae, or extension of severe inflammation in the bone to the adjacent spinal cord, without any cord compression. Mild paraparesis and proprioceptive deficits are the most common neurologic abnormalities reported.

Diagnosis

The diagnosis of diskospondylitis is suspected after physical examination and confirmed by radiographic examination of the affected vertebrae. Radiographic changes characteristically include narrowing of the disk space, irregularity or lysis of one or both vertebral end plates (especially ventrally), sclerosis at the margins of bone loss, and osseous proliferation of adjacent vertebral bone (Fig. 65.13). The most commonly affected sites are the midthoracic, caudal cervical, thoracolumbar, and lumbosacral spine. It is common for diskospondylitis to affect more than one disk space (Fig. 65.14), so survey radiographs of the entire spine are recommended. Radiographic signs of diskospondylitis may not be apparent for several weeks after the onset of clinical signs. MRI or CT can be used to identify subtle end-plate erosion before radiographically apparent lesions are visible. Ultrasound can also be used to identify diskospondylitis lesions in the cervical or lumbar spine.

Blood culture is the most rewarding noninvasive method of isolating the organism responsible for the vertebral infection, yielding the organism in approximately 35% of cases. Echocardiography and urine culture are routinely recommended to evaluate the cardiac and urogenital systems as potential sources of infection. Percutaneous needle aspiration of the infected disk during general anesthesia using fluoroscopy or ultrasound has been effective in yielding positive

cultures in some cases with negative blood and urine cultures, but this is usually reserved for cases in which other culture techniques have yielded negative results and the response to an empirically selected antibiotic is inadequate. A spinal needle is guided into the disk space and a small amount of sterile saline (0.3-0.5 mL) is injected and then aspirated for culture. *Brucella* serology or polymerase chain reaction (PCR) should be considered in all affected dogs because of the public health significance of brucellosis (see Chapter 55), despite its very low prevalence (<10%) in the United States and Canada.

Treatment

Initial treatment of diskospondylitis consists of antibiotics, cage rest, and analgesics. If an organism is isolated, susceptibility testing should guide antibiotic therapy. If an organism is not found, initial treatment attempts should be directed against *Staphylococcus* spp. Bactericidal antibiotics with a spectrum against gram-positive organisms and the ability to concentrate in bone are recommended. First-generation cephalosporins (cefazolin, 25 mg/kg IV q8h; cephalexin, 22 mg/kg PO q8h) and amoxicillin with clavulanate (Clavamox, 12.5-25 mg/kg PO q8h) have been effective. Quinolones can be added if gram-negative organisms are suspected. Ampicillin is the antibiotic of choice for *Actinomyces* infections associated with grass awn migration. Antibiotics are administered parenterally for the first 3 to 5 days whenever neurologic deficits are present, then oral administration is continued for at least 8 weeks and up to 6 months if necessary.

In addition to antibiotic therapy, the patient's activity should be restricted to minimize discomfort and decrease the chance of pathologic fracture and luxation. Analgesics may be administered for 3 to 5 days, but their use will make it difficult to assess the efficacy of antibiotic therapy and may make it more difficult to enforce strict cage rest. Most dogs show very rapid clinical improvement within the first week of treatment. Dogs treated medically should be reevaluated clinically and radiographically every 3 weeks. With time, the lytic process should resolve and the affected vertebrae should fuse. Antibiotics should be administered for a minimum of 8 weeks and may then be discontinued if the spine is no longer painful over the affected sites and there is no radiographically visible lysis. Most treated animals do not relapse unless a foreign body causes the diskospondylitis.

CHRONIC PROGRESSIVE DISORDERS

Neoplasia

Tumors that grow and compress or infiltrate spinal cord parenchyma frequently cause chronic, progressively worsening signs of spinal cord dysfunction. Spinal tumors can be primary or metastatic. The most common tumors affecting the spinal cord in the dog are extradural tumors arising from the vertebral body (e.g., osteosarcoma, chondrosarcoma, fibrosarcoma, myeloma) and extradural soft tissue tumors, including metastatic hemangiosarcoma, carcinoma, liposarcoma, and lymphoma. Intradural extramedullary tumors such as meningiomas, neuroepithelioma, and peripheral nerve sheath tumors are also common, accounting for 35% of all spinal tumors. Intramedullary tumors are relatively rare in the dog, with the exception of metastatic hemangiosarcoma. Lymphoma can be extradural, intradural/extramedullary, or intramedullary in the dog and is usually a manifestation of multicentric disease. Lymphoma is the only common spinal tumor in the cat, and in 85% of cats with spinal lymphoma the tumor is also found in extraneural sites.

Most spinal cord tumors occur in middle-aged and older dogs, with the mean age at the time of diagnosis being 5 to 6 years. Two noteworthy exceptions are lymphoma (which can affect dogs of any age) and neuroepithelioma, a primary intradural extramedullary tumor that has a predilection for T10-L1 in young dogs, particularly German Shepherd dogs and Golden Retrievers. In addition, vertebral osteomas may occur in young dogs and result in spinal cord compression, as can cartilaginous exostoses, benign proliferative lesions of the bone indistinguishable from neoplasia except by biopsy (Fig. 65.15; see also Fig. 59.2). Spinal lymphoma is most common in young (mean age, 4 years) adult feline leukemia (FeLV)-positive cats. Certainly, spinal neoplasia cannot be eliminated as a differential diagnosis strictly on the basis of signalment.

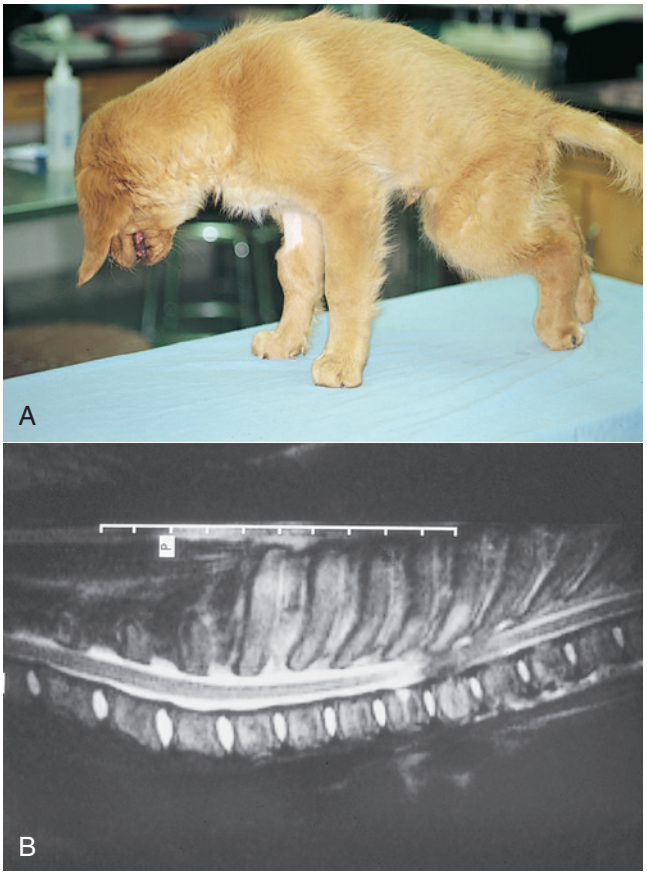

FIG 65.15
(A) A 3-month-old Golden Retriever puppy with spinal pain and progressive upper motor neuron (UMN) signs in both rear limbs resulting from a vertebral osteoma. **(B)** Magnetic resonance imaging showing severe compressive spinal cord damage from the caudal aspect of the T4 vertebral body extending caudally through the T6 vertebral body.

Clinical Features

Clinical signs are usually insidious and related to tumor location. Early diagnosis is difficult because neurologic abnormalities are not clinically apparent until there has been significant compression or destruction of the spinal cord. Many animals have months of slowly progressive clinical signs before a diagnosis is made. Pain may be a prominent feature in dogs and cats with nerve root tumors encroaching on the spinal cord, tumors involving the meninges, and aggressive tumors involving vertebral bone. Progressively worsening lameness and pain on limb manipulation (i.e., radicular pain, root signature) without initial neurologic deficits are common in dogs with peripheral nerve sheath tumors involving nerve roots in the cervical or lumbar intumescence. An ipsilateral Horner syndrome and/or loss of the panniculus reflex may be seen if the thoracic nerve roots are involved. Pain is not a common feature of intramedullary spinal cord primary tumors or metastases. Although animals with compressive lesions of the T3-L3 spinal cord typically maintain urinary and fecal continence until after the limbs are paralyzed, it is not uncommon for animals with intramedullary neoplasms affecting the central cord to become incontinent while still able to walk.

Differential diagnoses must include other disorders that cause slowly progressive neurologic dysfunction, including type II disk protrusion and degenerative myelopathy (DM). Rapidly growing extradural tumors such as lymphoma and primary or metastatic intramedullary tumors sometimes cause rapidly progressive neurologic signs more typical of inflammatory myelitis. Peracute paresis/paralysis is occasionally seen in dogs or cats with tumor-associated hemorrhage or vertebral pathologic fractures.

Diagnosis

Whenever a neoplasm is considered as a differential diagnosis for spinal cord dysfunction, a thorough physical examination, clinicopathologic evaluation, and systemic imaging are necessary to look for sites of primary tumor, metastases, and evidence of associated systemic disease. Fundic examination, palpation of lymph nodes, and rectal examination should be performed, as well as thoracic and abdominal radiographs

and abdominal ultrasound. In breeds at high risk for hemangiosarcoma, cardiac ultrasound may also be warranted. Aspiration of the lymph nodes, spleen, and/or liver and examination of peripheral blood or bone marrow smears may yield the diagnosis in dogs with lymphoma. Patients with multiple myeloma often secrete paraproteins, causing a hyperproteinemia and a monoclonal gammopathy. Most cats with spinal lymphoma are FeLV-positive (>80%), and many have obvious systemic disease and hematologic evidence of bone marrow involvement.

Survey radiographs of the affected region of the spine are recommended. Osteolysis or bone proliferation may be seen with vertebral tumors (Fig. 65.16). Fine-needle aspiration of a bone lesion sometimes yields a cytologic diagnosis. The entire axial and appendicular skeleton should be surveyed for lytic lesions if clinical findings make multiple myeloma likely. Soft tissue tumors of the spinal cord are almost never visible using survey radiographs. Although myelography is a fairly reliable method to localize and characterize spinal cord tumors, it is relatively invasive and provides less useful diagnostic information than MRI. CSF analysis should always precede myelography. With tumors compressing the spinal cord, CSF analysis typically reveals nonspecific changes, including slight increases in protein concentration and a mild mononuclear pleocytosis. Neoplastic cells are rarely identified except in cats and dogs with lymphoma (Fig. 65.17).

Myelography or MRI allows most spinal cord tumors to be characterized as intramedullary, extramedullary-intradural, or extradural. MRI adds valuable information regarding precise tumor location and degree of spinal cord involvement, which may be important when considering surgical treatment and/or radiation therapy.

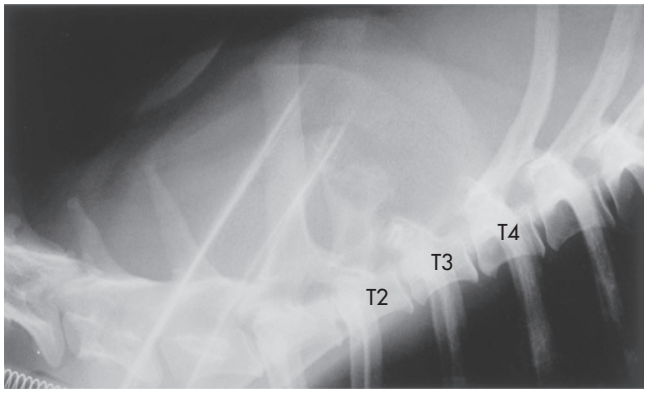

FIG 65.16
Lateral spinal radiograph from a 2-year-old Irish Setter with a 1-week history of progressive ataxia and a 12-hour history of upper motor neuron paralysis of the rear limbs and Schiff-Sherrington syndrome. The entire spinous process of T3, the roof of T3, and most of the spinous process of T2 are destroyed, most consistent with a neoplastic process. An undifferentiated sarcoma at this site was identified on postmortem examination.

Treatment

Surgical decompression and attempts at complete tumor excision are usually limited to well-encapsulated extradural tumors as a referral procedure. Feline meningiomas may have a good prognosis after surgical excision. Intramedullary tumors cannot usually be treated successfully with surgery because of their intimate involvement with neural tissue.

Radiation therapy may be of some benefit in dogs and cats with spinal lymphoma, plasma cell tumors, meningiomas, and some nerve sheath tumors. Chemotherapy is rarely effective because only a few of the commonly used drugs cross the blood-brain barrier. Corticosteroids may shrink lymphoreticular tumors such as lymphoma and myeloma and may decrease edema and inflammation associated with a variety of tumors, resulting in remarkable temporary improvement. Cytosine arabinoside has good CSF

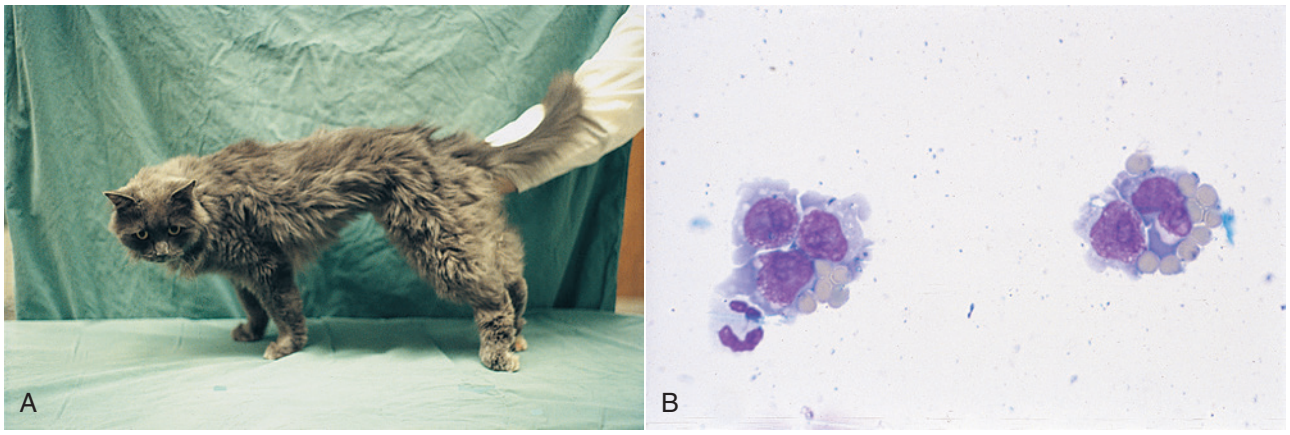

FIG 65.17
(A) A 2-year-old cat with a 5-day course of progressive rear limb ataxia and upper motor neuron paresis. **(B)** Cerebrospinal fluid analysis revealed an increased cell count consisting predominantly of neoplastic lymphoid cells.

penetration so may also be used to treat lymphoreticular tumors.

Spinal Articular Cysts

Cysts arising from the joint capsule of spinal facetal joints can, through enlargement, cause chronic progressive focal extradural compression of the spinal cord or nerve roots. These cysts can result from an outpouching of the synovium (i.e., synovial cysts), or they may arise from mucinous degeneration of periarticular connective tissue (i.e., ganglion cysts). Synovial cysts and ganglion cysts are clinically indistinguishable, and both arise secondary to degenerative changes in the facetal joints. Degenerative changes occur because of congenital malformations, vertebral instability, or trauma. Signs are referable to the site and degree of resulting spinal cord or nerve root compression. Young giant breeds of dogs such as Mastiffs, Great Danes, and Bernese Mountain Dogs most commonly develop single or multiple cysts in the cervical region, which cause a UMN myelopathy with proprioceptive ataxia, progressive tetraparesis, and occasionally cervical pain. Synovial cysts occur in 20% of dogs with CSM (wobbler syndrome). Older dogs, particularly German Shepherd dogs, have been identified with thoracolumbar or lumbosacral articular cysts that cause spinal cord or cauda equina compression.

Radiographs may reveal degenerative changes of the articular facets. Diagnosis of synovial cysts is best accomplished with MR imaging. The cysts are well-circumscribed extradural masses associated with the articular processes on one or both sides of the vertebral canal. CSF analysis reveals normal cytology and slightly increased protein, consistent with a noninflammatory chronic compressive myelopathy. Treatment usually consists of spinal cord decompression, cyst drainage, and arthrodesis of the facetal joint, and usually produces excellent results. A similar syndrome with degeneration and bony proliferation of multiple thoracolumbar articular facets causing spinal cord compression has been reported as a hereditary condition in 4- to 10-month-old Shiloh Shepherds.

Spinal Arachnoid Diverticula (Cysts)

Focal accumulations of CSF in cyst-like structures within the subarachnoid space can lead to slowly progressive, nonpainful spinal cord compression in young dogs (Fig. 65.18). The cyst-like structures containing CSF may represent a congenital intradural arachnoid diverticulum (most common) or a pocket caused by adhesions in the subarachnoid space secondary to trauma, disk extrusion or protrusion, or vertebral malformations. The cervical region and the caudal thoracic region are most often affected, with most diverticula in the dorsal aspect of the vertebral canal. A CSF flow disturbance may cause a functional one-way valve, so that as CSF fills the diverticulum it enlarges and causes compression of the spinal cord. Young large-breed male dogs are most likely to be affected by cervical diverticula, with Rottweilers overrepresented. Small-breed dogs, especially Pugs and French Bulldogs have a tendency to have thoracolumbar diverticula. Cats are rarely affected. Myelography or MRI reveals accumulation of CSF at the site (see Fig. 65.18). Exploration, fenestration of the diverticula with durotomy,

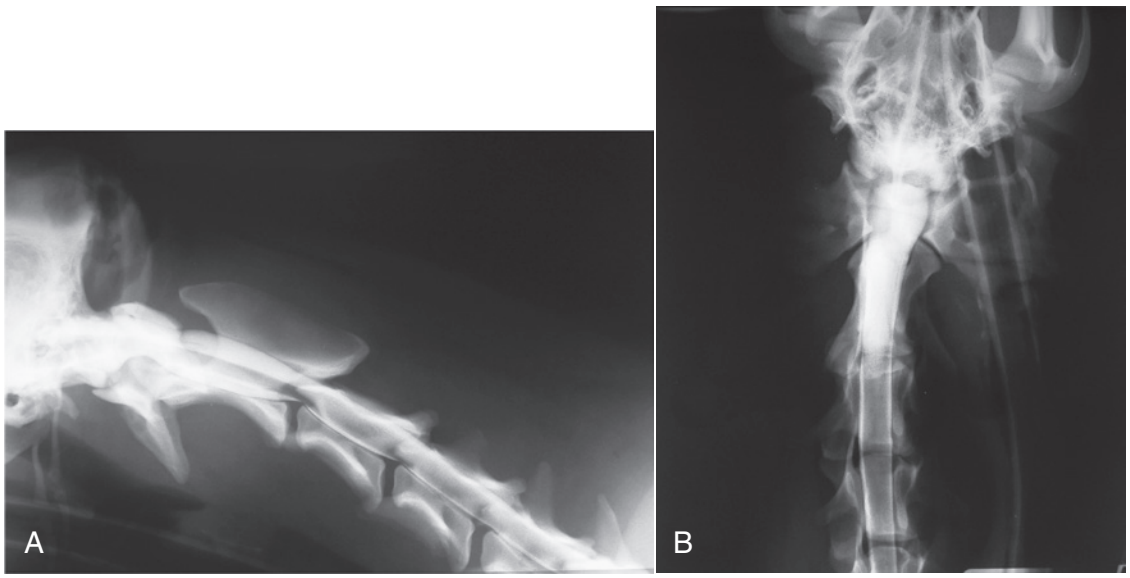

FIG 65.18
Lateral **(A)** and ventrodorsal **(B)** views of a myelogram from a 10-month-old Akita with progressive hypermetria of all four limbs and mild paraparesis. A well-defined bulbous dilation of the dorsal subarachnoid space communicating with the rest of the subarachnoid space was present at C2-C3, suggesting an arachnoid diverticulum. Surgical exploration and marsupialization resulted in rapid and persistent (>6 years) return to normal gait.

and marsupialization of the diverticulum are associated with a good prognosis for recovery if performed within 4 months of development of clinical signs and if neurologic deficits are not severe.

Type II Intervertebral Disk Protrusion

Fibroid degeneration of the IVD occurs in some dogs as part of the aging process, and this can lead to prolapse of a small amount of disk nucleus into the annulus fibrosus. A fibrotic reaction ensues, resulting in a round, dome-like dorsal bulging of the annulus so that it protrudes into the spinal canal and causes slowly progressive spinal cord compression (see Fig. 65.5). This type of disk protrusion (i.e., Hansen type II) is seen most commonly in aging large-breed nonchondrodystrophoid dogs, particularly German Shepherd dogs, Labrador Retrievers, and Doberman Pinschers, but it has also been recognized occasionally in small-breed dogs.

Clinical Features

Clinical signs result primarily from slowly progressive spinal cord compression, although spinal discomfort is apparent in a few dogs. Thoracolumbar type II disk protrusion results in UMN signs to the rear limbs, with normal forelimbs. Cervical type II disk disease may be seen in Doberman Pinschers, particularly in association with CSM (i.e., wobbler syndrome). In these dogs thoracic and pelvic limbs are affected, with UMN neurologic signs most prominent in the pelvic limbs.

Diagnosis

Slowly progressive signs of spinal cord dysfunction in an older dog should prompt consideration of type II disk protrusion, articular cysts, DM, or neoplasia. Neurologic examination localizes the lesion to a spinal cord region, but, because the site is not usually painful, spinal palpation rarely results in more precise localization. Survey radiographs of the spine are normal in most affected dogs, but disk space narrowing, osteophyte production, and end-plate sclerosis may be seen at the site of type II disk protrusion in some dogs. All of these are, however, common incidental findings, but these abnormalities are common at multiple sites in older large-breed dogs, so they may not help to further localize the lesion. Myelography or advanced imaging technique (i.e., CT, MRI) is necessary to determine the extent and location of the lesion and to distinguish type II disk protrusion from spinal neoplasia and DM.

Treatment

Restricted exercise, antiinflammatory drugs (NSAIDs or low-dose prednisone), and muscle relaxants will provide relief in dogs that are uncomfortable when the affected site is palpated or manipulated. The addition of methocarbamol or gabapentin may help to relieve cervical discomfort from muscle spasms or pinched nerve roots. Neurologic signs caused by spinal cord compression will continue to progress, however, and surgery is recommended as the definitive treatment. Ventral decompression is performed if the cervical vertebrae are affected, whereas hemilaminectomy for decompression at the site is usually attempted for type II disks in the thoracolumbar spine. Effective surgical decompression is often challenging to achieve because of the chronic nature of the lesion and the difficulty encountered in removal of the dorsal annulus. The goal of therapy is to stabilize the animal's neurologic status. The spinal cord has usually undergone considerable chronic compression before clinical signs appear, so full recovery is rare. A few dogs experience temporary or permanent worsening of clinical signs postoperatively.

Degenerative Myelopathy

A degenerative disorder of the spinal cord white matter characterized by widespread myelin and axon loss that is most severe in the mid to caudal thoracic spinal cord occurs most often in aging German Shepherd dogs. Affected dogs initially have a slowly progressive, often asymmetric, nonpainful, proprioceptive ataxia and UMN spastic paresis primarily affecting the pelvic limbs, suggesting a T3-L3 lesion. DM has been recognized in German Shepherd dogs from 5 to 14 years of age and is occasionally seen in older dogs of other large breeds including Boxers, Chesapeake Bay Retrievers, and Rhodesian Ridgebacks, and in Pembroke Welsh Corgis.

Etiology

The cause of the noninflammatory axonal degeneration that occurs in DM is uncertain. Some have speculated that deficiencies of nutrients or vitamins or vascular supply are responsible for the histologic changes. Recently homozygosity for a genetic mutation in the superoxide dismutase 1 (SOD1) gene has been identified as a necessary condition for the development of DM in breeds with a high familial predisposition for the condition. This mutation, together with the neuropathologic features of DM, suggests that it is a neurodegenerative spinal cord disorder similar to UMN-onset amyotrophic lateral sclerosis (ALS) in people.

Clinical Features

Clinically, DM results in a slowly progressive UMN paraparesis and ataxia of the rear limbs. A loss of proprioception results in knuckling, wearing of the dorsal nail surfaces of the digits of the rear limbs, and progressively worsening posterior ataxia. Most affected large-breed dogs progress from mild proprioceptive loss to nonambulatory UMN paraparesis within 6 to 9 months. A more slowly progressive form of DM has been identified in the Pembroke Welsh Corgi, with a median duration of progression of signs over 18 months. Although initially all dogs with DM show typical UMN paraparesis suggesting a T3-L3 lesion, if dogs are managed beyond the point of being unable to walk, their signs slowly progress to flaccid (LMN) paresis with muscle atrophy and loss of reflexes in all four limbs, suggesting widespread denervation.

Diagnosis

A diagnosis of DM should be suspected in any large-breed dog with slowly progressive UMN paresis in the rear limbs. Rear limb ataxia, a long-strided gait, toe scuffing, abnormal postural reactions (especially knuckling), and normal to increased rear limb reflexes are the most common findings. Affected dogs are systemically normal, with no site of localizable spinal pain. Neurologic findings distinguish DM from lumbosacral disease and from orthopedic disorders such as hip dysplasia and bilateral anterior cruciate ligament rupture. The primary differential diagnoses for chronic progressive UMN paresis in the rear limbs include DM, spinal cord neoplasia, spinal cord compression by articular cysts, and type II disk protrusion.

The antemortem diagnosis of DM is one of exclusion. Radiographs of the spine are normal, as is CSF analysis, although a slight increase in CSF protein concentration is occasionally found. Myelography or MRI must be performed to rule out spinal cord compression or focal spinal cord neoplasia. Normal spinal radiographs, a cytologically normal CSF, and normal spinal cord imaging in an older dog with slowly progressive UMN signs to the pelvic limbs warrant a diagnosis of DM. A DNA test based on the SOD1 mutation is commercially available but will only determine which dogs (homozygotes) are at risk of developing DM and which dogs are carriers for the trait. The test will not identify the cause of paraparesis in an individual dog. Recent reports suggest that measuring increased concentrations of a structural protein of myelinated motor axons (phosphorylated neurofilament heavy: pNF-H) in the CSF may be useful as a biomarker for the diagnosis of DM in dogs. Definitive diagnosis of DM can only be confirmed by postmortem identification of typical changes including axonal degeneration, demyelination, and astroglial proliferation in the lateral funiculus and dorsal columns of the thoracic spinal cord.

Treatment

No treatment has been proven effective in dogs with DM. Corticosteroids should not be administered, because they cause muscle wasting and exacerbate muscle weakness. Other immunosuppressive agents have not been shown to be beneficial. Some investigators have advocated vitamins (i.e., vitamin E, vitamin B complex, vitamin C), omega-3 fatty acids, and antioxidants, but conclusive evidence of benefit for any of these treatments is lacking. Exercise and intensive targeted physiotherapy may be helpful in slowing disease progression.

Cauda Equina Syndrome

In dogs, the last three lumbar spinal cord segments (L5, L6, L7) are within the fourth lumbar vertebra, the sacral segments (S1, S2, S3) are within the body of the fifth lumbar vertebra, and the coccygeal segments are within the sixth lumbar vertebra. Because nerve roots from these lumbar, sacral, and coccygeal segments of the spinal cord exit the spinal canal through the intervertebral foramina caudal to the vertebrae with the same number, they must course a considerable distance within the vertebral canal caudal to the point of termination of the spinal cord (Fig. 65.19; see also Table 65.2). This collection of nerve roots descending in the vertebral canal is termed the *cauda equina.* The spinal nerves from the sacral and caudal segments overlie the lumbosacral junction, so compressive disorders affecting this region are likely to involve the L7, sacral, and caudal nerves.

Compression of the nerves of the cauda equina (*cauda equina syndrome, degenerative lumbosacral stenosis*) is usually the result of acquired type II disk protrusion at the L7/S1 intervertebral space, together with progressive proliferation of joint capsules and ligaments in the region, perhaps caused by excessive motion or instability. This disorder is most common in large-breed dogs, including German Shepherd dogs, Labrador Retrievers, and Belgian Malinois, and particularly affects male working dogs older than 5 years of age. Rarely, compression of the cauda equina at this site could be

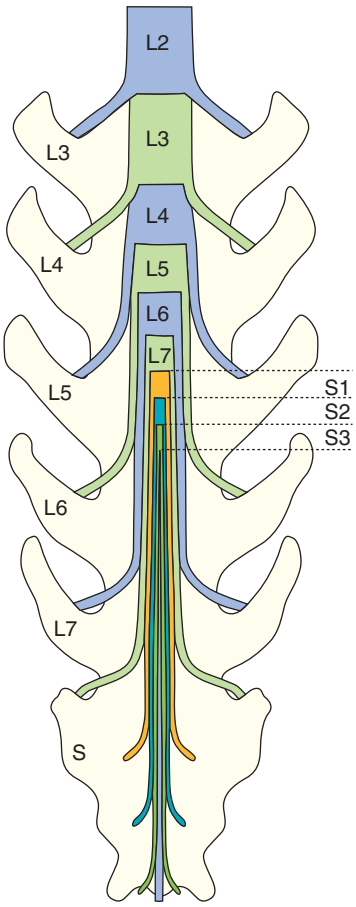

FIG 65.19
Anatomy of the cauda equina region in the dog. L5-L7 spinal cord segments sit within the L4 vertebra. S1-S3 spinal cord segments are within the L5 vertebra, and the coccygeal segments are within L6. Nerve roots from all of the lumbar, sacral, and coccygeal spinal cord segments leave the canal through the intervertebral foramen just caudal to the vertebra with the same number, so these nerve roots course a considerable distance within the vertebral canal.

caused by tumor, diskospondylitis, synovial cyst, vertebral or sacral osteochondrosis, or congenital bony malformations.

Genetic predisposition, conformation, and physical activity are all factors proposed to cause increased mechanical stress on the IVD at the lumbosacral junction, promoting type II disk prolapse at this site. Loss of the structural strength of the disk worsens instability at the site, resulting in proliferative changes in the articular facets, joint capsules, and ligamentum flavum. Proliferative changes result in further narrowing of the vertebral canal, compression of the cauda equina, and compression of the nerve roots as they exit the foramina (degenerative lumbosacral stenosis).

Clinical Features

Compression of the nerve roots of the cauda equina results in a very characteristic constellation of clinical signs. Affected dogs are slow to rise from a prone position and reluctant to run, sit up, jump, or climb stairs. Rear limb lameness worsens with exercise as the blood vessels accompanying the spinal nerve roots within the already crowded intervertebral foramen dilate and further compress the nerve roots. Affected dogs may be reluctant to raise or wag their tails.

The most consistent physical examination finding is pain elicited by deep palpation of the dorsal sacrum or by dorsiflexion of the tail or hyperextension of the lumbosacral region (Fig. 65.20). Most dogs have no neurologic deficits at the time of initial evaluation, making it difficult to distinguish affected dogs from those with pain and lameness caused by diskospondylitis, prostatic disease, or degenerative joint disease. When lumbosacral spinal canal and foraminal narrowing progress to cause compression of the L7, sacral, and caudal spinal nerves, subtle neurologic abnormalities including rear limb weakness, atrophy of the muscles of the caudal thigh and distal limb, and reduced or absent hock flexion during the withdrawal reflex will become apparent. The patellar reflex may appear increased in some dogs because there is a loss of tone in the opposing caudal thigh muscles (pseudohyperreflexia). In severely affected dogs, decreased anal tone and fecal and urinary incontinence will occur. Hyperesthesia or paresthesia of the perineum may develop, with self-inflicted moist dermatitis of the perineum and tail base.

Diagnosis

Historical, physical, and neurologic examination findings are the primary basis for reaching a tentative diagnosis of cauda equina syndrome in affected dogs. Spinal survey radiographs are useful to rule out unusual causes of lumbosacral pain (e.g., diskospondylitis, lytic vertebral neoplasia, fracture/luxation). Radiographs of this region in dogs with cauda equina syndrome may be normal or may reveal end-plate sclerosis and spondylosis of the L7 and S1 vertebral end plates and narrowing or collapse of the L7-S1 IVD space. These same abnormalities are common in clinically normal dogs.

Diagnosis is based on documentation of nerve compression using imaging. When available, MRI with the spine in extension provides the most sensitive, accurate, and noninvasive means of evaluating the lumbosacral region, allowing visualization of all components potentially involved in cauda equina compression (Fig. 65.21). There is some concern that routine use of MRI for diagnosis may lead to overinterpretation of incidental minor disk protrusions at this site, so clinical findings must support the MRI diagnosis. When available, electrophysiologic studies can be useful to confirm LMN disease and nerve root dysfunction of the rear limbs and tail.

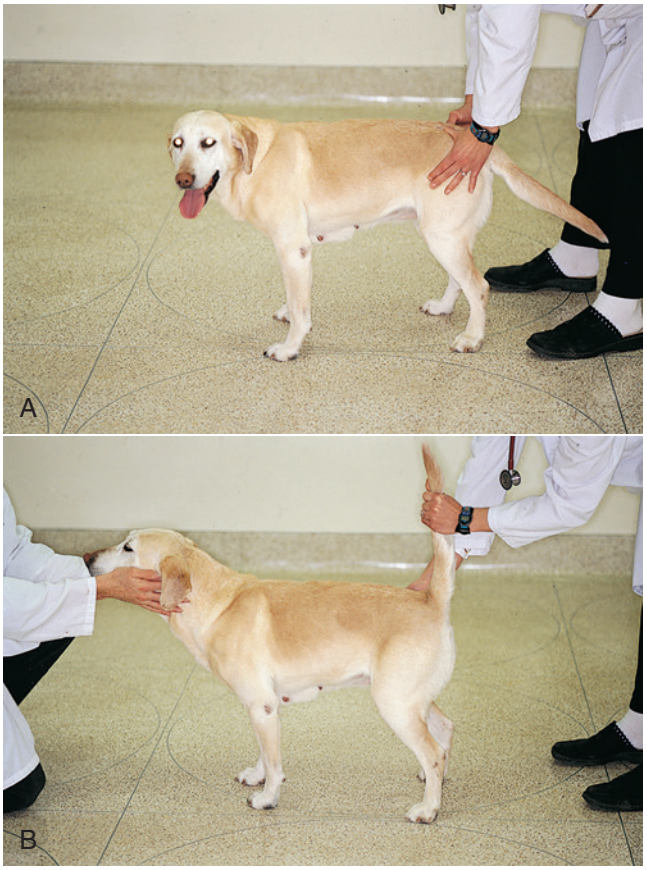

FIG 65.20
Dogs affected by cauda equina syndrome will often experience pain upon **(A)** deep palpation of the dorsal sacrum and **(B)** dorsiflexion of the tail.

Treatment

Restriction of exercise and the administration of analgesics or antiinflammatory drugs may result in temporary improvement in dogs with clinical signs limited to pain and lameness. Significant relief can often be achieved with gabapentin (8-10 mg/kg PO q8h) for neuropathic pain, together with NSAIDs and tramadol (3-5 mg/kg PO q8h). Signs usually recur when normal activity is resumed. More definitive treatment involves lumbosacral dorsal laminectomy, excision of compressing tissues, and foraminal decompression by foraminotomy when necessary. Decompressive surgery together with lumbosacral distraction and stabilization is recommended if instability is suspected. Descriptions of the surgical procedures are provided in the Suggested Readings.

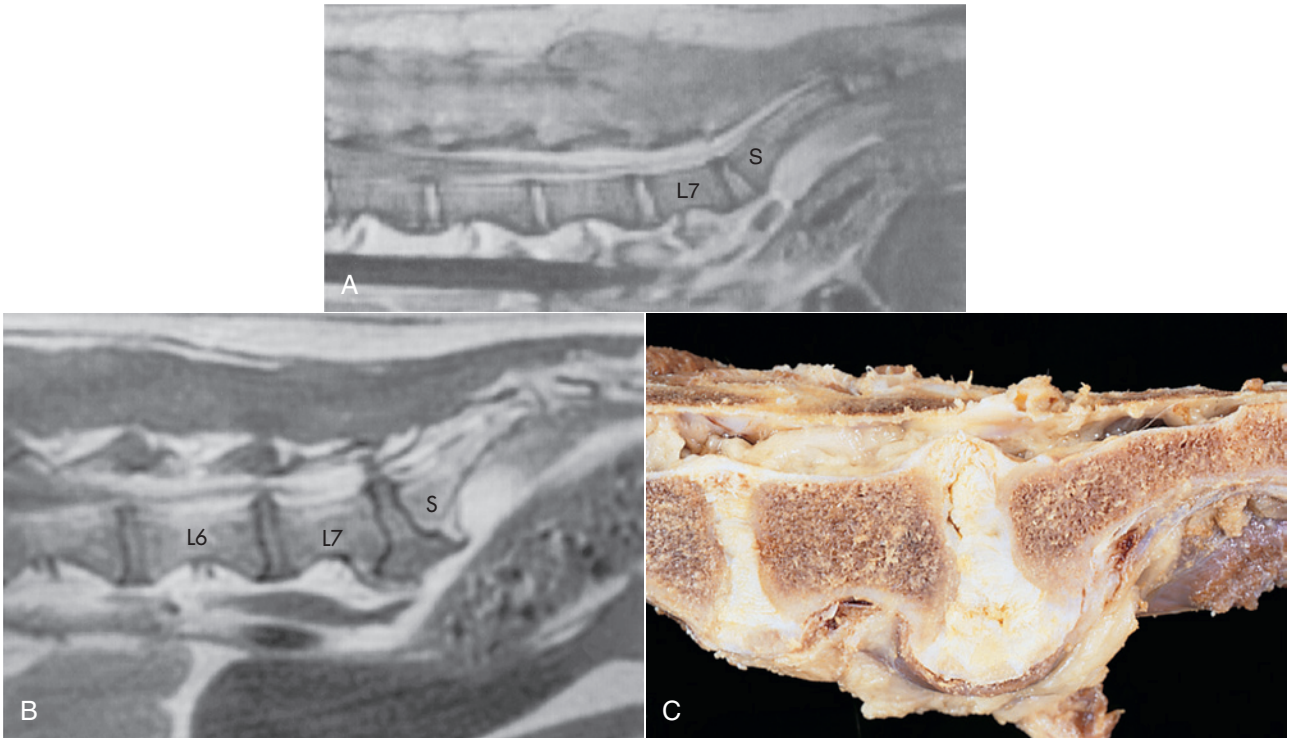

FIG 65.21
(A) Normal midline sagittal T1 on a magnetic resonance imaging (MRI) scan of the lumbar spine of a dog. (Image reveals high signal intensity *[white]* of the nucleus pulposus and epidural fat, in contrast to lesser signal density of the spinal cord and nerve roots of the cauda equina *[darker]*.) **(B)** MRI from a dog with lumbosacral pain showing T1-weighted midline sagittal, displacement of epidural fat, and ventral and dorsal compression of the nerve roots at the L7-S1 disk space. Spondylosis deformans ventral to the L7-S1 intervertebral disk space and disk protrusion at the L6-L7 space can also be seen. **(C)** Postmortem dissection of the lumbosacral region of a German Shepherd Dog with acquired degenerative lumbosacral stenosis and type II disk protrusion. The vertebral canal is compromised at the lumbosacral junction, resulting in compression of the nerves of the cauda equina. (**A** and **B** courtesy Dr. Greg Daniel, University of Tennessee.)

Rapid relief from pain occurs after surgery in most dogs. Strict postoperative confinement is important for 4 to 8 weeks, followed by a gradual return to exercise and work. The prognosis is good for resolution of lameness and mild neurologic deficits. Most dogs with mild to moderate deficits will return to working function, but occasionally there will be a recurrence of signs after 12 to 24 months. Dogs with severe LMN deficits or incontinence are likely to have permanent deficits.

Cervical Spondylomyelopathy (Wobbler Syndrome)

Cervical spondylomyelopathy (CSM), or *canine wobbler syndrome,* is a term used to describe caudal cervical spinal cord and nerve root compression in large- and giant-breed dogs that occurs secondary to developmental malformations, instability, or instability-associated changes in the spinal canal. Genetic predisposition, overnutrition, and conformation have all been implicated in the development of this disorder. Vertebral canal narrowing can be the result of malformed vertebral laminae, hypertrophy of the ligamentum flavum, articular facet enlargement, periarticular soft tissue hypertrophy, or (most often) a combination of these. In addition, changes in the vertebral body and end plates can lead to type II IVD protrusion, causing ventral spinal cord compression in affected dogs.

Great Danes with CSM typically have osseous narrowing of the spinal canal due to congenital malformations of their cervical vertebrae. Signs of spinal cord compression are usually evident before 2 years of age in this breed. Multiple vertebral sites (usually C4, C5, or C6) are often affected, and the degree of spinal cord compression and injury increases with cervical extension or dorsiflexion. In addition to the spinal cord compression caused by the bony malformations, most affected dogs have concurrent dorsal or lateral soft tissue compression of their spinal cord.

In dogs with CSM, hypertrophy of the ligamentum flavum leads to dorsal spinal cord compression. Dorsolateral and lateral compression occur secondary to articular process osteoarthritis and articular facetal joint hypertrophy. Young large-breed dogs such as Mastiffs, Rottweilers, and Bernese Mountain dogs with CSM most commonly experience dorsal

or dorsolateral spinal cord compression that becomes clinically evident when they are between 1 and 4 years of age. Degenerative changes of the articular facets, synovial cysts, and vertebral canal stenosis may all occur. Disk-associated wobbler syndrome (DAWS) causes ventral compression of the caudal cervical spinal cord in mature large-breed dogs, especially 6- to 8-year-old Doberman Pinschers. Affected Dobermans typically have a smaller than normal vertebral canal, hypertrophy of the ligamentum flavum, and protrusion of one or more intervertebral disks leading to their signs of spinal cord compression.

Clinical Features

A slowly progressive course of paresis and an uncoordinated or wobbling gait, particularly in the pelvic limbs, are characteristic of CSM. Affected dogs have a broad-based rear limb stance, ataxia, and abnormal postural reactions in the rear limbs (which are invariably more severely affected than the forelimbs). Neurologic findings in the forelimbs vary depending on whether spinal cord compression is centered in the cranial cervical region or in the caudal cervical region. Dogs with C1-C5 compression often have a floating or overreaching front limb gait. Dogs with caudal cervical lesions may have a short-strided, weak front limb gait with a weak withdrawal reflex and pronounced atrophy of the supraspinatus and infraspinatus muscles over the scapula. Lameness and muscle atrophy in one thoracic limb or pain when traction is applied to a limb (i.e., root signature; see Fig. 65.6) suggests that nerve root compression is present. Slowly progressive deterioration in neurologic status is common, but occasionally a traumatic episode or an acute disk extrusion results in sudden tetraplegia. Resistance to dorsal extension of the cervical spine is common, but overt cervical pain is the primary complaint in less than 10% of dogs with CSM.

Diagnosis

The diagnosis is suspected on the basis of signalment, history, and clinical findings. Survey radiographs are useful to rule out other disorders associated with cervical spinal cord compression but are not definitive for CSM. Severe articular facet changes or vertebral body malformations should raise the index of suspicion for CSM in a large-breed dog. Until recently, myelography or myelogram-CT has been the standard means of confirming a diagnosis of CSM, with the advantage that the degree of spinal cord compression could be observed with the spine in multiple positions, allowing differentiation between static and dynamic lesions. Compressive lesions that improve substantially with traction (dynamic lesions) include type II disks and ligamentous hypertrophy. Osseous lesions or type I disk extrusions are not expected to resolve with traction (static lesions; Figs. 65.22 and 65.23). This information can be used to determine whether the optimal surgery for a dog with CSM is direct decompression or indirect decompression through vertebral distraction.

MRI is now considered the gold standard test for evaluation of dogs suspected to have CSM. MRI is more accurate

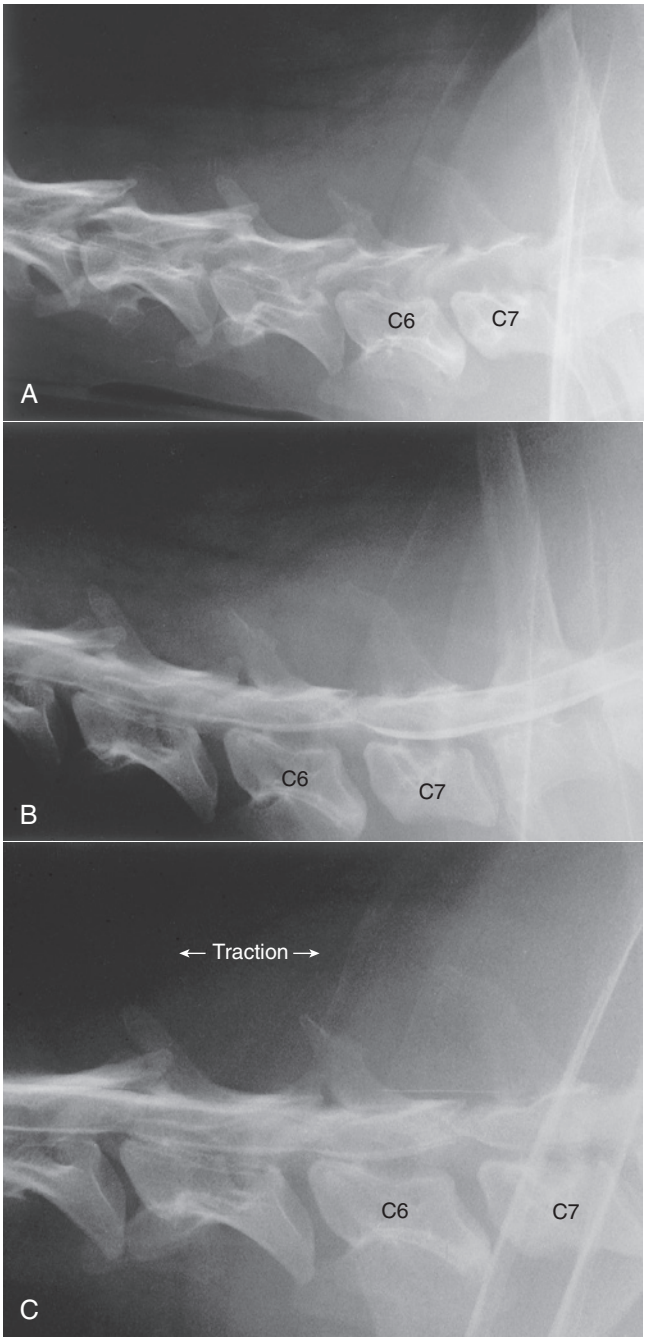

FIG 65.22
(A) Radiograph of the cervical region in a 6-year-old Doberman Pinscher "wobbler" with a sudden onset of ataxia, paraparesis, proprioceptive deficits and hyperreflexia in the rear limbs, and mild cervical pain. Slight narrowing of the C6-C7 disk space can be seen; vertebral canal is stenotic within the cranial aspect of C6 and C7. **(B)** Myelography shows spinal cord compression by a ventral extradural mass at C6-C7 that is not altered significantly with traction **(C).** Surgery revealed a large amount of disk material within the vertebral canal at this site.

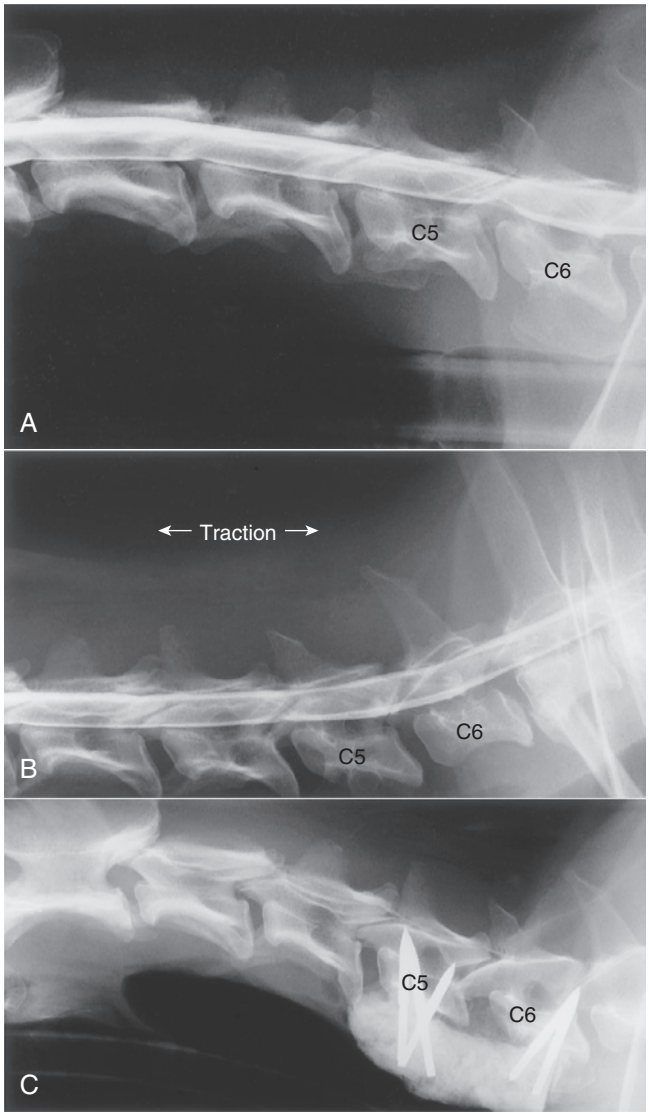

FIG 65.23
(A) Cervical myelogram of an 11-year-old Doberman/Weimaraner cross with a chronic history of nonpainful ataxia and hypermetria of all four limbs. Narrowing of the C5-C6 disk space and thinning of the dorsal contrast column over this site (in association with dorsal deviation and thinning of the ventral contrast column) can be seen. **(B)** Dramatic resolution of this spinal cord compression in the traction view suggests a dynamic compression by a bulging annulus fibrosus or ligamentum flavum. **(C)** Surgery was performed to maintain traction on the spine at this site.

in predicting the site, severity, and nature of spinal cord compression than other modalities. MRI also allows detection of signal changes within the spinal cord parenchyma that may be associated with prognosis for recovery.

Treatment

The clinical course of untreated wobbler syndrome is typically chronically progressive, but in up to 25% of mildly affected dogs signs will remain stable over time. Medical or surgical therapy can be used to attempt to relieve clinical signs of CSM. All affected animals should be evaluated for systemic disease before initiating medical or surgical therapy. In particular, Doberman Pinschers should be evaluated for concurrent hypothyroidism, von Willebrand disease, and cardiomyopathy.

Severe exercise restriction, use of a harness, and administration of antiinflammatory doses of prednisone may result in temporary improvement in neurologic function in dogs with CSM (prednisone, 0.5 mg/kg PO q12h for 2 days; then 0.5 mg/kg once daily for 2 days; then 0.5 mg/kg once every other day for 14 days; then 0.25 mg/kg once every other day for 2 months). NSAIDs can be used in place of corticosteroids if neck pain is severe or if the corticosteroids are not tolerated, but NSAIDs and corticosteroids should never be administered together. Medical management can be effective long term in 40% to 50% of dogs with minimal or mild signs of neurologic dysfunction.

Surgical treatment of CSM leads to a successful outcome in about 80% of cases, so it is recommended in most dogs with significant neurologic deficits. Surgery, however, does not alter long-term survival in dogs with CSM. Multiple lesions, chronic disease, and an inability to walk are all associated with a poor prognosis. Postoperative rehabilitation is critical to recovery. Primary factors determining the specific surgical procedure to be recommended are the degree and site of cord compression and the anatomic structures causing cord compression. Details of the surgical procedures and potential complications are discussed in the Suggested Readings.

PROGRESSIVE DISORDERS IN YOUNG ANIMALS

Breed-Associated Neuronal Abiotrophies and Degenerations

Neuronal abiotrophies and degenerative disorders have been recognized in many breeds of dogs. Progressive neurologic dysfunction usually begins early in life. In disorders affecting the entire spinal cord, clinical signs involving the rear limbs are often noted early in the course of disease, with progression to tetraparesis. Disorders that primarily affect white matter and result in UMN signs are most often seen in Rottweilers, Afghan Hounds, Dalmatians, and Jack Russell Terriers. Disorders primarily affecting gray matter and causing LMN signs are seen in Alaskan Malamutes, Boxers, Brittany Spaniels, German Shepherd dogs, English Pointers, and Maine Coon Cats. The disorders are diagnosed on the basis of the typical clinical course, signalment, and lack of any definable etiology on screening blood tests, spinal radiographs, CSF analysis, advanced imaging, and other diagnostic testing. Diagnosis is confirmed by necropsy examination in most cases. No treatment is available.

Metabolic Storage Diseases

A group of rare disorders characterized pathologically by accumulation of metabolic products in cells secondary to a genetically based enzyme deficiency may result in signs

of spinal cord dysfunction. The enzyme deficiency itself or accumulation of the metabolic intermediates within cells causes a gradual progression of neurologic signs. Spinal signs are usually UMN in nature, although peripheral nerve dysfunction may occur. Cortical signs (e.g., seizures) and cerebellar signs (e.g., hypermetria) are more common. Signs are gradually progressive and usually obvious within the first year or two of life. Metabolic storage diseases are diagnosed on the basis of the typical clinical course and signalment; the lack of any other identifiable etiology; and, in some cases, organomegaly, abnormal appearance, blindness, and other readily identifiable clinical abnormalities resulting from accumulation of metabolic products in extraneural sites.

Atlantoaxial Instability and Luxation

Normally, the atlas (C1) and axis (C2) are bound together by ligaments. The dens, a bony projection from the cranial aspect of the body of the axis, is held firmly against the floor of the atlas by the transverse ligament, maintaining alignment of these two vertebrae and integrity of the spinal canal. Malformation or absence of the dens leading to instability can be seen as a congenital defect in many small breeds of dogs, including the Yorkshire Terrier, Miniature or Toy Poodle, Chihuahua, Pomeranian, Maltese, and Pekingese. The malformation and resultant atlantoaxial instability can lead to dorsal displacement of the axis in relation to the atlas, with subsequent cervical spinal cord compression and repetitive spinal cord trauma. Trauma may cause C1/C2 luxation, precipitating a sudden onset of cervical pain, tetraparesis, paralysis, or death.

Clinical Features

Dogs with congenital atlantoaxial instability can present with acute or chronic signs of a C1-C5 myelopathy. Signs typically develop before 2 years of age. Clinical signs can include neck pain (50%-75%), low head carriage, ataxia, tetraparesis, and postural reaction, and proprioceptive deficits with normal to increased muscle tone and myotactic reflexes in all four limbs. Paralysis is rare, but if it does occur it may be accompanied by caudal brainstem signs such as hypoventilation and vestibular signs. Atlantoaxial luxation secondary to malformation should be suspected in any young (i.e., 6- to 18-month-old) toy-breed dog with a history of cervical pain, UMN tetraparesis, or tetraplegia, whether or not there is a history of trauma.

Diagnosis

Atlantoaxial subluxation can be diagnosed from survey radiographs of the cervical spine, but care must be taken to prevent inadvertent overflexion or twisting of the unstable cervical spine. Recumbent or standing lateral radiographs performed with minimal restraint are usually adequate to demonstrate dorsal displacement of the axis relative to the atlas. If sedation or anesthesia will be required, a Robert Jones–style bandage or splint can be applied to hold the neck in partial extension during induction, intubation, and imaging. Instability with significant luxation can be recognized on a lateral view as widening of the space between the dorsal lamina of the atlas and the dorsal spinous process of the axis and dorsal displacement of the body of the axis (Fig. 65.24). If preliminary radiographs are not diagnostic, the radiographs should be repeated with the head gently flexed to demonstrate instability.

Treatment

Emergency treatment for acute severe tetraparesis caused by atlantoaxial luxation should include medical treatment as for acute spinal cord trauma (see Fig. 65.4). Medical and surgical treatment options have been described. Nonsurgical treatment should include application of a ventrally reinforced neck brace to hold the head and neck in extension for 4 to 8 weeks, strict cage rest, and administration of analgesics. The aim is to stabilize the neck while the ligamentous structures heal. Medical treatment has been recommended for dogs younger than 6 months of age, those with mild neurologic deficits, those with an acute onset of clinical signs, small dogs that fracture a normal atlantoaxial articulation, and those owners with serious financial constraints. Surgical treatment is more effective but may be associated with high perioperative morbidity and mortality. Dorsal and ventral techniques are described in the Suggested Readings.

Prognosis

In dogs with congenital atlantoaxial instability that survive the perioperative period, the prognosis for recovery is good. Positive outcomes are more likely if onset of signs begins before the patient is 2 years old, signs have been present for less than 10 months, and surgical reduction is good.

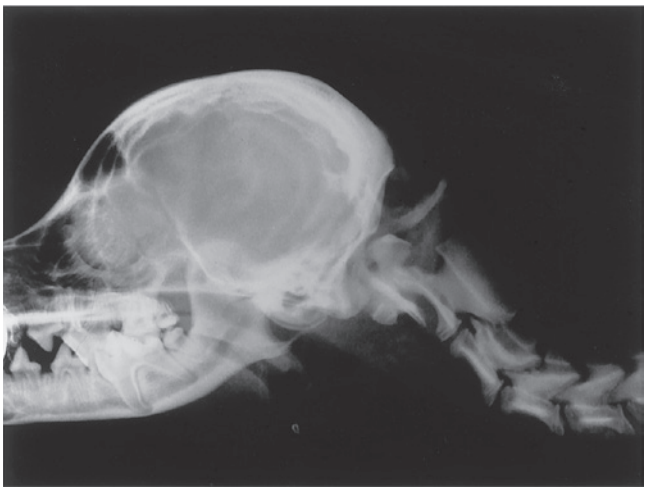

FIG 65.24
Atlantoaxial subluxation in a 7-month-old Bichon Frisé. The dens rises well above its normal position, consistent with rupture of its ligament and compression of the cervical spinal cord. The space between the arch of the atlas and the spinous process of the axis is increased. This dog had a chronic history of intermittent cervical pain and severe ambulatory upper motor neuron tetraparesis.

Syringomyelia/Hydromyelia

Cystic accumulations of fluid within the spinal cord causing compression of adjacent parenchyma are being recognized with increasing frequency as advanced diagnostic imaging techniques (i.e., CT, MRI) are used for neurologic diagnosis. *Syringomyelia* is development of a CSF-filled cavity (syrinx) within the parenchyma of the spinal cord, and *hydromyelia* is accumulation of excessive CSF within a dilated central canal. These disorders can develop as a result of altered CSF pressures within the spinal canal, a loss of spinal cord parenchyma, or secondary to obstructed CSF flow caused by congenital malformations, trauma, or inflammatory or neoplastic disorders. A relatively common cause of syringomyelia in dogs is a malformation of the skull (Chiari-like malformation [CM]) that reduces the volume of the caudal fossa and displaces the cerebellum and brainstem into the foramen magnum, obstructing CSF movement. The CSF, which normally flows through the foramen magnum during systole, becomes turbulent at the craniocervical junction, leading to syrinx formation. This disorder is inherited in the Cavalier King Charles Spaniel (CKCS). More than 95% of CKCS dogs have some degree of CM, 50% of those dogs have syringomyelia, and 35% of affected CKCS dogs show clinical signs.

Onset of clinical signs is usually in puppies and young-adult CKCS dogs, with most dogs showing signs before 4 years of age. The most consistent sign is neck pain that can be constant or intermittent. Some dogs randomly vocalize or resent touching of the ear, limb, face, or neck of the affected side. Others scratch repeatedly at their neck or shoulder, often without making skin contact (phantom scratching). Muscle atrophy and LMN weakness of the associated thoracic limb, and ataxia and UMN deficits of the rear limbs may also be seen. Scoliosis may develop as LMN damage within the cord causes asymmetric denervation of the paraspinal muscles, resulting in vertebral deviation.

CM and syringomyelia are hereditary conditions in the CKCS, suggested to be autosomal recessive with incomplete penetrance. Diagnosis is most reliably made with MRI, which shows a small caudal fossa secondary to a hypoplastic occipital bone, cerebellar crowding, and cerebellar compression or herniation through the foramen magnum (Fig. 65.25). Fluid-filled cavities (syrinxes) are sometimes identified within the spinal cord parenchyma, particularly in cervical regions. Maximum syrinx width is a strong predictor of the severity of signs in affected dogs.

Treatment is aimed at relieving pain and other neurologic signs. Analgesics such as NSAIDs, tramadol, gabapentin, or pregabalin may be recommended. Drugs to decrease CSF production (omeprazole, acetazolamide, prednisone) may also result in clinical improvement. If medical treatment does not alleviate the clinical signs, decompression of the caudal fossa with an occipital craniectomy to reestablish normal CSF flow can be effective, but recurrence is common in the long term and neuropathic pain may persist, requiring continued medical treatment.

(From Bonagura J, Twedt D: *Current veterinary therapy XIV,* St Louis, Elsevier, 2009, p 1102.)

CONGENITAL NONPROGRESSIVE DISORDERS IN YOUNG ANIMALS

Spina Bifida

Spina bifida results from embryonic failure of fusion of the two halves of the dorsal spinous processes of the vertebral arch. Although spina bifida may occur anywhere along the spinal canal, the caudal lumbar and lumbosacral region is most often affected. This malformation is most common in English Bulldogs and Manx cats. In the Manx cat, the condition is an autosomal recessive trait and may be associated with caudal agenesis. Clinical signs are nonprogressive and present from birth, including rear limb LMN paresis, fecal and urinary incontinence, loss of perineal sensation, and decreased tone of the anal sphincter. No therapy is available.

Caudal Agenesis of Manx Cats

Congenital malformations of the sacrococcygeal spinal cord and vertebrae are common in tailless Manx cats. Clinical signs result from agenesis or dysgenesis of the caudal vertebrae and sacral spinal cord. Signs are typically present from birth and include hopping or crouched pelvic limb gait, fecal and urinary incontinence, and chronic constipation.

Spinal Dysraphism

Spinal dysraphism is an inherited congenital malformation of the spinal cord. It results from abnormal development of the structures of the spinal cord along the central plane. The malformation includes a dilated or absent central canal, cavitation in the white matter, and the abnormal presence of ventral gray column cells across the median plane between the central canal and the ventral median fissure. Spinal dysraphism is recognized most commonly in Weimaraners, although other breeds are occasionally affected.

Clinical signs are present at birth. Affected dogs have a symmetric bunny-hopping pelvic limb gait, a wide-based stance, and depressed proprioception. The patellar reflex is normal. The pelvic limb flexor reflex stimulated in one limb usually elicits simultaneous flexion of both pelvic limbs.

Clinical signs caused by spinal dysraphism do not progress, and mildly affected dogs can live a normal life.

CHAPTER 66

Disorders of Peripheral Nerves and the Neuromuscular Junction

GENERAL CONSIDERATIONS

The clinically important peripheral nerves are the peripheral nerves arising from the spinal nerves in the cervical and lumbar intumescences to innervate the muscles of the limbs and the 12 pairs of cranial nerves originating in the brainstem. Spinal nerve or peripheral nerve lesions usually result in lower motor neuron (LMN) motor signs of weakness, decreased tone, and decreased reflexes in affected muscles and limbs. Sensory components of the peripheral nerves are rarely involved, but when they are, there may also be decreased, absent, or altered sensation in the skin supplied by that nerve and occasionally proprioceptive ataxia or postural reaction deficits.

At the neuromuscular junction (NMJ) a nerve impulse reaching the nerve terminal initiates the release of acetylcholine (ACh) into the synaptic cleft. ACh binds to ACh receptors (AChRs) on the postsynaptic (muscle) membrane, inducing a conformational change and ion flux that results in muscular contraction. Presynaptic NMJ disorders that interfere with the release of ACh from the nerve terminal result in generalized LMN signs of weakness and hyporeflexia similar to disorders affecting peripheral nerves. Myasthenia gravis (MG) is a unique postsynaptic disorder that causes partial failure of neuromuscular transmission, resulting in weakness with normal spinal reflexes, similar to the muscle disorders discussed in Chapter 67.

FOCAL NEUROPATHIES

TRAUMATIC NEUROPATHIES

Traumatic neuropathies are common. They result from mechanical blows, fractures, pressure, stretching, laceration, and the injection of agents into or adjacent to the nerve. Diagnosis is usually straightforward and is based on the history and clinical findings. Individual nerves or a group of adjacent nerves may be damaged. Traumatic radial nerve paralysis, complete avulsion of the entire brachial plexus, and sciatic nerve injury are most common in the dog and cat (Table 66.1; Fig. 66.1).

Electrodiagnostic testing, when available, can be used to evaluate the extent of nerve damage. In 5 to 7 days after denervation of a muscle, electromyography detects denervation action potentials (i.e., increased insertional activity and spontaneous action potentials) in the muscles normally supplied by the damaged nerve (see Table 66.1). Nerve conduction studies proximal and distal to the site of injury are also useful in assessing nerve integrity.

When an animal is presented with a peripheral nerve injury, careful mapping and assessment of cutaneous sensation and motor function help determine the precise location of the injury, and sequential mapping can be used to monitor progress (Fig. 66.2). The regenerative ability of a nerve is proportional to the continuity of connective tissue structures remaining around the damaged portion of the nerve. If adequate connective tissue scaffolding is left, axonal regeneration can occur at a rate of 1 to 4 mm/day. Severed nerve ends should be surgically brought into apposition and anastomosed to increase the likelihood of regeneration. The closer a nerve injury is to the innervated muscle, the better the chances of recovery.

Physical therapy such as swimming, limb manipulation, heat therapy, and massage help delay muscle atrophy and tendon contracture and speed return of function in animals with incomplete lesions. Self-mutilation may become a problem 2 to 3 weeks after injury because regeneration of sensory nerves can result in abnormal sensation lasting 7 to 10 days. Lack of improvement in motor function after 1 month warrants consideration of amputation of the affected limb or, when feasible, arthrodesis for limb salvage.

PERIPHERAL NERVE SHEATH TUMORS

Tumors of nerve sheath origin arise from cells surrounding the axons in peripheral nerves or nerve roots. Most of these tumors are anaplastic with a high mitotic index and aggressive biologic behavior and are therefore classified as malignant peripheral nerve sheath tumors (PNSTs) regardless of their cell of origin. These tumors are a relatively common cause of lameness and neuropathy when they involve the nerves of the brachial plexus. Lymphoma may also involve

TABLE 66.1

Traumatic Neuropathies

PERIPHERAL NERVES DAMAGED	MOTOR DYSFUNCTION	SKIN REGION OF SENSATION LOSS	MUSCLES AFFECTED
Lesions of Nerves of the Brachial Plexus			
Peripheral radial nerve damage (at level of elbow)	Loss of carpus and digit extension; may walk on dorsal paw or carry limb	Cranial and lateral forearm and dorsal forepaw	Extensor carpi radialis, ulnaris lateralis, extensors
Brachial plexus avulsion (proximal damage)			
Suprascapular nerve ([C5],C6,C7)	Loss of shoulder extension; muscle atrophy over scapular spine	None	Supraspinatus, infraspinatus
Axillary nerve ([C6],C7,C8)	Reduced shoulder flexion Deltoid muscle atrophy	Lateral brachium over humerus and scapula	Deltoideus, teres major, teres minor, subscapularis
Musculocutaneous nerve (C6,C7,C8)	Reduced elbow flexion	Medial forearm	Biceps brachii, brachialis, nerve coracobrachialis
Radial nerve (C7,C8,T1,[T2])	Reduced extension of elbow, carpus, and digits; cannot support weight	Cranial and lateral forearm and foot (except digit 5)	Triceps brachii, extensor carpi radialis, ulnaris lateralis, digital extensors
Median nerve (C8,T1[T2])	Reduced flexion of carpus and digits	None	Flexor carpi radialis, digital flexors
Ulnar nerve (C8,T1[T2])	Reduced flexion of carpus and digits	Caudal forearm distal to elbow, 5th digit	Flexor carpi ulnaris, deep and digital flexors
Lesions of Nerves of the Lumbosacral Plexus			
Femoral nerve damage L4,L5,L6	Inability to extend stifle Cannot support weight Atrophy of quadriceps Loss of patellar reflex	Medial limb (toes to thigh)	Iliopsoas, quadriceps, sartorius
Obturator nerve ([L4],L5,L6)	Abduction of limb at hip	None	External obturator, pectineus gracilis, adductor
Sciatic nerve paralysis (L6,L7,S1,[S2])	Reduced flexion and extension of hip; loss of stifle flexion; loss of hock flexion and extension; hock dropped; paw is knuckled, but weight bearing does occur; absent withdrawal reflex; atrophy of cranial, tibial, semimembranosus, and semitendinosus muscles	All regions below stifle except medial surface	Biceps femoris, semimembranosus, semitendinosus
Tibial branch (L7, S1,[S2])	Dropped hock	Plantar paw and limb distal to stifle	Gastrocnemius, popliteus, digital flexors
Peroneal branch (L6,L7,S1,S2)	Stands knuckled; no cranial tibial reflex; weak hock flexion	Cranial and lateral limb (distal to stifle)	Peroneus longus, digital extensors, cranial tibial
Cranial and caudal gluteal (L7,S1,S2)	Reduced hip flexion; stifle rotates laterally during weight bearing	None	Superficial, middle, and deep gluteals, tensor fascia lata

the nerve roots or peripheral nerves of dogs and cats (Fig. 66.3).

Clinical Features

Clinical signs depend on tumor location and the nerves involved. Trigeminal nerve sheath tumors cause ipsilateral atrophy of the temporalis and masseter muscles. Malignant PNSTs in dogs most commonly affect the caudal cervical (C6-C8) or cranial thoracic (T1-T2) nerve roots of the brachial plexus, resulting in lameness, muscle atrophy, and pain. There may be pain on shoulder manipulation, and at rest the dog may lift the affected leg to relieve muscle spasm

(root signature). The insidious onset of these tumors may make it difficult to differentiate them from lameness caused by a vague musculoskeletal injury or nerve root compression caused by intervertebral disk disease. With progression of the tumor, atrophy, weakness, and loss of reflexes may occur as the affected peripheral nerve is destroyed. Tumors involving the T1-T3 nerve roots commonly interrupt the sympathetic pathway and result in ipsilateral Horner syndrome. Similarly, the ipsilateral cutaneous trunci reflex will be absent if the C8-T1 ventral nerve roots are damaged. Tumors originating in the spinal canal and extending peripherally and tumors originating in the brachial plexus and extending proximally into the vertebral canal will often cause upper motor neuron (UMN) deficits in the ipsilateral hindlimb as the tumor expands, but this may not be clinically apparent until significant spinal invasion has taken place.

Diagnosis

Radiographs of the spine are indicated if a neoplasm involving a spinal nerve root is suspected. Nerve sheath tumors rarely cause bony changes, although expanding tumors that pass through an intervertebral foramen may cause widening of the foramen as a result of pressure necrosis. Myelography can be useful to identify spinal cord compression. Electromyography and nerve conduction velocity determinations may confirm the presence of a peripheral nerve lesion and aid in localization. Deep palpation and ultrasound examination of the axilla under general anesthesia may reveal a mass. MR imaging is the best way to

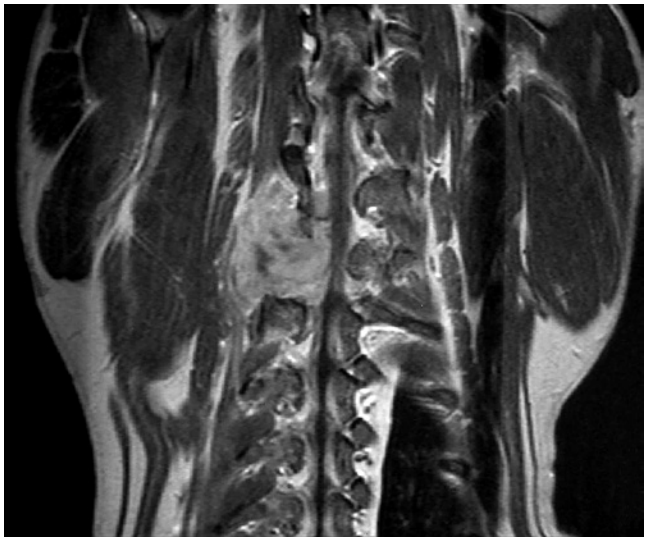

FIG 66.4
Magnetic resonance imaging of the spine of a dog with a nerve root tumor causing lameness and lower motor neuron paresis of the right forelimb reveals tumor invasion into the vertebral canal.

delineate tumor masses and detect vertebral canal invasion (Fig. 66.4).

Treatment

The treatment of choice for a PNST is early surgical removal. Aggressive removal of distally located tumors can result in a cure. Extensive neurologic damage by the tumor, damage affecting several spinal nerves or nerve roots, or severely atrophied muscles usually necessitate amputation of the limb. Nerve root tumors that have progressed to cause spinal cord compression usually involve multiple nerve roots, are rarely completely resectable, and are associated with a poor prognosis. Postoperative irradiation may be indicated in an attempt to slow tumor recurrence.

Facial Nerve Paralysis

Facial nerve (CN7) paralysis is recognized frequently in dogs and cats. In 75% of dogs and 25% of cats with acute facial nerve paralysis, there are no associated neurologic or physical abnormalities and no underlying cause can be found, prompting a diagnosis of idiopathic facial nerve paralysis. The most important differential diagnoses to consider include damage to branches of the facial nerve within the middle/inner ear secondary to inflammation, infection, neoplasia, or benign nasopharyngeal polyps. Traumatic injury to the facial nerve is unlikely without major trauma. Canine hypothyroidism is occasionally associated with a mononeuropathy involving the facial nerve, but the causality is uncertain.

Clinical Features

Clinical manifestations of facial nerve paralysis include an inability to close the eyelid, move the lip, or move the ear.

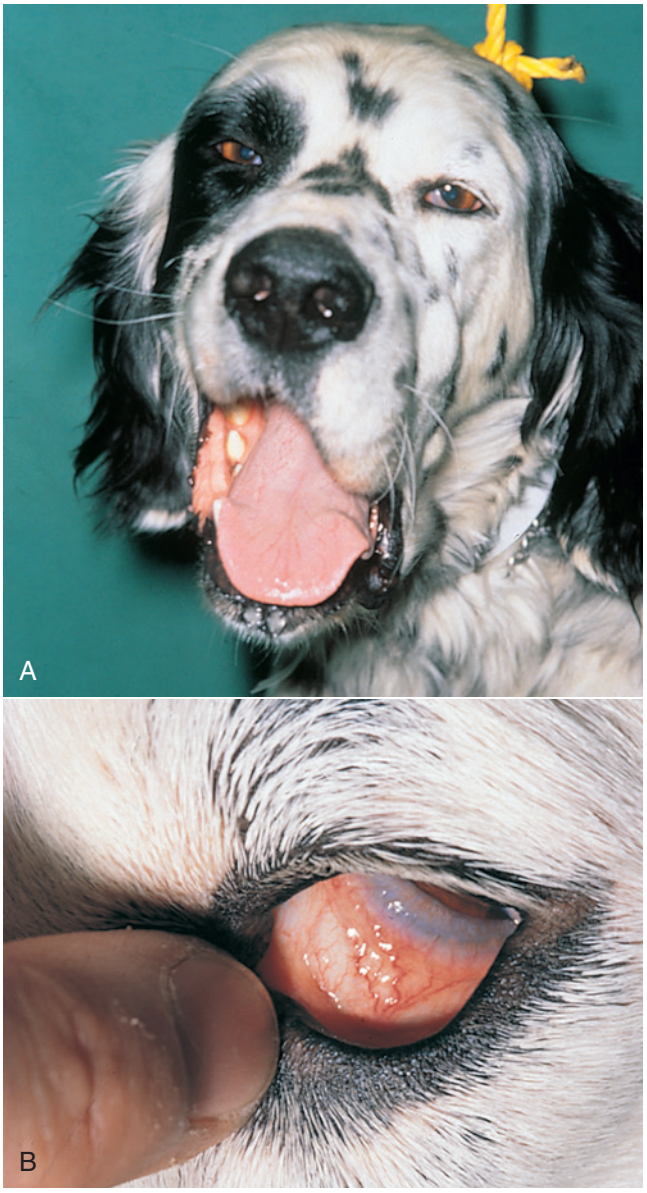

FIG 66.5
Idiopathic facial nerve paralysis in a 4-year-old English Setter. Note the drooping lip and ear **(A)** and the inability to blink **(B).** The paralysis resolved in 14 days without therapy.

Affected animals are unable to blink spontaneously or in response to visual or palpebral sensory stimulation. Corneal ulceration may occur because of an inability to distribute the tear film by blinking (neuroparalytic keratitis) and loss of facial nerve (parasympathetic)–stimulated lacrimal gland secretion (neurogenic keratitis). Drooping of the ear and lip as a result of loss of muscle tone on the affected side is common (Fig. 66.5). Rarely, a painful syndrome of hemifacial spasm with facial muscle contracture and lip retraction may occur as a result of facial nerve irritation. This should be differentiated from nonpainful muscle atrophy and contracture, which occur relatively commonly in animals with long-standing facial nerve paralysis (Fig. 66.6). Many dogs

FIG 66.6
Contraction of the muscles on the left side of the face developed in an adult dog with a 2-month history of idiopathic left-sided facial nerve paralysis. Note the erect left ear and nasal deviation to the left.

and cats with facial nerve paralysis caused by middle/inner ear disease also develop peripheral vestibular signs and/or Horner syndrome because of the close proximity of the nerves in the area of the middle and inner ear.

Diagnosis

Idiopathic facial nerve paralysis can be diagnosed only after excluding all other causes. A complete neurologic examination should be performed to ensure there are no other cranial nerve deficits, ataxia, or proprioceptive deficits suggesting a brainstem lesion. Clinicopathologic testing (i.e., complete blood count [CBC], serum biochemistry profile, urinalysis) is required to evaluate for systemic or metabolic disease. A suspicion of hypothyroidism warrants evaluation of thyroid function (see Chapter 48).

All dogs and cats with facial nerve paralysis should be evaluated carefully for disease of the middle and inner ear. Careful otoscopic examination is important even if general anesthesia is required. Most animals with otitis media or otitis interna have obvious otitis externa and a tympanic membrane that appears abnormal or ruptured, but occasionally the otoscopic examination is normal. If the suspicion for middle and inner ear disease is high, general anesthesia for radiographs or CT and myringotomy to collect a sample from the middle ear are warranted (Fig. 66.7).

Treatment

Medical treatment for bacterial otitis media/interna is discussed in Chapter 63. No treatment exists for idiopathic facial nerve paralysis. If keratoconjunctivitis sicca is present, the eye should be medicated as needed. The paralysis may be permanent, or spontaneous recovery may occur in 2 to 6 weeks.

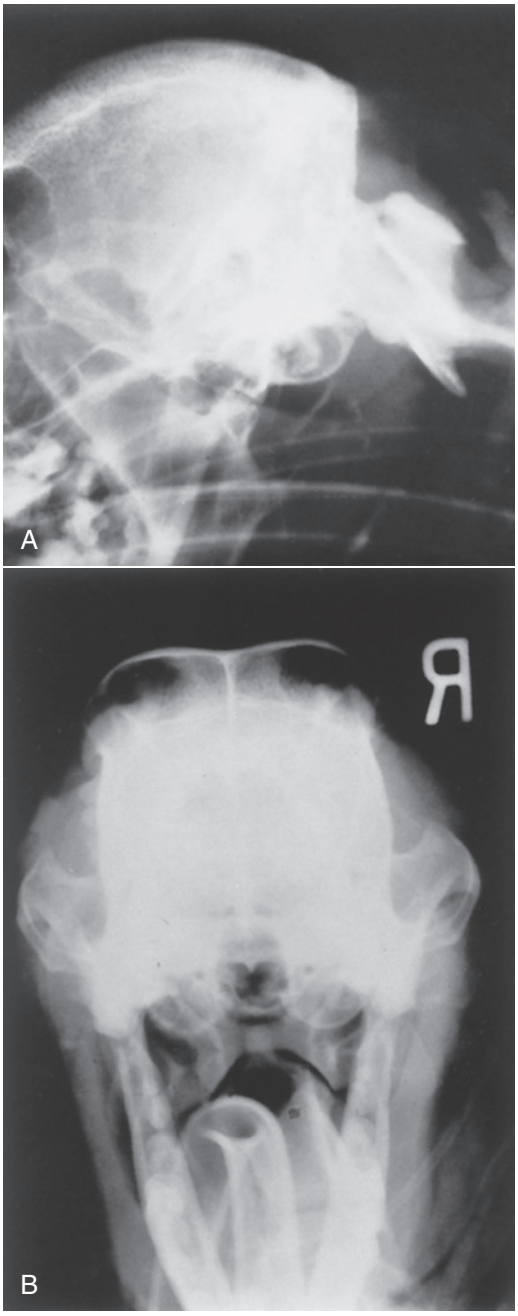

FIG 66.7
(A and B) Skull radiographs of a 4-year-old Cocker Spaniel with bilateral otitis media resulting in bilateral facial nerve paralysis. Both bullae chambers are opacified, and the left bulla is thickened by irregular and slightly indistinct new bone.

TRIGEMINAL NERVE PARALYSIS

Bilateral motor paralysis of the trigeminal nerves results in sudden onset of an inability to close the jaw or prehend food.

The mouth hangs open, but it can be physically closed and manipulated without resistance (Fig. 66.8). Swallowing is normal. Severe rapid atrophy of the muscles of mastication may occur, and about 8% of dogs display concurrent Horner syndrome or facial paresis. Sensory loss (trigeminal distribution) is variable, occurring in approximately 30% of dogs, if hyposensitization of the corneal surface occurs, there will be decreased reflex tear formation and loss of trophic factors, leading to corneal ulceration without significant discomfort (neurotrophic keratitis).

Idiopathic trigeminal paralysis is most commonly seen in middle-aged and older dogs, and Golden Retrievers are overrepresented. This disorder is rare in cats. The diagnosis relies on clinical signs and on ruling out other possible causes. Rabies and other inflammatory central nervous system (CNS) diseases are unlikely in the absence of other clinical signs, but *Neospora caninum* infection and severe idiopathic polyneuritis have occasionally been diagnosed in dogs with similar signs. Neoplastic and traumatic disorders are not usually bilateral, although bilateral motor trigeminal nerve infiltration has been reported in a dog and numerous cats with focal or multicentric lymphoma and dogs with myelomonocytic leukemia.

FIG 66.8
Idiopathic trigeminal nerve motor paralysis resulting in a dropped jaw and excessive drooling in a 9-year-old Labrador Retriever. Paralysis resolved in 14 days without therapy.

The etiology of this idiopathic disorder is unknown. If biopsy of the nerve is performed, it reveals bilateral nonsuppurative neuritis of all motor branches of cranial nerve 5 associated with demyelination. Treatment consists of supportive care. Most dogs can drink and maintain adequate hydration if they are given water in a deep container (e.g., bucket). Hand-feeding may be necessary. Holding the mouth partially closed in a sling may facilitate eating and drinking during recovery (Fig. 66.9). Lubricating eye ointments may help prevent corneal ulceration. The prognosis is excellent, with most animals recovering completely within 2 to 4 weeks. Repeat episodes are rare.

Hyperchylomicronemia

Peripheral neuropathies have been observed in cats of all ages with a mutation in the gene encoding lipoprotein lipase. Affected cats have delayed clearance of chylomicrons from the circulation, resulting in formation of lipid granulomas (xanthomas) in the skin and other tissues. These xanthomas may compress a nerve against bone, resulting in neuropathology. Horner syndrome and tibial and radial nerve paralysis are most often seen, but facial, trigeminal, and recurrent laryngeal nerve paralysis are also reported. Clinicopathologic testing reveals fasting hyperchylomicronemia and blood that looks like cream-of-tomato soup. Diagnosis is by biopsy of the xanthomas or measurement of lipoprotein lipase concentration. The neurologic signs are reversible if hyperchylomicronemia can be controlled by feeding affected cats a low-fat, high-fiber diet.

ISCHEMIC NEUROMYOPATHY

Caudal aortic thromboembolism causes paralysis from ischemic damage to affected muscles and peripheral nerves. Ischemia is caused by vasoconstriction of the collateral circulation to the limbs as a result of release of thromboxane A_2 and serotonin from activated platelets in a clot lodged in the aortic trifurcation. Caudal aortic thromboembolism is common in cats and rare in dogs. An acute onset of LMN pelvic limb paralysis or paresis is seen. Femoral pulses are weak or absent. The legs and feet are cool, and the pads and

FIG 66.10
(A) Acute severe lower motor neuron (LMN) paralysis of the rear limbs occurred in this 6-week-old Dalmatian puppy. The limbs were cool, and no femoral pulses were palpable. **(B)** The footpads on the front feet were warm and pink, whereas those on the rear feet were cool and pale. Ultrasound examination revealed a caudal aortic thrombus. **(C)** Acute LMN paralysis in the left hindlimb of a 9-year-old cat caused by an iliac artery thrombus. **(D)** The left hindlimb was cool, had no palpable femoral arterial pulse, and had pale footpads.

nailbeds are pale or cyanotic (Fig. 66.10). Hemorrhage does not occur when a toenail is cut short on an affected foot. The affected muscles are swollen and painful. LMN paralysis with complete areflexia of the rear limbs is common, although occasionally the patellar reflex is maintained. Within hours, rigid extension of the legs may occur as a result of contracture of ischemic muscle. In cats, cardiomyopathy is the most common cause, whereas in dogs some other disorder associated with hypercoagulability can usually be identified (see Chapter 12). Dogs should be evaluated for nephrotic syndrome, hyperadrenocorticism, heartworm disease, neoplasia, and endocarditis. Diagnosis and treatment of feline aortic thromboembolism is discussed in Chapter 12.

POLYNEUROPATHIES

Polyneuropathies affect more than one group of peripheral nerves, resulting in generalized LMN signs that include flaccid muscle weakness or paralysis, marked muscle atrophy, decreased muscle tone, and reduced or absent reflexes. Proprioception is normal unless the sensory portions of the nerves are severely affected. Electromyography, when available, reveals evidence of denervation, and nerve conduction velocity is decreased. Muscle biopsies reveal denervation and atrophy, and nerve biopsies typically reveal axonal degeneration and demyelination regardless of the underlying cause, so a thorough systemic investigation of possible etiologies is required to reach a diagnosis and recommend appropriate treatment (Box 66.1). A few of the inherited and acquired polyneuropathies have characteristic changes apparent on nerve biopsy.

CONGENITAL/INHERITED POLYNEUROPATHIES

A number of breed-associated degenerative peripheral neuropathies occur. They usually affect young animals (6 weeks to 6 months) and are presumed to have a hereditary basis. In some breeds, signs are not apparent until 1 to 4 years of age or older. Most of these disorders primarily affect the motor components of the nerves and cause progressive generalized LMN dysfunction. Pathologic lesions vary with each

disorder but may involve degeneration of the motor neurons in the ventral horn of the spinal cord (motor neuron diseases), degeneration of the peripheral nerves (axonopathies), degeneration of only the terminal and intramuscular branches of motor nerves (distal denervating disease), or demyelination of peripheral nerves. Many of the breed-specific disorders predominantly affect the rear limbs initially and then progress to affect the forelimbs. Most of these predominantly motor neuropathies cause severe tetraparesis, plantigrade stance, muscle wasting, and hyporeflexia, and some cause concurrent cranial nerve deficits.

Concurrent development of tetraparesis with laryngeal paralysis and megaesophagus due to widespread motor axonal degeneration has been recognized as an inherited syndrome called laryngeal paralysis polyneuropathy complex. Affected breeds include Rottweilers, Dalmatians, Alaskan Malamutes, Pyrenean Mountain dogs, Leonbergers, Russian Black Terriers, and others. Siberian and Alaskan Huskies, white German Shepherd dogs, Rottweilers, and Bouvier des Flandres have inherited polyneuropathies that cause laryngeal paralysis without clinically evident limb weakness due to neuronal degeneration that primarily involves the brainstem and peripheral cranial nerves. When a young dog of any of these breeds is evaluated for laryngeal paralysis, it is important to determine whether there are concurrent LMN deficits that would impact prognosis.

Many breeds of dogs have been identified with spinal muscular atrophy (degeneration of motor neurons in the brainstem and/or spinal cord), or inherited polyneuropathies with widespread axonal degeneration or demyelination. Signs are of progressive LMN paresis with muscle atrophy and loss of reflexes. Several breeds of cats also have hereditary neuropathies. Inherited peripheral neuropathies and neuronal degeneration disorders are caused by a variety of different mutations in genes that produce proteins involved in the structure and function of motor neurons, peripheral nerve axons, or the myelin sheath.

The typical neurologic findings in animals with a peripheral neuropathy include weakness, muscle atrophy, and loss of reflexes with no loss of proprioception and normal postural reactions. An exception occurs when sensory portions of the nerves are severely affected. Familial sensory or mixed sensory/motor neuropathies occur uncommonly, causing diminished or altered sensation/nociception and self-mutilation (English Pointers) or proprioceptive ataxia and dysmetria (Longhaired Dachshunds, Golden Retrievers, Boxers). All of these conditions are extremely rare and are reviewed in detail in the Suggested Readings and online sites. Presumptive diagnosis is by recognition of typical breed, age of onset, and presentation, and by ruling out other disorders. Genetic testing is available for a few disorders. Definitive diagnosis requires electrophysiologic evaluation of nerve function and nerve biopsy.

ACQUIRED CHRONIC POLYNEUROPATHIES

Diabetic Polyneuropathy

Poorly controlled diabetes mellitus causes distal axonal degeneration. Clinical signs of diabetic polyneuropathy are usually subtle or inapparent in the dog but may be dramatic in the cat. Weakness of the rear limbs, reluctance to jump, a plantigrade pelvic limb stance, and weakness of the tail are characteristic (Fig. 66.11). Physical examination findings may include marked muscle atrophy and rear limb hyporeflexia, particularly loss of hock flexion when the withdrawal reflex is tested. Over time the forelimbs can be affected as well. Severely affected dogs may also have proprioceptive deficits suggesting a mixed motor and sensory neuropathy, and concurrent laryngeal paralysis has been reported. Diagnosis is suspected in animals with poorly controlled diabetes mellitus and classic neurologic findings. Definitive diagnosis would require electrodiagnostic testing and peripheral nerve biopsy, but this is rarely performed (see Chapter 49 for more information). If diabetic polyneuropathy is recognized early, establishing improved glucose regulation can result in stabilization or improvement of neurologic signs in some cats and most dogs.

Hypothyroid Polyneuropathy

Hypothyroidism has been associated with a variety of peripheral nerve abnormalities, including diffuse LMN paresis, unilateral peripheral vestibular disease, facial nerve paralysis, laryngeal paralysis, and megaesophagus in dogs. The exact relationship between neuropathies and hypothyroidism is unclear. Nerve and muscle biopsies in affected dogs

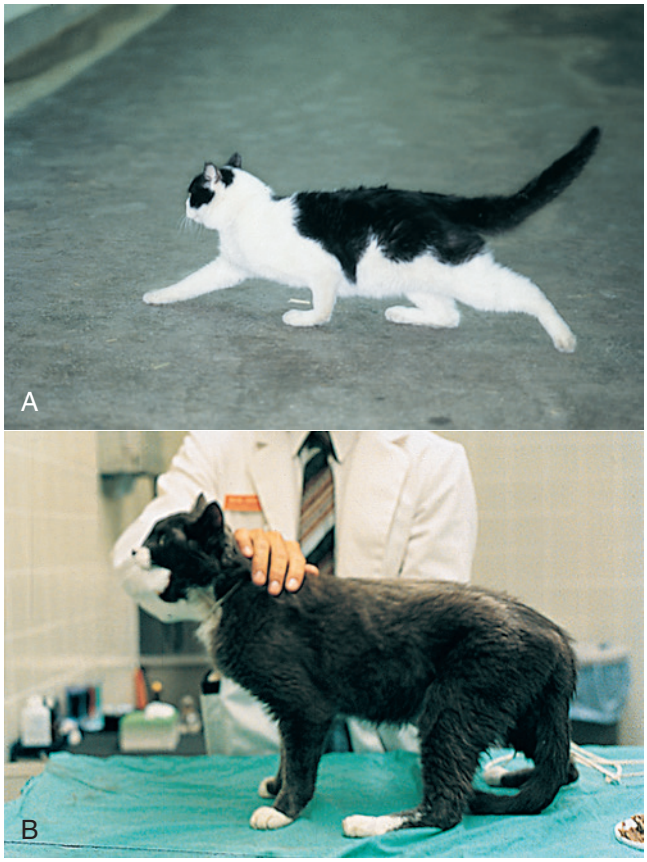

FIG 66.11
Plantigrade stance in **(A)** an 11-year-old cat and **(B)** a 6-year-old cat with polyneuropathy caused by diabetes mellitus.

may show neuronal degeneration and regeneration, as well as muscle fiber type grouping that is most indicative of denervation. In some hypothyroid dogs, neurologic signs resolve within 2 to 3 months once supplementation with thyroid hormone is initiated (Fig. 66.12) (see Chapter 48 for more information).

Insulinoma Polyneuropathy

Insulin-secreting tumors have been associated with a paraneoplastic polyneuropathy in dogs. Affected dogs may initially have a stiff rear limb gait, but this progresses to generalized weakness, muscle atrophy, and sciatic hyporeflexia. Treatment of the insulinoma may result in resolution of the polyneuropathy (see Chapter 49 for more information).

Paraneoplastic Polyneuropathy

Although clinically significant paraneoplastic neuropathies are infrequently recognized in dogs and cats, histologic lesions of polyneuropathy are evident in many dogs with cancer. LMN paresis caused by paraneoplastic polyneuropathy has been reported in dogs with bronchogenic carcinoma, hemangiosarcoma, mammary carcinoma, pancreatic carcinoma, prostatic carcinoma, lymphoma, and multiple myeloma. Complete systemic evaluation and cancer search

FIG 66.12

(thorough physical examination, thoracic and abdominal radiographs, abdominal ultrasound, lymph node aspirates) are warranted in all animals presented for chronic progressive LMN dysfunction. In some cases, treatment or removal of the offending neoplasm resolves clinical signs of polyneuropathy.

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) causes slowly progressive LMN tetraparesis in adult dogs and cats. Subtle weakness and exercise intolerance are the initial manifestations, followed by progressive muscle atrophy, hyporeflexia, and severe tetraparesis. Some animals develop concurrent laryngeal or facial paresis or paralysis. When clinical findings suggest a polyneuropathy, tests should be performed to eliminate endocrine and paraneoplastic causes and to look for other systemic manifestations of a polysystemic immune-mediated disease like systemic lupus (Fig. 66.13). CIDP is largely an elimination diagnosis, but, when performed, electrophysiologic studies and nerve biopsies reveal multifocal demyelination and a mononuclear infiltrate. Immunosuppressive therapy should be initiated using prednisone and azathioprine. The short-term prognosis for clinical response and recovery may be good, but there is a tendency for this idiopathic inflammatory disorder to relapse and progress over time.

Chronic Idiopathic Polyneuropathy

Chronic idiopathic demyelinating polyneuropathies occur in dogs and cats where systemic evaluation does not reveal an underlying cause and there is no response to treatment as an

FIG 66.13
A 4-year-old Great Dane with severe weakness, hyporeflexia, and muscle atrophy caused by polyneuritis resulting from systemic lupus erythematosus. The dog also had dermatitis, polyarthritis, glomerulonephritis, and a positive antinuclear antibody test. Polyneuritis was confirmed on postmortem examination.

immune-mediated disorder. The presumptive diagnosis is made of an idiopathic degenerative disorder with no available treatment. This is thought to be the cause of the subclinical idiopathic polyneuropathy present in many geriatric large-breed dogs presented for laryngeal paralysis and stridor. The tendency for laryngeal weakness to be the earliest manifestation of this very slowly progressive polyneuropathy has been attributed to the length of the recurrent laryngeal nerve. Over time, some affected dogs will exhibit other manifestations of a progressive polyneuropathy, including paraparesis or tetraparesis, sciatic hyporeflexia, proprioceptive deficits, dysphagia, and megaesophagus.

Acute Lower Motor Neuron Tetraparesis

Weakness that begins in the pelvic limbs and rapidly progresses over 4 to 72 hours to flaccid tetraparesis or tetraplegia is an uncommon presenting complaint in dogs and cats. The major disorders causing acute flaccid tetraparesis in dogs and cats are acute idiopathic polyradiculoneuritis, botulism, tick paralysis, and acute fulminating acquired myasthenia gravis. A complete neurologic examination with attention to detail can help to differentiate these disorders (Table 66.2). Acute polyradiculoneuritis is a disease of the peripheral nerves and nerve roots, so weakness, hyporeflexia, and rapid severe muscle atrophy are the characteristic features. Botulism and tick paralysis are presynaptic NMJ disorders, so profound weakness, loss of reflexes, and cranial nerve deficits but no muscle atrophy is expected. Animals with acute fulminating MG (discussed later in this chapter) are weak but typically have normal spinal reflexes and no muscle atrophy.

Acute Polyradiculoneuritis

Acute canine polyradiculoneuritis (ACP) is the only acute-onset polyneuropathy commonly diagnosed in dogs. The disorder is clinically and histologically very similar to human Guillain Barré syndrome (GBS), an autoimmune allergic neuritis thought to be caused by exposure to a triggering antigen. The similarities between GBS and ACP have prompted investigators to look for antigens, infectious processes, or events that are triggering the immune system in dogs with ACP to cause extensive demyelination, inflammatory cell infiltration, and disruption of the ventral (motor) nerve root and spinal nerve components of peripheral nerves.

The popular name for ACP, *Coonhound paralysis*, originates in the fact that many of the early cases developed signs 7 to 14 days after hunting dogs were bitten by a raccoon. Raccoon saliva injection does not reliably produce the disorder in every dog, but in roughly 50% of North American dogs with ACP there is documented recent raccoon exposure, and serum antibodies against raccoon saliva are demonstrable (Fig. 66.14).

Acute polyradiculoneuritis also occurs in many dogs with no possible exposure to raccoons. Previous systemic illness or vaccination, *Campylobacter jejuni* infection, and *Toxoplasma gondii* infection have all been implicated as potential initiating antigens, but in most cases no cause-and-effect relationship can be proven. Rarely, an acute onset of areflexic flaccid tetraparesis or tetraplegia similar to ACP has been diagnosed in the cat. An inciting event cannot usually be determined, but rabies virus vaccination has been implicated.

Clinical Features

Inflammation of the axons and myelin sheaths at the level of the ventral nerve roots causes an acute, rapidly progressive LMN paresis or paralysis. A stilted, short-strided, weak rear limb gait progresses rapidly over a few days to tetraparesis, with most affected dogs tetraplegic within 5 to 10 days of onset. The progression of signs is variable, with some dogs remaining ambulatory but weak and others developing a flaccid nonambulatory tetraplegia. In recumbent dogs, neurologic examination reveals remarkably decreased muscle tone, rapidly progressive muscle atrophy, and severely diminished or absent reflexes. Because the disease primarily affects the ventral nerve roots, proprioception and postural reaction testing remains normal if the animal can still move its limbs and its weight is supported during testing. Some dogs seem to be hyperesthetic, reacting vigorously to mild stimulation such as muscle palpation or pinching of the toes. This hyperesthesia is a feature of polyradiculoneuritis that does not occur in association with the NMJ disorders tick paralysis or botulism, the two major differential diagnoses for rapidly progressive LMN tetraplegia in dogs. Despite the severe paresis or paralysis, dogs with ACP remain bright and alert, continue to eat and drink when supported, and can vigorously wag the tail. Bladder and rectum functions remain normal. As a rule, cranial nerves are not involved; no problems with chewing or swallowing exist, nor do any pupillary abnormalities. Most dogs do, however, have a hoarse bark and a small percentage of very severely affected dogs have

TABLE 66.2

Clinical and Diagnostic Differences Among Disorders Causing Rapidly Progressive Lower Motor Neuron Tetraparesis in the Dog

DISEASE	WEAKNESS	MUSCLE TONE	SPINAL REFLEXES	MUSCLE ATROPHY	CRANIAL NERVES	SENSATION	CSF	EMG
Acute canine polyradiculoneuritis (Coonhound paralysis)	Generalized weakness, often progressing to paralysis within 5-10 days	Decreased	Decreased or absent	Rapid and severe	Hoarse bark Able to eat and drink normally Rarely facial paresis	Hyperesthetic	Normal or increased protein	Denervation after 4-5 days
Tick paralysis Geographic potential for exposure Rapid recovery after tick removal	Generalized weakness, rapid progression	Decreased	Decreased or absent	None	Hoarse bark Dysphagia Facial paresis Decreased jaw tone	Normal	Normal	Normal
Botulism Often a group outbreak	Generalized weakness, often progressing to paralysis within 24 hours	Decreased	Decreased or absent	None	Hoarse bark Dysphagia, megaesophagus Facial paresis Decreased jaw tone Dilated pupils, absent PLR	Normal	Normal	Normal
Acute fulminating myasthenia gravis Some (50%) respond to anticholinesterase administration (see Box 66.2)	Generalized weakness but maintains ability to move	Decreased	Normal	None	Hoarse bark Dysphagia, mega-esophagus, aspiration pneumonia Facial nerve paresis (±), fatigable palpebral reflex	Normal	Normal	Normal

PLR, Pupillary light reflex.

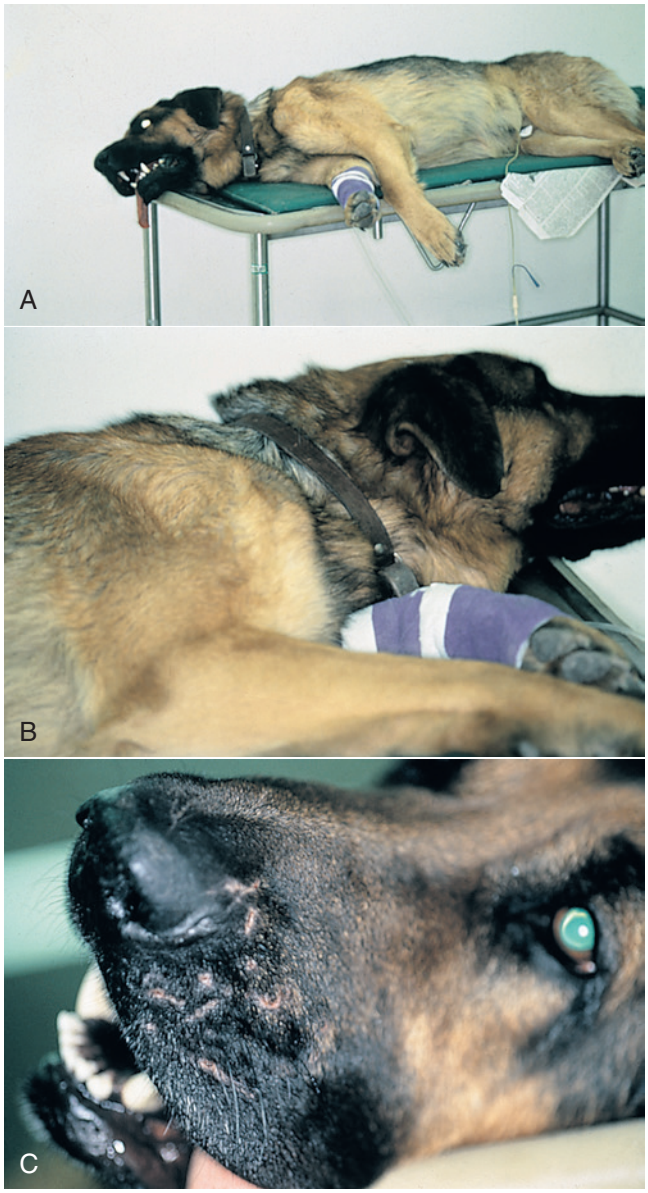

FIG 66.14
A 4-year-old German Shepherd dog with **(A)** rapidly progressive ascending lower motor neuron paralysis, **(B)** severe appendicular muscle atrophy, and **(C)** healing facial wounds presumed to be from an encounter with a raccoon. The tentative diagnosis in this dog was acute polyradiculoneuritis. Supportive care was initiated, and the dog returned to normal after a prolonged recovery lasting 3 months.

concurrent bilateral facial nerve paresis. In a few dogs, respiratory paralysis can lead to death or require mechanical ventilation.

Diagnosis

The diagnosis of ACP is suspected on the basis of historical, clinical, and neurologic findings. The most important and challenging aspect of diagnosis is differentiating this disorder from NMJ disorders causing acute LMN tetraparesis (e.g., tick paralysis, botulism, acute fulminating myasthenia gravis) using clinical features and (when available) electrodiagnostic testing (see Table 66.2). Owners should be questioned about any possible inciting event or exposure 7 to 14 days earlier. Systemic evaluation including routine bloodwork, urinalysis, thoracic radiographs, and abdominal ultrasound are usually recommended. Normal cranial nerve and esophageal function and the presence of hyperesthesia and rapidly progressive muscle atrophy make ACP most likely. When performed 6 or more days after the onset of paresis, electromyography reliably reveals diffuse denervation (fibrillation potentials and positive sharp waves), a finding not expected with NMJ disorders. Additional EMG features described in the Suggested Readings indicate a motor axonopathy and demyelination that is most pronounced in the ventral nerve roots and proximal nerves. Lumbar CSF analysis typically reveals a normal cell count and distribution as well as an increase in CSF protein, particularly 7 days or more into clinical signs. In cases where there is no history of potential raccoon exposure or recent vaccination, diagnostic testing for an inciting cause (*Toxoplasma, Neospora*) should be considered. Definitive diagnosis can also be established by nerve biopsy, but this is rarely necessary.

Treatment

No specific treatment exists for ACP. During the initial progressive phase, dogs must be monitored for respiratory compromise, especially if they have had a rapid progression to recumbency. Signs typically stabilize after 5 to 10 days, after which patients can usually be managed with supportive care at home. They may require assistance in sitting up to eat and drink. If possible, they should be kept on an air mattress, waterbed, lounge chair, or bed of straw and turned periodically to prevent lung atelectasis and pressure sores. Glucocorticoid treatment is not beneficial, and may actually slow recovery, but treatment with human intravenous immunoglobulin (IVIG, 0.5 g/kg slow intravenous [IV] infusion q24h for 4 doses) (Sandoglobulin [Behring]) may help speed recovery.

Prognosis

The prognosis for recovery in the dog is good. Most dogs begin to improve after the first week and are fully recovered within 3 to 4 weeks. Recovery may take 4 to 6 months in severely affected dogs, and some dogs never recover completely. The prognosis for complete recovery in the cat is poor. Affected animals that have recovered may be prone to recurrences, particularly if exposed again to the initiating antigen.

DISORDERS OF THE NEUROMUSCULAR JUNCTION

Presynaptic disorders that prevent ACh release into the NMJ cause rapidly progressive generalized LMN paresis or paralysis and loss of reflexes. Careful attention to clinical clues or diagnostic evaluation is required to differentiate these

disorders of neurotransmission (tick paralysis, botulism) from the more common acute peripheral nerve disorder ACP.

TICK PARALYSIS

A rapidly ascending flaccid motor paralysis has been recognized in dogs infested with certain species of ticks. Most of the reported cases in North America are associated with selected strains of ticks including *Dermacentor andersoni* in the Pacific Northwest and *Dermacentor variabilis* in the East. When a female tick feeds, she elaborates a circulating salivary neurotoxin that interferes with ACh release at the NMJ, causing presynaptic neuromuscular blockade.

Clinical Features

Dogs with tick paralysis exhibit a rapidly progressive ascending flaccid paralysis 4 to 9 days after tick attachment, when the tick is fully engorged. Signs begin in the pelvic limbs and progress rapidly to LMN tetraplegia within 12 to 72 hours. Muscles are flaccid, and spinal reflexes are decreased or absent, but muscle atrophy is not pronounced. Pain is perceived normally, with no evidence of hyperesthesia. In most cases the cranial nerves are not significantly affected, but facial weakness, an altered voice, dysphagia, or decreased jaw tone may be recognized. Without treatment, death due to respiratory paralysis may occur in 1 to 5 days.

Diagnosis

Tick paralysis is often confused with other causes of acute tetraparesis such as acute polyradiculoneuritis, botulism, and acute fulminating MG (see Table 66.2). Tick paralysis is suspected on the basis of the history, clinical signs, and knowledge of the geographic region. Sometimes a tick can be found on the animal, and diagnosis is confirmed by documenting rapid (hours to days) improvement after tick removal. Electromyography, if performed, does not reveal spontaneous muscle activity, because the muscles are not denervated as they would be in ACP. There is diminished amplitude of the muscle action potential in response to a single supramaximal stimulus, as expected with a defect in neuromuscular transmission.

Treatment

Removal of a tick or dipping the animal in an insecticidal solution results in dramatic recovery within 24 to 72 hours. The prognosis for complete recovery is good when the proper diagnosis is made.

BOTULISM

Botulism is rarely recognized in dogs and has been reported only once in cats. It results from ingestion of spoiled food or carrion (usually raw meat) containing a preformed type C neurotoxin produced by the bacterium *Clostridium botulinum*. This toxin blocks the release of ACh at the NMJ, resulting in complete presynaptic neuromuscular blockade and LMN paralysis. Clinical signs occur hours to days after ingestion of the toxin.

Clinical Features

Affected dogs develop a short-strided, weak, shuffling gait that rapidly progresses from pelvic limb weakness to recumbency over 12 hours to 4 days. Muscle tone is poor and spinal reflexes are absent, but there is no significant muscle atrophy. The tail wag is preserved. Proprioception and pain perception are normal, without hyperesthesia. By the time they are unable to rise, most affected dogs have multiple cranial nerve deficits causing dilated pupils with a sluggish pupillary light reflex, weak palpebral response, drooling, dysphagia, decreased jaw tone, and a hoarse voice/weak bark. Megaesophagus and regurgitation are common. The amount of ingested toxin determines severity of signs. Clinical signs can last for weeks, and death can occur if respiratory muscles are impaired.

Diagnosis

The diagnosis is based on clinical findings and/or a history of ingestion of spoiled food. Botulism is especially likely if an outbreak of areflexic LMN paralysis is seen in a group of dogs with access to rotting garbage or carrion. Rabies must be considered as a differential diagnosis in severely affected individual dogs, but it is usually associated with abnormal mentation. Weakness of the muscles of the face, jaw, and pharynx is much more pronounced with botulism than would be expected with acute polyradiculoneuritis or tick paralysis. When electromyography is available, it reveals no evidence of denervation, but there is diminished amplitude of the muscle action potential in response to a supramaximal stimulus, similar to the findings in tick paralysis. A definitive diagnosis is based on demonstration of botulinum neurotoxins (BoNT) in blood, vomitus, feces, or stomach contents from affected dogs, or in remnants of the spoiled food that they ingested, but often the toxin is no longer detectable by the time neurologic signs are evident, making this a presumptive diagnosis.

Treatment

No specific treatment for botulism exists. Laxatives and enemas may help remove unabsorbed toxin from the gastrointestinal tract if ingestion was recent. Antitoxin, if it was available, would simply bind and inactivate circulating toxin that had not yet penetrated nerve endings, potentially limiting the severity of clinical signs but not reversing them. Commercially available human trivalent antitoxin are directed against toxin types A, B, and E, so it will not be effective for canine or feline cases, which are all type C. Supportive care should include fluid and nutritional support and esophageal and gastric suctioning to prevent aspiration. Ventilatory support may be required in severely affected dogs. Most dogs recover in 1 to 3 weeks with supportive care, although aspiration pneumonia is a common complication during recovery.

MYASTHENIA GRAVIS

MG is the most common disorder of the NMJ diagnosed in dogs and cats, but because it is an incomplete postsynaptic

disorder, many of the clinical findings are much more suggestive of a muscle disorder than a complete NMJ blockade, such as occurs in botulism or tick paralysis. MG is characterized by a normal neurologic examination at rest, normal muscle mass and reflexes, and weakness exacerbated by exercise and alleviated by rest. Congenital and acquired forms of MG have been recognized. The congenital myasthenic syndromes (CMSs) are a rare group of hereditary disorders of neuromuscular transmission caused by structural or functional defects of the neuromuscular junction. Most CMSs result from an inherited deficiency of AChRs at the postsynaptic membranes in skeletal muscle, causing initial signs of impaired neuromuscular transmission in puppies or kittens 6 to 9 weeks old. The disorder has been recognized in English Springer Spaniels, Smooth Fox Terriers, and Jack Russell Terriers, with rare reports in other breeds and a few cats. The genetic mutation causing this CMS has been identified in Jack Russell Terriers. More recently, genetic mutations have been identified causing CMSs in Golden Retriever and Labrador Retriever puppies. An unusual, poorly classified transient CMS has also been identified in Miniature Dachshunds; the signs in these dogs resolve with maturation.

The acquired form of MG is a common immune-mediated disorder in which antibodies are directed against a portion of the nicotinic AChRs of skeletal muscle. Antibodies bind to the receptors, reducing sensitivity of the postsynaptic membrane to ACh. When nerve stimulation occurs and ACh is released into the synapse, there are less successful interactions between ACh and AChRs, causing smaller muscle endplate potentials and failure to reliably generate a muscle action potential, resulting in weakness. Weakness is compounded during exercise when some of the functional AChRs are already bound by ACh.

Acquired MG affects dogs of all breeds and both genders. German Shepherd dogs, Golden Retrievers, Labrador Retrievers, and Dachshunds are most commonly affected, but this may merely reflect the popularity of these breeds. Breeds that seem to be at increased risk for acquired MG relative to their popularity include the Akita, some terrier breeds, German Shorthaired Pointers, and Chihuahuas. A familial form of acquired MG occurs in young (2-year-old) Newfoundlands and Great Danes. Young-adult dogs (mean age, 2-3 years) and older dogs (mean age, 9-10 years) make up most of the affected population. Cats are rarely affected, but breed predispositions include the Abyssinian and Somali.

Clinical Features

Most dogs (50%-60%) with acquired MG have generalized MG with appendicular muscle weakness that worsens with exercise and improves with rest. Mentation, postural reactions, and limb reflexes are normal. Excessive salivation and regurgitation are common, caused by megaesophagus (seen in 80% of dogs with acquired generalized MG). Megaesophagus is less common in cats with MG (40%) and in dogs with congenital MG. Cats with acquired MG usually present for persistent generalized weakness (floppy cats) and cervical ventroflexion. Dysphagia, hoarse character of the bark or meow, persistently dilated pupils, and facial muscle weakness are sometimes seen.

A focal form of MG causing megaesophagus or dysphagia with no detectable appendicular weakness occurs in approximately 25% to 40% of dogs and 14% of cats with acquired MG. In addition to regurgitation, affected dogs may exhibit weakness of the pharyngeal, laryngeal, and/or facial muscles, and dogs and cats may have a fatigable palpebral reflex. About 25% to 40% of all dogs with adult-onset megaesophagus actually suffer from acquired focal MG, so this disorder should always be considered as a differential diagnosis early in the course of evaluation of dogs with megaesophagus.

An acute fulminating form of acquired MG occurs in 5% to 15% of dogs and cats with acquired MG, causing a sudden onset and rapid progression of severe appendicular muscle weakness that does not improve with rest. They are often nonambulatory and in lateral recumbency with profound weakness but preserved reflexes. Weakness may affect the intercostal muscles and/or the diaphragm resulting in respiratory distress. This form of MG is commonly associated with severe megaesophagus, pharyngeal and laryngeal muscle weakness, aspiration pneumonia, respiratory failure, and death.

Diagnosis

MG should be considered as a differential diagnosis in any dog with a normal neurologic examination and generalized muscular weakness and in all dogs with megaesophagus. Definitive diagnosis of acquired MG is made by demonstrating circulating antibodies against AChRs by immunoprecipitation radioimmunoassay. This test is readily available (Comparative Neuromuscular Laboratory, University of California, San Diego) and is positive in 85% of all dogs and cats with acquired disease and in 98% of those with generalized acquired disease. False-positive results have not been documented. Rarely, dogs with acquired MG are negative for circulating AChR antibodies, perhaps because of very high affinity antibodies that remain bound to AChRs or antibodies directed against junctional antigens other than AChRs.

When results of the serum test for antibodies are not yet available, or in animals with suspected congenital disease, support for the diagnosis of MG can be gained by demonstrating a positive response to administration of a short-acting anticholinesterase. Edrophonium chloride (Tensilon; 0.1 mg/kg), the ultra–short-acting anticholinesterase that was traditionally used for this purpose, is no longer available, so Neostigmine methylsulfate is used instead (Box 66.2). Anticholinesterase drugs inhibit enzymatic hydrolysis of ACh at the NMJ, increasing the effective concentration of ACh and the duration of its effect in the synaptic cleft, optimizing the opportunities for successful interactions between ACh and the AChRs. Atropine (0.02 mg/kg) is administered with the Neostigmine to minimize muscarinic effects. Equipment should be available for intubation and ventilation in the event that anticholinesterase administration results in neuromuscular blockade. Most animals with generalized

BOX 66.2

Anticholinesterase Test Protocol

1. Place an intravenous catheter.
2. Mix together in one syringe:
   Neostigmine methylsulfate 0.01 mg/kg
   Atropine 0.02 mg/kg
3. Have equipment available for intubation and ventilation.
4. Exercise to the point of detectable weakness.
5. Administer the Neostigmine/Atropine combination
6. Monitor weakness.

Route	Onset of Effect	Maximum Effect	Duration
IV	4-8 min	20-30 min	45-60 min
IM	20-30 min	30 min	60-90 min

MG exhibit obvious improvement in clinical signs (e.g., resolution of weakness) within 5 to 10 minutes after administration of intravenous Neostigmine, with the effect lasting approximately 60 minutes (see Box 66.2). A dramatic unequivocal response is very suggestive of MG. Failure to respond does not rule out MG. The response can be difficult to assess in dogs and cats with focal MG, and approximately 50% of dogs with acute fulminating MG will have no response because there has been marked antibody-mediated destruction of AChRs. A negative test also does not completely exclude the diagnosis of congenital MG because several of the CMSs have a poor response.

Electrodiagnostic testing (showing a decremental response of the compound muscle action potentials during repetitive nerve stimulation) can be performed as an aid to reaching a definitive diagnosis of MG, but this test requires general anesthesia—something that should be avoided whenever possible in animals with megaesophagus because of the risk of aspiration during recovery.

Whenever MG is considered as a diagnosis, thoracic radiographs should be assessed for megaesophagus, aspiration pneumonia, or thymoma, and the animal should be evaluated systemically for underlying or associated immune-mediated and neoplastic disorders. If a cranial mediastinal mass is identified, fine-needle aspiration cytologic evaluation should be used to confirm the suspicion that it is a thymoma—a tumor that has been identified in fewer than 5% of dogs with acquired MG but in more than 25% of cats. Concurrent immune-mediated disorders are common in dogs with MG, including hypothyroidism, immune-mediated thrombocytopenia, immune-mediated hemolytic anemia, hypoadrenocorticism, polymyositis, and SLE. Rarely, MG and polyradiculoneuritis occur simultaneously in dogs. MG may also develop as a paraneoplastic disorder in association with a wide variety of tumors, including hepatic carcinoma, anal sac adenocarcinoma, osteosarcoma, cutaneous lymphoma, and primary lung tumors. Acquired drug-induced MG has also been documented in hyperthyroid cats treated with methimazole.

FIG 66.15
Upright feeding in animals with megaesophagus facilitates emptying of esophageal contents into the stomach. Animals should be maintained in this position for 10 to 15 minutes after eating.

Treatment

Treatment of acquired MG includes supportive care and the administration of anticholinesterase drugs and occasionally immunosuppressive agents. Animals with megaesophagus and regurgitation should be maintained in an upright position during feeding, while drinking, and for 10 to 15 minutes afterward to facilitate the movement of esophageal contents into the stomach, decreasing the chance of aspiration (Fig. 66.15). Dogs can be trained to eat and drink while standing with their front feet on a raised platform, or a vertical feeding system (Bailey chair) can be used. If severe regurgitation remains a problem, a gastrostomy tube can be placed to assist in the delivery of nutrients, fluids, and medications, but this will require a short general anesthesia (see Chapter 28). Whenever aspiration pneumonia is present, a transtracheal wash (see Chapter 20) should be performed for culture, and then aggressive treatment for the pneumonia should be initiated using antibiotics, fluids, nebulization, and coupage. Administration of antibiotics that impair neuromuscular transmission (e.g., ampicillin, aminoglycosides) should be avoided.

Anticholinesterase drugs are commonly administered in an attempt to improve muscular strength in dogs and cats with MG. Pyridostigmine bromide (oral [PO] Mestinon, 1-3 mg/kg q8h) has been used in dogs. In cats pyridostigmine bromide syrup (0.25-1 mg/kg PO q12h, diluted 1:1 with water to decrease gastric irritation) has been recommended. For both dogs and cats the dose must be individualized on the basis of clinical response. Ideally, feeding should be timed to coincide with peak drug effect (2 hours). In dogs initially unable to tolerate oral medication because of severe

megaesophagus, neostigmine methylsulfate (0.04 mg/kg IM q6-8h) can be used.

If an animal appears to be responding to anticholinesterase treatment but then suddenly gets worse, it is important to determine whether the deterioration is due to underdosage of the anticholinesterase drug (myasthenic crisis) or overdosage (cholinergic crisis). These are clinically indistinguishable, but administering one dose of a short-acting anticholinesterase (Neostigmine methylsulfate) allows the clinician to distinguish between them. The animal in a myasthenic crisis improves after anticholinesterase administration, whereas the condition of an animal in a cholinergic crisis becomes transiently worse or does not change.

Acquired MG is an immune-mediated disease, and administration of glucocorticoids and other immunosuppressive drugs may be associated with a more rapid clinical response, a decrease in AChR antibody, and an improved outcome in some dogs. Ideally, immunosuppressive drugs should be administered only to stable patients without aspiration pneumonia. Glucocorticoids at standard immunosuppressive doses commonly cause transient worsening of muscular weakness in dogs with MG, so treatment should be initiated with a low dose (oral prednisone, 0.5 mg/kg/day) and the dosage gradually increased over 2 to 4 weeks. Oral administration of azathioprine (Imuran, 2 mg/kg/day) or mycophenolate mofetil (CellCept, 10-20 mg/kg q12h) or Cyclosporine (5-6 mg/kg q12h) alone or in combination with prednisone has been associated with a positive clinical response in some dogs.

If a thymoma is identified during initial evaluation of a dog or cat with acquired MG, prompt surgical removal should be considered if the animal can be stabilized for surgery. Megaesophagus, dysphagia, and aspiration pneumonia are all risk factors decreasing the odds of short-term survival. Many animals with MG will have a decrease in AChR antibody titer and dramatic resolution of their signs after thymectomy. Adjunctive treatment may be required to prevent thymoma regrowth and recurrence of the signs of MG.

Prognosis

Response to medical management of MG can be good if aspiration pneumonia is not severe. Severe aspiration pneumonia, persistent megaesophagus, acute fulminating MG, and the presence of a thymoma or another underlying neoplasm are all associated with a poor prognosis for recovery. Many affected dogs die of either acute fatal aspiration or euthanasia within 12 months of diagnosis. Anticholinesterase drugs effectively control appendicular muscle weakness in most animals, but their effect on esophageal and pharyngeal function is variable. Response to various immunosuppressive protocols is difficult to determine because most dogs with acquired MG (>85%) will go into a spontaneous permanent clinical and immunologic remission within 18 months after diagnosis (average, 6.4 months) regardless of the treatment used. Spontaneous remission is unlikely in animals with thymoma or other neoplastic disease and in cats with MG. Because sequential antibody determinations in an individual animal are correlated with disease progression or remission, it is recommended that AChR antibody concentrations be measured and monitored every 4 to 8 weeks in animals treated for MG.

DYSAUTONOMIA

Dysautonomia is a polyneuropathy affecting sympathetic and parasympathetic nerves of the autonomic nervous system. Historically, it was recognized as a problem of cats in the United Kingdom, but since the late 1980s it more commonly affects dogs in the Midwestern United States, particularly in rural Kansas, Missouri, Oklahoma, and Wyoming. The etiology is unknown, although toxic and autoimmune mechanisms have been proposed. Clinical signs reflect failure of autonomic function in multiple organ systems.

Clinical Features

The disease affects primarily young adult dogs from rural environments, with a median age of 18 months. Cats are occasionally affected. Affected animals have a rapid onset of clinical signs that progress over days to weeks. Common presenting complaints are vomiting or regurgitation, straining to urinate, dribbling urine, photophobia, purulent nasal discharge, depression, and anorexia. Physical examination findings include decreased or absent anal tone, dilated pupils that do not respond to light; dry nose, eyes, and mucous membranes; and prolapse of the nictitating membranes. The bladder may be distended and easy to express.

Diagnosis

Diagnosis is suspected on the basis of the observed clinical signs. Thoracic and abdominal radiographs may reveal megaesophagus, aspiration pneumonia, generalized ileus, constipation/obstipation, and a large distended urinary bladder. The bladder is easily expressed, suggesting diminished urethral sphincter tone. Anal tone is usually decreased. Pharmacologic testing can be used to support the diagnosis. When very dilute (0.05%-0.1%) pilocarpine (Isopto Carpine 1% [Alcon Laboratories] diluted with saline) is applied to the eye of a dog with dysautonomia, pupillary constriction and nictitating membrane retraction will occur within 60 minutes or less, documenting denervation hypersensitivity. There should be no response when this solution is applied to the eye of a normal dog or cat. Subcutaneous (SC) administration of bethanechol (0.04 mg/kg) may also enable an affected dog with a distended bladder and urine dribbling to void normally. SC administration of atropine (0.04 mg/kg) does not produce a change in heart rate in affected dogs. These findings suggest the diagnosis of dysautonomia, but definitive diagnosis requires the demonstration of lesions within the autonomic nervous system at postmortem examination. Loss of nerve cell bodies results in decreased neuron density in all autonomic ganglia, especially the pelvic, mesenteric, and ciliary ganglia.

Treatment

Treatment is largely supportive and includes administering fluids, total parenteral nutrition or percutaneous gastrostomy tube feeding, bladder and colon emptying, lubricating eye ointments, and physical therapy. Pilocarpine (1%, one drop q6-12h) may improve lacrimation and decrease photophobia. SC bethanechol (0.05 mg/kg q8-12h) may improve urinary function, and prokinetic drugs (metoclopramide, cisapride) may improve gastrointestinal tract motility. The prognosis is generally poor, with a mortality rate of about 70% to 90%.

CHAPTER 67

Disorders of Muscle

GENERAL CONSIDERATIONS

Skeletal muscle functions to maintain posture and produce movement. Patients with generalized muscle disease generally present with weakness. This may manifest as a stiff and stilted gait, trembling while standing, a low head carriage (ventral neck flexion), and exercise intolerance. When a complete nervous system examination is performed, animals with muscle disease are not ataxic and most have normal postural reactions and spinal reflexes. Most muscle disorders cause muscle atrophy and/or fibrosis, whereas others cause muscle pain and muscle swelling.

Myopathies in dogs and cats can be either inherited or acquired. Genetic testing or phenotype recognition can be useful in diagnosing some of the inherited disorders. Acquired muscle disorders include infectious and immune-mediated inflammatory disorders as well as metabolic and endocrine disorders. Characteristic clinical findings may suggest a specific diagnosis, but systemic evaluation and muscle biopsies submitted to a laboratory specializing in canine and feline muscle disorders may be required for definitive diagnosis. Results of histologic examination may identify a specific disease or guide additional diagnostic testing required to demonstrate and characterize functional abnormalities.

INFLAMMATORY MYOPATHIES

MASTICATORY MYOSITIS

Masticatory muscle myositis (MMM) is a common immune-mediated disorder involving only the muscles of mastication in dogs. The masticatory muscles are composed primarily of a unique myofiber (type 2M) not present in limb muscles, and in dogs with MMM, immunoglobulin (Ig)G is directed against the unique myosin component of these fibers. Masticatory myositis can occur in any breed of dog, but the German Shepherd dog, retrieving breeds, Doberman Pinscher, and other large breeds are most commonly affected. Primarily young or middle-aged dogs are affected, but the diagnosis has been made in puppies as young as 3 months of age. No apparent gender predilection exists. The disorder has not been documented in cats.

Clinical Features

The acute form of the disease involves recurrent painful swelling of the temporalis and masseter muscles. Pyrexia, submandibular and periscapular lymphadenopathy, and tonsillitis are variably present. Dogs are reluctant to eat and are usually presented for anorexia and depression. Palpation of the muscles of the head and attempts to open the mouth are met with resistance because of pain.

As this disorder progresses, there is progressive severe atrophy of the temporalis and masseter muscles, resulting in a skull-like appearance of the head. Although this is a bilateral disease, the atrophy can be asymmetric. Opening the mouth is not painful in chronic MMM but is restricted by atrophy and fibrosis of the masticatory muscles (Fig. 67.1). The globes may sink deep into the orbits because of the dramatic loss of muscle mass (see Fig. 61.9). Many dogs are presented for evaluation as they progress from the acute to the chronic form of the disease wherein they have pain on opening the mouth, together with muscle atrophy. Some dogs with MMM will present with nonpainful severe atrophy of the muscles of mastication without any history of signs related to previous acute episodes of pain.

Diagnosis

Diagnosis is suspected on the basis of the clinical findings. In dogs presented for pain on opening the mouth, differentials must include retrobulbar abscess or mass, dental disease, and abnormalities of the temporomandibular joint or the bullae. The severe atrophy observed in chronically affected dogs must be differentiated from atrophy caused by disorders of the trigeminal nerves, widespread polymyositis (PM; any etiology), polyneuropathy, or systemic disorders such as hypothyroidism, hyperadrenocorticism, or cancer cachexia.

A hemogram may be normal or reveal mild anemia and neutrophilic leukocytosis; occasionally a peripheral eosinophilia is found. Serum creatine kinase (CK), aspartate

FIG 67.1
Chronic masticatory muscle myositis (MMM) causing **(A)** severe temporalis and masseter muscle atrophy and **(B)** inability to open the mouth more than a few centimeters in an adult Vizsla.

aminotransferase (AST), and globulin concentrations are occasionally increased. Proteinuria sometimes occurs. Circulating antibodies against masticatory myosin binding protein-C can be detected in the serum of many (80%-90%) dogs with acute MMM, but they may not be present in dogs with chronic disease. Electromyography (EMG), when available, can demonstrate acute myositis in the masticatory muscles and confirm that other muscle groups are unaffected, making PM less likely. Histopathologic evaluation of a biopsy from the affected muscles establishes the diagnosis. Fresh and formalin-fixed muscle should be submitted to permit the use of histochemical and immunohistochemical stains to identify antibody bound to type 2M muscle fibers.

Treatment

Oral (PO) administration of glucocorticoids (prednisone, 1-2 mg/kg q12h) usually results in rapid elimination of pain

FIG 67.2
Bilateral exophthalmos and upper eyelid retraction caused by extraocular myositis in a Border Collie.

in acutely affected dogs and a more gradual improved ability to open the mouth in chronically affected dogs. After about 3 weeks, the dose of corticosteroids can be decreased (to 1 mg/kg q24h) and then gradually tapered over 4 to 6 months to the lowest possible alternate-day dose. Inadequate dosing or treatment for an insufficient period of time is associated with a high rate of relapse. Dogs that do not respond adequately to corticosteroid therapy and dogs that relapse each time attempts are made to decrease the dose may benefit from use of other immunosuppressive drugs, such as azathioprine (Imuran [Burroughs Wellcome] given 2 mg/kg PO once daily until the patient shows signs of improvement, then every 48 hours) or cyclosporine (Atopica, 6 mg/kg PO q12h). Dogs treated aggressively have a good prognosis for recovery. They should be carefully monitored for relapse (using jaw mobility and discomfort, and serum CK), particularly as the glucocorticoid dose is tapered. Lifelong treatment may be required.

Historically it was recommended that dogs with chronic MMM have their jaws opened by force under anesthesia to stretch the fibrous tissue and muscle. This practice is not recommended because it does not improve clinical outcome, it increases the inflammation in torn muscle fibers, and it carries an inherent risk of iatrogenic mandibular luxation or fracture.

EXTRAOCULAR MYOSITIS

A unique form of myositis confined to the extraocular muscles, resulting in acute exophthalmos, has been described in dogs (Fig. 67.2). Affected dogs are usually young, with a

median age at presentation of 8 months. Golden Retrievers, Labrador Retrievers, and other large-breed dogs are especially susceptible, with females most predisposed. Bilateral exophthalmos and eyelid retraction are common, often with concurrent chemosis but without third eyelid prolapse. Vision may be impaired. Serum CK concentrations are usually normal. Orbital sonography or magnetic resonance imaging (MRI) confirms swollen extraocular muscles and eliminates retrobulbar abscess or mass as differentials. Definitive diagnosis requires biopsy of affected muscles (but this is rarely performed), revealing a lymphocytic inflammatory infiltrate. Response to treatment with oral prednisone (1-2 mg/kg q24h) is generally rapid and complete. Treatment should continue for at least 4 to 6 weeks. If relapse occurs during prednisone dose tapering, additional immunosuppression should be considered with Imuran or cyclosporine as for MMM. There is a good prognosis for complete and permanent recovery with proper therapy. Unilateral or bilateral restrictive ventromedial strabismus due to scarring has developed in a few young dogs with atypical extraocular muscle myositis, requiring surgical correction to restore eye position and vision.

CANINE IDIOPATHIC POLYMYOSITIS

Idiopathic PM is a diffuse inflammation of skeletal muscle presumed to be an autoimmune process. Large-breed adult dogs are most commonly affected, with many reported cases in German Shepherd dogs, Boxers, Newfoundlands, Pembroke Welsh Corgis, and Labrador and Golden Retrievers. A breed-specific PM primarily involving the masticatory, pharyngeal, and esophageal muscles has been described as a cause of dysphagia and regurgitation in Viszlas.

Clinical Features

Mild to severe weakness and a stiff, stilted gait that may be exacerbated by exercise are the most common features in dogs with PM. Muscles are painful in some dogs, whereas nonpainful severe atrophy occurs in others. Regurgitation caused by megaesophagus, dysphagia, excessive salivation, and a weak bark may occur, particularly in Newfoundlands with PM. Signs may be intermittent in mild cases or early in the course of the disease. Some dogs with acute severe disease are pyrexic and experience generalized pain. Muscle atrophy is usually prominent, especially involving the temporalis and masseter muscles and often the proximal limb muscles. Neurologic examination typically reveals normal mental status, cranial nerve examination, proprioception, and spinal reflexes, but spinal reflexes may be diminished in dogs with concurrent polyneuritis.

Diagnosis

The diagnosis of PM is based on clinical signs, CK determination, EMG, and muscle biopsy. High serum CK (2- to 100-fold increase) and AST activities are seen in most affected dogs at rest, and even more dramatic increases occur after exercise. Gamma globulins may also be increased. When available, EMG can be performed to document that multiple muscle groups are involved and to select a severely affected muscle for biopsy. A definitive diagnosis of idiopathic PM requires muscle biopsy and elimination of infectious causes of PM. Typical histopathologic findings include multifocal necrosis and phagocytosis of myofibers, and lymphocytic and plasmacytic infiltration into muscle. Muscle biopsy results may be normal in some dogs because of the multifocal patchy nature of the disease, so this should not preclude a diagnosis of myositis if the clinical findings, EMG, and serum CK concentration suggest the diagnosis. MR imaging using rapidly acquired short tau inversion recovery (STIR) sequences or postcontrast T1-weighted images has recently been shown to be a useful test to document the location of inflamed muscle prior to biopsy.

PM can occur as an idiopathic primary immune-mediated disorder, or it can be secondary to systemic immune-mediated disease (e.g., systemic lupus erythematosus), or systemic neoplasia. All dogs with PM should have a complete blood count (CBC), biochemistry profile, synovial fluid analysis, urinalysis, serum antinuclear antibody (ANA) titer, and protozoal serology, and/or immunohistochemical staining of muscle biopsies for protozoal antigens (to eliminate protozoal PM). Assessment of thoracic radiographs and abdominal ultrasound should focus on a search for systemic infection or neoplasia and identification of megaesophagus and aspiration pneumonia. Lymph node, spleen, and liver aspirates and bone marrow biopsy may be indicated because many dogs with a diagnosis of PM (including 20% of Boxers) develop lymphoma within a few months, suggesting that PM may be a preneoplastic syndrome in these dogs. If all these tests are normal, a diagnosis of idiopathic PM is made.

Treatment

Prednisone administration (1-2 mg/kg q12h for 14 days, then q24h for 14 days, then q48h) results in dramatic clinical improvement and recovery for most dogs. In dogs with megaesophagus, upright feeding of small meals (see Fig. 66.15) may be beneficial to prevent aspiration. Aspiration pneumonia, if it occurs, should be treated with antibiotics. Prednisone treatment should continue for at least 4 to 6 weeks at decreasing doses, with long-term treatment for 12 months or longer occasionally required. Azathioprine should be administered if the response to prednisone is inadequate or if relapse occurs during dose tapering.

Prognosis

The prognosis is good for recovery in dogs without severe dysphagia, megaesophagus, or aspiration pneumonia if no underlying neoplastic cause for the PM can be identified. Spontaneous recovery before treatment is initiated occurs in a few dogs.

FELINE IDIOPATHIC POLYMYOSITIS

An acquired inflammatory disorder of skeletal muscle similar to canine PM has been described in a few cats. Affected cats experience a sudden onset of weakness with pronounced

ventral neck flexion, an inability to jump, and a tendency to sit or lie down after walking short distances. Muscle pain may be evident. Neurologic examination reveals normal mentation, cranial nerves, proprioception, and reflexes.

Diagnosis is made on the basis of clinical features, increases of serum CK and AST activities, and multifocal EMG abnormalities. Many affected cats (70%) are slightly hypokalemic, suggesting a possible relationship between this disorder and hypokalemic polymyopathy. Because some clinical features of PM also mimic mild thiamine deficiency, evaluating the cat's response to thiamine injections (intramuscular [IM], 10-20 mg/day) and correcting hypokalemia are recommended before proceeding with extensive diagnostic testing for PM.

Serum titers against *Toxoplasma gondii* should be evaluated, as should tests for feline leukemia virus (FLV) antigen and feline immunodeficiency virus (FIV) antibody. A complete drug history should be obtained to eliminate the possibility of drug-induced PM. Thoracic and abdominal radiographs and abdominal ultrasound should be considered to look for an underlying neoplastic cause. PM has been diagnosed in many cats with thymoma, sometimes concurrent with acquired myasthenia gravis. Muscle biopsy reveals my fiber necrosis and phagocytosis, muscle regeneration, variation in muscle fiber size, lymphocytic inflammation, and fibrosis. Empirical treatment for *Toxoplasma* myositis is sometimes recommended (clindamycin, 12.5-25 mg/kg PO q12h); if the animal has a dramatic response to clindamycin, the treatment should be continued for at least 6 weeks. It is important to realize, however, that spontaneous recovery or remission is observed in at least one third of all cats with PM. Glucocorticoid therapy (prednisone, 4-6 mg/kg/day initially, tapered over 2 months) may aid recovery in some cats. Recurrences are common.

DERMATOMYOSITIS

Dermatomyositis is an uncommon disease characterized by dermatitis and PM. Familial canine dermatomyositis is an autosomal dominant condition with incomplete penetrance recognized in juvenile Rough-Coated and Smooth-Coated Collies, Shetland Sheepdogs (i.e., Shelties), Kelpies, Beauceron Shepherds, and Pembroke Welsh Corgis. Sporadic cases have been observed in a few other breeds, including Australian Cattle Dogs and Border Collies. The disease has not been recognized in cats. Dermatomyositis is a complement-mediated microangiopathy in which complement deposition in small vessels leads to vascular damage and skin and muscle ischemia. Skin lesions include erythema, crusts, scales, and scarring alopecia on the inner surfaces of the pinnae and on the face, distal extremities, tail tip, and other boney prominences subjected to mechanical trauma (Fig. 67.3). With progression, erosions and ulcerations are common and secondary pyoderma may be superimposed, resulting in pruritus. Histopathologic findings include hydropic degeneration of basal cells and separation of the dermoepidermal junction. A perivascular mononuclear infiltrate may be seen. Dermatologic lesions appear during the first 3 months of life and may improve or resolve with time. The course often fluctuates.

FIG 67.3
Shetland Sheepdog with typical skin lesions of dermatomyositis. This dog also had megaesophagus and generalized muscular weakness.

Dogs severely affected by dermatomyositis may develop signs of concurrent muscle disease, especially in the muscles of mastication making it difficult to prehend and chew food and lap water. Generalized muscle weakness and atrophy and a stiff gait may also occur. Megaesophagus occurs occasionally. Mentation, proprioception, and reflexes are normal. Dysphagia is common, as is regurgitation due to megaesophagus. EMG reveals spontaneous my fiber discharges, including fibrillation potentials, positive sharp waves, and bizarre high-frequency discharges in affected muscles by 13 to 19 weeks of age, even in dogs without clinical signs of muscle weakness. Nerve conduction velocities are normal. Muscle biopsies reveal my fiber necrosis with mononuclear cell infiltrates, atrophy, regeneration, and fibrosis.

Diagnosis of dermatomyositis relies on recognition of typical clinical dermatologic changes and confirmation with histology of skin and muscle. Breeding should be discouraged. Dogs with muscular manifestations of this disorder are usually treated with immunosuppressive doses of glucocorticoids, with a variable response. Additional immunosuppressive treatments are administered as needed. Dermatologic lesions may respond to oral administration of tetracycline and niacinamide (250 mg of each q8h if <10 kg, 500 mg of each q8h if >10 kg) or pentoxifylline (Trental, 10-25 mg/kg q8-12h) and vitamin E (200-600 IU orally every 12 hours).

INFECTIOUS INFLAMMATORY MYOSITIS

Infectious myositis can be caused by protozoal, viral, rickettsial, and bacterial infections, many of which are multisystemic. Myositis caused by *T. gondii* or *N. caninum* can occur alone or in conjunction with lumbar polyradiculoneuritis in dogs, causing severe muscle atrophy and weakness of the pelvic limbs followed by rigid pelvic limb hyperextension (see Chapter 64). In cats, *T. gondii* more often causes fever and diffuse PM with muscle pain and weakness. Leishmaniasis may cause bilateral masticatory muscle pain and atrophy

with or without involvement of the limb muscles in dogs. Muscle inflammation is common in dogs with acute Leptospirosis and dogs with tick-borne infections, but signs referable to muscular involvement are often overlooked due to the severity of systemic disease. Clinical signs of muscle inflammation typically include focal or diffuse muscle pain, muscle atrophy, and weakness. Increases in CK concentration are common, and serum titers or cultures of infected tissues may be positive for the offending organism. EMG reveals spontaneous activity in affected muscles. Definitive diagnosis of infectious myositis requires muscle biopsy and identification of organisms within tissues using molecular or immunohistochemical methods. More discussion of *Neospora caninum* PM and polyradiculoneuritis can be found in Chapter 64.

ACQUIRED METABOLIC MYOPATHIES

In addition to the myopathies associated with infectious and inflammatory disease, myopathies may accompany hyperadrenocorticism (i.e., Cushing's disease), administration of exogenous corticosteroids, and perhaps hypothyroidism. In cats, a myopathy associated with hypokalemia has been recognized, and a poorly defined diffuse myopathy causing weakness is common in hyperthyroidism.

GLUCOCORTICOID EXCESS

Glucocorticoid excess due to spontaneous hyperadrenocorticism or exogenous administration of high doses of glucocorticoids can cause a degenerative myopathy. Muscle weakness and atrophy are common. Atrophy may be most pronounced in the muscles of mastication. Diagnosis is suspected on the basis of a history of exogenous steroid administration or clinical findings consistent with steroid excess (e.g., polyuria, polydipsia, hair loss, pendulous abdomen, thin skin). Muscle biopsy reveals nonspecific changes, including type 2 my fiber atrophy, focal necrosis, and fiber size variation. Diagnostic tests for hyperadrenocorticism may confirm the diagnosis (see Chapter 50). Supplementation with L-carnitine, coenzyme Q10, and riboflavin may improve muscular strength. Control of excess glucocorticoids may result in some clinical improvement.

Rarely, dogs with hyperadrenocorticism or chronic exogenous glucocorticoid administration develop a myotonia-like disorder manifested by limb rigidity, stiff gait, and hypertrophy of proximal limb muscles. CK may be mildly increased. EMG confirms repetitive high-frequency myotonic discharges, resulting in this disorder being called pseudomyotonia. Treatment consists of resolving the glucocorticoid excess whenever possible, and attempting to stabilize muscle fiber membranes (see congenital myotonia, page 1186), but the prognosis is guarded for resolution of the muscular signs.

HYPOTHYROIDISM

Hypothyroidism may be associated with a mild myopathy in dogs, causing weakness, muscle cramping, atrophy, and reduced exercise tolerance. Spinal reflexes are normal unless concurrent polyneuropathy is present. Serum CK may be normal or elevated. Biopsy typically reveals mild type 2 my fiber atrophy, an increase in type 1 myofibers, and multifocal nemaline rod inclusions. Documentation of hypothyroidism and response to thyroid hormone supplementation are required for diagnosis. Physical therapy and oral carnitine supplementation have been recommended to speed recovery.

FELINE HYPOKALEMIC POLYMYOPATHY

A polymyopathy linked to decreased dietary intake or increased urinary excretion of potassium leading to total body potassium depletion has been recognized in cats of all breeds, ages, and genders. Cats with chronic renal failure and those consuming acidifying diets are most commonly affected, but cats with polyuria or polydipsia secondary to hyperthyroidism, cats with anorexia from any etiology, and Burmese kittens with an inability to maintain a balance between their intracellular and extracellular potassium are at risk. Cats with primary hyperaldosteronism because of functional adrenal neoplasia also commonly present with weakness secondary to hypokalemic polymyopathy.

The predominant clinical feature in all of these cats is weakness characterized by persistent ventroflexion of the neck (Fig. 67.4), a stiff stilted gait, and reluctance to move.

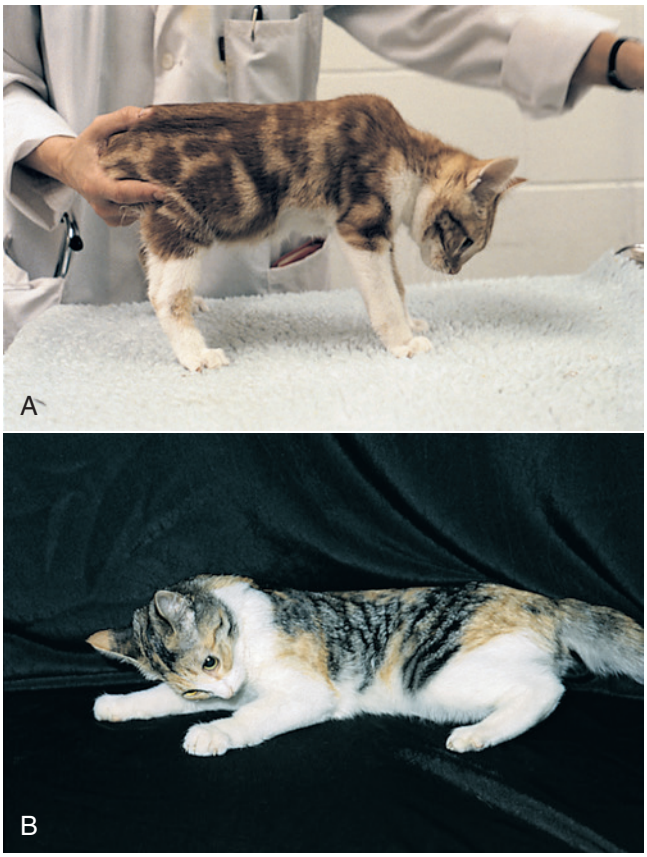

FIG 67.4
Feline hypokalemic myopathy resulting in weakness and cervical ventroflexion in **(A)** a kitten with congenital renal disease and **(B)** a hyperthyroid cat. The weakness resolved in both cats after potassium supplementation.

Some cats exhibit excessive dorsal scapular movement during walking, exertional tremor, and even collapse. Muscle pain may be apparent, but the neurologic examination is otherwise unremarkable, with normal postural reactions and spinal reflexes. Clinical signs may have an acute onset and be episodic. Serum CK activity is usually increased (10-30 times normal), and serum potassium concentration is decreased (usually <3.0 mmol/L). Adequate dietary intake of potassium should be verified, and renal function should be evaluated by measuring serum urea and creatinine concentrations, and performing a urinalysis and urine specific gravity. Interpretation of these parameters can be difficult because hypokalemia can itself decrease renal blood flow and glomerular filtration rate (GFR), interfering with urine-concentrating mechanisms. All cats with persistent hypokalemia and weakness should be tested for hyperthyroidism, and imaging should be performed to evaluate the kidneys and adrenal glands.

In cats with hypokalemic polymyopathy, EMG abnormalities are found in multiple muscle groups and include frequent positive sharp waves, fibrillation potentials, and occasional bizarre high-frequency discharges with normal nerve conduction velocities. Muscle histopathology is normal.

Signs of hypokalemic polymyopathy usually resolve after parenteral or oral supplementation of potassium and resolution of the underlying reason for hypokalemia if it can be identified. Oral treatment with potassium gluconate is recommended for mildly affected cats (Kaon Elixir, Adria Laboratories, Columbus, Ohio) at a dose of 2.5 to 5 mEq/cat twice a day for 2 days, then once a day. The dose administered is adjusted on the basis of serum potassium levels. Cats with more dramatic hypokalemia (<2.5 mEq/L) or those with severe muscular weakness with the potential to cause respiratory compromise require parenteral administration of lactated Ringer's solution, intravenously or subcutaneously, supplemented with at least 80 mEq/L of potassium chloride per liter of fluid. Intravenous (IV) supplementation of potassium should not exceed 0.5 mEq/kg/h. Long-term oral supplementation with potassium gluconate may be required. Periodic monitoring of serum potassium concentration is recommended.

NONINFLAMMATORY INHERITED MYOPATHIES

MUSCULAR DYSTROPHY

The muscular dystrophies (MDs) are a heterogeneous group of inherited degenerative noninflammatory muscle disorders. Most of the MDs recognized in dogs and cats are associated with absence or abnormalities of the cytoskeletal protein dystrophin, caused by genetic mutation of the dystrophin gene. This very large dystrophin gene is located on the X-chromosome, so MD is generally inherited as an X-linked recessive trait, clinically apparent in male dogs and transmitted by female carriers that are asymptomatic. Canine X-linked muscular dystrophy (CXMD) has been most completely described in Golden Retrievers but has also been reported in many other breeds of dogs.

Dogs with CXMD typically show clinical signs at birth or very early in life. Golden Retriever muscular dystrophy (GRMD) has been well described, and, despite the fact that all affected male dogs have the same genetic lesion, the severity of clinical expression within a litter is variable. Puppies with GRMD are often stunted even before weaning. Abduction of the elbows, a bunny-hopping gait, and difficulty opening the mouth may be noted. With time, affected puppies develop a progressively stilted gait, exercise intolerance, a plantigrade stance, muscle contractures, and atrophy of the truncal, limb, and temporalis muscles. Muscle strength deteriorates until approximately 6 months of age, when the signs tend to stabilize. Most dogs retain the ability to walk. Proprioceptive positioning and spinal reflexes are normal, but spinal reflexes may be difficult to elicit once muscle fibrosis and joint contractures occur. Severely affected dogs may develop hypertrophy of the tongue and pharyngeal or esophageal dysfunction, making it difficult to eat. Respiratory or cardiac failure may occur at 1 to 2 years of age, resulting in death.

MD should be suspected when typical clinical signs are seen in a young male puppy of a predisposed breed. Serum CK levels are markedly increased as early as 1 week of age and peak at 6 to 8 weeks of age. Very dramatic increases in CK occur after exercise. Genetic testing is available to confirm dystrophin-deficient MD in Golden Retrievers but not in other breeds. EMG reveals pseudomyotonic discharges in most muscles by 10 weeks of age. Muscle biopsies reveal marked my fiber size variation, necrosis, and regeneration, with multifocal my fiber mineralization. Immunocytochemical studies document the absence of the sarcolemmal protein dystrophin. Rarely, genetic mutations occur in dogs and cats that affect other proteins in the dystrophin-glycoprotein complex, resulting in signs identical to dystrophin-deficient MD but muscle biopsies that are not dystrophin-deficient. Importantly, many of these disorders are inherited as an autosomal recessive trait, so males and females may be affected equally.

An X-linked dystrophin-deficient MD has also been reported in the cat. Clinical signs first appear at 5 to 6 months of age. Affected cats exhibit marked generalized muscular hypertrophy, protrusion of the tongue, excessive salivation, stiff gait, and bunny hopping. Megaesophagus is common. Serum CK is greatly elevated (often >30,000 U/L). Diagnosis requires muscle biopsy and dystrophin immunostaining. No effective treatment exists for MD in dogs or cats. Low-dose prednisone (0.5 mg/kg orally q24h) and physical therapy have been recommended to help slow the progression of muscular weakness.

CENTRONUCLEAR MYOPATHY OF LABRADOR RETRIEVERS

An inherited myopathy of Labrador Retrievers known as *centronuclear myopathy* (CNM) may occur in as many as 1% of dogs of this breed tested either because of clinical signs

or for prebreeding purposes. This disorder has been previously reported as hereditary Labrador Retriever myopathy (HLRM), autosomal recessive muscular dystrophy, and type 2 my fiber deficiency. Affected puppies appear normal at birth. Muscular weakness, an awkward gait, exercise intolerance, and muscle atrophy without myalgia typically become apparent by 3 to 5 months of age, with a few puppies showing signs at 6 to 8 weeks. The age of onset and severity of clinical signs vary dramatically among affected litter mates. Severely affected dogs exhibit a low head carriage and a short-strided, stilted gait (Fig. 67.5). Their back may be arched, and a bunny-hopping gait may develop with exercise. Muscle atrophy may be marked, especially in the proximal limbs and the muscles of mastication. Neurologic examination is normal except for consistent patellar hyporeflexia or areflexia. Megaesophagus causing regurgitation has been seen in a few affected dogs. Clinical signs are worse with stress, exercise, excitement, or cold temperatures. Muscular weakness and atrophy are typically slowly progressive, but a few affected puppies will be recumbent within 1 to 2 months. Clinical signs stabilize after 12 months of age in mildly affected dogs. Serum CK is normal or moderately elevated, and on EMG examination spontaneous electrical activity and bizarre high-frequency discharges are seen. CNM is histologically characterized by mild to marked variation in fiber size, atrophic type 1 and type 2 myofibers, replacement of type 2 myofibers by type 1 myofibers resulting in a type 2 predominance, and a marked increase in centralization of nuclei within muscle cells. CNM has an autosomal recessive inheritance pattern. The causative protein tyrosine phosphatase-like A (PTPLA) genetic mutation has been identified, and a DNA test is commercially available. Dogs homozygous for the mutation are symptomatic whereas carriers are normal. No treatment is available, but mildly affected dogs can function as pets.

FIG 67.5
A 1-year-old Labrador Retriever with centronuclear myopathy (CNM) exhibiting proximal muscle atrophy, a stiff stilted gait, and ventroflexion of the neck that worsens with exercise.

X-LINKED MYOTUBULAR MYOPATHIES

X-linked myotubular myopathies are a subgroup of centronuclear myopathies characterized by a very early onset of signs and the presence of very small muscle fibers with centrally located nuclei resembling fetal myotubes. Affected puppies, all male, are presented at less than 3 months of age for rapidly progressive severe weakness, muscle atrophy, and failure to thrive. CK is normal or slightly increased. This disorder, associated with absence of the protein myotubularin, is a very rare inherited condition identified in Labrador Retrievers, Manchester Terriers, and Rottweilers. A genetic mutation causing myotubularin-deficient X-linked myotubular myopathy has been identified in Labrador Retrievers and Rottweilers, and testing is possible.

INHERITED MYOPATHY OF GREAT DANES

Inherited myopathy of Great Danes (IMGD) is a hereditary noninflammatory myopathy similar to other centronuclear and myotubular myopathies. Weakness, muscle atrophy and exercise intolerance are evident before 6 months of age and progress rapidly. Most dogs lose the ability to walk and die or are euthanized, but approximately 20% are less severely affected and survive to adulthood. This disorder is inherited as an autosomal recessive trail and is seen in male and female, fawn- or brindle-colored Great Danes. CK is normal or mildly increased. A genetic test is available.

MYOTONIA

Myotonia is a rare disorder of muscle recognized in Chow Chows, Cocker Spaniels, Staffordshire Bull Terriers, Miniature Schnauzers, Labrador Retrievers, Rhodesian Ridgebacks, Samoyeds, West Highland White Terriers, Great Danes, and individual dogs of a number of breeds. Affected kittens have also been identified. Myotonia causes a failure of muscle relaxation so that muscle contraction persists after voluntary movement or muscle percussion. Congenital myotonia usually results from altered chloride conductance, which causes postexcitement depolarization of the muscle membrane and continued contraction, but sodium, potassium, and chloride channel defects may also

occur. In Miniature Schnauzers, Australian Cattle dogs, and Jack Russell Terriers, mutant skeletal muscle chloride channel alleles have been identified, and genetic testing is available.

Clinical signs include generalized muscle stiffness and hypertrophy that begin at a young age (i.e., 1-4 months) and difficulty rising after a period of inactivity. Dogs with myotonia are neurologically normal. No abnormalities of proprioception or mentation exist. Cold weather, excitement, sudden changes in position or posture, and exercise exacerbate the clinical signs. Affected dogs may remain in rigid recumbency for up to 30 seconds if they are suddenly placed in lateral recumbency. Hypertrophy of the proximal appendicular and axial skeletal muscles is common. Serum CK and AST activities may be mildly increased, indicating muscle fiber necrosis. Bizarre high-frequency discharges that wax and wane ("dive-bomber sound") are revealed by EMG and, when present, confirm the diagnosis. Muscle biopsy alone is rarely diagnostic. Membrane-stabilizing agents such as procainamide (10-30 mg/kg PO q6h) and the sodium channel blocker mexiletine (Mexitil [Boehringer Ingelheim], 8 mg/kg PO q8h) have been beneficial in the treatment of some cases. Avoidance of cold temperatures is also advised. Most dogs are euthanized because of the severity of their signs.

INHERITED METABOLIC MYOPATHIES

Genetically based metabolic myopathies caused by a biochemical defect of the skeletal muscle energy system are infrequently described in dogs and cats. All such disorders cause signs of muscle dysfunction, including exercise intolerance, muscular weakness, a stiff stilted gait, muscle pain, muscle tremors, and muscle atrophy. Mitochondrial myopathies, glycogen storage diseases, lipid storage myopathies, and disorders causing nemaline rod accumulation within myofibers have all been reported. Genetic tests are available for a few disorders. Establishing the precise cause of a metabolic myopathy can be difficult because of the wide range of biochemical abnormalities that can arise and the codependence of all the structural proteins making up a muscle fiber. Sometimes metabolic testing can be beneficial; for example, inappropriate lactic acid accumulation with exercise suggests mitochondrial dysfunction. Evaluation of plasma lactate and pyruvate before and after exercise and quantitative analysis of urinary organic acids and plasma, urine, and muscle carnitine will help document that a metabolic myopathy is present and may help determine the affected biochemical pathway. After metabolic testing, histologic and ultrastructural examination of skeletal muscle should be performed. This metabolic testing and biopsy evaluation should be performed by a laboratory specializing in metabolic disorders of dog and cat muscle. When testing suggests a mitochondrial myopathy or a lipid myopathy, nonspecific treatment with an oral combination of L-carnitine (50 mg/kg q12h), coenzyme Q10 (100 mg/dog q24h), and riboflavin (100 mg/dog q24h) may result in improved muscle strength.

INVOLUNTARY ALTERATIONS IN MUSCLE TONE AND MOVEMENT

Tetanus, opisthotonos, myoclonus, and dyskinesias are all involuntary alterations of muscle tone or movement that are not the result of muscle disease. Tetanus is a sustained tonic contraction of the muscles. Opisthotonos is a very severe form of tetanus in which spasm of the limb and neck muscles results in lateral recumbency with dorsiflexion of the neck and extensor rigidity of the limbs. Myoclonus is the rhythmic repetitive contraction of a particular group of muscles. Dyskinesias, a group of poorly defined movement disorders that can be hard to differentiate from partial seizures, were previously discussed in Chapter 62.

OPISTHOTONOS

Opisthotonos is a very severe form of sustained muscular contraction resulting in dorsiflexion of the neck and extensor rigidity of the limbs. Opisthotonos can be seen during seizure activity, as a component of generalized extensor rigidity in patients with tetanus, or in animals with decerebrate or decerebellate rigidity (see Fig. 58.9).

TETANUS

Tetanus, defined as sustained contraction of extensor muscles without relaxation, is most often seen in dogs and cats and is due to infection with the bacterium *Clostridium tetani* and its production of tetanospasmin toxin. *C. tetani* is a gram-positive anaerobic bacillus that produces spores that persist for long periods in the environment. If a deep wound or an area of tissue damage becomes contaminated with these spores, the spores may be anaerobically converted to a vegetative form, and a toxin (tetanospasmin) is produced. The toxin ascends peripheral nerves to the spinal cord, where it blocks release of neurotransmitter from the inhibitory interneurons (Renshaw cells), releasing extensor muscles from inhibition and resulting in tetany. Cats are more resistant to the toxin than dogs.

Clinical signs of tetanus appear 5 to 18 days after wound infection. Animals with mild or early tetanus show a stiff gait, erect ears, an elevated tail, and contraction of the facial muscles (risus sardonicus; Fig. 67.6). The signs may be most severe in the area of the body adjacent to where the toxin is being produced. In severe disease the animal is recumbent and shows extensor rigidity of all four limbs and opisthotonos. The animal may die as a result of an inability to ventilate adequately. A presumptive diagnosis of tetanus is usually made on the basis of clinical signs and history of a recent wound.

Treatment should consist of rest in a warm, dark, quiet environment, immediate wound debridement, antibiotics, and intensive supportive care. Initially, aqueous penicillin (potassium or sodium salt, 40,000 units/kg IV q8h) can be given. Alternatively, metronidazole (10-15 mg/kg IV q8h) may be administered; it is bactericidal against most anaerobes and achieves a therapeutic concentration even in

FIG 67.6
Tetanus in two dogs, with the erect ears and risus sardonicus resulting from contraction of the head and facial muscles. Both dogs had wounds on a forelimb, which were presumed to be the site of entry of the toxin.

necrotic tissues. Antibiotics are administered for 2 weeks or until clinical recovery occurs.

When available, tetanus antitoxin is given to neutralize any toxin that remains unbound to the central nervous system (CNS) to prevent progression of signs. Anaphylactic reactions occasionally occur, so a test dose (0.1 mL) of tetanus antitoxin (equine origin) is injected intradermally 15 to 30 minutes before administering a treatment dose. If no wheal develops after the test dose, the antitoxin is given intravenously (200-1000 units/kg; maximum, 20,000 units). This dose is *not* repeated; a therapeutic blood concentration persists for 7 to 10 days after a single injection, and repeated administration of antitoxin increases the chance of an anaphylactic reaction. Injecting a small dose of antitoxin (1000 units) just proximal to the wound site may be beneficial in dogs and cats with localized tetanus.

The animal is maintained in a quiet, dark environment to minimize sensory stimulation. Muscle spasms are controlled with intermittent IV boluses (1 mg/kg) or an IV constant rate infusion (CRI; 1 mg/kg/h) of diazepam or subcutaneous acepromazine (0.05-0.1 mg/kg q8-12h as needed), methocarbamol (50-100 mg/kg IV q8h), and phenobarbital (2-6 mg/kg IV or IM q6h). Magnesium sulfate ($MgSO_4$) 70 mg/kg over 30 minutes followed by a low-dose CRI (100 mg/kg/day) may improve relaxation and decrease the need for additional sedative medications. If needed, treatment can be intensified as for status epilepticus (see Chapter 62). Nutritional support may have to be provided through an esophageal or gastrostomy tube until the animal can eat and drink. The animal is hand-fed as soon as it is able to prehend food and swallow. In some animals, urinary and fecal retention must be managed by repeated catheterization and enemas. Physiotherapy and massage can improve blood and lymph flow to and from the muscles, promote relaxation, decrease discomfort, and aid return of muscle function. Improvement is usually noticeable within 1 week, but signs may persist for 3 to 4 weeks. The prognosis is poor if the signs progress rapidly, but about 50% of affected dogs survive if managed intensively.

MYOCLONUS

Myoclonus movements are sudden, brief, shock-like involuntary movements resulting in contraction of a portion of a muscle, an individual muscle, or a group of muscles. A constant repetitive myoclonus, occurring as often as 60 times per minute, is commonly observed in dogs currently or previously affected by canine distemper encephalomyelitis (see Chapter 64). Limb and facial muscles are most often involved, and these rhythmic contractions do not abate during sleep or general anesthesia. Meningoencephalomyelitis causes focal lesions of the lower motor neurons of the spinal cord or cranial nerve nuclei resulting in creation of an autonomous pacemaker, generating these rhythmic muscle contractions. Although myoclonus is most commonly associated with canine distemper meningoencephalomyelitis, other focal inflammatory or neoplastic lesions of the spinal cord can also produce myoclonus in rare cases. The prognosis for resolution of the myoclonus is grave.

Familial reflex myoclonus causing intermittent spasms of the axial and appendicular muscles with occasional episodes of opisthotonos has been recognized in 4- to 6-week-old Labrador Retriever litter mates. These signs worsen when the animal is stressed or excited. Treatment with diazepam and clonazepam has not been successful. The prognosis for recovery is grave.

Animals with progressive myoclonic epilepsy experience seizures characterized by sudden muscular twitching, jerky involuntary movements, or muscle fasciculations that may or may not progress to generalized tonic-clonic seizures. Myoclonic seizures often occur in response to specific tactile, visual, or auditory stimuli (see reflex seizures, Chapter 62). Myoclonic epilepsy has been recognized as a

slowly progressive disorder in adult (mean 7 years) Miniature Wirehaired Dachshunds, Bassett Hounds, Beagles, and others with Lafora disease, a degenerative brain disorder. Audiogenic reflex seizures have also been described in cats. Levetiracetam appears to be the most effective AED for treatment of myoclonic seizures in dogs and cats.

TREMORS

A tremor is a rhythmic, oscillatory movement of a body part. Intention tremors of the head, usually associated with cerebellar disease, substantially worsen as the animal intends to initiate movement, as when the head nears a target during goal-oriented movement such as attempts to eat, drink, or sniff an object.

When animals are presented with a single occurrence of an acute onset of generalized tremors and increased extensor muscle tone, a toxic cause should be suspected (see Box 62.3). Strychnine, metaldehyde, chlorinated hydrocarbons, tremorgenic mycotoxins, and organophosphates are the most common toxic causes of tremors. Drug-induced tremor can be associated with metoclopramide, fentanyl/droperidol, or diphenhydramine administration. Metabolic disturbances such as hypoglycemia, hepatic encephalopathy, and hypocalcemia can also cause tremors, muscle fasciculations, and tetany.

Young-adult (5 months to 3 years of age) small-breed dogs presenting with an acute onset of generalized head and body tremors may have steroid-responsive encephalitis. Historically this disorder was first identified only in white dogs (Maltese, West Highland White Terrier), and the syndrome was called "little white shaker syndrome." Diagnosis requires testing to eliminate toxic and metabolic disorders as well as infectious causes of encephalitis (described in further detail in Chapter 64—meningoencephalitis).

A congenital diffuse tremor syndrome associated with abnormal development of myelin in the CNS has been observed in puppies. Affected puppies stand with a wide-based stance and show whole-body tremors that worsen with exercise or excitement. This syndrome is progressive and severe in male Welsh Springer Spaniels, usually resulting in death within 2 to 4 months. Less progressive tremor syndromes have been recognized in the Weimaraner, Bernese Mountain dog, Samoyed, Dalmatian, and Chow, as well as sporadically in other breeds, with signs apparent by 4 weeks of age. Diagnosis is based on the signalment and clinical findings in the absence of other neurologic deficits or clinicopathologic abnormalities. In the Chow and Weimaraner, gradual clinical recovery may occur within 1 to 3 months without treatment. Genetic testing is available for these hypomyelination disorders in Springer Spaniels, Chow Chows, and Weimaraners.

Trembling of the pelvic limbs (senile tremors) may develop in older dogs that are weak but otherwise neurologically normal. The trembling disappears at rest but is apparent when the animal stands, and it worsens with exercise. Results of all tests are normal, and there is no effective treatment. Diagnostically, it is important to rule out electrolyte disturbances, hypothyroidism, hypoadrenocorticism, hip dysplasia, and lumbosacral disease.

DYSKINESIAS

Dyskinesias are CNS disorders that result in involuntary movements in fully conscious individuals. These movement disorders have only occasionally been described in dogs and cats and may be difficult to distinguish from focal seizures or stereotypical behavior disorders (see Chapter 62). Signs consist primarily of episodic, unpredictable, rhythmic, involuntary limb hyperextension or hyperflexion; head bobbing; or the adoption of abnormal postures.

DISORDERS CAUSING EXERCISE INTOLERANCE OR COLLAPSE

Reluctance to exercise or inability to exercise for a prolonged period is a common complaint among dog owners. Exercise intolerance can result from orthopedic, cardiovascular, respiratory, hematologic, metabolic/endocrine, neurologic, neuromuscular, and muscular disorders (Box 67.1). When evaluating a dog for a primary complaint of exercise intolerance, the veterinarian must perform a careful physical and neurologic examination. Muscle atrophy or pain and weakness at rest but normal postural reactions and reflexes may suggest a muscle disorder. Joint pain may indicate that the dog has polyarthritis, orthopedic disease, or degenerative joint disease. Abnormalities of cardiac auscultation or arterial pulse character should prompt thorough cardiac evaluation. Routine systemic evaluation with clinicopathologic tests and survey radiographs should be completed. When all examinations and tests are normal at rest, affected dogs should be evaluated while performing the exercise historically associated with their exercise intolerance. Characteristic clinical features during the exercise intolerance (e.g., weakness, cyanosis, stridor, lameness, arrhythmia) sometimes provide a clue about etiology. Depending on clinical findings, additional testing may be recommended, including measuring antibodies against acetylcholine receptors (AChRs), continuous electrocardiographic monitoring, thyroid and adrenal function evaluation, arterial blood gas, and measuring preexercise and postexercise parameters (i.e., electrolytes, glucose, creatinine kinase). Canine dynamin-associated exercise-induced collapse (dEIC) in Labrador Retrievers and other breeds and Border Collie collapse (BCC) have been well characterized and should be recognizable based on classical signalment and signs; a genetic test is available for dEIC. These two conditions are described in Chapter 62 because they are paroxysmal disorders often confused with partial seizures. When neurologic examination and ancillary testing suggests an unknown muscular cause for exercise intolerance, special metabolic testing should be considered (urinary organic acid and plasma amino acid analysis, carnitine measurement and pre- and postexercise

BOX 67.1

Drugs Used in Neurologic Disorders

DRUG NAME (TRADE NAME)	PURPOSE	RECOMMENDED DOSE	
		DOG	CAT
Acepromazine	Relaxation (tetanus), sedation, decrease urethral smooth muscle tone	0.1-0.2 mg/kg IV, SC, IM q6h 1-2 mg/kg PO q6-8h	Same 0.5-2 mg/kg PO q6-8h
Activated charcoal (1 g/5 mL water)	Gastrointestinal adsorbent	10 mL/kg PO	Same
Ampicillin	Antibiotic	22 mg/kg PO q8h or 22 mg/kg IV, SC, IM q6h	Same
Amoxicillin with clavulanic acid (Clavamox)	Antibiotic	12.5-25 mg/kg PO q8h	Same
Apomorphine	Emetic	0.08 mg/kg SC or 6 mg (1 crushed tablet) in conjunctival sac	Use alternative (xylazine)
Atropine	Premedication for anticholinesterase testing for myasthenia gravis Antidote for cholinergic toxins	0.02 mg/kg IV or 0.04 mg/kg IM 0.5 mg/kg IV, then 1.5 mg/kg SC q6-8h	Same Same
Azathioprine (Imuran)	Immune-mediated diseases	2 mg/kg PO q24h	Do not use
Bethanechol (Urecholine)	Treat bladder atony	0.04 mg/kg PO, SC q8h	Same
Calcium gluconate (10%)	Treat hypocalcemia	0.5-1 mL/kg IV	Same
Cefotaxime	Antibiotic	20-40 mg/kg IV q6h	Same
Ceftriaxone	Antibiotic	25 mg/kg, IV or SC, q12-24h	Same
Cephalexin (Keflex)	Antibiotic	20-40 mg/kg PO q8h	Same
Chlorpromazine (Thorazine)	Antiemetic (vestibular)	0.5 mg/kg IV, SC, IM q8h	Same
Clindamycin	Antibiotic	10-15 mg/kg PO q8h	Same
Cyclosporine (Atopica)	Treat GME	6 mg/kg PO q12h	None
Cytosine arabinoside (Cytosar)	Treat GME	50 mg/m^2 SC q12h on 2 consecutive days q21d	None
Dextrose (50%)	Treat hypoglycemia	2 mL/kg IV	Same
Diazepam (Valium)	Anticonvulsant, chronic seizure management Status epilepticus	0.3-0.8 mg/kg PO q8h 5-20 mg, IV or rectal	Same 5 mg, IV or rectal
Diphenhydramine	Antiemetic (vestibular)	2-4 mg/kg, IM or SC	1-2 mg/kg, IM or SC
Doxycycline	Antibiotic	5-10 mg/kg PO, IV q12h	Same
Edrophonium chloride (Tensilon)	Tensilon test for myasthenia gravis	0.1-0.2 mg/kg IV	0.2-1 mg/cat IV
Enrofloxacin (Baytril)	Antibiotic	5-20 mg/kg PO, IV, IM q24h	5 mg/kg, PO or IM, q24h
Felbamate (Felbatol)	Anticonvulsant	15 mg/kg PO q8h	Same
Furosemide (Lasix) Decrease intracranial pressure	Diuretic	2-4 mg/kg IV, IM 1 mg/kg IV	Same Same
Gabapentin (Neurontin)	Anticonvulsant	10-20 mg/kg PO q8h	Same
Ipecac syrup	Emetic	6.6 mL/kg PO	Same
Leflunomide	Treat GME	2-4 mg/kg PO q24h	10 mg/cat PO

Drugs Used in Neurologic Disorders—cont'd

DRUG NAME (TRADE NAME)	PURPOSE	RECOMMENDED DOSE	
		DOG	CAT
Levetiracetam (Keppra)	Anticonvulsant (chronic) Anticonvulsant (status epilepticus)	20 mg/kg PO q8h 60 mg/kg IV	Same Unknown
Mannitol 20%	Cerebral edema treatment	1-3 g/kg IV over 15 min	Same
Meclizine	Vestibulosedative antiemetic	1-2 mg/kg PO q24h	Same
Methocarbamol (Robaxacin)	Muscle relaxant	20 mg/kg PO q8-12h	None

PART TEN ▪ Joint Disorders

Susan M. Taylor

CHAPTER 68

Clinical Manifestations of and Diagnostic Tests for Joint Disorders

GENERAL CONSIDERATIONS

Disorders affecting the joints can be either noninflammatory or inflammatory (Box 68.1). Noninflammatory joint disorders including developmental, degenerative, neoplastic, and traumatic conditions are discussed in greater detail elsewhere (Rychel, 2010). Inflammatory joint disorders can be infectious or immune-mediated, and may affect one or multiple joints (polyarthritis). Immune-mediated polyarthritis is further classified as being erosive or nonerosive on the basis of physical examination and radiographic findings. Immune-mediated nonerosive polyarthritis (IMPA) is the most common type of polyarthritis recognized in dogs. It results from immune-complex deposition within the synovial membrane, causing a sterile synovitis. IMPA usually occurs as an idiopathic or primary isolated immune-mediated disorder, but it may also be a feature of the multisystemic immune-mediated disorder systemic lupus erythematosus (SLE) or may occur secondary to antigenic stimulation (reactive polyarthritis) in animals with chronic infection or neoplastic disease, or following administration of certain drugs. Some breed-associated immune-mediated syndromes of polyarthritis, polyarthritis/meningitis, or polyarthritis/myositis are also believed to be immune-mediated but have a genetic basis in dogs (see Chapter 64).

CLINICAL MANIFESTATIONS

Traumatic or developmental joint disorders typically involve only one or two joints, with lameness consistently described in the same limb(s). Animals with degenerative joint disease (DJD) typically exhibit low-grade chronic discomfort that causes lameness and a reluctance to exercise without systemic signs of illness and signs that are fairly consistent from day to day. In contrast, the pain associated with inflammatory arthritis—especially polyarthritis—is often much more severe than that of degenerative arthritis, and affected animals may refuse to walk or may cry in pain when moved or touched (Fig. 68.1). A shifting-leg lameness or "walking on egg shells" gait is commonly observed in dogs with polyarthritis. Some patients with polyarthritis are not obviously lame but have a vague history of decreased appetite, fever, weakness, stiffness, or exercise intolerance; in fact, polyarthritis is a common cause of persistent or cyclic fever in dogs (Battersby, 2006). Because some animals with polyarthritis do not have obvious lameness, joint pain, or detectable joint swelling or effusion, it is important to maintain a high index of suspicion for this disorder.

DIAGNOSTIC APPROACH

Animals with nonspecific pain, a stiff gait, reluctance to exercise, or fever of unknown origin should always be evaluated with a careful physical examination in an attempt to localize a region of pain or inflammation. Observation of the animal's posture and gait and thorough manipulation and palpation of the spine and all the muscles, bones, and joints of each limb are important. Palpation of the bones themselves will elicit pain in some animals with traumatic injuries and in dogs affected by panosteitis, hypertrophic osteodystrophy, osteomyelitis, or bone neoplasia. Palpation of affected muscles will be painful in animals with myositis or strain/sprain injuries. Spinal or cervical pain are expected with a variety of spinal cord or vertebral disorders, intracranial mass lesions, meningitis, or polyarthritis; inflammation of the intervertebral facetal joints can manifest as neck or back pain (see Box 58.8 and Box 64.1).

Most animals with joint inflammation experience obvious discomfort during joint manipulation. Flexing and extending a joint affected by degenerative or erosive inflammatory disease commonly reveals a restricted range of motion and crepitation, suggesting articular wear, the presence of

osteophytes, or other periarticular changes. The stability of affected joints should be evaluated to assess the integrity of the supporting ligaments. Animals with nonerosive polyarthritis commonly have joint swelling and pain on manipulation of affected joints but the joints should not be

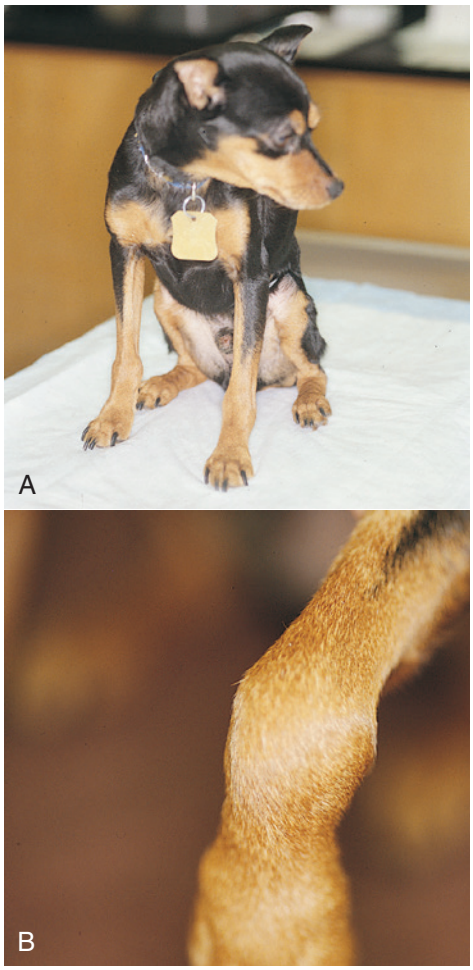

FIG 68.2

deformed or subluxated. (Fig. 68.2). *It is important to realize that approximately 25% of dogs with IMPA have no detectable joint swelling or pain, so normal joint palpation should not preclude further diagnostic evaluation for polyarthritis.*

Synovial fluid analysis is necessary to confirm a diagnosis of inflammatory arthritis. Synovial fluid should be collected and evaluated from multiple (three or more) joints in all dogs and cats with suspected polyarthritis and also those with apparently monoarticular disease whenever there is evidence of systemic or local inflammation. Synovial fluid analysis will differentiate inflammatory from noninflammatory joint disease (Table 68.1). When synovial fluid analysis reveals inflammation, infectious causes should be the first consideration. Infectious causes of arthritis include bacteria, *Mycoplasma* spp., bacterial L-forms, spirochetes, rickettsial agents, protozoa, and fungi (Table 68.2). Infectious agents may either directly invade the joint or cause clinical signs by triggering an immune-mediated polyarthritis due to circulating immune complex deposition (Sykes, 2006). Diagnostic tests used to differentiate infectious from immune-mediated

causes of arthritis include a complete blood count (CBC); urinalysis; culture of urine, blood, and synovial fluid; and serology for tick-borne diseases. Thoracic radiographs and fungal serology may also be warranted. Once infectious causes of polyarthritis have been ruled out, immune-mediated conditions should be considered.

Noninfectious IMPA is common in dogs but uncommon in cats. Immune-mediated polyarthritis can occur as an idiopathic syndrome, as a feature of SLE, or secondary to systemic antigenic stimulation (reactive polyarthritis). In reactive polyarthritis, articular deposition of immune complexes causes synovitis. Reactive polyarthritis has been reported in association with chronic bacterial or fungal infections, neoplasia, and administration of drugs or vaccines (Sykes, 2006). An extensive diagnostic evaluation is sometimes required to rule out reactive polyarthritis (e.g., CBC, thoracic and abdominal radiographs, ophthalmologic examination, bacterial culture of urine and blood, lymph node aspirates, cardiac ultrasonography, abdominal ultrasound). Normal results on all of these tests warrant a diagnosis of idiopathic IMPA. Diagnostic testing for SLE is indicated if there is evidence of multiple organ involvement. Testing for SLE should include a CBC, platelet count, urine protein/creatinine ratio, antinuclear antibody (ANA) titer, and organ-specific tests such as measurement of creatine kinase for suspected myositis.

Because most dogs with IMPA have nonerosive disease, radiographs are not always performed during the initial diagnostic evaluation. If dogs with presumed IMPA do not respond quickly and completely to treatment, or if joints are unstable or deformed on palpation, radiography should be employed to evaluate for evidence of erosive disease affecting the articular surfaces, focal "punched out" lesions of lysis in subchondral bone, and proliferation and calcification of periarticular soft tissues. Erosive polyarthritis is characterized by progressive joint inflammation, destruction, and deformity and is an uncommon immune-mediated disorder in dogs. Serologic testing for rheumatoid factor (RF) (see p. 1204) and synovial membrane biopsy (see p. 1194) aid in the diagnosis of this rare disorder.

Polyarthritis is uncommon in cats. Infectious arthritis may be caused by bacteria, *Mycoplasma* spp., calicivirus infection, fungi, and some tick-borne pathogens (Lemetayer and Taylor, 2014). Forms of nonerosive immune-mediated polyarthritis include idiopathic/primary IMPA, reactive polyarthritis, rheumatoid arthritis, and (rarely) SLE. Two uncommon erosive immune-mediated disorders causing joint damage and destruction in cats are periosteal proliferative polyarthritis and rheumatoid-like polyarthritis.

DIAGNOSTIC TESTS

MINIMUM DATABASE

A minimum database (CBC, serum biochemistry profile, and urinalysis) should be normal in animals with noninflammatory joint disease. In dogs and cats with polyarthritis, it is common to identify a leukocytosis, hyperglobulinemia, and mild hypoalbuminemia. Thrombocytopenia is common in polyarthritis caused by tick-borne pathogens. Organisms may be identified within red or white blood cells in animals with some infectious causes of polyarthritis (Fig. 68.3). Proteinuria and hypoalbuminemia may be present in dogs with concurrent glomerulonephritis. Cats with polyarthritis should always be tested for feline leukemia virus (FeLV) antigen and feline immunodeficiency virus (FIV) antibody. Normal clinical pathologic findings do not rule out polyarthritis.

SYNOVIAL FLUID COLLECTION AND ANALYSIS

Synovial fluid collection and analysis is the most useful test for establishing a diagnosis in dogs and cats with joint disease. It is of greatest value in confirming that a specific joint is abnormal and in differentiating inflammatory from noninflammatory disease. Synovial fluid collection and analysis may also provide information regarding a specific diagnosis.

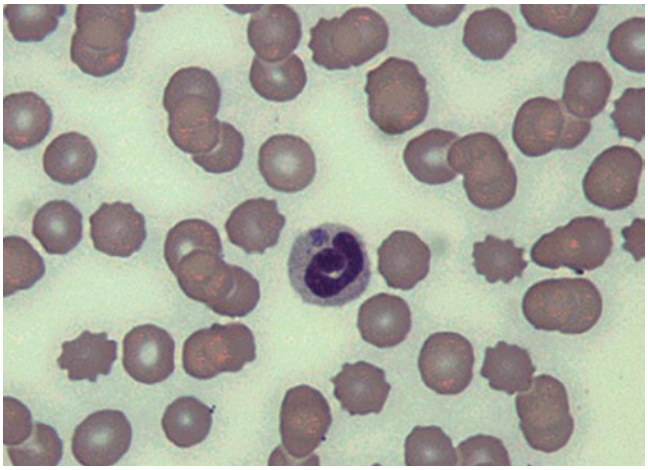

FIG 68.3
Anaplasma phagocytophilum morula in peripheral blood neutrophil from a dog with polyarthritis.

FIG 68.4
Arthrocentesis is performed using a small-gauge needle attached to a 3-mL syringe.

Collection Method

Arthrocentesis requires little in the way of expertise or equipment, involves minimal risk to the animal, is inexpensive to perform, and has a high diagnostic yield. In dogs, light tranquilization or sedation is usually administered for pain relief and restraint. General anesthesia is recommended for collection of synovial fluid in cats. Immunologically mediated disease tends to be most prominent in the distal small joints, but reports differ on whether the hock or carpal joints are most likely to be diagnostic in dogs with primary IMPA (Colopy et al., 2010; Stull et al., 2008). Whenever polyarthritis is suspected, synovial fluid should be analyzed from at least three to four joints, including at least one carpus, one hock, and one stifle. The joints that are clinically most severely affected should always be sampled. Elbows and shoulders should be tapped in animals with poorly localized forelimb lameness. When they are swollen or painful, the smaller metacarpophalangeal and interphalangeal joints can also be sampled. Even if only one joint is clinically affected, synovial fluid should be analyzed from multiple joints if polyarthritis is suspected clinically.

Arthrocentesis should be performed using sterile technique (sterile gloves, needles, and syringes). The hair should be clipped from the area and the skin surgically scrubbed. Arthrocentesis in dogs and cats typically requires a 25-gauge needle attached to a 3-mL syringe (Fig. 68.4). A 22-gauge, 1- to 1½-inch needle is used for the shoulder, elbow, and stifle joints of dogs, depending upon joint size. Large dogs may require a 3-inch spinal needle to enter the hip joint.

Landmarks for arthrocentesis vary according to personal preference, but some recommended approaches are outlined in Fig. 68.5. After aseptic preparation, the joint should be stabilized by an assistant and flexed and extended while the joint space is palpated using a gloved finger. For most joints, the joint space is easiest to access with the joint in moderate flexion. The needle is attached to the syringe and then introduced into the joint space. Once the tip of the needle is in the joint space, gentle negative pressure is applied to the syringe. Only a very small amount of joint fluid (one to three drops) is needed for determination of viscosity and cytologic examination to estimate cell count and to determine the differential white blood cell (WBC) count (Video 68.1). Once fluid is obtained, the negative pressure on the syringe is released before withdrawal of the needle through the skin to decrease the chance of blood from cutaneous vessels entering the syringe. The appearance of blood at any time during the procedure should prompt immediate release of suction and withdrawal of the needle. Synovial smears should be prepared immediately (Fig. 68.6); one drop of synovial fluid is placed onto each slide, and a second slide is used to make a smear. Additional drops of synovial fluid should be submitted for culture and sensitivity. Selection of the most appropriate joint to culture is based on clinical findings or on the gross characteristics of the joint fluid (cloudy, discolored, loss of viscosity). Fluid from at least one joint should be submitted for culture even if IMPA is suspected clinically. When synovial fluid from one or more joints appears grossly abnormal, it may be worthwhile to perform a second arthrocentesis on the most abnormal joint to collect a larger volume of fluid for culture. For aerobic culture, synovial fluid should be submitted in a sterile tube or on a sterile swab. If anaerobic infection is suspected, synovial fluid should be placed in an anaerobic culture tube containing transport medium (e.g., Port-a-Cul). When there is a limited sample volume, both aerobic and anaerobic bacteria can be isolated from an anaerobic culture tube.

Analysis of Gross Appearance

Normal synovial fluid is clear and colorless. Cloudiness or turbidity is observed when red blood cells (RBCs) or WBCs enter the joint in high numbers. A color change may be an indication of blood contamination or a pathologic condition. Hemorrhage from an earlier puncture attempt or an ongoing disease process typically results in a diffuse red discoloration

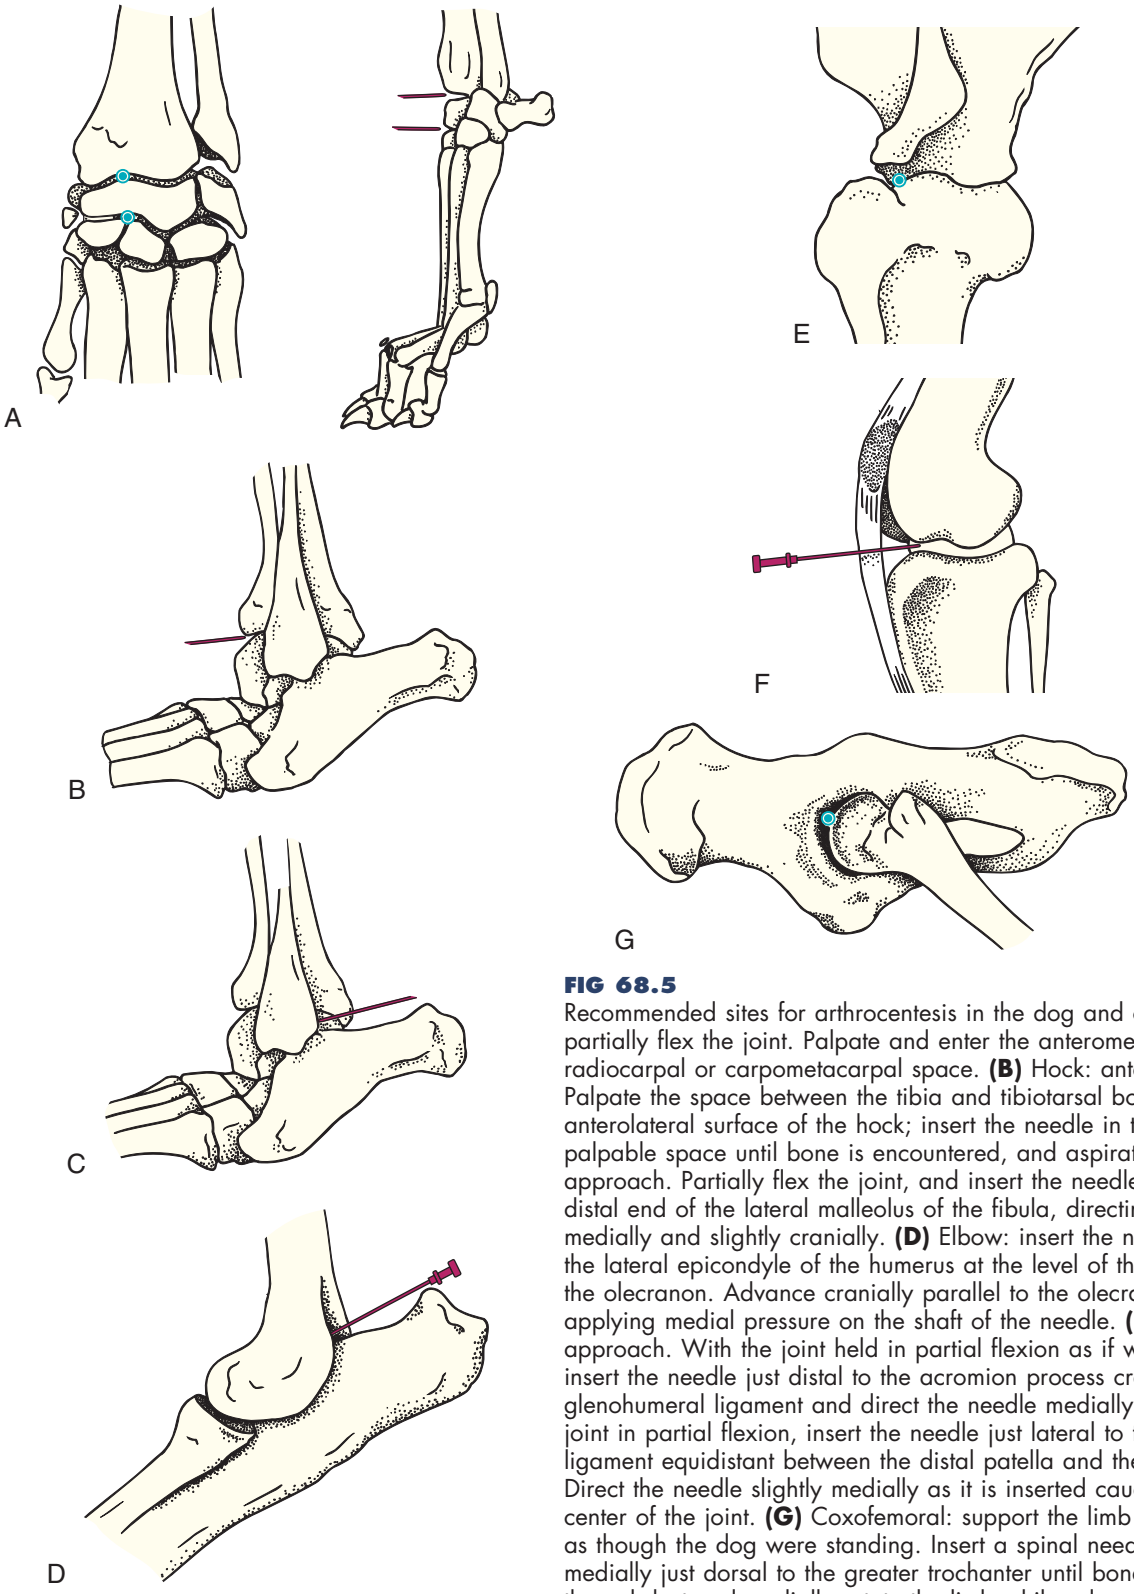

FIG 68.5
Recommended sites for arthrocentesis in the dog and cat. **(A)** Carpus: partially flex the joint. Palpate and enter the anteromedial aspect of the radiocarpal or carpometacarpal space. **(B)** Hock: anterior approach. Palpate the space between the tibia and tibiotarsal bone on the anterolateral surface of the hock; insert the needle in the shallow palpable space until bone is encountered, and aspirate. **(C)** Hock: lateral approach. Partially flex the joint, and insert the needle just caudal to the distal end of the lateral malleolus of the fibula, directing the needle medially and slightly cranially. **(D)** Elbow: insert the needle just medial to the lateral epicondyle of the humerus at the level of the dorsal edge of the olecranon. Advance cranially parallel to the olecranon process while applying medial pressure on the shaft of the needle. **(E)** Shoulder: lateral approach. With the joint held in partial flexion as if weight bearing, insert the needle just distal to the acromion process cranial to the glenohumeral ligament and direct the needle medially. **(F)** Stifle: with the joint in partial flexion, insert the needle just lateral to the straight patellar ligament equidistant between the distal patella and the tibial tuberosity. Direct the needle slightly medially as it is inserted caudally towards the center of the joint. **(G)** Coxofemoral: support the limb parallel to the table as though the dog were standing. Insert a spinal needle straight in medially just dorsal to the greater trochanter until bone is encountered, then abduct and medially rotate the limb while advancing the needle ventrally and caudally.

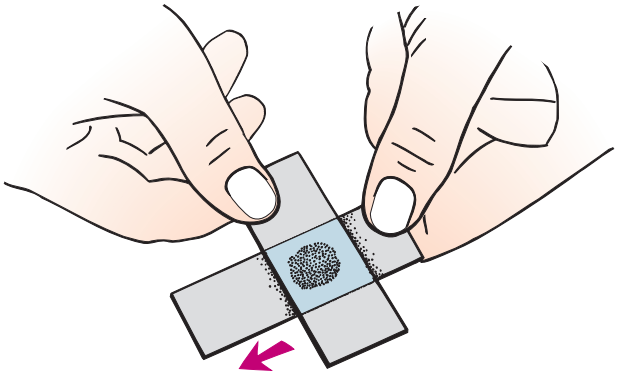

FIG 68.6
Preparing a smear of synovial fluid. A drop of fluid is placed onto a slide. A second slide is used to gently spread the fluid using a pull smear technique.

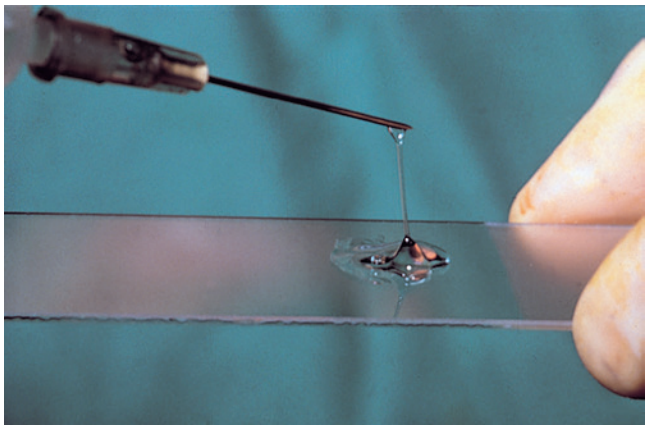

FIG 68.7
Normal synovial fluid is clear and viscous.

of the synovial fluid, whereas blood from a traumatic tap is not usually homogeneously mixed with the joint fluid. A yellowish fluid (xanthochromia) may indicate previous hemorrhage into the joint and is occasionally seen in degenerative, traumatic, and inflammatory joint diseases.

Normal synovial fluid is very viscous. It forms a long string (>2.5 cm) when allowed to drop from the tip of a needle onto a slide (Fig. 68.7, see Video 68.1). A thin or watery consistency indicates that the synovial fluid is deficient in polymerized hyaluronic acid. This may occur after dilution by serum or through degradation of hyaluronic acid by an intense intra-articular inflammatory reaction.

Analysis of Microscopic Appearance

Cytologic evaluation is the most important aspect of synovial fluid analysis. Usually only a few drops of synovial fluid are collected, and estimates of cell numbers are made from a stained direct smear of the fluid. One drop of fluid can be placed on a slide and a second slide used to spread the fluid to make a thin smear (see Fig. 68.6). This smear should be air-dried and then stained with Diff-Quik or Wright-Giemsa

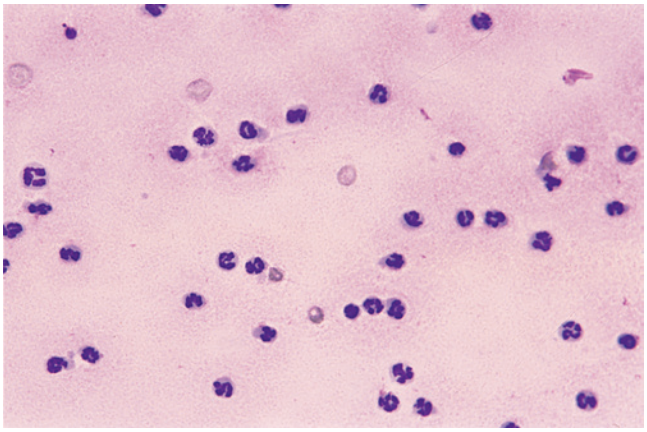

FIG 68.8
Synovial fluid with an increased nucleated cell count consisting primarily of neutrophils from an adult dog with idiopathic immune-mediated polyarthritis.

stain. Because normal synovial fluid contains fewer than 3000 WBCs/μL, no more than three WBCs should be observed per high-dry power (40×) field on a stained smear. Simple microscopic scanning of a stained slide of synovial fluid allows the clinician to estimate cell numbers as normal, mildly increased, or greatly increased.

Normal synovial fluid contains a mixture of large and small mononuclear cells that frequently contain many vacuoles and granules. An occasional neutrophil may be observed, but these cells should represent less than 10% of the total. Blood contamination during synovial fluid collection will result in approximately 1 neutrophil for every 500 RBCs contaminating the fluid. The presence of platelets indicates recent intra-articular hemorrhage or significant blood contamination. Hemosiderin-laden macrophages and erythrophagia confirm prior hemorrhage.

DJD causes a slightly increased cell count (<6000 cells/μL) and an increased volume of synovial fluid, but almost all of the cells are mononuclear cells (see Table 68.1). An increase in the number of neutrophils within a joint indicates inflammation of the synovial lining. The more inflamed the synovium, the greater the number of WBCs in the synovial fluid and the greater the percentage of neutrophils (Fig. 68.8).

In addition to the actual or estimated WBC count and WBC differential, cytologic evaluation of the cells in the joint fluid is important. Neutrophils in the synovial fluid of dogs and cats with immune-mediated disease should have a normal appearance. In acute or severe cases of septic arthritis, bacteria may be observed within the neutrophils, which may be toxic, ruptured, or degenerate. Organisms may occasionally be observed within the cells in the synovial fluid of animals with polyarthritis caused by rickettsial infections *(Ehrlichia canis, Ehrlichia ewingii, Anaplasma phagocytophilum)* or leishmaniasis. In dogs with SLE-induced polyarthritis, lupus erythematosus (LE) cells or ragocytes may rarely be seen within the synovial fluid (Fig. 68.9).

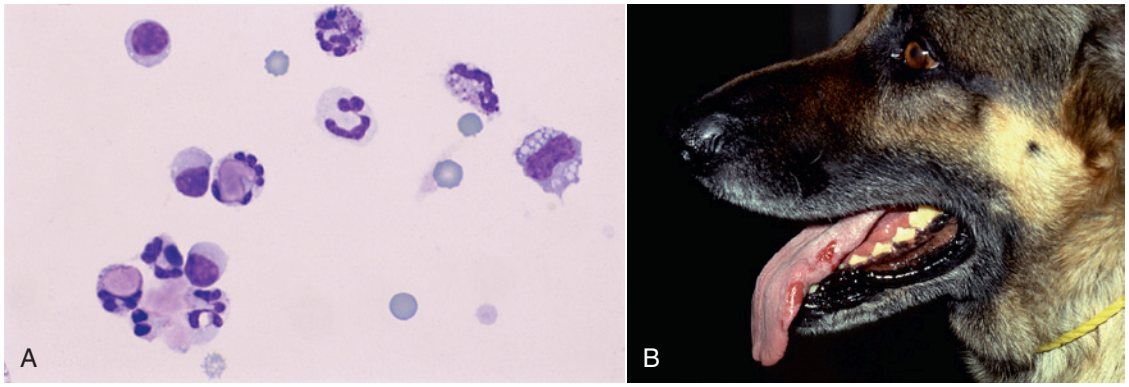

FIG 68.9
Synovial fluid from an adult German Shepherd dog with polyarthritis. **(A)** Some of the cells are lupus erythematosus (LE) cells containing phagocytized, opsonized, amorphous nuclear material. Finding these LE cells supports a diagnosis of systemic lupus erythematosus (SLE). **(B)** This dog also has proteinuria, tongue ulcers caused by vasculitis, and a positive antinuclear antibody test.

SYNOVIAL FLUID CULTURE

Bacteria are the most common cause of joint infection. Septic arthritis can often be diagnosed on the basis of the appearance of toxic changes within neutrophils and identification of bacteria on stained smears of synovial fluid (Clements, 2005). Some organisms (e.g., *Mycoplasma* spp.) do not induce characteristic cytologic abnormalities, so any joint fluid with an increased nucleated cell count and a high percentage of neutrophils warrants a culture. Synovial fluid should be submitted for aerobic and anaerobic culture and for specific *Mycoplasma* spp. culture. Because direct bacterial culture of synovial fluid is positive in less than half of all cases of septic arthritis, failure to grow bacteria in synovial fluid does not rule out septic arthritis. The diagnostic yield can be greatly improved (50%-100% positive) if infected synovial fluid is collected and inoculated into broth-enrichment media (e.g., thioglycolate blood culture bottles) and incubated for 24 hours prior to culture. Microbiologic culture of blood, urine, and synovial membrane biopsy specimens should also be considered to improve the chance of recovering a clinically relevant pathogen.

SYNOVIAL MEMBRANE BIOPSY

Performing synovial membrane biopsy can support a diagnosis already suspected on the basis of history, physical examination, radiographic studies, and synovial fluid analysis. It may also be used to collect a sample for microbiologic culture in cases of suspected septic arthritis. Examination of the synovial membrane is especially valuable in the diagnosis of neoplasia and in differentiating infectious arthritis from immune-mediated disorders.

Synovial membrane biopsies may be obtained by needle biopsy or surgical arthrotomy. Surgical excision of a wedge of synovial membrane allows visualization of the entire joint and selection of a specific site from which to obtain the biopsy. Needle biopsy of the synovial membrane is quick and minimally traumatic, but samples are small and easily obtained only from the stifle joint.

RADIOGRAPHY

Radiography is an important component of the initial diagnostic evaluation when only one joint is clinically affected or when joint palpation reveals crepitation, instability, or a restricted range of motion. Physical examination findings should be used to determine which joints should be radiographed, and two views (i.e., lateral and anterior/posterior) should be made of each joint. Radiographic abnormalities of the joints and periarticular region are expected in animals with DJD, chronic septic arthritis, and erosive immune-mediated arthritis. Radiographs of the carpus are abnormal in up to 75% of dogs with erosive polyarthritis at the time of first evaluation for polyarthritis. In dogs with presumed nonerosive IMPA and dogs with infectious polyarthritis, radiographs are generally not recommended if the response to treatment is rapid and complete, because the only abnormalities observed are mild effusion, joint capsule distention, and associated soft tissue swelling.

Radiographs of the thorax and abdomen and abdominal ultrasound are often recommended in dogs and cats with polyarthritis to evaluate for underlying infectious or neoplastic disease that could lead to reactive polyarthritis. In addition, radiographs of the spine should be performed in dogs with concurrent neck or back pain to screen for diskospondylitis as a cause for reactive polyarthritis.

Radiography is an important tool but has limited utility. Many of the bony changes seen with DJD and erosive immune-mediated disease are not apparent for weeks to months after the onset of signs. Although positive findings contribute a great deal to the diagnosis, negative findings should be interpreted with caution. Sequential radiographic studies may be warranted.

IMMUNOLOGIC AND SEROLOGIC TESTS

Lyme Disease Titers

Infection with the spirochete *Borrelia burgdorferi,* the etiologic agent for Lyme disease, causes primary infectious synovitis as well as immunologically mediated synovitis resulting from immune complex deposition. Affected dogs develop an antibody response that can be detected using an indirect fluorescent antibody (IFA) test or an enzyme-linked immunosorbent assay (ELISA). High serum titers are common in dogs with clinical signs of Lyme disease and also in asymptomatic dogs in endemic areas. A positive antibody titer merely indicates exposure to the organism and cannot be used to diagnose active disease. A surface peptide (C6) is expressed when Bb is transmitted to dogs but is not expressed in the tick, in tissue culture, or in Lyme vaccines. Therefore antibodies against C6 prove that natural exposure to *B. burgdorferi* has occurred. A quantitative version of this test (Lyme Quant C6 Test, IDEXX, Westbrook, Maine) is available, but positive results still indicate exposure rather than clinical disease. A diagnosis of Lyme disease polyarthritis must rely on a combination of the history (i.e., recent exposure to an area in which the disease is enzootic), clinical signs, identification of polyarthritis through arthrocentesis elimination of other known causes of polyarthritis, serologic testing, and response to therapy (see p. 1200).

Rickettsial Titers

Serologic testing plays an important role in the diagnosis of Rocky Mountain spotted fever (RMSF), canine monocytotropic ehrlichiosis, canine granulocytotropic anaplasmosis, and bartonellosis (see Chapter 95 for more discussion of rickettsial diseases and Chapter 94 for more discussion of bartonellosis). Demonstration of a rising titer is necessary to make the diagnosis of acute RMSF, with a fourfold increase between acute and convalescent titers expected. Demonstration of antibody against *E. canis, E. ewingii,* and *A. phagocytophilum* indicate prior exposure, with antibody levels remaining increased for months after successful treatment.

Systemic Lupus Erythematosus

Tests used to diagnose SLE include the ANA titer and the LE cell test. These tests should only be used when clinical criteria for diagnosis of SLE have been met (see Chapter 71). The ANA titer is positive when circulating antibodies to nuclear material are present in the blood. These antibodies are the most prominent of the autoantibodies associated with canine and feline SLE. The ANA test is a sensitive indicator for the diagnosis of SLE and is positive in 55% to 90% of SLE cases. The ANA is constant from day to day and is less steroid labile than the LE cell test. Unfortunately, a positive ANA test is not specific for SLE, and false-positive results may be seen in dogs and cats with many other systemic inflammatory or neoplastic diseases. The LE cell test requires identification of an LE cell, which is a neutrophil that has phagocytized, opsonized nuclear material. The cytoplasm of these cells is filled with amorphous purple material (see Fig. 68.9). The LE cell test is labor intensive, requires an experienced technician, and rapidly becomes negative after administration of corticosteroids, so it is rarely performed in clinical practice.

Rheumatoid Factor

The laboratory test for RF detects serum agglutinating antibody directed against the patient's own immunoglobulin (Ig) G. The reliability of the test increases with the severity and chronicity of the disease. The test is reported to be positive in 20% to 70% of dogs with erosive (rheumatoid-like) arthritis. Any disease associated with systemic inflammation and immune complex generation and deposition can result in weak false-positive results.

CHAPTER 69

Disorders of the Joints

GENERAL CONSIDERATIONS

The diagnostic approach to dogs and cats with joint disease is discussed in detail in Chapter 68. Joint disorders are characterized as inflammatory or noninflammatory on the basis of synovial fluid analysis. The most common noninflammatory joint disease is degenerative joint disease (DJD). Inflammatory joint disorders can be due to either infectious or immune-mediated causes. Animals with immune-mediated polyarthritis (IMPA) usually have primary idiopathic immune-mediated disease, but immune complex–mediated polyarthritis may also occur secondary to prolonged systemic antigenic stimulation (reactive polyarthritis; see Chapter 68). Most IMPA syndromes are nonerosive. Disorders causing radiographic evidence of bone destruction (erosive disease) are rare.

NONINFLAMMATORY JOINT DISEASE

CANINE DEGENERATIVE JOINT DISEASE

Etiology

DJD, or osteoarthritis, is a chronic progressive disorder of joints that results in articular cartilage loss, osteophyte formation, and periarticular fibrosis. DJD can affect any size, breed, and age of dog, and any joint may be affected, including smaller joints such as the vertebral facets and metacarpophalangeal and metatarsophalangeal joints. Most DJD occurs secondary to joint instability, trauma, or developmental orthopedic diseases that damage articular cartilage, but primary DJD can occur as an intrinsic problem of cartilage homeostasis associated with aging. Although considered noninflammatory on the basis of synovial fluid cytology, inflammatory mediators are involved in the clinical manifestations and progression of DJD. An estimated 20% of the adult canine population in North America is affected by DJD in at least one joint.

Clinical Features

The clinical signs of DJD are usually insidious in onset and confined to the musculoskeletal system, with no associated systemic signs. Lameness and stiffness may initially be prominent only after periods of overexertion and may worsen in cold and damp weather. Mildly affected dogs may "warm out" of their lameness with exercise. As DJD progresses, fibrosis and pain lead to decreased exercise tolerance, persistent lameness, and, in severe cases, muscular atrophy. Either a single joint or multiple joints may be affected.

Diagnosis

DJD is usually diagnosed on the basis of history, physical examination findings, and characteristic radiographic features. Clinical examination may reveal pain in the affected joint(s), decreased range of motion, crepitation on flexion and extension of the affected joint(s), and sometimes appreciable joint swelling. Radiographic changes characteristic of DJD include joint effusion, periarticular osteophyte formation, subchondral bone sclerosis, joint space narrowing, and bone remodeling (Fig. 69.1). A predisposing condition is often identified, such as trauma, rupture of supporting ligaments, poor conformation, or a congenital deformity. Animals with DJD do not exhibit the fever, leukocytosis, and depression commonly seen in animals with inflammatory joint disease.

Synovial fluid from a joint with DJD may be slightly less viscous than normal. The total nucleated cell count (TNCC) is normal or slightly increased, but it rarely exceeds 5000 cells/μL. Mononuclear cells usually constitute at least 80% of the cells, and neutrophils are rare (<10%). Acute joint injury or ligament rupture occasionally incites a more inflammatory response, with moderate increases in synovial fluid neutrophil count for days to weeks following injury.

Treatment

The goals of treatment in dogs with DJD are to alleviate discomfort and prevent further joint degeneration. Surgical intervention may be necessary to eliminate joint instability or to correct anatomic defects. Options such as femoral head/neck ostectomy, joint arthrodesis, intra-articular regenerative stem cell therapy, or joint replacement surgery may be considered to relieve discomfort when response to medical therapy is inadequate.

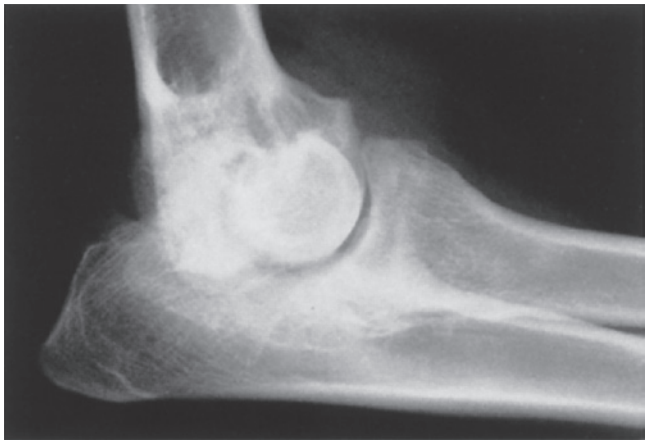

FIG 69.1
Close-up mediolateral radiograph of left elbow joint of a 14-month-old female German Shepherd dog with severe degenerative changes secondary to a fragmented coronoid process.

Medical treatment is symptomatic and nonspecific. Weight reduction may decrease the stresses acting on the joint. Rest often helps decrease the discomfort associated with acute exacerbations of disease. High-impact exercise, such as running and jumping, should be discouraged, whereas low-impact exercise done in moderation, such as swimming, leash walking, and walking on an underwater treadmill is recommended to maintain mobility and muscle strength. Other forms of rehabilitation therapy may include passive range-of-motion exercises, cryotherapy (ice compresses), muscle and joint massage, ultrasound, laser therapy, and electrical stimulation. Dietary supplementation with omega-3 polyunsaturated fatty acids (PUFAs), eicosapentaenoic acid (EPA), and antioxidants (vitamin E, vitamin C, beta carotene, zinc, selenium) or feeding commercial "joint diets" containing these supplements may decrease the inflammation and pain of DJD.

Pharmacologic therapies may be used to decrease further degradation of the articular cartilage, inhibit release of inflammatory mediators, and control pain. The nonsteroidal antiinflammatory drugs (NSAIDs) are often recommended because of their antiinflammatory and analgesic effects. The primary action of most NSAIDs is reversible inhibition of cyclooxygenase, preventing synthesis of the prostaglandins responsible for pain and inflammation. Selective inhibition of two forms of cyclooxygenase (COX-1 and COX-2) may explain some of the differences in efficacy and toxicity among the available NSAID agents. Preferential inhibition of COX-2 with relative sparing of COX-1 by an NSAID may be associated with improved control of inflammation and decreased potential for gastric irritation and ulceration or renal toxicity. Renal function should be assessed before prescribing any NSAID, after 7 days of treatment, and then at least every 6 months during chronic administration. Owners should also be instructed to monitor for inappetence, vomiting, or melena, which could indicate gastrointestinal toxicity. Because the clinical response to each NSAID varies between dogs, it is reasonable to switch drugs when the response to one drug is inadequate (Table 69.1). When switching from one NSAID to another, a washout period of at least 3 days without NSAID administration is recommended to prevent toxicity. In dogs that are intolerant of NSAIDs or those that require further analgesia, oral tramadol (2-5 mg/kg q8-12h), gabapentin (2.5-10 mg/kg oral [PO] q8-24h), or amantadine (3-5 mg/kg PO q24h) can be helpful in pain management.

Oral and injectable chondroprotective agents and nutraceuticals may improve cartilage biosynthetic activity, decrease synovial inflammation, and inhibit intra-articular degradative enzymes. Oral glucosamine and chondroitin sulfate can be administered separately or in combination. An orally administered combination of glucosamine HCl, chondroitin sulfate, and manganese ascorbate has also been recommended (Cosequin RS [regular strength], 1-2 tablets q24h in cats or small dogs; Cosequin DS [double strength], 2 to 4 tablets q24h in large dogs [Nutramax Labs, Edgewood, MD]). Polysulfated glycosaminoglycans (Adequan) or pentosan polysulfate may be beneficial when administered intramuscularly (see Table 69.1). Hyaluronic acid is a nonsulfated glycosaminoglycan that can be administered as an intra-articular injection to improve synovial viscosity and decrease inflammation. To achieve the maximum theoretic benefit from all these products, they should be administered before DJD has occurred; therefore they may be indicated for treating dogs that have sustained trauma or undergone surgery known to have damaged articular cartilage. Clinical trials are necessary to evaluate their efficacy.

FELINE OSTEOARTHRITIS

Cats are smaller and more agile than most dogs, and their clinical manifestations of discomfort are often subtle. Clinically significant DJD involving the elbow and hip joints is, however, very common in aging cats. Signs include reduced activity, decreased appetite, weight loss, irritability, and occasionally lameness. Diagnosis is based on physical findings and radiographic features. Treatment of DJD in cats is similar to that recommended in dogs and includes weight loss, rehabilitation therapy, and administration of chondroprotective medications, nutraceuticals, and analgesics. NSAIDs are potentially more toxic in cats than in dogs due to deficient glucuronidation pathways leading to a prolonged duration of effect so they should only be administered to normotensive, normovolemic adult cats with no history of renal or hepatic disease. Meloxicam has been shown to be safe and effective when administered chronically to cats with DJD, and many cats have a good clinical response to very low doses of meloxicam (0.1 mg/kg/day PO × 4 days, then 0.1 mg/cat/day). Other commonly prescribed analgesic medications include buprenorphine (0.01-0.03 mg/kg bid to tid via buccal mucosa), gabapentin (5-10 mg/kg bid-tid), tramadol (2 mg/kg bid PO), and amantadine (3-5 mg/kg PO q24h).

TABLE 69.1

Dosages of Selected Drugs for Treating Degenerative Joint Disease in Dogs

GENERIC NAME	DRUG NAME	DOSE
Nonsteroidal Antiinflammatory Drugs (NSAIDs)		
Acetylsalicylic acid	(Aspirin)	10-20 mg/kg PO q8-12h
Carprofen	(Rimadyl)	2.2 mg/kg PO q12h
Deracoxib	(Deramaxx)	1-2 mg/kg PO q24h
Etodolac	(Etogesic)	10-15 mg/kg PO q24h
Firocoxib	(Previcox)	5 mg/kg PO q24h
Meloxicam	(Metacam)	0.2 mg/kg PO once, then 0.1 mg/kg PO q24h
Piroxicam	(Feldene)	0.3 mg/kg PO q48h
Disease-Modifying Chondroprotective Agents		
Chondroitin sulfate		15-20 mg/kg PO q12h
Glucosamine		15-20 mg/kg PO q12h
Pentosan polysulfate	(Pentosan 100)	3 mg/kg IM q7d
Polysulfated glycosaminoglycans	(Adequan)	3-5 mg/kg IM q4d for 8 tx, then q30d
Analgesics		
Tramadol		2-5 mg/kg PO q8-12h
Gabapentin	(Neurontin)	2.5-10 mg/kg PO q8-12h
Amantadine		3-5 mg/kg PO q24h

IM, Intramuscular; *PO,* oral; *tx,* treatments.

INFECTIOUS INFLAMMATORY JOINT DISEASES

SEPTIC (BACTERIAL) ARTHRITIS

Etiology

Septic arthritis can result from a blood-borne infection, from direct inoculation of a joint, or by local spread from adjacent infected tissue. Bacterial infection of multiple joints suggesting hematogenous spread of bacteria is uncommon except in immunosuppressed animals and neonates with omphalophlebitis. Monoarticular septic arthritis is much more common than polyarticular and usually follows direct inoculation of bacteria into a single joint as a result of surgery, a bite wound, trauma, or foreign body penetration. Most septic joints with no physical or historical evidence of direct inoculation have radiographic evidence of preexisting osteoarthritis, potentially causing increased synovial vascularity and predisposing to hematogenous bacterial infection. *Staphylococcus* spp., *Streptococcus* spp., and coliform organisms are most often incriminated in dogs, and *Pasteurella* spp. are the most common cause in cats. Septic arthritis, regardless of the cause, is more common in dogs than cats, is most common in large-breed dogs, and more frequently affects males than females.

Clinical Features

Animals with septic polyarthritis are often systemically ill, febrile, and depressed. The affected joints are usually very painful, especially when manipulated, and may be palpably distended with synovial fluid. The periarticular soft tissues may be inflamed and edematous. Septic arthritis most commonly involves the elbow or stifle joints.

Diagnosis

To confirm a diagnosis of septic arthritis, bacteria must be identified in cytologic preparations of synovial fluid or cultured in synovial fluid, synovial membrane, blood, or urine from an animal with appropriate clinical signs and inflammatory synovial fluid. Synovial fluid obtained by arthrocentesis from infected joints is often yellow, cloudy, or bloody and less viscous than normal as a result of dilution and degradation of synovial mucin by bacterial hyaluronidase and the enzymes released from the inflammatory cells within the joint. Smears of synovial fluid should be made for Gram staining and cytologic evaluation. Because it is common for synovial fluid from infected joints to clot rapidly, a portion of the fluid should be immediately placed in an anticoagulant (i.e., ethylenediaminetetraacetic acid [EDTA]) tube for future cytologic evaluation if an adequate sample volume is obtained. In animals with septic arthritis, there is a marked

increase in the number (40,000-280,000/μL) of nucleated cells in the synovial fluid, with neutrophils predominating (usually >90%). In very acute or severe cases, it is common to see bacteria within the cells, and the neutrophils may be toxic, ruptured, or degranulated. Organisms that do not cause rapid destruction of articular cartilage (i.e., streptococci, *Mycoplasma*) may not cause remarkable toxic or degenerative changes in synovial fluid neutrophils. In chronic infections or in animals that have received prior treatment with antibiotics, bacteria may no longer be evident and neutrophils may appear healthy.

Synovial fluid should be cultured for aerobic and anaerobic bacteria. Direct bacterial culture of synovial fluid is positive in less than half of all animals with septic arthritis; improved diagnostic yield may be obtained by inoculating synovial fluid into blood culture medium (9:1 ratio) and incubating it for 24 hours at 37° C before inoculation. Bacteria can also be recovered from cultures of synovial membrane biopsy, blood, or urine specimens.

Radiographic changes of the involved joints in septic arthritis may initially be minimal and nonspecific, and limited to thickening of the joint capsule, widening of the joint space, and irregular thickening of periarticular soft tissues (Fig. 69.2). In chronic infections, cartilage degeneration, periarticular new bone formation, a marked periosteal reaction, and subchondral bone lysis may be observed (Fig. 69.3).

If septic arthritis is suspected and the animal has no history of direct inoculation of the joint with bacteria, diagnostic evaluation for a source of bacteremia should be performed, although often the cause cannot be identified. Radiographs of the thorax, abdomen, and spine, as well as cardiac and abdominal ultrasonography, are especially helpful in identifying a focal site of infection. Culture of material from any suspected site of infection should be performed if possible.

Treatment

The goals of therapy are to rapidly resolve the bacterial infection and remove intra-articular accumulations of enzymes and fibrin debris. Identifiable systemic sources of infection should also be eliminated. In an animal suspected of having septic arthritis, antibiotics should be administered as soon as possible after all samples are collected. Until culture results are available, a broad-spectrum, β-lactamase-resistant antibiotic such as a first-generation cephalosporin (e.g., cephalexin, 20-40 mg/kg PO q8h) or Clavamox (Zoetis; 12-25 mg/kg PO q8h) is indicated. Initially the antibiotic can be administered parenterally, followed by long-term oral administration. Quinolones should be used if gram-negative organisms are suspected; retinal toxicity is a potential concern in cats receiving quinolones, but pradofloxacin has an improved safety profile. Metronidazole should be added if anaerobic infection is suspected. Animals with acute septic

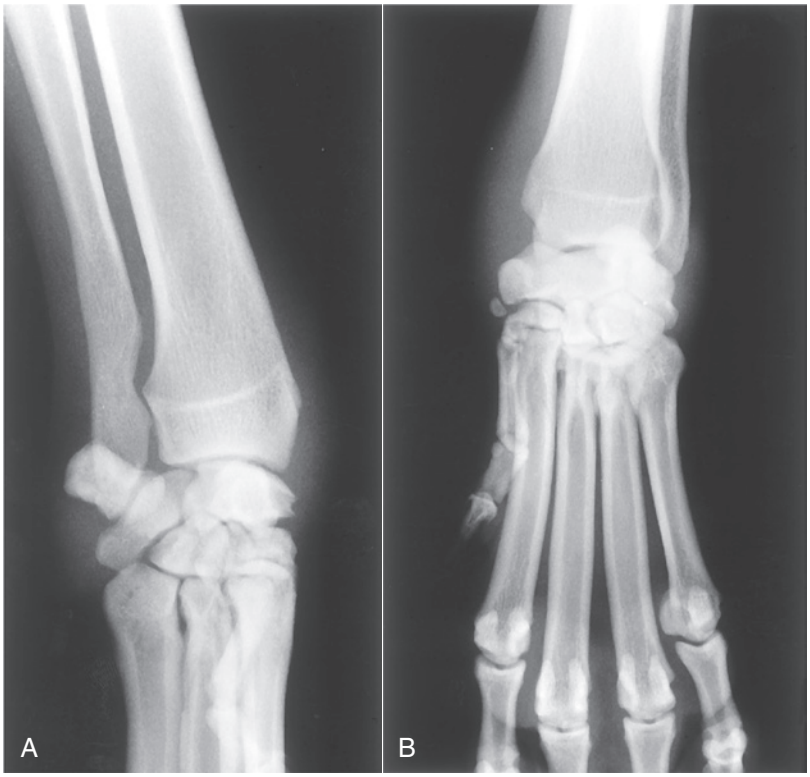

FIG 69.2
Lateral **(A)** and dorsopalmar **(B)** radiographs of the swollen left carpus of a 2-year-old Bullmastiff with a 1-week history of lameness caused by septic arthritis. Surgical exploration revealed two porcupine quills within the infected joint.

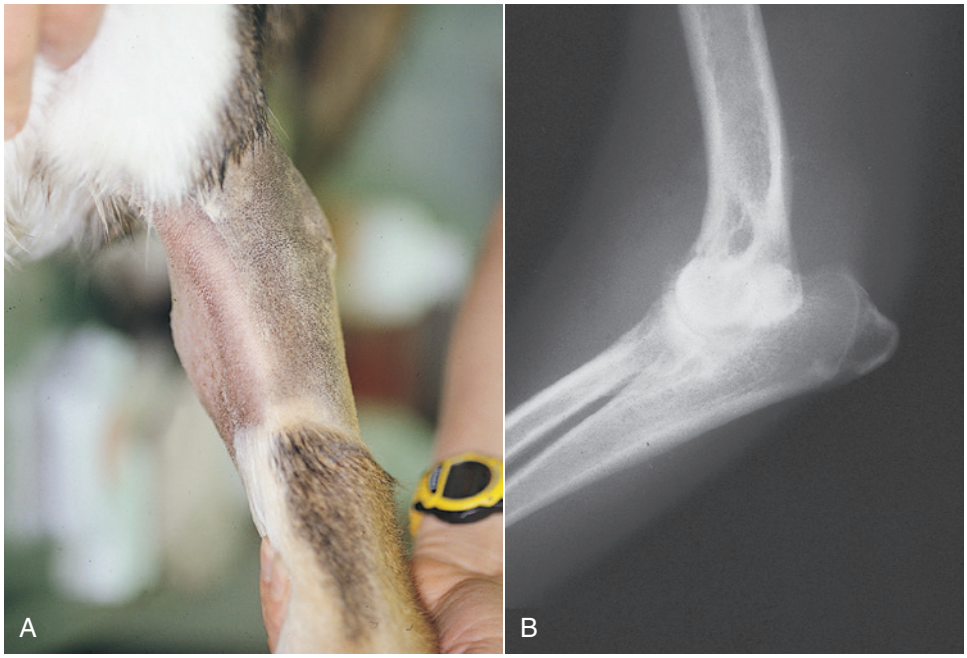

FIG 69.3
(A) Very swollen elbow in a Husky-cross dog with a 3-month history of non–weight-bearing lameness not responding to antibiotics. **(B)** Radiographs reveal marked swelling within the joint and diffuse periosteal proliferation. Synovial fluid showed septic inflammation, and surgical exploration revealed a single porcupine quill within the joint. The dog recovered completely.

arthritis can initially be treated conservatively with systemic antibiotics; however, if dramatic improvement is not seen within 3 days, surgery should be performed. Chronic infections, suspected intra-articular foreign bodies, postoperative joint infections, and infection in immature animals with open growth plates should all be treated with immediate surgical debridement and lavage. A minimum of 6 weeks of antibiotic therapy is administered, and cage rest is recommended to facilitate healing of articular cartilage.

Prognosis

The prognosis for a return to normal function depends on the severity of the damage to the articular cartilage at the time the infection is brought under control. Secondary DJD commonly occurs.

MYCOPLASMA POLYARTHRITIS

Mycoplasma spp. are normal inhabitants of the conjunctival membranes, pharynx, upper respiratory, and urogenital tracts of most species, and are generally considered nonpathogenic. *Mycoplasma gatea* and *Mycoplasma felis* have, however, been associated with erosive and nonerosive polyarthritis and tenosynovitis in cats. Mycoplasma polyarthritis occurs primarily in immunosuppressed or debilitated cats but has rarely been reported in apparently immunocompetent cats.

Mycoplasma polyarthritis typically results from hematogenous spread of the bacteria to the joints. Clinical signs include lameness, joint pain, depression, and fever. Synovial fluid analysis reveals an increase in nondegenerate neutrophils with no visible organisms. Routine aerobic and anaerobic cultures of joint fluid are negative because successful culture of *Mycoplasma* requires specific transport media and sample handling. Inflammatory joint fluid from cats should always be specifically cultured for *Mycoplasma spp,* and empirical treatment with oral doxycycline (5-10 mg/kg q12h) for 3 weeks is recommended before treating with immunosuppressant drugs for presumed idiopathic IMPA. Cats with polyarthritis should also be tested for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV), and radiographs should be made of the affected joints to investigate for erosive changes. Treatment of Mycoplasma arthritis with doxycycline, enrofloxacin, or pradofloxacin should result in rapid clinical improvement, but treatment for 6 to 8 weeks may be necessary to prevent relapse.

RICKETTSIAL POLYARTHRITIS

Nonerosive polyarthritis has been recognized in association with several tick-borne rickettsial diseases, including Rocky Mountain spotted fever (RMSF) caused by *Rickettsia rickettsii, Ehrlichia canis, Ehrlichia ewingii,* and *Anaplasma phagocytophilum*. The polyarthritis that occurs in these disorders is believed to be due at least in part to immune complex deposition in the joints (reactive polyarthritis). Most infected dogs have other systemic signs of illness. Joint pain and effusion may be noted, and increased numbers of nondegenerate

neutrophils are identified in the joint fluid; occasionally, *Ehrlichia* or *Anaplasma* morulae can be identified in cytologic preparations of joint fluid. Fever and polyarthritis may be the only clinical abnormalities in dogs with ehrlichiosis and anaplasmosis, although concurrent hematologic abnormalities such as thrombocytopenia and anemia are common. Serologic testing for *E. canis, E. ewingii,* and *A. phagocytophilum* is widely available, but positive results merely indicate prior exposure and not necessarily active infection. Also, because polyarthritis often occurs early in acute ehrlichiosis and anaplasmosis, it is common for symptomatic dogs to have negative serologic results. Convalescent titers (10-14 days later) might be required to document infection.

Dogs with polyarthritis caused by RMSF typically show a variety of clinical signs resulting from widespread vasculitis, including fever, petechiae, lymphadenopathy, neurologic signs, edema of the face or extremities, and pneumonitis. Hematologic abnormalities, including thrombocytopenia, are common. Diagnosis is made on the basis of the results of serologic testing and demonstration of a fourfold increase in serum immunoglobulin (Ig)G concentrations over 2 to 3 weeks.

Acute rickettsial infections causing polyarthritis are best treated with oral doxycycline (5 mg/kg q12h). Empirical antibiotic treatment is warranted in all dogs with confirmed polyarthritis from endemic areas, especially if there is concurrent thrombocytopenia or other evidence to support rickettsial infection. Concurrent glucocorticoid therapy (prednisone, 0.5-2 mg/kg PO q24h) may be necessary in some dogs with confirmed rickettsial polyarthritis if antimicrobial therapy alone does not eliminate the fever, lameness, and joint swelling. Antibiotic treatment should continue for at least 3 weeks.

LYME DISEASE

Etiology

Infection by the tick-borne spirochete *Borrelia burgdorferi* (Bb) can cause illness (Lyme disease) in dogs. Ticks of the genus *Ixodes* transmit the spirochete, requiring at least 50 hours of tick attachment for transmission. Although serologic evidence of exposure is common in dogs throughout North America, most reports of canine Lyme disease have occurred in dogs from the northeastern and mid-Atlantic states, with Minnesota, Wisconsin, California, and Oregon accounting for most of the remaining cases.

Clinical Features

Most dogs bitten by ticks infected with Bb develop an antibody response but remain asymptomatic. Acute polyarthritis is the most common form of Lyme borreliosis diagnosed, and it occurs in fewer than 5% of naturally infected dogs. Clinical features of Lyme polyarthritis include shifting leg lameness, joint swelling, fever, lymphadenopathy, and anorexia. Cytologic examination of synovial fluid reveals neutrophilic inflammation. Cardiac, renal, and neurologic manifestations (e.g., seizure, behavior change) have also been attributed to Bb infection in dogs. There are reports of dogs with Bb antibodies developing a unique progressive renal disorder characterized by immune-mediated glomerulonephritis, tubular necrosis, and lymphocytic-plasmacytic interstitial nephritis. This disorder, which is often called Lyme nephritis, is most common in Labrador and Golden Retrievers and Shetland Sheepdogs, and causes progressive uremia, proteinuria, peripheral edema, body cavity effusions, and often death. Because of the high rate of seropositivity in endemic areas and the frequency of concurrent infection with other tick-borne diseases, it is difficult to determine how common Lyme disease is in clinical practice. The rate of veterinary diagnosis of canine Lyme polyarthritis certainly far exceeds its actual prevalence. Bacterial DNA was detected by polymerase chain reaction (PCR) in dogs with naturally occurring anterior cranial cruciate rupture but not in dogs with experimentally induced cranial cruciate rupture. Whether Lyme borreliosis plays a part in the pathogenesis of cranial cruciate rupture in dogs is unclear (Muir et al., 2007).

Diagnosis

Fever, lameness, and anorexia in dogs from endemic areas should raise the suspicion of Lyme disease. Synovial fluid analysis confirms polyarthritis. Attempts to culture Bb from the blood, urine, and synovial fluid of affected dogs are usually unsuccessful. Lyme disease polyarthritis should be diagnosed only if the animal has a history of recent potential exposure, the synovial fluid is confirmed to be inflammatory and sterile, serologic testing is positive, infection with other tick-borne diseases is eliminated, and a prompt and permanent response to appropriate antibiotic therapy is seen. The diagnosis can be supported by identifying *Borrelia* organisms in biopsy specimens of tissues prepared using special stains and monoclonal antibodies.

Treatment

Antibiotics are the treatment of choice. Oral doxycycline (5 mg/kg q12h), amoxicillin (22 mg/kg PO q12h), ampicillin (22 mg/kg PO q8h), Clavamox (12.5-25 mg/kg PO q8-12h), and cephalexin (20-40 mg/kg PO q8h) are all effective. Treatment during the acute stage of the disease should result in rapid clinical improvement (i.e., within 2-3 days). Treatment for at least 4 weeks is advised. Failure to recognize acute disease or institution of inappropriate treatment can allow chronic disease to develop, including relapsing polyarthritis, glomerulonephritis, and cardiac abnormalities.

Prevention

The prevention of Lyme disease is discussed in Chapter 93.

LEISHMANIASIS

Leishmaniasis is a chronic systemic disease caused by a protozoan parasite found mainly in Central and South America, Africa, India, and the Mediterranean. In the United States, *Leishmania* spp. are endemic in Ohio, Oklahoma, and Texas.

Clinical abnormalities develop 3 months to 7 years after infection and typically consist of vague signs, including weight loss, lymphadenopathy, and splenomegaly. Hyperglobulinemia, hypoalbuminemia, and proteinuria are expected. Polyarthritis causing lameness and exercise intolerance is common. Many affected dogs will have erosive disease with radiographic evidence of periarticular lysis and periosteal proliferation. Diagnosis is made when organisms are identified within macrophages in lymph node or splenic aspirates or in joint fluid (see Chapter 98).

FUNGAL ARTHRITIS

Fungal infection of the joints is very rare. When it does occur, it is usually as an extension of fungal osteomyelitis caused by *Coccidioides immitis, Blastomyces dermatitidis,* or *Cryptococcus neoformans.* More commonly a reactive, immunologically mediated, culture-negative polyarthritis occurs in dogs and cats with systemic fungal infections.

VIRAL ARTHRITIS

Calicivirus

Natural calicivirus infection and attenuated live calicivirus vaccination have been associated with development of transient polyarthritis in 6- to 12-week-old kittens. Clinical signs include lameness, stiffness, and fever that usually resolve spontaneously after 2 to 4 days (Fig. 69.4). Some kittens go on to develop overt calicivirus infection, with glossal and palatine vesicles or ulcers and signs of upper respiratory tract disease. Synovial fluid analysis reveals a mildly to greatly increased nucleated cell count, with small mononuclear cells and macrophages predominating, some of which contain phagocytosed neutrophils. Two specific strains of calicivirus have been implicated. Attempts to isolate the virus from affected joints has been unrewarding, although the virus can be found in the oropharynx of some infected cats. The polyarthritis in these kittens is likely to be immune complex mediated (reactive polyarthritis) rather than infectious.

FIG 69.4
Presumed calicivirus polyarthritis in a 10-week-old kitten exhibiting swollen joints, lameness, and fever 6 days after modified-live virus vaccination.

NONINFECTIOUS POLYARTHRITIS: NONEROSIVE

Noninfectious inflammatory (immune-mediated) joint diseases are very common in the dog but rare in the cat. IMPA is classified as either erosive or nonerosive on the basis of the presence or absence of radiographically evident joint destruction. Erosive disorders are very rare (<1% of canine polyarthritis cases). Nonerosive IMPA is believed to be mediated through immune complex formation and deposition in the synovial membrane. Immune-mediated nonerosive polyarthritis occurs secondary to antigenic stimulation from chronic infection, neoplasia, or drugs (i.e., reactive polyarthritis), as an idiopathic syndrome, and as a feature of systemic lupus erythematosus (SLE). Breed-associated syndromes of polyarthritis or polyarthritis/meningitis or polyarthritis/myositis also exist and are thought to have a genetic basis.

REACTIVE POLYARTHRITIS

Reactive polyarthritis accounts for some 25% of all nonerosive IMPAs cases and has been documented in association with chronic bacterial, fungal, or rickettsial infections; neoplasia; and drug administration. When it occurs secondary to chronic infection, the joints themselves are not infected, but immune complex deposition causes immune mediated synovitis. Reactive polyarthritis has been documented in dogs with endocarditis, foreign body abscesses or granulomas, diskospondylitis, heartworm disease, pancreatitis, prostatitis, pyelonephritis, pneumonia, other chronic bacterial and rickettsial infections, and a variety of tumors (Fig. 69.5). Drugs that have been implicated in causing reactive polyarthritis include sulfadiazine-trimethoprim, phenobarbital, erythropoietin, penicillin, cephalexin, and routine vaccinations. Rarely, gastrointestinal disorders such as inflammatory bowel disease, salmonellosis, and chronic active hepatitis have also been associated with reactive polyarthritis.

Because many animals with reactive polyarthritis have vague or minimal clinical signs referable to their underlying disease, they may be presented for veterinary evaluation when their joint inflammation makes them reluctant to walk. Therefore it is important to perform a thorough physical examination of every animal with polyarthritis and obtain a complete history regarding medication administration and the presence or absence of systemic signs. Once infectious causes of polyarthritis have been eliminated, screening tests (i.e., complete blood count [CBC], biochemical panel, urinalysis, thoracic and abdominal radiography, abdominal ultrasonography, culture of urine and blood, lymph node aspirates, cardiac ultrasonography) may be required to identify underlying chronic infections or neoplasia (Fig. 69.6).

FIG 69.5
(A) Two-year-old German Shepherd dog/Labrador Retriever cross with reactive polyarthritis. The dog was seen because of a 3-month history of shifting leg lameness and weight loss. There was joint swelling and pain and a grade IV/VI diastolic cardiac murmur. Synovial fluid was inflamed but sterile. **(B)** A cardiac ultrasound study suggested infective endocarditis of the aortic valve, which was confirmed by postmortem evaluation.

Serology or PCR testing may be necessary to evaluate for systemic infections known to cause reactive polyarthritis (*Bartonella, Anaplasma* and *Ehrlichia* spp).

Clinical signs in dogs with reactive polyarthritis typically include cyclic fevers, stiffness, and lameness. Synovial fluid analysis reveals an increase in both white blood cell (WBC) count and the percentage of neutrophils in affected joints, but synovial fluid culture is negative. Radiographically, the only finding is joint swelling.

Treatment must be directed at eliminating the underlying disease or antigenic stimulus whenever possible. If this can be achieved, polyarthritis usually resolves without additional therapy. Short-term low-dose glucocorticoid therapy (prednisone, 0.25-1 mg/kg PO q24h) or NSAID therapy may be warranted to control synovitis in severe cases.

IDIOPATHIC IMMUNE-MEDIATED NONEROSIVE POLYARTHRITIS

Nonerosive noninfectious polyarthritis in which a primary or underlying disease cannot be identified is referred to as *idiopathic immune-mediated polyarthritis*. This disorder can be diagnosed only by ruling out the other causes of polyarthritis, but it is the most common form of polyarthritis diagnosed in dogs (Box 69.1). It is especially common in sporting and large breeds. Dogs of any age can be affected, but the incidence peaks at 2.5 to 4.5 years. Idiopathic immune-mediated nonerosive polyarthritis is uncommon in cats.

BOX 69.1

Classification of Polyarthritis in Dogs

Infectious

Bacterial
Mycoplasma
Rickettsial
Lyme borreliosis
Leishmaniasis
Fungal
Viral

Noninfectious, Nonerosive

Idiopathic immune-mediated polyarthritis (IMPA)
Systemic lupus erythematosus (SLE)
Reactive polyarthritis (bacterial, fungal, parasitic, neoplastic, enterohepatic, drug reaction, vaccine induced)
Breed-associated syndromes
  Polyarthritis (Akita, Newfoundland, Weimaraner)
  Polyarthritis/meningitis (Akita, Beagle, Bernese Mountain dog, Boxer, German Shorthaired Pointer)
  Polyarthritis/polymyositis (Spaniels)
  Familial Shar-Pei fever
Lymphoplasmacytic synovitis

Noninfectious, Erosive

Rheumatoid-like arthritis
Erosive polyarthritis of Greyhounds

Clinical Features

The most common manifestations of idiopathic IMPA are cyclic fever, stiffness, and lameness. Multiple joints are usually involved, with the small distal joints (i.e., carpus, hock) affected most frequently. Approximately 20% to 50% of affected dogs lack palpable joint effusion or joint pain. Cervical pain and vertebral hypersensitivity are sometimes present, reflecting either intervertebral facetal joint involvement or the presence of concurrent steroid-responsive meningitis-arteritis (see Chapter 64). Some affected dogs are not obviously lame but are evaluated because of a vague history of decreased appetite or fever of unknown origin.

Diagnosis

Idiopathic IMPA is diagnosed on the basis of the results of synovial fluid analysis, failure to identify an infectious cause, and the absence of evidence to support a diagnosis of SLE or reason to suspect reactive polyarthritis (see Fig. 69.6). A CBC can be normal or inflammatory. Hyperglobulinemia

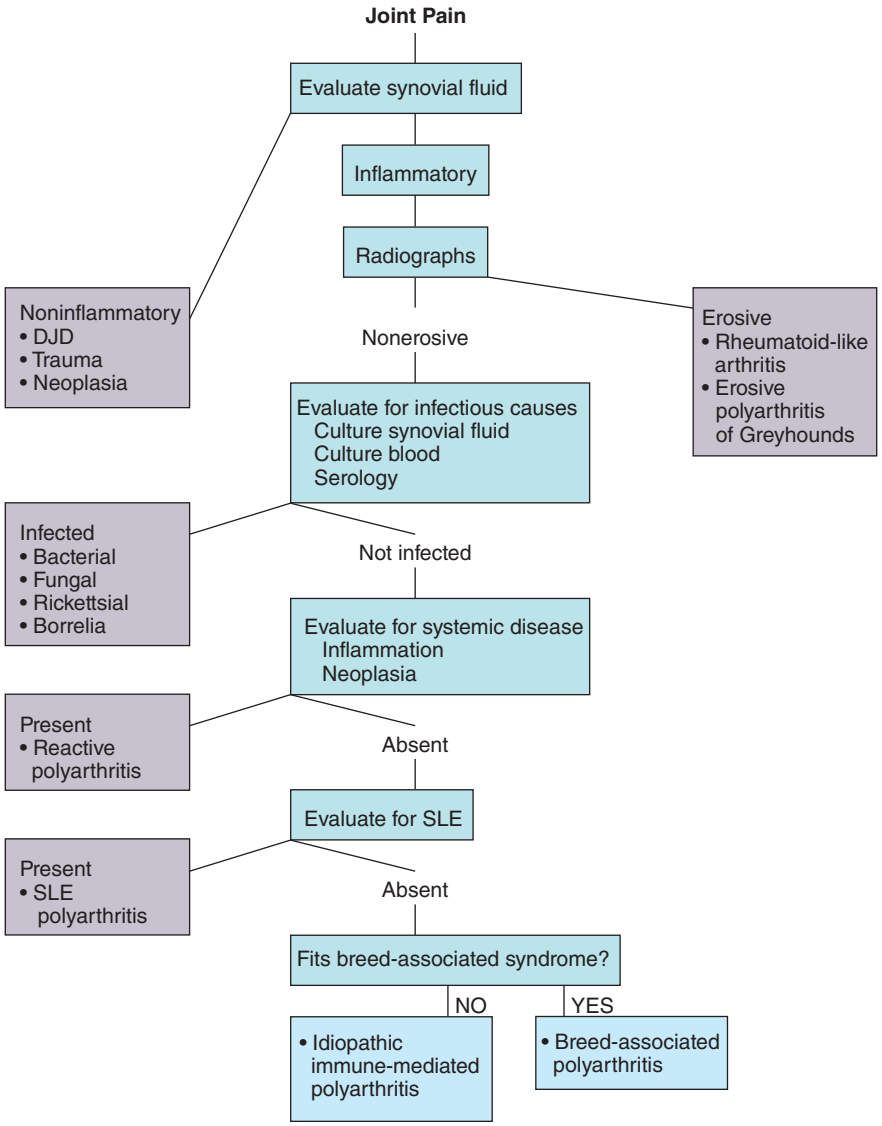

FIG 69.6
Algorithm for diagnostic evaluation of dogs with joint pain.

and hypoalbuminemia are common, reflecting ongoing systemic inflammation. Radiographs are either normal or demonstrate joint and periarticular swelling with no bone or cartilage abnormalities. Synovial fluid usually has decreased viscosity and may be turbid. Nucleated cell counts are increased (4000-370,000 cells/μL), with nondegenerate neutrophils predominating (usually >80%). In animals with less severe or waxing and waning disease and animals that have received glucocorticoids, there may be a lower synovial fluid WBC count and a lower percentage of neutrophils (15%-80%). Blood, urine, and synovial fluid cultures are negative for bacteria and *Mycoplasma* spp.

Treatment

In areas endemic for infectious causes of polyarthritis, empirical treatment with doxycycline is usually instituted while awaiting the results of diagnostic testing for infectious agents. A rapid and complete response makes a diagnosis of idiopathic IMPA less likely. Glucocorticoids are the initial treatment of choice for dogs with idiopathic IMPA. Prednisone treatment alone results in remission in 50% of cases. Immunosuppressive doses are initially administered, and the dosage is gradually decreased every 3 to 4 weeks if the animal is clinically normal and the inflammation in the synovial fluid has subsided (Box 69.2). The gold standard for response to therapy is resolution of synovial inflammation, so, ideally, arthrocentesis should be used to monitor response to therapy. Synovial fluid should be monitored carefully during treatment, and resolution of inflammation should be demonstrated prior to each decrease in drug dose. Repeated arthrocentesis may rarely be associated with mild mononuclear joint inflammation but does not cause neutrophilic inflammation in healthy dogs (Berg et al., 2009). If a dog with IMPA can be maintained on a low alternate-day

BOX 69.2

Treatment Recommendations for Canine Idiopathic Immune-Mediated Polyarthritis

1. Prednisone 2 mg/kg q12h orally for 3-4 days
2. Prednisone 2 mg/kg q24h orally for 14 days
3. Assess clinical response and synovial fluid cytology:
   - If clinical signs have resolved, the dose of prednisone is gradually tapered, evaluating clinical response and synovial fluid before each dose reduction:
     1 mg/kg q24h × 4 weeks
     1 mg/kg q48h × 4 weeks
     0.5 mg/kg q48h × 4 weeks
     0.25 mg/kg q48h × 8 weeks
   - If clinical signs of joint inflammation are present at any recheck, return to step 2 and add azathioprine (2 mg/kg/day PO) to treatment. Continue prednisone taper after signs resolve and synovial fluid is normal.

dose of prednisone (0.25 mg/kg PO q48h) for 2 months and the synovial fluid is not inflammatory, it is often possible to discontinue all therapy. However, approximately 50% of affected dogs will need at least alternate-day low-dose prednisone therapy for the remainder of their lives. In dogs receiving a stable dose of medication, synovial fluid should be evaluated every 4 to 6 months.

Additional immunosuppressive drugs should be administered to dogs with persistent inflammation of synovial fluid despite prednisone therapy and to dogs that cannot be maintained on a low dose of prednisone without relapse. Azathioprine (Imuran) is often used for this purpose, and it may also be used as initial treatment in dogs that are known to not tolerate prednisone therapy. Azathioprine (2.2 mg/kg) is administered PO once daily for 4 to 6 weeks. The frequency of administration can be decreased to every other day and then discontinued if the animal is doing well clinically and synovial fluid inflammation has resolved; however, some dogs will require lifelong azathioprine therapy. In most dogs azathioprine is well tolerated, with myelosuppression the most common adverse effect. A CBC and platelet count should be performed initially every 2 weeks and then every 4 to 8 weeks during treatment. See Chapter 72 for more information on azathioprine treatment. Azathioprine, leflunomide, mycophenolate mofetil, cyclosporine, and cyclophosphamide have all be shown to be effective add-on treatments for idiopathic IMPA in dogs. Cats with idiopathic IMPA can be treated with cyclosporine, leflunomide, chlorambucil, or methotrexate if prednisolone alone is ineffective.

Idiopathic nonerosive IMPA is easy to control in most patients. If the polyarthritis is refractory to treatment, the patient should be reevaluated for infectious disease, reactive polyarthritis, and erosive disease prior to considering alternative or additional immunosuppressive agents (Table 69.2). In addition to medical treatment, management should initially include restricted exercise, followed by regular gentle exercise and weight control. Chondroprotective agents, omega-3 fatty acids, and antioxidants may also prove beneficial. (See Chapters 72 and 73 for more information on immunosuppressive treatment.)

TABLE 69.2

Drugs Used in the Treatment of Immune-Mediated Polyarthritis in Dogs

DRUG	DOSAGE
Prednisone	Variable
Azathioprine (Imuran [GlaxoSmithKline, Philadelphia, PA])	2.2 mg/kg PO q24-48h
Cyclosporine (Atopica [Novartis, Greensboro, NC])	2.5-5 mg/kg PO q12h Target blood level 400 ng/mL
Leflunomide (Arava [Aventis Pharma, Bridgewater, NJ])	3-4 mg/kg q24h Target trough blood level 20 µg/mL
Cyclophosphamide (Cytoxan [Bristol-Myers-Squibb, Princeton, NJ])	50 mg/m^2 PO q48h
Chlorambucil (Leukeran [GlaxoSmithKline])	Dogs: 0.1-0.2 mg/kg PO q24h initially, then taper to every other day once a response is seen
Methotrexate (Rheumatrex [Wyeth, Philadelphia, PA])	2.5 mg/m^2 PO q48h

PO, Oral.

Prognosis

The prognosis for animals with idiopathic immune-mediated nonerosive polyarthritis is good in most cases. Approximately 80% of dogs respond well to initial treatment, and 50% of these dogs can be weaned off therapy after 3 to 4 months. An occasional dog is very difficult to control initially or keep in remission. In such cases reevaluation of the diagnosis should be considered to make sure a diagnosis of erosive polyarthritis or SLE has not been missed. Dogs that require long-term (4-5 years) high-dose immunosuppressive drug therapy for polyarthritis may develop symptomatic DJD secondary to chronic low-grade synovial inflammation and the detrimental effects of glucocorticoids on cartilage synthesis and repair.

SYSTEMIC LUPUS ERYTHEMATOSUS–INDUCED POLYARTHRITIS

SLE is a multisystemic immune-mediated disorder in which autoantibodies against tissue proteins and DNA result in circulating immune complexes that, when deposited in tissues, induce inflammation and organ damage (see Chapter 73).

Although SLE is a relatively uncommon cause of polyarthritis in dogs compared with idiopathic IMPA, its effects on other organ systems can be devastating, which makes accurate diagnosis important. SLE is most commonly diagnosed in dogs 2 to 4 years old. German Shepherd dogs and Shetland Sheepdogs may be predisposed, but any breed of dog may be affected.

Clinical Features

The clinical manifestations of SLE depend on the organs involved and include intermittent fever, polyarthritis, glomerulonephritis, skin lesions, hemolytic anemia, immune-mediated thrombocytopenia, myositis, and polyneuritis. Polyarthritis is the most common manifestation, occurring in 70% to 90% of dogs diagnosed with SLE. Some affected dogs show no signs referable to their joint disease, and polyarthritis is detected when synovial fluid is examined as part of a workup for fever or polysystemic immune-mediated disease. More often, dogs with SLE polyarthritis show generalized stiffness, joint swelling, or shifting leg lameness. SLE causes a sterile nonerosive polyarthritis, with distal joints (i.e., hocks, carpi) usually more severely affected than proximal joints. Synovial fluid analysis reveals an increased WBC count (5000-350,000/mL) consisting primarily of nondegenerate neutrophils (>80%). In rare instances, lupus erythematosus (LE) cells or ragocytes are detected in the synovial fluid (see Fig. 68.9).

Diagnosis

SLE should be considered in any dog with noninfectious polyarthritis. A thorough physical examination, CBC, platelet count, biochemistry profile, urinalysis, fundic examination, and protein/creatinine ratio determination should be performed to search for other manifestations of this disease. Laboratory tests that may aid in the diagnosis of SLE polyarthritis include the LE cell test and the antinuclear antibody (ANA) test. An animal is diagnosed with SLE if there are two or more of the major clinical abnormalities known to be associated with SLE (e.g., polyarthritis, glomerulonephritis, hemolytic anemia, thrombocytopenia, leukopenia, polymyositis, dermatitis) and either the ANA or LE test is positive. When two or more of the common clinical syndromes are recognized but none of the serologic tests is positive, the dog is determined to have an SLE-like multisystemic immune-mediated disease. See Chapter 73 for more information on the diagnosis of SLE.

Treatment

Treatment for SLE-associated polyarthritis is the same as that used for idiopathic IMPA; however, addition of other cytotoxic drugs (e.g., azathioprine, cyclosporine) is usually necessary to induce or maintain remission. See Chapter 73 for more information on treatment of SLE.

Prognosis

The prognosis for dogs with SLE is guarded to poor. Relapse is common regardless of the drug protocol used, and long-term and often lifelong immunosuppressive therapy is necessary to control the disease. Relapses may involve different organ systems and clinical signs than at initial presentation (e.g., hemolytic anemia initially and polyarthritis at relapse).

BREED-SPECIFIC POLYARTHRITIS SYNDROMES

There are a number of breed-specific IMPA syndromes in dogs. A heritable polyarthritis has been documented in Akitas younger than 1 year of age, and a similar disease is reported sporadically in Newfoundlands and Weimaraners. Many of these dogs have concurrent meningitis resembling the meningeal vasculitis syndromes seen in other breeds (see Chapter 64). ANA tests are negative in these animals, and generally they respond poorly to routine immunosuppressive therapy so more aggressive immunosuppressive treatment is recommended. In contrast, polyarthritis that accompanies meningeal vasculitis in Boxers, Bernese Mountain Dogs, German Shorthaired Pointers, and Beagles often responds completely to immunosuppressive therapy.

Familial polyarthritis with concurrent myositis has been rarely reported in Spaniel breeds. Affected dogs are exercise intolerant and exhibit a crouched stance at rest. Widespread muscle atrophy is common, occasionally leading to muscle fibrosis, contracture, and reduced mobility. Muscle enzymes (creatine kinase [CK], aspartate aminotransferase [AST]) may be increased. Response to therapy is often poor.

FAMILIAL CHINESE SHAR-PEI FEVER

Familial Chinese Shar-Pei fever, also known as Shar-Pei Autoinflammatory Disease (SPAID), is an inherited inflammatory disease that occurs in nearly 25% of all Shar-Peis. The disorder was initially thought to be due to a genetic mutation that increased production of hyaluronic acid (HA) by dermal fibroblasts, causing mucinosis and triggering an inflammatory response (Olsson et al., 2011). More recent genetic studies have identified a missense mutation in affected dogs that works directly to strongly promote proinflammatory reactions. The disease is usually first manifested prior to 18 months of age and is characterized initially by intermittent episodes of inflammation and fever lasting 24 to 36 hours. Some 50% of affected dogs develop periarticular swelling around the hock joints during the febrile episodes, and some dogs develop polyarthritis, particularly of the hocks. Affected dogs are at increased risk for systemic amyloidosis, often leading to renal or hepatic failure. Renal amyloid deposition is primarily medullary, so not all dogs will exhibit proteinuria. Hyperglobulinemia and increased serum concentrations of the cytokine interleukin-6 are common. Glomerulonephritis, pyelonephritis, renal infarcts, and systemic thromboembolic disease may occur. This disorder is inherited as an autosomal incompletely dominant trait. Treatment relies on symptomatic control of fever and inflammation. Oral administration of colchicine (0.03 mg/kg q24h) may decrease amyloid deposition.

LYMPHOPLASMACYTIC SYNOVITIS

Lymphoplasmacytic synovitis is present in some dogs with partial and complete tears of the cranial cruciate ligament, but the relationship between the immune-mediated response and the ligament rupture is uncertain. Partial tears or ruptures of the cruciate ligament commonly initiate an inflammatory reaction directed against the collagen of the ligament, resulting in mildly inflammatory synovial fluid and synovial fluid antibodies directed against type 1 and type 2 collagen. An alternative theory is that lymphoplasmacytic synovitis is a primary immune-mediated disorder that causes joint laxity and instability, eventually leading to rupture of the cranial cruciate ligament. Some investigators have estimated that perhaps as many as 10% to 25% of cruciate ruptures in dogs are caused by this immunologic disorder, but this is a controversial claim.

Dogs diagnosed with lymphoplasmacytic synovitis are the same dogs typically presented for cruciate ligament rupture, with Rottweilers, Newfoundlands, Staffordshire Bull Terriers, and Labrador Retrievers most commonly affected. Clinical signs are limited to acute or chronic lameness involving one or both stifles. Cruciate ligament rupture at the time of diagnosis may be partial or complete, and often there is no history of trauma. Arthroscopy or magnetic resonance imaging (MRI) may be required to confirm the diagnosis of partial rupture. Affected animals are in good body condition and are not systemically ill; CBC is normal. Synovial fluid is thin and turbid, with an increased nucleated cell count (5000-20,000 cells/μL, but occasionally > 200,000/μL). Lymphocytes and plasma cells predominate (60%-90%) in the synovial fluid. Biopsy of ligament and synovium should be performed at the time of surgical exploration and repair in all dogs with nontraumatic cruciate ligament ruptures. Characteristic histopathologic changes in the synovial lining include lymphocytic and plasmacytic infiltration and villous hyperplasia. Surgical stabilization of the stifle and treatment with NSAIDs usually result in rapid resolution of clinical signs. Some dogs will have persistent effusion and discomfort that responds well to immunosuppressive treatment with prednisone and/or azathioprine, initiated a minimum of 3 days after NSAID therapy is discontinued.

NONINFECTIOUS POLYARTHRITIS: EROSIVE

CANINE RHEUMATOID-LIKE POLYARTHRITIS

A disorder resembling human rheumatoid arthritis (RA) is a rare cause of erosive polyarthritis and progressive joint destruction in dogs. Small and toy breeds are most commonly affected (mean body weight 8 kg). Cocker Spaniels and Shetland Sheepdogs may be predisposed. The age of onset is variable (i.e., 9 months to 13 years), but most affected dogs are young or middle-aged at the time of diagnosis. Initially, the disease is indistinguishable from idiopathic nonerosive polyarthritis, but the joints are destroyed over time (months to years), with distal joints most severely affected.

Etiology

The pathogenesis of canine RA-like polyarthritis is poorly understood. Antibodies directed against IgG (i.e., rheumatoid factors [RFs]) form and complex with IgG within the synovium. This results in complement activation and the chemotactic attraction of plasma cells, lymphocytes, and neutrophils into the joint fluid. The synovial membrane thickens and develops a fibrous, vascular granulation tissue (pannus) that invades articular cartilage, tendons, ligaments, and subchondral bone. Proteolytic enzymes are released that erode the articular cartilage and subchondral bone, leading to joint collapse and radiographically visible "punched-out" subchondral bone lesions. Articular and periarticular inflammation and instability lead to joint subluxation and luxation, resulting in joint deformity.

Clinical Features

Affected dogs initially have signs indistinguishable from those of other forms of polyarthritis. A low-grade fever, depression, anorexia, and reluctance to exercise are common. Joint-related clinical signs such as joint pain and stiff gait are prominent. Signs may be sporadic initially, and stiffness is generally worse after rest and improves with mild exercise. The joints may appear normal or be swollen and painful. The joints most commonly affected are the carpi, hocks, and phalanges, although stifles, elbows, and shoulders can also be affected. As the disease progresses, clinical examination reveals crepitus, laxity, luxation, and deformity of affected joints, especially the carpus bilaterally (Fig. 69.7). Unilateral or bilateral anterior cruciate ligament rupture is also common.

Radiographic features may be subtle at the time of initial diagnosis, with intracapsular swelling the only consistent

FIG 69.7
Complete collapse of both carpi, resulting in luxation and severe distortion of the forelimbs in a Dachshund with rheumatoid arthritis. (Courtesy Dr. D. Haines, University of Saskatchewan.)

FIG 69.8
Radiographs of both carpal joints of a 9-year-old female Shih Tzu. Both carpi are severely deformed secondary to erosive rheumatoid-like polyarthritis. The intercarpal spaces have thinned laterally, and there are focal radiolucent cyst-like areas of subchondral bone destruction and regional soft tissue swelling. There is dislocation of the radius and ulna from the carpus bilaterally.

finding. Later, characteristic changes consist of focal, irregular, radiolucent, cyst-like areas of subchondral bone destruction (Fig. 69.8); joint space collapse; and joint subluxation and luxation. Erosive changes are common in the carpus at the time of diagnosis (75% of affected dogs) and are evident radiographically in all affected dogs within 1 year of diagnosis. Whenever RA is suspected, carpi should be radiographed bilaterally.

Diagnosis

RA-like polyarthritis should be suspected in any dog with erosive polyarthritis once infectious causes have been eliminated. The synovial fluid in affected joints is thin, cloudy, and hypercellular, with an increased TNCC similar to dogs with nonerosive idiopathic IMPA (mean 7200 WBCs/μL). Neutrophils are usually the predominant cell (20%-95%; average 74%), but mononuclear cells may sometimes predominate. Lymphocyte numbers are often increased in synovial fluid from dogs with erosive polyarthritis. Culture of synovial fluid is negative. Whenever possible, the synovial fluid should be collected during a period when the dog is most symptomatic, because the cyclical nature of the disease occasionally makes diagnosis difficult.

Serologic tests for circulating RF are positive in 20% to 70% of affected dogs (see Chapter 68). Weak false-positive results are common in dogs with other systemic inflammatory diseases. Synovial biopsy may help establish the diagnosis, revealing synovial thickening, hyperplasia, and proliferation with pannus formation. The pannus is composed primarily of proliferating activated synoviocytes, lymphocytes, plasma cells, macrophages, and neutrophils. Culture of the synovial biopsy is negative. RA is diagnosed on the basis of the typical clinical findings and radiographic features, characteristic synovial fluid features, a positive RF test result, and the typical histopathologic changes seen in a synovial biopsy specimen.

Treatment

Early treatment of RA is important to prevent irreversible changes and progressive disease. Medical treatment usually includes immunosuppressive drugs and chondroprotective agents. Initially, most dogs are treated with oral prednisone (2-4 mg/kg q24h for 14 days, then 1-2 mg/kg q24h for 14 days) and azathioprine (2.2 mg/kg PO q24h), administered as described for the treatment of refractory idiopathic nonerosive polyarthritis. Oral chondroprotective agents (see Table 69.1) should be administered concurrently. Subjective improvement has also been observed in dogs receiving injectable chondroprotective agents (e.g., Adequan).

If there is a good response to treatment, based on both resolution of clinical signs and synovial fluid inflammation, the glucocorticoid dose should be decreased to 1 to 2 mg/kg orally every 48 hours, and treatment with azathioprine is continued. If the response to treatment is inadequate after 1 month of treatment with glucocorticoids and azathioprine, more aggressive immunosuppressive therapy should be considered (see Table 69.2). Few published data exist regarding treatment of RA in dogs, so choice of immunosuppressive agents is usually based on individual clinical experience and response to therapy. Leflunomide has been reported to be

effective as monotherapy in some dogs with idiopathic polyarthritis and is well tolerated. Leflunomide is administered at an initial dose of 3 to 4 mg/kg PO q24h, and the dose is adjusted to maintain a trough plasma level of 20 mg/mL. (See Chapter 72 for more information on immunosuppressive treatment.)

Some therapeutic success may be expected if treatment is initiated before joint damage is severe. In most cases, however, damage to the articular cartilage is severe before the diagnosis is made. Many dogs require additional therapy with analgesics such as tramadol to control joint discomfort. RA is a relentlessly progressive disorder, and even with appropriate therapy most dogs show deterioration with time. Surgical procedures can occasionally be used to improve joint stability and pain. Synovectomy, arthroplasty, joint replacement, and arthrodesis may decrease pain and improve function.

EROSIVE POLYARTHRITIS OF GREYHOUNDS

An erosive IMPA occurs in Greyhounds from 3 to 30 months of age. This disorder is primarily seen in Australia and Great Britain. The proximal interphalangeal joints, carpi, hocks, elbows, and stifles are most commonly affected. Clinical signs include generalized stiffness, joint pain or swelling, and a single or multiple-limb lameness that may be intermittent. The synovial membrane is infiltrated with lymphocytes and plasma cells, and synovial fluid analysis also reveals an increase in lymphocytes. There is extensive necrosis of deep articular cartilage zones, with relative sparing of the superficial surface cartilage. *Mycoplasma spuman* was isolated from one affected Greyhound, so it is important to rule out infectious causes of polyarthritis in affected dogs; trial therapy with antibiotics may be warranted. Therapy is as for refractory idiopathic immune-mediated nonerosive polyarthritis. Response to treatment is variable.

FELINE EROSIVE IMMUNE MEDIATED POLYARTHRITIS

Two uncommon immune mediated disorders cause joint damage and destruction in cats. One is a periosteal proliferative polyarthritis characterized by marked periosteal new bone formation and the second is a deforming arthritis resembling RA in humans and dogs. When first described, both of these disorders were thought to be variants of one disorder referred to as chronic progressive polyarthritis (CPP). All of the originally reported cases were male cats, all were positive for antibodies against feline syncytium-forming virus (FeSFV), and approximately 60% were infected with FeLV or FIV or both. There was speculation that CPP was caused by chronic immune stimulation secondary to FeSFV infection in immunosuppressed genetically predisposed cats. FeSFV is, however, a widespread retrovirus of cats, and experimental infection with FeSFV does not cause polyarthritis, so the association between this virus and the manifestations of CPP is uncertain.

FELINE PERIOSTEAL PROLIFERATIVE POLYARTHRITIS

Periosteal proliferative polyarthritis occurs most often in young adult male cats, but female cats can also be affected. Clinical signs include fever, stiff gait, joint pain, lymphadenopathy, and edema of the skin and soft tissues overlying the joints, particularly the carpus and hock. Synovial fluid analysis reveals a neutrophilic pleocytosis, and culture is negative. Initially, the radiographic changes are mild and include periarticular soft tissue swelling and mild periosteal proliferation. With time, the periosteal proliferation worsens and periarticular osteophytes, subchondral cysts, and collapse of the joint space may be noted. A treatment trial with doxycycline to rule out infectious polyarthritis should be considered prior to institution of immunosuppressive treatment. Treatment with glucocorticoids (prednisolone or prednisone) lessens the severity of signs and may slow progression of disease, but it is not curative. About half of treated cats have a reasonable quality of life when treated lifelong with glucocorticoids and analgesics. There may be further improvement when more potent immunosuppressive drugs are administered. (Table 69.3)

FELINE RHEUMATOID-LIKE ARTHRITIS

Feline rheumatoid-like arthritis has an insidious onset, with the slow development of lameness, stiffness, and joint deformity over weeks to months. Middle-aged and older cats are affected, and Siamese cats may be predisposed. Systemic illness and fever do not usually occur, so most affected cats are not examined until severe joint deformities are evident (Lemetayer et al., 2014). Synovial fluid analysis reveals mild to moderate mixed inflammation. Radiographically there are severe subchondral central and marginal erosions, and periarticular swelling that initially progresses to extensive bone destruction and gross joint deformities. Rheumatoid-like arthritis should be suspected in cats with erosive, deforming polyarthritis once infectious causes have been eliminated

TABLE 69.3

Drugs Used in the Treatment of Immune-Mediated Polyarthritis in Cats

Prednisolone	2 mg/kg q12h initially, then taper
Cyclosporine	2.5-5.0 mg/kg PO q12h
Leflunomide	10 mg/cat PO q24h
Chlorambucil	2 mg/cat PO q48h
Methotrexate	2.5 mg/m^2 PO q48h
Leflunomide/Methotrexate Protocol for Rheumatoid-Like Arthritis:	
Leflunomide	10 mg/cat PO q24h until improvement Then 10 mg/cat PO twice weekly
Methotrexate	2.5 mg/cat PO q12h for 3 doses once a week until improvement Then 2.5 mg/cat PO weekly

and a treatment trial with doxycycline has been ineffective. Serologic tests for circulating RF (using the canine Rose-Waaler or ELISA test) are positive in most literature reports of cats with rheumatoid-like arthritis, but a positive test is not essential for diagnosis (Hanna, 2005).

Rheumatoid-like arthritis is an aggressive, destructive, and irreversible disease. Most cats have only a minimal response to treatment with NSAIDs or glucocorticoids. There have, however, been reports of remarkable improvement in cats treated with methotrexate in combination with leflunomide (Hanna, 2005) (see Table 69.3). Treatment with other potent immunosuppressive agents should also be considered. Concurrent treatment with analgesics such as amantadine (3 mg/kg PO q24h), amitriptyline (0.5-2 mg/kg PO q24h), or gabapentin (2-10 mg/kg PO q24h) may make affected cats more comfortable.

PART ELEVEN ▪ Immune-Mediated Disorders

Andrew Woolcock and J. Catharine R. Scott-Moncrieff

CHAPTER 70

Pathogenesis of Immune-Mediated Disorders

GENERAL CONSIDERATIONS AND DEFINITION

Immune-mediated disorders occur when the protective immune response is activated inappropriately, resulting in organ or cellular injury. Pathologic immune reactions may occur in response to infectious pathogens and contribute to the clinical disease presentation for that pathogen (e.g., the hemolytic anemia associated with *Mycoplasma haemofelis* infection) or be stimulated by otherwise innocuous foreign substances (e.g., the allergic reactions that occur to house dust) or by self-antigens (primary autoimmunity). Autoimmunity is defined as a condition characterized by a specific humoral or cell-mediated immune response against constituents of the body's own tissues (self-antigens or autoantigens). The term *primary autoimmune disease* is reserved for disorders in which no underlying cause can be identified and the cause of the autoimmunity is believed to be an underlying immune system dysfunction or imbalance. The term *secondary autoimmunity* (also termed *secondary immune-mediated disease*) is used to describe immune-mediated disorders in which an underlying reason for the autoimmune response can be identified. Examples of secondary causes of autoimmunity include infection, exposure to certain drugs or toxins, neoplasia, and vaccine administration.

IMMUNOPATHOLOGIC MECHANISMS

Immunopathologic injury occurs as a result of a hypersensitivity reaction, for which there are four major mechanisms (Table 70.1). Each mechanism may be either part of an appropriate response to a foreign antigen or an inappropriate response that can lead to allergic or immune-mediated disease. The immune response can be rapid, representing the innate immune system, with an adaptive immune response that follows. This adaptive immune response is mediated primarily by T-lymphocytes. Depending on the most appropriate immune response, inflammatory cytokines mediate a Th1 (cell-mediated) or Th2 (humoral) lymphocytic response which, in turn, activates the appropriate immune cells for the antigen encountered. More than one mechanism may be involved in some immune-mediated disorders.

Type I hypersensitivity involves the humoral immune system, immunoglobulin E (IgE), and mast cells. Exposure of the immune system to antigens by way of the skin, respiratory tract, or gastrointestinal tract leads to activation of antigen-specific subsets of T-helper lymphocytes and initiation of B-cell differentiation to plasma cells. Plasma cells secrete IgE, which attaches to receptors on mast cells. On future exposure to the same antigen, cross-linking of the IgE molecules on the mast cells occurs, which leads to mast cell degranulation. The potent inflammatory mediators that are released lead to vasodilation, edema, eosinophil chemotaxis, pruritus, and bronchoconstriction. Some drugs (e.g., doxorubicin) can induce mast cell degranulation independent of IgE (i.e., anaphylactoid reaction). Examples of diseases mediated primarily by a type I response include allergic bronchitis (feline asthma) and acute anaphylactic reactions.

Type II (cytotoxic) hypersensitivity involves the binding of antibody (IgG or IgM) and/or complement to specific molecules on the surface of a cell. This binding typically results in destruction of the cell or receptors on the cell. Less commonly, antibodies may induce a biologic effect such as stimulation of the thyroid-stimulating hormone receptor and induction of hyperthyroidism in humans with Graves disease. The target of antibody binding may be normal self-antigens, infectious agents bound to the cell surface, or nonbiologic antigens such as drugs bound to the cell surface (hapten mediated). Antibodies to self-antigens may be formed due to cell damage, resulting in exposure of previously hidden antigens, similarity between self-antigens and foreign antigens such as infectious agents and drugs, and primary immune system dysfunction or imbalance. Classic

TABLE 70.1

Mechanisms of Immunopathologic Injury

TYPE OF MECHANISM	IMMUNE SYSTEM EFFECTORS	ORGAN SYSTEMS COMMONLY AFFECTED	EXAMPLES
Type I (immediate)	Humoral immune system (T-helper cells and B cells), IgE, mast cells, inflammatory mediators	Skin, respiratory tract, gastrointestinal tract	Acute anaphylactic reactions, atopy, allergic bronchitis (feline asthma)
Type II (cytotoxic)	Humoral immune system, IgG and IgM	Hematologic, neuromuscular junction, skin	Immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, myasthenia gravis, pemphigus foliaceous
Type III (immune complex)	Soluble immune complexes	Kidney, joints, skin	Glomerulonephritis, systemic lupus erythematosus, rheumatoid arthritis
Type IV (delayed type)	Sensitized T lymphocytes, cytokines, neutrophils, and macrophages	Endocrine glands, muscle, skin	Lymphocytic thyroiditis, myositis

examples of diseases mediated by type II mechanisms include immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, pemphigus foliaceous, and myasthenia gravis. Antibodies involved in type II responses are usually tissue specific, and the consequences of antibody binding vary from tissue to tissue. For example, in immune-mediated hemolytic anemia, antibody binding results in either intravascular or extravascular red blood cell hemolysis, whereas in pemphigus foliaceous, antibody binding results in disruption of keratinocyte adhesion and vesicle formation. In myasthenia gravis, antibodies directed against acetylcholine receptors cross-link and internalize the receptors, which results in failure of neuromuscular transmission.

Type III (immune complex) hypersensitivity involves the formation and deposition of soluble immune complexes (predominantly IgG) within tissues. Deposition of immune complexes in tissues results in complement fixation and a localized inflammatory response characterized by mast cell degranulation, platelet activation, and neutrophil chemotaxis. Phagocytosis of immune complexes by macrophages causes release of more inflammatory cytokines. In the presence of antibody excess, the inflammatory reaction typically remains localized at the site of the initiating antibody; in the presence of antigen excess, however, soluble immune complexes enter the circulation and become deposited in vascular beds in the kidney, joints, eye, and skin. The location and extent of antibody deposition depend on a number of variables, including complex size, charge, degree of glycosylation, and Ig subclass. Classic examples of diseases mediated by type III mechanisms include infections (e.g., feline infectious peritonitis), glomerulonephritis, systemic lupus erythematosus (SLE), and rheumatoid arthritis.

Type IV (delayed-type) hypersensitivity involves the cell-mediated immune system. Exposure to either soluble or cell-associated antigen results in sensitization of specific subsets of T cells. Reexposure to the same antigen results in activation of sensitized lymphocytes, subsequent release of cytokines, and recruitment of neutrophils and macrophages. Cytotoxic destruction of target cells may also occur by this mechanism. Activation of sensitized lymphocytes requires 24 to 72 hours to occur, which is why this type of response is termed "delayed." Persistence of the antigen can result in formation of multinucleate giant cells and tissue granulomas. Examples of diseases mediated by type IV immune responses include the protective immune response to intracellular microbes (e.g., leishmaniasis), contact hypersensitivity, polymyositis, and immune-mediated thyroiditis.

PATHOGENESIS OF IMMUNE-MEDIATED DISORDERS

In normal animals the adaptive immune system should be tolerant of self. A number of mechanisms prevent B and T lymphocytes from becoming self-reactive. Most autoreactive B and T cells are deleted during maturation in the thymus, and those that escape to the periphery are either directed against cryptic epitopes, undergo peripheral deletion by apoptosis, are rendered anergic in the peripheral circulation, or are actively suppressed by regulatory T cells. When autoimmunity occurs, these mechanisms responsible for tolerance break down. Factors that may play a role in loss of tolerance include genetics, environmental factors, age, hormonal influences, and other diseases that lead to perturbations of the immune system.

Genetics clearly play an important role in the development of autoimmune disease. In some autoimmune diseases, certain breeds of dog are at increased risk

TABLE 70.2

Suspected Autoimmune Disorders of Various Organ Systems in Dogs and Cats

ORGAN SYSTEM	DISEASE	POSTULATED IMMUNOPATHOLOGIC MECHANISM	BREED PREDISPOSITION
Hematologic	Immune-mediated hemolytic anemia	Type II	American Cocker Spaniel, Bichon Frise, Miniature Pinscher, Miniature Schnauzer, Rough-Coated Collie, English Springer Spaniel, Finnish Spitz
	Pure red cell aplasia	Type II	
	Immune-mediated thrombocytopenia	Type II	Cocker Spaniel, Poodle (all varieties), German Shepherd Dog, and Old English Sheepdog
	Idiopathic neutropenia	Type II	
Joints	See Table 73.7	Type III	
Skin	Various	Types II, III, and IV	
Eye	Uveitis, retinitis	Type III	
	Uveodermatologic syndrome	Type IV (suspected)	Akita, Samoyed, Siberian Husky, Shetland Sheepdog
Kidney	Glomerulonephritis	Type III	Bernese Mountain dog, Bull Terrier, Cocker Spaniel, Dalmatian, Doberman, Shar-Pei, Soft-coated Wheaten Terrier
Respiratory tract	Allergic rhinitis	Type I	
	Allergic bronchitis (asthma)	Type I	
	Pulmonary infiltrates with eosinophils	Type I	Husky, Malamute
Gastrointestinal tract	Feline stomatitis/gingivitis, lymphocytic plasmacytic enteritis, anal furunculosis (perineal fistula)	Type IV	German Shepherd dog
Neurologic system	Myasthenia gravis	Type II	Abyssinian, Somali
	Myositis	Type IV	Boxer, Newfoundland
	Polyradiculoneuritis	Unknown	
	Granulomatous meningoencephalomyelitis	Unknown	
	Polyarteritis	Unknown	Beagle
Endocrine glands	Thyroiditis (hypothyroidism)	Type IV	Beagle, Golden Retriever
	Adrenalitis (hypoadrenocorticism)		Standard Poodle, Leonberger, Duck Tolling Retriever
	Insulitis (diabetes mellitus)		Keeshond
Multisystemic immune disease	Systemic lupus erythematosus	Type III	German Shepherd dog

(Table 70.2). Autoimmunity is also reported more commonly in some families than others. Examples of immune-mediated diseases in dogs in which genetics clearly predispose to the disease include SLE, immune-mediated hemolytic anemia, and thyroiditis. The inbreeding that occurs in many dog breeds exacerbates the effects of such familial traits. Purebred dogs represent up to 90% of the cases of primary immune-mediated hemolytic anemia, further supporting a familial component to the immunopathologic disease. Familial autoimmunity is not as well documented in the cat, although the Abyssinian and Somali breeds are at increased risk of myasthenia gravis. The underlying genetic changes that result in such predispositions are not yet well characterized in the dog and cat.

Environmental factors are believed to be important in the development of autoimmunity; exposure to infectious agents either during natural infection or as a result of vaccination is the most common factor identified. Other

possible environmental factors include environmental toxins and drug exposure. Some drugs have been clearly linked to induction of autoimmunity, and many other drugs can likely cause idiosyncratic autoimmune reactions. Examples include the risk of systemic immune disease (polyarthritis, glomerulonephritis, cutaneous lesions, retinitis, polymyositis, anemia, and thrombocytopenia) in Doberman Pinschers treated with trimethoprim-sulfadiazine and development of immune-mediated hemolytic anemia in some cats treated with thioureylene drugs such as propylthiouracil and methimazole. Myasthenia gravis has also been reported in cats treated with methimazole.

Mechanisms by which infectious agents may induce autoimmunity include molecular mimicry, exposure of cryptic antigens after cellular damage, nonspecific polyclonal activation by superantigens, production of interferon-γ that induces major histocompatibility complex class II expression on cells that do not usually express them (e.g., thyroid follicular cells), and the innocent bystander effect in which the immune response is directed against a microbial antigen or other antigen on the surface of the cell. A complicating factor is that some infections (e.g., ehrlichiosis, borreliosis, and many other vector-borne diseases) may either mimic an autoimmune disease or cause true autoimmunity, and clinically differentiating the two can be difficult. This is clinically relevant because the clinician is faced with a decision whether to include immunosuppressive drugs in the treatment protocol.

The role of vaccination in the precipitation of autoimmunity is unclear. Currently the evidence is weak and based on anecdotal observation of a temporal association of immune-mediated disease with vaccination in some studies but not others. A cause-and-effect relationship has been difficult to establish definitively because of the high frequency of vaccination and the low prevalence of reported adverse effects. Specific evidence for association of individual disease syndromes with vaccination is discussed in the sections on individual diseases. Altered immunoregulation and evidence of immune-mediated disease may also occur in other underlying diseases such as lymphoid neoplasia or IgA deficiency, and after chemotherapy administration.

ORGAN SYSTEMS INVOLVED IN AUTOIMMUNE DISORDERS

Any organ system in the body may be targeted by immune-mediated disease processes (see Table 70.2). The most common systems involved in the dog and cat are the joints, skin, kidney, and hematologic system, although, in general, immune-mediated diseases are less common in the cat than the dog. Other organs commonly involved in immune-mediated diseases are the eye, neurologic system, gastrointestinal tract, respiratory tract, and endocrine glands (see Table 70.2). Some immune-mediated diseases such as SLE involve multiple organ systems, although not all organ systems may be involved in every animal. Dogs with systemic immune-mediated disorders frequently present with one manifestation of the disorder (e.g., immune-mediated hemolytic anemia) and later relapse with another (e.g., immune-mediated thrombocytopenia, polyarthritis). In some of these cases, the underlying disorder may be SLE, but this is not always the case.

Many canine and feline diseases involve immune-mediated mechanisms. The autoimmune disorders discussed in detail in the following chapters focus on the more common autoimmune diseases, especially those in which the treatment of choice is immunosuppression. Other disorders in which the pathogenesis is immune mediated, but in which immunosuppression is not part of the treatment (e.g., hypothyroidism from thyroiditis), are discussed in the parts on diseases of the appropriate organ system.

CHAPTER 71

Diagnostic Testing for Immune-Mediated Disease

CLINICAL DIAGNOSTIC APPROACH

The diagnostic approach to a dog or cat with suspected immune-mediated disease depends on the clinical presentation and organ(s) involved. A complete history, including questions regarding environmental or drug exposures, previous medical history, exposure to infectious agents, and vaccination history, should be obtained. A thorough physical examination should also be performed. The next step is to define the extent of the problem and rule out other more common and/or secondary causes of the clinical signs. A typical minimal database includes a complete blood count (CBC), serum biochemical profile, and urinalysis. Because many immune-mediated diseases are characterized by fever and leukocytosis, ruling out infectious agents as the primary cause of the clinical signs is important before pursuing other less common causes. The diagnostic evaluation for immune-mediated disease is similar to that for fever of unknown origin (see Chapter 90). Bacterial culture of the urine, blood, or both—testing for common viral pathogens such as feline leukemia virus, feline immunodeficiency virus, and feline infectious peritonitis—and diagnostic imaging (thoracic and abdominal radiographs, abdominal ultrasonography) are important. Investigation for vector-borne diseases such as ehrlichiosis, anaplasmosis, bartonellosis, borreliosis, and leishmaniasis, as well as more fastidious organisms such as mycoplasma and L-forms, is usually only considered once more common bacterial and viral infections have been excluded because these tests are more expensive and the results are often not immediately available. The specific infectious agents tested for depend on whether the patient is a dog or cat, as well as the disease presentation and geographic location, because many infectious diseases have regional distributions.

If infection is ruled out or considered unlikely, further diagnostic evaluation should focus on organs identified as potentially involved according to the physical examination and results of the minimal database and diagnostic imaging. Chronic inflammatory and neoplastic causes should be investigated as part of this organ-specific evaluation. Organ-specific diagnostic tests may include evaluation of joint or cerebrospinal fluid (CSF), quantification of urine protein excretion, and biopsy of affected organs. (These tests are discussed in more detail in the sections on specific diseases.)

Specific tests of immune dysfunction are indicated once infectious and neoplastic diseases have been excluded and when the organ system(s) of interest has been identified. For example, in a dog with regenerative anemia the clinician should consider doing a direct antiglobulin (Coombs) test, whereas in a dog with erosive polyarthritis a test for rheumatoid factor (RF) would be indicated. Immune panels that include a selection of tests with different indications are rarely necessary and may result in excessive testing and results that are difficult to interpret; in addition, the tests are often positive in dogs with infectious diseases. For example, a positive Coombs test has little relevance in a dog that is not anemic.

SPECIFIC DIAGNOSTIC TESTS

SLIDE AGGLUTINATION TEST

The slide agglutination test is used to detect the presence of spontaneous agglutination of red blood cells (RBCs). Spontaneous agglutination (autoagglutination) is a three-dimensional clustering of RBCs that occurs from cross-linking of RBC surface-associated antibodies. Autoagglutination occurs as a result of the presence of either high-titer immunoglobulin (Ig) G or IgM on the RBC membrane. Agglutination must be distinguished from rouleaux formation (stacking of RBCs that occurs most often in the presence of high globulin concentrations). To evaluate for the presence of agglutination, 1 drop of saline should be added to 5 to 10 drops of blood and mixed. The RBC suspension is then evaluated both by macroscopic and microscopic examination at a temperature as close to 37° C as possible. The temperature is important because clinically insignificant cold-acting agglutinins are common in normal dogs. A positive slide agglutination test does indicate the presence

of surface-associated antibodies, but it does not distinguish primary from secondary immune-mediated hemolytic anemia (IMHA) (see Chapter 73).

COOMBS TEST (DIRECT ANTIGLOBULIN TEST)

The direct Coombs test, or direct antiglobulin test (DAT), detects the presence of antibody and/or complement bound to patient RBC membranes. The test is used for diagnosis of IMHA. The DAT uses anti–dog antiglobulin antibody or anti–cat antiglobulin antibody produced in a different species (usually goats or rabbits); the reagents are species specific. The DAT is usually performed on ethylenediamine tetraacetic acid (EDTA) anticoagulated blood at body temperature (37° C). Most frequently a combined Coombs reagent containing goat anti–canine IgG, IgM, and complement component C3 is used. Addition of the Coombs reagent to washed patient RBCs results in agglutination if more than approximately 100 IgG antibody or C3 molecules are bound to the RBCs. Because the end point of the test is agglutination, the test cannot be interpreted if spontaneous agglutination persists after washing the RBCs. Results of the DAT may be reported in various forms depending on the laboratory: positive or negative, 1+ to 4+ agglutination, or as the lowest dilution of the reagent that results in agglutination. Modifications of the DAT that may improve diagnostic performance include use of monospecific antisera (usually IgG, IgM, and C3); using more dilutions of the reagents than typically performed to avoid a prozone effect; and testing at 4° C, as well as 37° C. Use of monospecific antisera has been shown to improve sensitivity of the DAT for diagnosis of IMHA in dogs, but the reported patterns vary between investigators and this technique is not available in commercial laboratories. Using more dilutions of reagent can potentially improve the sensitivity of the DAT because it allows detection of the prozone effect in which a lack of reactivity is observed with high concentrations of antibody. Another modification of the DAT involves performing the test at 4° C to identify cold-acting agglutinins. This test is best used in animals with clinical signs of cold agglutinin disease (e.g., ear or tail tip necrosis) because nonspecific RBC agglutination occurs at 4° C in some healthy dogs; however, this technique can be useful to increase the sensitivity of the Coombs test in cats. Although these modifications of the Coombs test have been shown to increase sensitivity of the DAT for diagnosis of IMHA by some investigators, it is important to remember that test results should always be interpreted in the context of the clinical and hematologic data. A diagnosis of IMHA should not be based on the Coombs test alone. Both false-positive and false-negative results may occur with the DAT (Box 71.1).

In some dogs with IMHA that have spontaneous agglutination, agglutination will resolve after washing of the RBCs. In this scenario a DAT may still be indicated because resolution of a previously positive DAT may be useful for disease monitoring. Recognizing that a positive Coombs test does not distinguish primary from secondary IMHA is also important (see Chapter 73). Other more sensitive techniques such as enzyme-linked antiglobulin tests, flow cytometric techniques, and antiglobulin gel tests have also been used to detect the presence of antibody on RBCs; however, these tests are not yet widely available in commercial laboratories.

ANTIPLATELET ANTIBODIES

Detection of platelet surface–associated antibody (direct antibody) or serum platelet bindable antibody (indirect antibody) may be useful in evaluation of dogs and cats with suspected immune-mediated thrombocytopenia. Tests for antiplatelet antibody are most commonly performed by using flow cytometric techniques. Detection of platelet surface–associated IgG (direct) is more sensitive than detection of serum platelet–bindable antibodies (indirect), presumably because the majority of antiplatelet antibody is bound to platelets rather than free in the circulation. The direct assay has a sensitivity of greater than 90% in dogs with confirmed idiopathic thrombocytopenic purpura (ITP). Because of the high sensitivity of the direct assay, a negative result for platelet surface–associated antibody makes a diagnosis of ITP unlikely. Detection of antiplatelet antibodies by either the direct or indirect technique implies an immune-mediated pathogenesis for thrombocytopenia but is not specific for primary immune-mediated thrombocytopenia. Many infectious and neoplastic diseases, as well as drug exposure, may

BOX 71.1

Causes of False-Positive and False-Negative Results for the Direct Antiglobulin (Coombs Test)

False-Positive Result	False-Negative Result
Chronic inflammatory disease	Technical problems (washing, dilution, centrifugation errors)
Technical problems (contamination, overcentrifugation)	Delay in running test (e.g., mail-in samples)
Poor sample quality (clotted samples, use of serum separator tubes, collection from dextrose-containing infusion lines)	Contamination or repeated freezing of reagents
	Low quantities of antibody present on cell
Septic patient	
Clinically insignificant, naturally occurring cold autoantibody	
Hypergammaglobulinemia	
Interference by drugs (e.g., amiodarone in dogs)	

cause thrombocytopenia by immune-mediated mechanisms; therefore blood samples from such patients may be positive for platelet-associated antibody. A flow cytometric assay for platelet surface–associated IgG for both dogs and cats is currently available at Kansas State University. The test requires 2 mL of EDTA blood and currently costs $71.50 plus shipping. Blood samples should be shipped overnight on ice.

ANTINUCLEAR ANTIBODY TEST

Measurement of antinuclear antibody (ANA) is useful in the evaluation of dogs and cats with suspected systemic lupus erythematosus (SLE). SLE should be suspected in patients with evidence of an immune-mediated process affecting a minimum of two organ systems (see Chapter 73). Antinuclear antibodies are heterogenous antibodies directed against nuclear antigens. They are typically detected by immunofluorescent staining of frozen sections of rat liver or tissue culture monolayers of human epithelial cell lines. Results are reported as a titer that is the highest dilution of patient serum that causes definitive immunofluorescent nuclear staining. Various patterns of nuclear staining (diffuse, speckled, peripheral, and nucleolar) can be identified, but the clinical significance of the various staining patterns is still under investigation in dogs and cats. Measurement of ANA antibodies is sensitive for diagnosis of SLE in dogs and cats, although ANA-negative cases of SLE do occur. In one study of 75 dogs with SLE, 100% had a positive ANA titer. In most cases the ANA titer was greater than 1:256, and the magnitude of the titer correlated with disease severity. Other studies have demonstrated lower sensitivity of the ANA for diagnosing SLE. The variability in diagnostic sensitivity probably arises from differences in stringency in the diagnostic criteria for confirming a diagnosis of SLE and variability among laboratories in assay sensitivity and specificity. Many normal animals have low positive titers for ANA, so a cutoff for a significant positive titer should be established for each individual laboratory. The cutoff titer varies depending on the substrate and techniques used by the laboratory. Low positive ANA titers may also occur after exposure to certain drugs and in animals with chronic inflammatory or neoplastic diseases. ANAs are detected in 10% to 20% of dogs with seroreactivity to *Bartonella vinsonii, Ehrlichia canis,* and *Leishmaniasis infantum*. Dogs with seroreactivity to multiple pathogens are more likely to be ANA positive. Chronic or high-dose corticosteroid treatment may decrease the ANA titer.

LUPUS ERYTHEMATOSUS TEST

The lupus erythematosus (LE) test is a highly specific test for SLE but is rarely used clinically because it lacks sensitivity, and the ANA test is more sensitive and less time consuming. LE cells are neutrophils that contain phagocytosed nuclear material. The test is performed in vitro. Blood collected from the patient is allowed to clot and is damaged in order to release free nuclei. If ANA is present it binds to nuclear material. The resulting complex is phagocytosed by neutrophils and can be identified as an LE cell by visual inspection. LE cells may also rarely be identified in vivo in blood, bone marrow, or joint fluid and, when present, are highly suggestive of SLE. The LE cell test is more sensitive to the effects of steroids than is the ANA titer. The test has been reported to be positive in the blood of 30% to 90% of dogs with SLE but may also be positive in other immune or neoplastic disorders. This test is not used frequently in practice.

RHEUMATOID FACTOR

RF is antibody directed against an individual's own IgG. The antibody is directed against sites on the Fc portion of immunoglobulin molecules that become exposed only after antibody binds to antigen. The test is used as one of the diagnostic criteria for rheumatoid arthritis; however, the utility of the test is limited by a lack of sensitivity and specificity. The most common technique for detection of RF is the Rose-Waaler test, which uses sheep RBCs sensitized to rabbit IgG. If RF is present in patient serum, agglutination occurs. The test is performed on refrigerated serum. Samples should not be frozen because RF activity may be destroyed. Only 40% to 75% of dogs with rheumatoid arthritis are positive for RF, so a negative titer does not rule out the disease. In addition, any disease with longstanding immune complex formation may eventually cause RF, so a positive titer should not be the sole criterion for a diagnosis of rheumatoid arthritis.

C-REACTIVE PROTEIN

C-reactive protein (CRP) is a molecule that is rapidly produced as part of the nonspecific acute-phase response to most forms of inflammation. This production, principally by hepatocytes, is stimulated by cytokines originating from the site of inflammation. CRP is a very sensitive biomarker of inflammation. It increases rapidly in response to inflammatory cytokines, and does not demonstrate diurnal or post-prandial variation. Biologically, CRP binds to a variety of ligands, can bind complement proteins, and can activate the classical complement pathway similar to antibody binding.

The CRP concentration is a useful but nonspecific biochemical marker of inflammation. CRP concentrations have been shown to be increased in many inflammatory diseases of the dog and cat including sepsis, pancreatitis, IMHA, inflammatory bowel disease, rickettsial diseases, chronic valvular disease, and certain neoplasia. Thus CRP values are not specific for diagnosis of immune-mediated diseases but are a sensitive marker of inflammation that can be useful for monitoring treatment response.

CRP is consistently increased in dogs with primary IMHA, and CRP concentrations decrease in response to immune-suppressive treatment. Measurement of CRP is not useful for predicting outcome or survival in primary IMHA, and therefore it may not be any more useful than standard hematologic monitoring in this disease. CRP concentration is used to monitor therapy in people with rheumatoid arthritis, and so it has been investigated in dogs with immune-mediated polyarthritis (IMPA). As would be expected, all

dogs with IMPA had increased CRP concentrations at the time of diagnosis; 82% of dogs demonstrated a significant decrease in CRP concentrations within 5 days of corticosteroid therapy. CRP concentrations measured at 1 to 2 weeks following initiation of treatment were predictive that continued treatment with immune-suppressive medications would still be required to manage IMPA at the 6-month follow up. CRP concentrations also correlated with resolution of clinical signs by 1 to 2 weeks following initiation of corticosteroid therapy. Therefore, although measurement of CRP is not useful for diagnosis of IMPA, it should be considered as a monitoring tool in lieu of repeated arthrocentesis in dogs that are clinically responding well to treatment.

IMMUNOFLUORESCENCE AND IMMUNOHISTOCHEMISTRY

In many type II and type III immune-mediated diseases, the presence of antibody in fixed tissues (e.g., kidney, skin) can be detected by immunofluorescence or immunoperoxidase techniques. Numerous variations on these methods exist, but, in general, sections of tissue are labeled with a primary antibody (e.g., rabbit anti–dog IgG) and then a secondary antibody is added (e.g., anti–rabbit IgG), which has been conjugated to either fluorescein or the enzyme peroxidase. If antibodies are present in the tissue sample, apple green fluorescence is seen under ultraviolet light with immunofluorescent staining. In the case of immunoperoxidase peroxide, when a substrate is added in the presence of hydrogen peroxide, deposition of a brown color can be visualized with the light microscope. Tissue samples for immunofluorescence testing should be collected in Michel's medium. Routinely fixed tissue can be used for immunohistochemistry. Common uses for immunofluorescence staining include evaluation of renal biopsies in dogs with suspected glomerulonephritis, detection of antibodies directed against megakaryocytic cells in the bone marrow, and evaluation of skin biopsies from patients with suspected immune-mediated skin disease.

AUTOIMMUNE PANELS

Many laboratories offer an immune panel that typically includes a CBC and platelet count, Coombs test, ANA, and RF. It would be unusual for all these tests to be appropriate in an individual patient (Table 71.1). In addition to the cost of running such a panel, the significance of a positive test may be difficult to determine in patients in which the test was initially not indicated, and some of these tests can be positive in dogs and cats with infectious diseases. For these reasons the clinician is encouraged to pick individual tests rather than automatically choosing an autoimmune panel in a dog or cat with suspected autoimmune or immune-mediated disease.

TABLE 71.1

Clinical Indications for Use of Diagnostic Tests in Suspected Immune-Mediated Disease

CLINICAL SYNDROME	POTENTIAL IMMUNE-MEDIATED CONDITIONS TO CONSIDER	TESTS INDICATED TO CONFIRM	LIMITATIONS
Anemia (regenerative or nonregenerative)	Immune-mediated hemolytic anemia, pure red cell aplasia	Coombs test, slide agglutination test, review of CBC smear for spherocytes or ghost cells Bone marrow aspirate and core (if anemia is nonregenerative)	A negative Coombs test result does not rule out immune-mediated hemolytic anemia; false-positive Coombs test results may also occur
Thrombocytopenia	Immune-mediated thrombocytopenia, infectious causes of thrombocytopenia, megakaryocytic aplasia	Platelet-associated antibody, platelet-bindable antibody, bone marrow aspirate and core	Positive platelet-associated antibody test does not distinguish primary from secondary immune-mediated thrombocytopenia
Anemia and thrombocytopenia	IMHA, Evans syndrome	Coombs test Slide agglutination test Review of slide for spherocytes or ghost cells Platelet-associated antibody, platelet-bindable antibody, bone marrow aspirate and core	May be hard to distinguish blood loss anemia from hemolytic anemia in dogs with severe thrombocytopenia; Coombs test may be positive after transfusion
Shifting leg lameness, joint pain, or effusion	Polyarthritis SLE, immune-mediated polyarthritis, rheumatoid arthritis	Synovial fluid collection, radiographs of joints, RF, ANA (if other organ systems involved)	Negative RF does not rule out rheumatoid arthritis; in early rheumatoid arthritis erosive changes may not be present

TABLE 71.1

Clinical Indications for Use of Diagnostic Tests in Suspected Immune-Mediated Disease—cont'd

CLINICAL SYNDROME	POTENTIAL IMMUNE-MEDIATED CONDITIONS TO CONSIDER	TESTS INDICATED TO CONFIRM	LIMITATIONS
Proteinuria	Glomerulonephritis	Urinalysis; protein/creatinine ratio; renal biopsy for histopathology, immunofluorescence, electron microscopy	Need to rule out inflammation arising from the lower urinary tract before interpreting protein/creatinine ratio
Two of the previous clinical syndromes together or in combination with dysfunction of other organ system	SLE	ANA, LE preparation	LE has very low sensitivity for diagnosis of SLE; ANA titer is more sensitive, but some dogs with SLE may have a negative ANA

ANA, Antinuclear antibody; *CBC,* complete blood count; *IMHA,* immune-mediated hemolytic anemia; *LE,* lupus erythematosus; *SLE,* systemic lupus erythematosus.

CHAPTER 72

Treatment of Primary Immune-Mediated Diseases

PRINCIPLES OF TREATMENT OF IMMUNE-MEDIATED DISEASES

Immunosuppressive drugs are the mainstay of treatment for patients with immune-mediated disease; however, it is critical that any underlying disease is also identified and treated to achieve a good response. In patients with secondary immune-mediated disease, effective treatment of underlying disease may minimize the duration of required immunosuppressive therapy. The aim of treatment of immune-mediated diseases is to control the immune-mediated process while minimizing the adverse effects of the drugs used. In many situations short-term adverse effects must be tolerated initially to achieve disease remission. For long-term management, it is critical that medications are tapered to the lowest possible dose to minimize adverse effects. If this is not possible or if the initial drug chosen is not effective for disease management, alternate or additional therapy should be considered. Monitoring the patient carefully to assess response to treatment before each dose reduction is critical, and drug tapering should be individualized depending on the underlying disease process, other concurrent illness, and the sensitivity of the patient to the drugs chosen. For example, in immune-mediated hemolytic anemia (IMHA), monitoring the complete blood count (CBC), reticulocyte count, and the Coombs test is adequate, whereas in dogs with immune-mediated polyarthritis, repeated joint taps for synovial fluid analysis before dose reduction may be necessary. There is wide interpatient variability in sensitivity to immunosuppressive drugs, particularly glucocorticoids, and these individual variations need to be taken into account during treatment.

Supportive care and aggressive monitoring for potential complications of immunosuppressive drug therapy are also critical. Detection and treatment of complications of therapy can improve long-term outcome and minimize adverse sequelae. For example, patients receiving glucocorticoids should be carefully monitored for evidence of gastrointestinal hemorrhage, and animals receiving azathioprine should be monitored for hepatotoxicity and bone marrow suppression. Supportive care is necessary while waiting for the effects of immunosuppressive therapy to manifest. For example, dogs with IMHA, immune-mediated thrombocytopenia (ITP), and Evans syndrome may require several transfusions before immunosuppressive treatment adequately controls the immune-mediated destruction of red blood cells (RBCs) or platelets. Other forms of supportive care that may be necessary include care of the skin in animals that are recumbent, nutritional support, monitoring for and treatment of infection, ventilatory support, and prevention of gastrointestinal ulceration.

OVERVIEW OF IMMUNOSUPPRESSIVE THERAPY

The initial treatment for the majority of immune-mediated diseases is treatment with glucocorticoids. The reasons for using glucocorticoids as the first line of therapy include rapid onset of action, broad immune-suppressive effects, low risk of immediate toxicity, and low cost. Even in patients with concurrent conditions such as diabetes mellitus, in which long-term glucocorticoid treatment is relatively contraindicated, in most cases glucocorticoids should be used initially until alternative drugs that are less likely to complicate management of the concurrent disease have time to become effective. Exceptions to this include diseases such as myasthenia gravis and immune-mediated polyarthritis (see Chapter 73). Although glucocorticoids are used in the initial management of the majority of immune-mediated diseases, there are some immune-mediated diseases such as myasthenia gravis for which glucocorticoid treatment is avoided (see Chapter 73). In some immune-mediated diseases additional immunosuppressive drugs should be added at the start of treatment. These are diseases in which a positive response to glucocorticoids alone is unlikely. Examples include canine Evans syndrome; canine IMHA with multiple poor prognostic indicators (intravascular hemolysis, agglutination that persists after washing of RBCs, high bilirubin concentration); systemic lupus erythematosus (SLE); rheumatoid

arthritis (RA); and the polyarthritis syndrome of Akitas. In most other immune-mediated diseases, the response to glucocorticoids should be assessed before adding other immunosuppressive drugs. If immune-mediated disease has an underlying infectious cause, more caution should be used before adding another immunosuppressive drug. If response to glucocorticoids is inadequate or the adverse effects of glucocorticoids are unacceptable, adjunctive immunosuppressive medications should be considered. Adjunctive immunosuppressive medications should not be assumed to provide immediate additional suppression to the immune response. Some confusion exists in the veterinary literature about the length of time required for the adjunctive immunosuppressive medications to have a clinical effect. For example, in one study azathioprine inhibited blastogenic response of canine lymphocytes to mitogens after 7 days of treatment, although serum immunoglobulin concentrations were unchanged. The authors recommend that at least 7 days of therapy are necessary to gain clinical effect. If there is any concern for lack of clinical effect, several of the adjunctive immunosuppressive medications have pharmacokinetic or pharmacodynamic monitoring tests available to aid in guiding therapy.

Common adjunctive immunosuppressive medications include those that interfere with nucleotide synthesis such as azathioprine, mycophenolate, and leflunomide, as well as cytotoxic drugs like cyclosporine and chlorambucil. Historically, azathioprine has been the most common second-line immunosuppressive medication used in dogs; the authors consider azathioprine, cyclosporine, and mycophenolate to all be acceptable second-line immunosuppressive medications in dogs, although there is a larger body of literature in support of azathioprine. The risks and benefits of each should be considered when selecting an adjunctive immunosuppressive medication. Chlorambucil or cyclosporine would be the most appropriate second-line immunosuppressive medications to consider in cats. Drugs such as cyclophosphamide and leflunomide are typically considered third-line drugs. When adding a third-line drug, in most circumstances it should replace the second-line drug. Treatment with two or more adjunctive immunosuppressive drugs at the same time (e.g., azathioprine and cyclosporine together) is likely to cause much more severe immunosuppression and a high risk of secondary infection and should be avoided. Bacterial infections that may develop in dogs and cats on long-term immunosuppressive drugs include lower urinary tract infections, pyelonephritis, cholangiohepatitis, hepatic abscesses, and pyoderma; however, the overall prevalence of secondary infections in patients properly dosed with immunosuppressive drugs is low. Fungal infections such as candidiasis may also occur. These serious infections can be extremely difficult to manage once established and should therefore be prevented, if at all possible, by judicious use of immunosuppression and careful patient monitoring.

Some exceptions exist in which a typically adjunctive immunosuppressive is more appropriate as first-line or primary therapy. For example, cyclosporine is used as a first-line drug in treatment of perianal fistulas in dogs. These exceptions are discussed in the sections on the individual immune-mediated diseases (see Chapter 73).

GLUCOCORTICOIDS

Glucocorticoids (corticosteroids with primarily glucocorticoid activity) are the mainstay of treatment of most immune-mediated diseases because they are effective, rapid acting, and inexpensive. Several different glucocorticoid drugs are used in veterinary medicine, and they vary according to duration, potency, and route of administration. Glucocorticoids are characterized by their biologic half-life as measured by duration of suppression of the hypothalamic pituitary adrenocortical axis (Table 72.1). Short-acting glucocorticoids such as hydrocortisone and cortisone have a biologic half-life of less than 12 hours. Intermediate-acting steroids such as prednisone, prednisolone, methylprednisolone, and triamcinolone have a biologic half-life of 12 to 36 hours; and betamethasone, dexamethasone, and flumethasone have a biologic half-life of 48 hours or longer. The duration of effect of a glucocorticoid preparation is also influenced by the chemical form of the steroid. Parenteral glucocorticoid preparations are either esters or free steroid alcohols. Highly soluble esters (e.g., dexamethasone sodium phosphate, prednisolone sodium succinate) and solutions of free steroid alcohols in polyethylene glycol (dexamethasone, flumethasone) have a duration of action similar to the biologic half-life, but long-acting suspensions of insoluble steroid esters (e.g., methylprednisolone acetate suspension, triamcinolone acetonide suspension) are absorbed slowly from the injection site, which markedly prolongs the duration of effect. Long-acting suspensions of glucocorticoids do not achieve high plasma concentrations and are therefore not ideal for use in management of immune-mediated diseases. Oral preparations are usually composed of the free steroid alcohol; because absorption from the gastrointestinal tract is quite rapid, the duration of effect is similar to the biologic half-life. The antiinflammatory effects of corticosteroids correlate with their glucocorticoid activity, whereas undesirable adverse effects such as sodium retention and edema formation are due to their mineralocorticoid activity. Most synthetic steroids such as prednisone and dexamethasone have higher glucocorticoid and lower mineralocorticoid activity than hydrocortisone. Prednisone has four times the potency of hydrocortisone but 0.3 times the mineralocorticoid activity; dexamethasone has 30 times the potency of hydrocortisone (≈8 times the potency of prednisone) with no mineralocorticoid activity.

In most patients with immune-mediated disease, the ideal route of glucocorticoid administration is oral; however, in animals that are vomiting or that have diseases that interfere with swallowing or gastrointestinal absorption, intravenous administration of either prednisolone or dexamethasone may be necessary. The use of long-acting parenteral drugs for treatment of immune-mediated disease is not recommended

TABLE 72.1

Comparison of the Properties of Synthetic Glucocorticoids

COMPOUND	DURATION OF ACTION*	ANTIINFLAMMATORY POTENCY	EQUIVALENT DOSE (mg)	MINERALOCORTICOID POTENCY	APPROPRIATE FOR ALTERNATE-DAY USE
Cortisone	Short	0.8	5.0	0.8	No
Hydrocortisone	Short	1.0	4.0	1.0	No
Prednisone/ prednisolone	Intermediate	4.0	1.0	0.3	Yes
Methylprednisolone	Intermediate	5.0	0.8	0	Yes
Triamcinolone	Intermediate (up to 48 h)	5.0	0.8	0	No
Flumethasone	Long	15.0	0.3	0	No
Dexamethasone	Long	30.0	0.15	0	No
Betamethasone	Long	35.0	0.12	0	No

*Short = <12 hours; intermediate = 12 to 36 hours; long = >48 hours.

because of the failure to achieve high plasma concentrations and the long duration of effect.

Glucocorticoids bind to a cytosolic glucocorticoid receptor, which then moves to the nucleus, binds to DNA, and influences gene transcription. Cellular effects include stabilization of cell membranes, inhibition of phospholipase A_2 with resultant inhibition of the cyclooxygenase and lipoxygenase pathways, decreased release of cytokines interleukin (IL)-1 and IL-6, and downregulation of Fc receptor expression on macrophages. The early effects of corticosteroids are believed to predominantly result from a rapid decrease in the phagocytic activity of splenic and hepatic macrophages, whereas the long-term effects result primarily from suppression of cell-mediated immunity. How much suppression of antibody production occurs in steroid-resistant species such as the dog and cat is controversial, but effects on B lymphocytes likely occur from suppression of T-helper cells required for full antibody response to an antigen. Effects of corticosteroids that make them useful drugs in the treatment of various immune-mediated diseases are shown in Box 72.1.

BOX 72.1

Actions of Corticosteroids That Play a Role in Treatment of Immune-Mediated Disease

- Inhibition of macrophage and neutrophil phagocytosis and chemotaxis
- Decreased neutrophil margination and migration
- Decreased lymphocyte proliferation
- Decreased numbers of circulating lymphocytes
- Altered cytokine production (decreased production of T-cell cytokines)
- Decreased cellular response to inflammatory mediators
- Inhibition of complement pathways
- Inhibition of immune complex passage through basement membranes
- Decreased prostaglandin and leukotriene synthesis
- Altered expression of phenotypic markers on canine lymphocytes
- Induction of lymphocyte apoptosis (in vitro)

For treatment of most immune-mediated diseases, an intermediate-acting corticosteroid such as prednisone is considered the treatment of choice because transition to an alternate day schedule will decrease long-term adverse effects of glucocorticoids. Prednisone undergoes hepatic metabolism to prednisolone. The two drugs have historically been considered clinically identical except in the presence of hepatic failure; however, prednisone has much lower bioavailability in cats than prednisolone. Thus prednisolone is the authors' preferred drug for immunosuppression in cats. In healthy dogs the relative bioavailability of prednisone is 65% that of prednisolone, so prednisolone rather than prednisone should also be considered in dogs, especially if there is any concern about gastrointestinal absorption or glucocorticoid efficacy (Boothe, 2012). Glucocorticoid resistance is a major cause of glucocorticoid treatment failure in humans. It is hypothesized that a similar phenomenon occurs in dogs and cats, but the incidence of this problem in dogs is unknown (Whitley et al., 2011). Decreased bioavailability due to poor gastrointestinal absorption or use of prednisone rather than prednisolone could mimic glucocorticoid resistance.

The typical starting dose for prednisolone/prednisone in dogs is 2 mg/kg/day PO, usually given in two divided doses. In individual cases, higher doses may be required (2-4 mg/kg/day orally). Cats are more resistant to the effects of glucocorticoids than are dogs. In cats, doses of 2 to 4 mg/kg/day of oral prednisolone or 4 mg/week per cat of dexamethasone are

recommended. For immunosuppressive therapy with other glucocorticoids, the dose is based on the drug's comparative potency to prednisone. For example, the dose of dexamethasone should be approximately eight times less than the dose of prednisone for an equivalent effect. Other than this difference in potency, no evidence currently suggests that dexamethasone is more effective than prednisone or prednisolone in the treatment of immune-mediated disease. The most common reason for choosing dexamethasone rather than prednisone is for parenteral administration in patients that are vomiting or cannot tolerate oral medication. Dexamethasone has a longer biologic half-life than prednisone or prednisolone, so it is not suitable for chronic use.

Although glucocorticoids are extremely useful in the management of immune-mediated disease, long-term adverse effects may be debilitating to the animal and intolerable to the owner. Common adverse effects include polyuria, polydipsia, panting, weakness, dermatologic changes, predisposition to infection, gastrointestinal hemorrhage, and muscle atrophy (Fig. 72.1). Glucocorticoids may also cause insulin resistance, hyperglycemia, vacuolar hepatopathy, and hypercoagulability as assessed by thromboelastography. Individual patients vary in their tolerance of the side effects of glucocorticoid therapy, with larger dogs often being particularly sensitive. Cats seem to be much less likely to have debilitating adverse effects of glucocorticoid treatment than dogs.

Strategies to minimize the adverse effects of glucocorticoid therapy include using the lowest dose possible, using shorter-acting rather than longer-acting steroids, and switching to alternate-day therapy as soon as feasible. To maximize the likelihood of a good response, treatment should start with high doses initially, and the dose should then be slowly tapered rather than starting with a more conservative dose and increasing the dose if required. Tapering of the dose should be based on an objective measure of response to treatment (e.g., hematocrit or joint fluid analysis) and should be done slowly to minimize the chance of disease relapse. As a general rule when managing immune-mediated diseases, the glucocorticoid dose should not be tapered by more than 50% per month. Remission may be harder to achieve a second time if the disease is allowed to relapse because of premature dose reduction. If clinical signs of glucocorticoid treatment are intolerable, other immunosuppressive drugs should be added to the treatment protocol so that the dose of glucocorticoids can be tapered more rapidly and, if possible, ultimately discontinued.

FIG 72.1
Severe temporal muscle atrophy in a 7-year-old castrated male Weimaraner treated with immunosuppressive doses of prednisone for immune-mediated disease.

AZATHIOPRINE

Azathioprine (Imuran) is a thiopurine antimetabolite that is a sulfur analog of adenine. After absorption, azathioprine is converted into 6-mercaptopurine (6-MP) and then into a number of thiopurine antimetabolites within the liver. The active cytotoxic metabolites of azathioprine are the 6-thioguanine nucleotides, which compete with purines in the synthesis of nucleic acids. This results in formation of nonfunctional nucleic acid strands. DNA and RNA synthesis is inhibited, leading to decreased proliferation of rapidly dividing cells such as lymphocytes. Azathioprine has a preferential effect on T lymphocyte function and inhibits cell-mediated immunity and T lymphocyte–dependent antibody synthesis. Numbers of circulating monocytes are also decreased. In hepatic insufficiency, the immunosuppressive effects of azathioprine are diminished while concurrent administration of allopurinol results in increased concentration of active metabolites. The enzyme thiopurine methyltransferase (TPMT) is important in metabolism of 6-MP and its metabolites. TPMT is found in highest concentrations in the liver and kidney, but RBC activity is a convenient and accurate indirect indicator of whole body enzyme activity in humans. Variation in RBC TPMT activity has been correlated with clinical outcome. Patients with low activity are at increased risk of myelosuppression, whereas those with high activity may have an inadequate response to treatment with azathioprine.

Azathioprine is commonly used as a second-line drug in a variety of immune-mediated diseases, including IMHA, ITP, immune-mediated polyarthritis, inflammatory bowel disease, and SLE (see Chapter 73 for the specific indications for each of these diseases). Azathioprine at the typical starting dose of 2 mg/kg PO q24h is well tolerated in dogs. Adverse effects are uncommon, but bone marrow suppression, gastrointestinal upset, pancreatitis, and hepatotoxicity have been reported. A small percentage of canine patients experience life-threatening myelosuppression, characterized by neutropenia, thrombocytopenia, and sometimes anemia, when treated with azathioprine; in some dogs, only thrombocytopenia occurs. Hepatotoxicity, characterized by a primary increase in the alanine aminotransferase (ALT) concentration occurs in approximately 15% of dogs within 14 to 21 days after initiation of therapy. German Shepherds

were shown to be over-represented in the dogs experiencing this hepatotoxicity. Bone marrow suppression usually occurs within 1 to 4 months after initiation of therapy and is typically reversible within 7 to 14 days after discontinuation of therapy. Because of the potential for myelosuppression and hepatotoxicity, dogs receiving azathioprine should have a CBC evaluated and hepatic enzyme activities measured every 1 to 2 weeks for the first month of treatment and then every 1 to 3 months indefinitely. Lower doses of azathioprine (2 mg/kg PO q48h) should be considered in dogs that show evidence of myelosuppression at the typical 2 mg/kg daily dose. Preliminary studies of TPMT activity on dogs have not been useful in predicting which patients are likely to have adverse reactions from azathioprine. However, several breed variations were identified. Giant Schnauzers were shown to have decreased TPMT activity, whereas Alaskan Malamutes were shown to have increased TPMT activity. These variations have not been correlated with any decreased activity or increased risk of toxicity, respectively. *Azathioprine is not recommended for use in cats because severe neutropenia and thrombocytopenia have been reported to occur even at reduced doses.*

Azathioprine is typically used in conjunction with immunosuppressive doses of prednisone. If a positive response is observed to combined therapy, the prednisone dose should be tapered over a period of 2 to 4 months. During this time daily azathioprine should be continued at the same dose (if adverse effects are not seen). If complete discontinuation of prednisone is possible without disease relapse, then the dose of azathioprine can be gradually decreased. This is usually accomplished by initially changing the dose schedule to every other day and then to every third day before complete cessation of treatment. In patients for whom prior relapse of immune-mediated disease has already occurred, the clinician may choose to continue lifelong low-dose azathioprine treatment (2 mg/kg q48h). Of note, bone marrow suppression has been reported as long as 12 months after starting azathioprine treatment, so monitoring of CBC and hepatic enzymes should be continued for the duration of treatment.

CHLORAMBUCIL

Chlorambucil (Leukeran) is an alkylating agent used to treat lymphoid neoplasms as well as immune-mediated disease. Chlorambucil is a prodrug that is metabolized to the active metabolite, phenylacetic acid mustard. It can be used as an alternate immunosuppressive drug in dogs that do not tolerate the more commonly used cytotoxic drugs. Historically, chlorambucil has been used most commonly in cats with immune-mediated disease due to their intolerance of azathioprine. Due to its common use in chemotherapy protocols for gastrointestinal lymphoma, chlorambucil has gained popularity as an adjunctive treatment for other infiltrative gastrointestinal diseases, such as inflammatory bowel disease. The usual starting dose for treatment of immune-mediated diseases in both dogs and cats is 0.1 to 0.2 mg/kg PO q24h (see Table 72.2). Adverse effects include bone marrow suppression, gastrointestinal upset, and predisposition to infection.

CYCLOSPORINE (CICLOSPORIN)

Cyclosporine, a potent immunomodulating agent, is a cyclic polypeptide extracted from fungi. The major mode of action is by inhibition of the initial activation phase of CD4 T lymphocytes. Cyclosporine blocks the transcription of genes encoding several cytokines, in particular IL-2. This prevents the activation and proliferation of T lymphocytes and the secondary synthesis of other cytokines. Cyclosporine does not affect the humoral immune system; therefore treatment with cyclosporine should not influence response to vaccination.

Cyclosporine is approved for management of atopic dermatitis in dogs and cats, and is the treatment of choice for perianal fistulas in dogs. Cyclosporine has also been used to treat a variety of other immune-mediated diseases in dogs and cats. Cyclosporine is a common adjunctive medication used for the treatment of IMHA and pure red cell aplasia. Immunophenotyping of dogs with IMHA showed an upregulation of IL-2, which may help explain why cyclosporine is beneficial with this disease. In addition, cyclosporine has been investigated as a monotherapy for dogs with immune-mediated polyarthritis, with a high rate of remission. Cyclosporine has also been used in other, refractory immune-mediated diseases in dogs and cats such as ITP, inflammatory bowel disease, myasthenia gravis, granulomatous meningoencephalomyelitis, chronic stomatitis, and a variety of immune-mediated dermatologic diseases.

Cyclosporine is available as a veterinary-labeled product in a formulation that forms a microemulsion in an aqueous environment (Atopica, Novartis Animal Health, Basel, Switzerland). Two human products are available, one formulated in vegetable oil (Sandimmune, Sandoz) and one that is a microemulsion (Neoral, Sandoz). Caution should be used when prescribing the human products as the bioavailability is lower than that of the veterinary-labeled product. Also, the doses recommended for the different products are not interchangeable because bioavailability of the microemulsion is higher than that of the oil-based product, and there is less variability in absorption of the microemulsions. Because food intake delays drug absorption and increases variability of absorption, the microemulsion form of cyclosporine should be given 2 hours before or after feeding. Doses of cyclosporine depend on the product used and the disease being treated but range from 5 mg/kg q24h to 10 mg/kg PO q12h (Tables 72.2 and 72.3). Measurement of blood cyclosporine concentration for dose individualization is recommended; therapeutic drug monitoring is available through the Clinical Pharmacology Laboratory at Auburn University (Clinical Pharmacology Laboratory, 1500 Wire Road, 142-A McAdory Hall, Auburn University, AL 36849; clinpharm@auburn.edu). In addition, pharmacodynamic

TABLE 72.2

Immunosuppressive Drugs Used in Treatment of Immune-Mediated Diseases in Dogs and Cats

DRUG	DOSE (DOG)	DOSE (CAT)	ADVERSE EFFECTS	RECOMMENDED MONITORING
Prednisone	2-4 mg/kg/day	2-8 mg/kg/day	Signs of hyperadrenocorticism, gastrointestinal ulceration, predisposition to infection	History and physical examination, CBC, biochemical panel; monitor parameters of disease progression
Azathioprine	2 mg/kg/day initially. Dose can be decreased to every other day to reduce risk of toxicity	Not recommended	Bone marrow suppression, gastrointestinal upset, hepatotoxicity, pancreatitis	CBC, platelet count, liver enzymes biweekly for 2 months, then monthly
Chlorambucil	0.1-0.2 mg/kg PO q24h initially, then taper to every other day once a response is seen	0.1-0.2 mg/kg PO q24h initially, then q24-72h	Myelosuppression	CBC and platelet count weekly initially; may decrease to biweekly or monthly once stable
Cyclosporine	5-10 mg/kg PO q12-24h Recommend using only Atopica® due to concerns for bioavailability of other products. Lower doses of 1-2.5 mg/kg q12h if in conjunction with ketoconazole (see Table 72.4)	3-5 mg/kg PO q12h Recommend using only Atopica® due to concerns for bioavailability of other products	Gastrointestinal upset, infection, gingival hyperplasia, papillomatosis, increased shedding	CBC and biochemical panel monthly
Vincristine	0.02 mg/kg IV as a single dose for treatment of ITP	NA	Myelosuppression, thrombophlebitis if allowed to extravasate outside vein	Daily CBC and platelet count to monitor response of platelets
hIVIG	0.25-1.5 g/kg as an IV infusion over 6-12 h (one dose only)	NA	Vomiting, mild thrombocytopenia in normal dogs	Monitor animal during administration by frequent TPR measurements, CBC and platelet count for disease monitoring
Mycophenolate mofetil	10 mg/kg PO q12h	10 mg/kg PO q12h	Gastrointestinal upset, hemorrhagic diarrhea	CBC and biochemical panel monthly
Leflunomide	2-4 mg/kg PO q24h	NA	Decreased appetite, lethargy, mild anemia, and hematemesis or hematochezia	

CBC, Complete blood count; *hIVIG,* human intravenous immunoglobin; *ITP,* immune-mediated thrombocytopenia; *NA,* not applicable; *TPR,* total parenteral nutrition.

monitoring is available to assess the degree of T-cell suppression achieved by a given dose of cyclosporine. This monitoring is available through the Pharmacodynamic Laboratory at Mississippi State University (Diagnostic Laboratory Services, 240 Wise Center Drive, Mississippi State, MS 39762; [662]312-8836). There is considerable interindividual variability in the concentration of cyclosporine required to achieve a therapeutic goal. Therefore following the guidelines of individual laboratories regarding the therapeutic range is important. However, clinical response is a very important

TABLE 72.3

Selected Studies of Dosing Recommendations and Therapeutic Monitoring for Dogs Treated With Cyclosporine

REFERENCE	NUMBER OF CASES	PRODUCT USED	EFFECTIVE DOSE	CLINICAL INDICATION	TARGET THERAPEUTIC RANGE (trough)*	INITIAL RESPONSE RATE
Mathews, 1997	20	Sandimmune	5 mg/kg q12h	Perianal fistulas	400-600 ng/mL	85%

*Except where indicated.

monitoring tool as positive clinical responses for some disorders may be observed at lower concentrations. Therefore therapeutic drug monitoring is most recommended in those patients where a clinical response has not been achieved, or where signs of toxicity are noted at lower doses than would be expected.

Numerous interactions between cyclosporine and other drugs occur because of shared metabolic pathways involving the cytochrome P450 enzyme system. Therapeutic monitoring is especially important in animals receiving concurrent therapy with such drugs (Table 72.4). In dogs treated with cyclosporine, concurrent ketoconazole administration (5-10 mg/kg q24h) can be used to decrease the required dose of cyclosporine, with resultant cost savings. This strategy has primarily been used in dogs with perianal fistulas and dogs undergoing organ transplantation; however, it could also be considered for other immune-mediated diseases, although the effectiveness is unproven. Similarly, concurrent itraconazole administration (10 mg/kg q24h) increased the bioavailability of orally administered cyclosporine in cats (Katayama et al., 2010). Therapeutic monitoring of the cyclosporine concentration is important when using this strategy.

Adverse effects of cyclosporine in dogs include gastrointestinal disturbance, predisposition to infection, gingival hyperplasia, papillomatosis, and increased shedding. A dermatosis from atypical staphylococcal infection (psoriasiform lichenoid–like dermatosis) has also been reported in dogs treated with cyclosporine. Affected dogs improved after antibiotic therapy and a decreased dose of cyclosporine. At the doses used to treat atopic dermatitis (5 mg/kg PO q24h), no difference in prevalence of bacterial infection was demonstrated between dogs treated with prednisone and those treated with cyclosporine. The risk of infection is increased in dogs treated with higher doses of cyclosporine, such as those used to prevent transplant rejection (20 mg/kg PO q24h), and when cyclosporine is combined with other immunosuppressive drugs such as prednisone and azathioprine. Cats treated with cyclosporine have adverse effects similar to what dogs have but may also develop anorexia, weight loss, bone marrow hypocellularity, and hepatic lipidosis.

LEFLUNOMIDE

Leflunomide is metabolized to teriflunomide, which inhibits its pyrimidine synthesis. Leflunomide also inhibits tyrosine kinases involved in cell differentiation and signal transduction. The drug inhibits T- and B-cell proliferation and has

antiinflammatory effects. Leflunomide is most commonly used to treat RA in people. In dogs, leflunomide was first used as part of an immunosuppressive protocol for renal transplantation but is now also used as adjunctive treatment in dogs that are refractory to more traditional immunosuppressive drugs and in patients in which glucocorticoids are contraindicated. Published studies regarding leflunomide use in dogs are limited, but a retrospective study reporting its use as a monotherapy for immune-mediated polyarthritis in dogs was encouraging. Leflunomide has also been used for treatment of Evans syndrome, IMHA, and polymyositis.

Adverse effects are uncommon but include decreased appetite, lethargy, mild anemia, and hematemesis or hematochezia when used in conjunction with corticosteroids. An idiosyncratic thrombotic microangiopathy is also described in dogs but is reversible with discontinuation of the drug. The current recommended dose is 2 to 4 mg/kg PO q24h. Therapeutic monitoring for leflunomide is available through the Clinical Pharmacology Laboratory at Auburn University (Clinical Pharmacology Laboratory, 1500 Wire Road, 142-A McAdory Hall, Auburn University, AL 36849; clinpharm@auburn.edu).

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil is a prodrug of mycophenolic acid (MPA), an inhibitor of the enzyme inosine monophosphate dehydrogenase (IMPDH) required for purine synthesis. MPA inhibits proliferation of B and T cells and decreases antibody production. Mycophenolate mofetil was developed as an alternative to azathioprine due to its similar mechanism of action and low risk of myelotoxicity. Mycophenolate has most commonly been used in transplantation medicine for prevention of rejection; however, it has become widely used in clinical veterinary medicine for immunosuppression, particularly for treatment of IMHA and ITP. Mycophenolate has also been used in refractory cases of mysathenia gravis, inflammatory bowel disease, and meningoencephalomyelitis of unknown etiology.

Advantages of mycophenolate include its availability as both an oral and parenteral product, which is appealing for anorectic patients. Other advantages include a low risk of toxicity. The most common adverse effects are gastrointestinal toxicity, which previously occurred in up to 67% of patients. Gastrointestinal toxicity, including hemorrhagic diarrhea, has the potential to be severe, but

has been found to be dose-dependent. Doses of greater than 15 mg/kg PO q12h are associated with higher risk of gastrointestinal toxicity. Mild suspected allergic reactions have been reported with use of the parenteral product. The current recommended dose in dogs is 10 mg/kg PO q12h. The concentration of MPA in the plasma of cats following administration of mycophenolate is highly variable, so the safety and efficacy of this drug is unknown in cats (Slovak et al., 2017).

SPLENECTOMY

Splenectomy is an adjunctive therapy recommended in the management of hematologic immune-mediated diseases such as IMHA and ITP. Splenectomy is theorized to decrease the number of mononuclear phagocytic cells available for phagocytosis of antibody-coated RBCs and platelets. It is typically recommended in dogs with IMHA or ITP resistant to medical therapy. There is evidence to support splenectomy in dogs with ITP that relapse after tapering of prednisone and azathioprine therapy. The merits of splenectomy in dogs with IMHA are less clear. One retrospective case series documented a positive clinical response after splenectomy in 10 dogs with IMHA that were not responding to immunosuppressive treatment. Nine of ten dogs survived to 30 days, and the hematocrit increased while transfusion requirements decreased after surgery. Interpretation of this study is difficult because most dogs were treated concurrently with corticosteroids, and the positive outcome could have been a delayed response to medical treatment. Potential risks of splenectomy include hemorrhage and thromboembolic complications. The spleen is also an important site of extramedullary hematopoiesis, so splenectomy has the potential to impair RBC regeneration.

HUMAN INTRAVENOUS IMMUNOGLOBULIN

Human intravenous immunoglobulin (hIVIG) is a preparation of polyspecific IgG obtained by pooling the plasma of a large number (>1000) of healthy human blood donors. hIVIG is available as either a solution or a lyophilized product, and a wide range of concentrations and vial sizes are available. Numerous commercial products are available and vary in price and availability (e.g., Gammagard S/D, Baxter Healthcare Corporation, Deerfield, Ill; Gamimune N, Bayer Pharmaceuticals, Leverkusen, Germany). hIVIG is the treatment of choice for immune-mediated thrombocytopenic purpura in people and is also used for the treatment of a wide variety of other immune-mediated diseases. Numerous mechanisms by which hIVIG modulates the immune system have been documented in humans, including decreased production of autoantibodies, possibly due to antiidiotypic antibodies in hIVIG, functional modulation of T cells, decreased natural killer cell activity, blockade of complement-mediated cell damage, and modulation of the release and function of proinflammatory cytokines. In dogs, hIVIG binds to Fc receptors on mononuclear phagocytes, thereby inhibiting phagocytosis. Whether other mechanisms also play a role is unknown. hIVIG has been used in veterinary medicine to treat IMHA, pure red cell aplasia, myelofibrosis, ITP, erythema multiforme, pemphigus foliaceus, and toxic epidermal necrolysis. Doses of hIVIG that have been used in dogs range from 0.25 to 1.5 g/kg; hIVIG is administered as an intravenous infusion over 6 to 12 hours. Mild thrombocytopenia and occasional vomiting have been reported in healthy dogs treated with hIVIG. The most serious concern for use of hIVIG in dogs and cats is that administration of an infusion containing human protein could lead to sensitization and potential anaphylaxis if the treatment is repeated. There are few reports of anaphylactic reactions in dogs or cats treated with hIVIG despite repeated administration in some case reports; however, anaphylaxis was reported to occur in a dog with myasthenia gravis treated with four doses of hIVIG. The other potential adverse effect documented in dogs is increased risk of thromboembolism. In a study of healthy dogs treated with hIVIG, a prothrombotic and proinflammatory effect was demonstrated (Tsuchiya et al., 2009). Risk of thromboembolism is also a concern in people treated with hIVIG, especially in those already at risk. A high prevalence of thromboembolism was reported in dogs with IMHA treated with hIVIG; however, whether this related to the underlying disease or the hIVIG treatment was not clear. The major limitation of hIVIG treatment is the expense; consequently prospective studies of hIVIG treatment in veterinary medicine have been limited, and the evidence for its efficacy in disorders other than canine ITP is weak. Immunoglobulin is currently most commonly used as an adjunctive treatment in dogs with severe ITP and as a rescue agent in dogs with immune-mediated diseases (IMHA, myasthenia gravis, dermatologic drug reactions, pemphigus foliaceus) that are not responding to conventional immunosuppressive agents. Because of the rapid but short-acting effect of hIVIG on phagocytosis, the most logical use is as a bridge to suppress phagocytosis in diseases such as IMHA and ITP while waiting for other immunosuppressive drugs to become effective; however, clinical studies to support this hypothesis are lacking except in canine ITP.

PENTOXIFYLLINE

Pentoxifylline belongs to the methylxanthine drug class and is a derivative of theobromine. Despite this derivation, the drug does not have cardiac or bronchodilatory effects. The major properties of pentoxifylline relate to its effects on the immune system and blood viscosity. Pentoxifylline improves the deformability of RBCs by unknown mechanisms. Pentoxifylline also has a number of immunomodulating effects, including inhibition of IL-1, IL-6, and tumor necrosis factor-α, as well as inhibition of B- and T-cell activation.

The pharmacokinetics of pentoxifylline have been described in the dog, and the current dose recommendation is 10 to 15 mg/kg PO q8h. In veterinary medicine, pentoxifylline has primarily been used for the management of cutaneous immune-mediated diseases, including dermatomyositis, SLE, and various forms of vasculitis. Whether the drug might be beneficial in other immune-mediated diseases is not known. Adverse effects in dogs are uncommon but may include vomiting, diarrhea, bone marrow suppression, and flushing.

VINCRISTINE

Vincristine is an alkaloid derived from the periwinkle plant. It is used as an antineoplastic and immunosuppressive agent. Vincristine binds to the microtubular structural protein tubulin, which is abundant within platelets. At low doses the drug causes a transient increase in circulating platelet numbers; at higher doses it can cause myelosuppression and thrombocytopenia. Proposed mechanisms for increased platelet numbers in normal dogs include stimulation of thrombopoiesis by circulating thrombopoietic factors (perhaps by concealing platelets from the thrombopoietic regulatory system) or by inducing acute fragmentation of mature megakaryocytes. In ITP, in which stimulation of thrombopoiesis is already maximal, the mechanisms for increased platelet numbers are most likely increased platelet release from the bone marrow and impaired platelet destruction from inhibition of phagocytosis, or interference with antibody binding to platelets. Decreased antibody synthesis seems less likely considering the short time course for the increase in platelet count (median 3 days for platelet recovery). Disruption of structure and function of platelets has been reported after exposure to vincristine in vitro and in vivo in dogs with lymphoma; however, the clinical significance of this finding is unclear.

The major indication for vincristine in treatment of immune-mediated disease is as adjunctive therapy for dogs with severe ITP. Vincristine-treated dogs with ITP have a more rapid increase in platelet number and shorter duration of hospitalization than dogs treated with prednisone alone. Vincristine is administered at 0.02 mg/kg IV as a single dose in conjunction with glucocorticoids. The advantages of vincristine are that it is readily available and inexpensive. Although bone marrow suppression may occur at higher doses, this has not been reported at the low single dose used for treatment of ITP. Care should be taken during intravenous administration because the drug is highly caustic if extravasation occurs.

CHAPTER 73

Common Immune-Mediated Diseases

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Etiology

Immune-mediated hemolytic anemia (IMHA) is a clinical syndrome in which anemia results from the accelerated destruction of red blood cells (RBCs) by immune-mediated mechanisms (see Chapter 70). IMHA is the most common cause of hemolytic anemia in dogs but is uncommon in cats. In primary IMHA (true autoimmune hemolytic anemia) antibodies are directed against RBC membrane antigens. The target antigens have not been well characterized in the dog or cat, but antibodies directed against spectrin, band 3, and the family of erythrocyte membrane glycoproteins, known as *glycophorins,* have been identified in some dogs. True autoimmune hemolytic anemia may also be a manifestation of systemic lupus erythematosus (SLE). In secondary IMHA, an underlying disease is implicated as a precipitating factor. Causes of secondary IMHA include infection and neoplastic diseases (Box 73.1). Secondary IMHA may also occur after exposure to certain drugs, venoms, and possibly vaccines. Most studies in dogs suggest that primary autoimmune hemolytic anemia is more common than the secondary form, although the frequency of identification of a secondary cause likely depends on the extent of the diagnostic evaluation because a diagnosis of primary IMHA is usually made by ruling out secondary causes.

The common antibody classes identified on the RBC in both dogs and cats with IMHA are, in order from most to least common, immunoglobulin (Ig) G, IgM, and IgA. Complement is usually also present. In secondary IMHA antibodies may be directed against antigens that adsorb to the RBC membrane or against a microbial antigen combined with a self-determinant, with the RBCs destroyed as "innocent bystanders." Alternatively, previously hidden membrane antigens may be exposed by membrane damage due to microbes or toxins, or microbial and drug antigens may be cross-reactive with self-determinants. Lastly, nonspecific activation of lymphocytes can result in formation of self-reacting lymphocytes in any chronic inflammatory process.

Recent vaccination has been implicated in the pathogenesis of IMHA. The occurrence of IMHA within 2 to 4 weeks of vaccination has been a clinical observation of concern for many owners and veterinarians. In one study of 58 dogs with IMHA, 26% of dogs had been vaccinated within 4 weeks of developing IMHA compared with a control group in which only 5% had been vaccinated within the previous 4 weeks. Mortality rates between the recently vaccinated dogs and unvaccinated dogs were not significantly different. In a later study that compared 72 dogs with IMHA with a control group, a temporal association between vaccination and development of IMHA was not identified. The importance of vaccination in the etiology of IMHA thus remains unclear.

IMHA clearly has a genetic predisposition, with the disease recognized more frequently in certain breeds (Box 73.2). The Cocker Spaniel is the breed at greatest risk, accounting for as many as one third of cases. The presence of dog erythrocyte antigen 7 has been investigated for its possible protective effect in Cocker Spaniels, but consistent association has not been identified with this or other cell surface antigens.

In IMHA the presence of antibody and/or complement on the RBC ultimately results in intravascular or extravascular hemolysis (see Chapter 82). Extravascular hemolysis is more common than intravascular hemolysis, is typically a less acute process, and is commonly accompanied by spherocytosis and hyperbilirubinemia (Figs. 73.1 and 73.2). Although hyperbilirubinemia is a common feature of IMHA, it does not occur in all cases, and lack of hyperbilirubinemia does not rule out IMHA. In one study, bilirubin concentrations were significantly higher in nonsurvivors when compared with survivors (Harkin et al., 2012). Factors that determine the presence and severity of hyperbilirubinemia include the rate of hemolysis and hepatic function. Hepatic function may be compromised by hypoxia and hepatic necrosis in dogs with IMHA. In one study of 34 dogs that died of IMHA, 53% had moderate to severe centrilobular hepatic necrosis at necropsy.

BOX 73.1

Infectious Diseases Implicated as Causing IMHA in Dogs and Cats

Dogs

Dirofilariasis
Hemotrophic mycoplasmosis
Ehrlichia canis infection
Anaplasma phagocytophilum infection

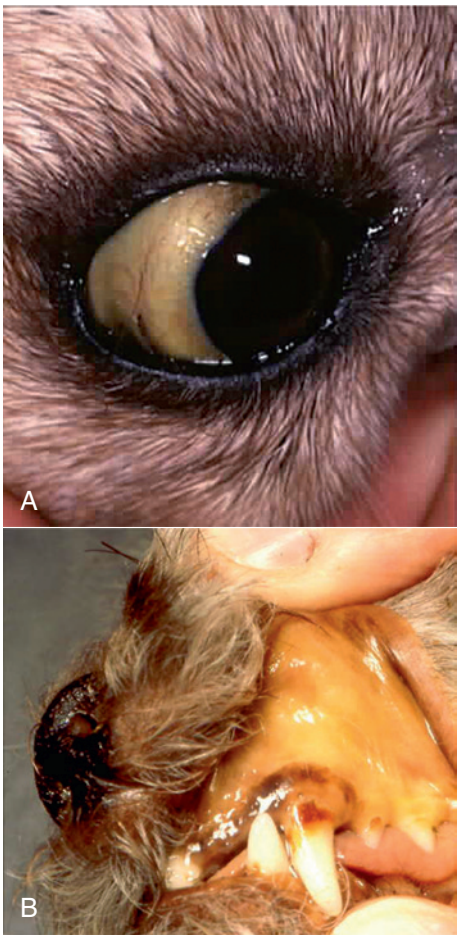

FIG 73.1
Mixed-breed dog with moderate icterus of the sclera **(A)** and the oral mucous membranes **(B).**

Clinical Features

Dogs with primary IMHA are typically young to middle-aged adults, with a reported age range of 1 to 13 years and a median age of 6 years. Females and neutered dogs of both sexes appear predisposed compared with sexually intact male dogs, and several breeds are overrepresented (see Box 73.2). Common clinical signs of IMHA are listed in Box 73.3. The duration of clinical signs before presentation to the veterinary hospital is typically short, with a median of 4 days. Seasonal increases in diagnosis of IMHA have been reported, although the findings are not consistent among studies. The majority of reports suggest an increased frequency of IMHA during the warmer months of the year.

Diagnosis

Diagnosis of IMHA relies on identifying abnormalities consistent with hemolytic anemia on a complete blood count (CBC), serum biochemistry panel, and urinalysis (Box 73.4) followed by identification of antibodies directed against the RBC membrane. Further diagnostic testing is then directed

at establishing whether a secondary underlying cause for IMHA can be identified.

The first requirement for making a diagnosis of IMHA is the presence of anemia. The anemia is typically moderate to marked (median hematocrit of 13%) and is usually regenerative, although in approximately 30% of dogs and more than 50% of cats a nonregenerative anemia is present either because of acute onset before the bone marrow has had time to respond (typically takes 3-5 days for maximal regenerative response) or because of antibodies directed against bone marrow precursors. In the latter situation, reticulocytes are destroyed before they enter the peripheral circulation. In the absence of a regenerative response, a rapid fall in the hematocrit with little change in the serum total protein or albumin concentration should be considered suspicious for hemolysis. In anemia caused by decreased RBC production from the bone marrow, the hematocrit should not decrease by more than approximately 1% per day, whereas in blood loss anemia, the drop in the hematocrit is usually accompanied by a concurrent decrease in the total protein or albumin (Table 73.1). Most dogs with IMHA also have an inflammatory leukogram, often with a shift toward immature cells, and mild to severe thrombocytopenia in 60% of cases. Proposed mechanisms for thrombocytopenia include the presence of antibodies directed against platelets and RBCs (Evans syndrome), disseminated intravascular coagulation (DIC), and splenic sequestration.

Identification of autoagglutination or spherocytosis (2+ or more) on a blood smear is considered definitive evidence of antibody-mediated RBC hemolysis (Fig. 73.3). Autoagglutination is detected by macroscopic or microscopic examination of the blood smear and is generally considered diagnostic for IMHA. Autoagglutination has been reported in up to 78% of canine IMHA. Agglutination must be distinguished from rouleaux formation (see Chapter 82).

In dogs with IMHA, spherocytes are formed by partial removal of antibody-coated RBC membranes by macrophages (see Fig. 73.2). This results in loss of the normal discoid shape, decreased size, and loss of central pallor. Spherocytes are more rigid and less deformable than normal RBCs and are removed when they pass through the spleen. Spherocytes are readily identified in the dog but difficult to recognize in cats because of the lack of significant central pallor in their normal RBCs. Spherocytes are considered a hallmark morphologic change in IMHA, and when present in sufficient numbers (2+ or greater) may be regarded as diagnostic for IMHA in dogs. However, because spherocytes are the results of phagocytic activity on the RBCs, they can also be present in other disorders, such as hemophagocytic syndrome, hemophagocytic histiocytosis, and zinc-induced hemolysis, although their numbers tend to be low when compared with dogs with IMHA (i.e., 1+ versus 2+). Techniques for quantification of spherocyte numbers are typically semiquantitative (Table 73.2). In retrospective studies approximately 90% of dogs with IMHA have spherocytes present on the blood smear; however, low numbers may be present in dogs with peracute hemolysis. Ghost cells are remnant membranes of RBCs that have undergone intravascular lysis. Lysis can be induced by immune- or non–immune-mediated mechanisms, so ghost cells are not diagnostic for IMHA.

The direct Coombs test with polyvalent antisera is the most commonly used diagnostic test for IMHA when autoagglutination or spherocytosis is not present; however, this test is neither particularly sensitive nor specific for

TABLE 73.1

Expected Changes on the CBC in Different Causes of Anemia

TYPES	RATE OF DECREASE OF HEMATOCRIT	RETICULOCYTE COUNT	SERUM PROTEINS	EVIDENCE OF INFLAMMATION ON CBC	THROMBOCYTOPENIA
Hemolytic anemia	Fast	High	No change	Yes	Yes (mild to severe)
Nonregenerative anemia	Slow	Low	No change	No	Depends on cause
Blood loss anemia	Fast	High	Decreased	No	Yes (mild only)

CBC, Complete blood cell count.

confirming a diagnosis of IMHA. A positive Coombs test indicates that antibody, complement, or both are on the surface of the RBC but does not mean that the antibody is directed specifically against the RBC membrane or that the antibody is causing hemolysis. Approximately 60% to 80%

TABLE 73.2

Semiquantitative Scoring System for Numbers of Spherocytes on a Slide

APPROXIMATE NUMBER OF SPHEROCYTES PER × 1000 FIELD	ASSIGNED SCORE
1-10	1+
11-50	2+
51-150	3+

of canine patients with IMHA have a positive Coombs test. Conversely, a positive Coombs test can occur in a variety of other inflammatory diseases causing false-positive results. False-negative results can also occur and might reflect a low concentration of antibody present (see Chapters 72 and 82). In people, the Coombs test is performed at two different temperatures, to detetct cold and warm agglutinins, maximizing the possibility of identifying a positive result. There is some evidence in people that cold agglutinin positive/warm agglutinin negative Coombs tests are more likely to indicate IMHA due to a secondary cause. This has not been shown to be true in dogs, but certain laboratories will still report cold and warm agglutinin Coombs test results.

A search for secondary causes of IMHA should always be undertaken in a dog or cat with IMHA because the underlying disease may influence both management strategy and prognosis. Potential secondary causes of IMHA are listed in Table 73.3. The diagnostic approach to ruling out secondary IMHA includes a thorough history of drug, vaccine, and toxin exposure; detailed physical examination, including rectal, ophthalmologic, and neurologic examinations; tests for specific infectious diseases; investigation into causes of chronic antigenic stimulation; and a search for evidence of neoplasia. Diagnostic tests to consider in addition to a CBC, biochemical panel, and urinalysis include urine culture, abdominal and thoracic radiographs, abdominal ultrasound, bone marrow cytology and/or histopathology (if the anemia is nonregenerative), and appropriate titers for infectious diseases.

TABLE 73.3

Secondary Causes of IMHA in Dogs and Cats

	EXAMPLES	DIAGNOSTIC TESTS INDICATED

Exposure to drugs vaccines or toxins	Antibiotics (sulfonamides, β-lactam antibiotics)	Detailed history

IFA, Immunofluorescent antibody; *IMHA,* immune-mediated hemolytic anemia; *PCR,* polymerase chain reaction.

Results of bone marrow evaluation in dogs with nonregenerative primary IMHA typically reveal erythroid hyperplasia with a low myeloid/erythroid (M/E) ratio, although maturation arrest at the rubricyte or metarubricyte stage may also be observed. Some dogs initially suspected to have IMHA on the basis of the presence of spherocytosis or a positive Coombs test have pure red cell aplasia (PRCA). Myelofibrosis is identified on bone marrow core biopsy in many dogs with nonregenerative IMHA. In dogs with myelofibrosis, collection of adequate bone marrow elements by aspiration cytology is difficult. Myelofibrosis is likely a secondary response to bone marrow injury and usually resolves in dogs that respond to treatment.

In dogs without the classic morphologic changes of immune-mediated hemolysis (regenerative anemia, autoagglutination, spherocytes), confirming a diagnosis of IMHA is challenging. A positive direct Coombs test should be interpreted cautiously in such cases because false-positive results may occur. The logical approach is to rule out other causes of anemia (see Chapter 82) and use the Coombs test and other indications of hemolysis as supporting evidence of IMHA if no other cause of anemia is identified.

Treatment

Choosing an appropriate treatment regimen for dogs with IMHA is a frustrating task for the clinician. Lack of prospective studies of treatment efficacy, the poor prognosis associated with the disease, and the high cost of treatment and supportive care are some reasons for this frustration. In addition, serious complications such as pulmonary thromboembolism and DIC are relatively common occurrences but are hard to anticipate in individual patients. Because of the lack of prospective studies of treatment efficacy, recommendations for approach to treatment in dogs with IMHA are based primarily on clinical experience rather than objective data.

When planning the management of a dog with IMHA, the goals of treatment should include prevention of RBC hemolysis, alleviation of tissue hypoxia by blood transfusion, prevention of thromboembolism, and provision of supportive care.

PREVENTION OF HEMOLYSIS

Immunosuppressive drugs are the key for prevention of hemolysis in dogs with IMHA. The mechanism of action and adverse effects associated with the use of various immunosuppressive drugs recommended for use in dogs and cats with autoimmune disorders were discussed in Chapter 72.

High doses of glucocorticoids are the first line of treatment for controlling hemolysis in dogs with IMHA. In dogs that can tolerate oral medication, prednisolone or prednisone at a dose of 2-4 mg/kg/day orally (PO) is the authors' corticosteroid of choice. Prednisolone may have higher bioavailability than prednisone in cats and possibly dogs, so it is the best choice in both species. The higher end of the dose range is recommended as a starting dose except in large-breed dogs (>30 kg). Most dogs that respond to prednisolone show some improvement within the first 7 days of treatment, but the full therapeutic effect may not be evident until 2 to 4 weeks after initiation of treatment. Indications suggesting resolution of hemolysis include stabilization and then an increasing hematocrit, conversion from a positive to negative Coombs test, resolution of autoagglutination, resolution of spherocytosis, normalization of the reticulocyte

count, and resolution of the inflammatory leukogram. Once the hematocrit increases above 30%, a taper of the prednisone dose can be initiated The dose is tapered by a maximal rate of 20% to 30% per month over a 3- to 6-month period depending on the hematocrit and severity of adverse effects. If after 6 months the prednisolone dose is tapered to a low every-other-day dose and the disease is in remission, discontinuation of medication should be attempted. A CBC and reticulocyte count should be performed before and 2 weeks after any change in immunosuppressive therapy.

Some dogs with IMHA do not respond to glucocorticoid treatment alone, or the dose of prednisolone required for disease control results in unacceptable adverse effects. In these cases, an additional immunosuppressive drug should be added to the treatment regimen. One common clinical dilemma is whether all dogs with IMHA should be treated with an additional immunosuppressive drug early in the course of treatment, or whether waiting and identifying which dogs are likely to benefit is more appropriate. The advantage of starting another immunosuppressive drug early is that no time is lost waiting to identify which patients will respond to glucocorticoid treatment alone. Most adjunctive immunosuppressive drugs take 2 to 4 weeks to have an appreciable effect on immune cells, so an argument could be made that starting them earlier will save time. The disadvantages include the risk of adverse effects, the cost of immunosuppressive drugs, the lack of evidence of benefit, and the lack of consensus about which adjunctive agent should be considered "second line" after glucocorticoids. In a retrospective study comparing a cohort of dogs treated with prednisolone and azathioprine with a cohort of dogs treated with prednisolone alone, no benefit of azathioprine therapy could be identified. Despite this finding, other large IMHA retrospective studies report that the majority of IMHA cases are managed with glucocorticoids and adjunctive immunosuppressive agents. Use of more than one adjunctive immunosuppressive drug concurrently is strongly discouraged because of the potential for severe immunosuppression and resultant susceptibility to infection.

The choice for adjunctive immunosuppression varies among clinicians. The most common drugs used are azathioprine, cyclosporine, and mycophenolate. The authors consider any of these to be appropriate adjunctive immunosuppressive medications, especially in dogs that do not respond within 5 to 7 days of initiating glucocorticoid treatment and in dogs that require more than two blood transfusions. Adjunctive immunosuppressive medications should also be used in dogs known to have a poor tolerance of the adverse effects of glucocorticoids (e.g., large-breed dogs) and in those with other poor prognostic indicators (e.g., intravascular hemolysis, serum bilirubin concentration greater than 8 to 10 mg/dL, persistent autoagglutination, Evans syndrome).

The adjunctive immunosuppressive medication should be initiated at a recommended dose to achieve appropriate suppression of immune cells, namely lymphocytes. Once the anemia is controlled, the adjunctive immunosuppressive medication is continued at the same dosage while the dose of prednisolone is tapered. The adjunctive medication can then be tapered once prednisolone has been discontinued. If a relapse occurs during tapering of the drugs, lifelong prednisolone, the adjunctive medication, or both are recommended at the lowest dose that controls hemolysis.

Azathioprine has the most evidence for its use in canine IMHA, though there is no evidence that its use improves response to treatment or survival. Azathioprine requires more regular monitoring of the CBC and hepatic enzymes due to the risk of bone marrow suppression and hepatotoxicity. Current recommendations are to reduce the frequency of administration of azathioprine to every other day after the first 2 weeks of daily administration to reduce the risk of toxicity.

Cyclosporine is being used with greater frequency for the treatment of canine IMHA. The cost of cyclosporine is a major deterrent to its use, and its potent immunosuppressive effects mandate frequent monitoring of the patient for secondary infections (bacterial, fungal, protozoal). The bioavailability of some cyclosporine formulations has been shown to be poor in dogs, making Atopica® the most appropriate formulation to use in veterinary patients. In a prospective study of 38 dogs with IMHA, no difference in survival was found between dogs treated with prednisone alone and those treated with prednisone and cyclosporine; however, most of the deaths occurred early, before the effects of cyclosporine had likely reached maximal effect. In a study to characterize the predominant inflammatory cytokines in canine IMHA, interleukin-2 (IL-2) was consistently increased in dogs with IMHA. This might suggest that cyclosporine has good potential for success, as the calcineurin inhibition leads to a decreased transcription of cytokines, primarily IL-2. Cyclosporine appears to be relatively safe in dogs with IMHA, and clinical experience suggests that it is useful and effective in the treatment of dogs with IMHA that do not respond to prednisolone or azathioprine. (For dosing and monitoring recommendations for cyclosporine, see Chapter 72 and Tables 72.3 and 72.4.)

Mycophenolate mofetil (MMF) has historically been used in refractory cases of IMHA and other immune-mediated diseases. The mechanism of MMF is similar to that of azathioprine. It was originally designed as an alternative to azathioprine in human transplant patients, due to fewer side effects. A retrospective evaluation of dogs with IMHA treated with prednisolone and mycophenolate reported dose-dependent gastrointestinal toxicity including severe hemorrhagic diarrhea. However, when used at recommended doses, mycophenolate is well tolerated in dogs. Mycophenolate is also available for intravenous administration, so it is a good option for patients unable/unwilling to take oral medications in the early stages of the disease.

There are anecdotal reports and a few retrospective case series reporting positive responses to treatment of canine IMHA with human intravenous immunoglobulin (hIVIG). In a controlled, blinded, prospective study of 28 dogs with IMHA, no benefit was evident when three doses of hIVIG

were administered together with glucocorticoids compared with prednisone alone. Cost is often a deterrent to using hIVIG, and there is potential for sensitization to human proteins, so caution is advised when administering more than one dose.

BLOOD TRANSFUSION

Most dogs and cats with acute, severe IMHA need oxygen-carrying support. Oxygen supplementation alone is of limited benefit. The need for blood transfusion depends on the severity, rate of onset and chronicity of the anemia, and the presence and severity of concurrent disease such as pulmonary thromboembolism and gastrointestinal blood loss. No specific hematocrit level should be used as a transfusion trigger; rather, each patient should be considered individually. In general, transfusion should be considered when the dog has problems with tachycardia, tachypnea, anorexia, lethargy, or weakness while at rest. Most dogs with acute IMHA and a hematocrit less than 15% have some degree of tissue hypoxia and will benefit from a blood transfusion regardless of how the dog appears clinically. Severe tissue hypoxia likely exacerbates the complications of IMHA, such as hepatic necrosis, DIC, and thromboembolism.

Transfusion of packed RBCs (pRBCs) is ideal; whole blood is acceptable but less ideal because the plasma component is not necessary and may increase the risk of a transfusion reaction. (See Chapter 82 for more information about blood transfusions.)

PREVENTION OF THROMBOEMBOLISM

The majority of dogs with IMHA are hypercoagulable on presentation as assessed by thromboelastrography (TEG), a viscoelastic assessment of coagulation, and some have evidence of DIC. Abnormalities of the hemostatic system that have been identified include prolongation of activated partial thromboplastin time (aPTT) and prothrombin time, increased D-dimer, increased fibrinogen degradation products (FDPs), decreased antithrombin (AT) concentration, and hyperfibrinogenemia.

Thromboembolic events (TEs) are a common complication and important cause of death in dogs with IMHA. TEs have been documented at necropsy in 29% to 100% of dogs with IMHA. Intravenous catheter placement and identification of certain clinicopathologic abnormalities, such as thrombocytopenia, hyperbilirubinemia, leukocytosis, and hypoalbuminemia, are associated with an increased risk of TE in dogs with IMHA. The pathogenesis of thrombus formation is unknown, and effective regimens for prophylaxis have not been established. Treatment options currently used for prevention of thromboembolic complications include heparin, low-molecular-weight heparin, aspirin, clopidogrel, or a combination of these modalities. The recommended starting dose for heparin in patients with IMHA is 200 to 300 U/kg subcutaneous (SC) q6h, and the dose is adjusted by measuring anti-Xa activity (0.35-0.7 U/mL) or, less ideally, monitoring the aPTT with the aim to prolong aPTT by 25% to 50% of baseline. An individually adjusted heparin dosing regimen for thromboprophylaxis based on measurement of anti-Xa activity is associated with a better outcome in dogs with IMHA rather than a fixed dose of 150 U/kg SC q6-8h heparin (Helmond et al., 2010). (For a discussion of the use of low-molecular-weight heparin, see Chapter 87.) Low-dose aspirin (0.5 mg/kg PO q24h) has also been used to prevent thromboembolic complications in dogs with IMHA. Weinkle et al. (2005) reported that dogs treated with a protocol that included prednisone, azathioprine, and low-dose aspirin had the longest survival times. Low-dose aspirin may not result in appropriate platelet inhibition in all dogs. Aspirin resistance was identified in 30% of dogs in one study, yet another 30% experienced only partial responsiveness to low-dose aspirin. Clopidogrel bisulfate is an inhibitor of the ADP receptor on platelets and is the gold standard for prevention of cardiogenic arterial thromboembolism in cats. Clopidogrel was compared with low-dose aspirin, prospectively, in a group of dogs with IMHA, and survival was similar between the two groups. (See Chapters 12 and 87 for more information on treatment and prevention of thromboembolism.)

SUPPORTIVE CARE

Aggressive supportive care is critical to a good outcome in dogs with IMHA. Identification and treatment of underlying disease, detection of complications associated with immunosuppressive drug therapy, and good nursing care positively influence outcome. In addition to transfusion, fluid therapy should be administered in dogs with evidence of dehydration to improve tissue perfusion. In dehydrated dogs, fluid therapy will decrease the measured hematocrit, but this does not change the total RBC mass. Fluid therapy should not be withheld because of fear of exacerbating anemia. In reality, fluid therapy reveals the true severity of the anemia.

Careful investigation and treatment of underlying disease in dogs with IMHA is important. Immunosuppressive therapy is usually still necessary in dogs with secondary IMHA. However, the duration of immunosuppression may be shorter if an underlying cause can be identified and treated. If an infectious disease is identified, addition of adjunctive immunosuppressive drugs should be avoided.

Complications of immunosuppressive drug therapy include bone marrow suppression, infection, gastrointestinal ulceration, and iatrogenic hyperadrenocorticism. Gastrointestinal hemorrhage can contribute to anemia in dogs with IMHA, either from the gastrointestinal effects of high doses of glucocorticoids or concurrent thrombocytopenia, vasculitis, ischemia, or other concurrent disease. Recognition of occult gastrointestinal hemorrhage is important because the resulting anemia may be confused with a failure to respond to treatment for IMHA (see Chapter 80). Drugs used for treatment of gastrointestinal hemorrhage include gastrointestinal protectants such as sucralfate, H_2 blockers (e.g., famotidine), and proton pump inhibitors (e.g., omeprazole).

Prognosis

In approximately 60% of dogs with IMHA, medications can ultimately be discontinued after a slow tapering of the

immunosuppressive drugs. The remaining dogs require long-term immunosuppressive therapy. Factors that clinically appear to confer a good prognosis in dogs with IMHA include a rapid response to treatment with glucocorticoids, ability to maintain the packed cell volume above 30% with glucocorticoids alone, and identification of a treatable secondary cause.

The prognosis is guarded in dogs that require multiple drugs to control the disease and those with persistent autoagglutination, azotemia, an elevated bilirubin concentration, marked thrombocytopenia, and severe leukocytosis. In a multicenter study, prognostic factors for canine IMHA were investigated, and a model using the presence of SIRS, bilirubin, urea, and creatinine concentrations, and ASA score was predictive of outcome in 80% of cases. In this model, bilirubin concentration and azotemia were independently associated with death. Reported mortality rates of dogs with primary IMHA range from 26% to 70%; thromboembolism is the cause of death in 30% to 60% of cases. Other common causes of death include infection due to immunosuppression, DIC, and failure to control anemia. Interestingly, patients that are hypercoagulable as assessed by TEG have a better prognosis than those that have normal coagulability; it has been proposed that, in these dogs, there is an underlying consumptive coagulopathy. If a major TE does occur in a dog with IMHA, particularly if the blood supply to a major organ is disrupted, the long-term prognosis is poor. Contrary to popular opinion, the prognosis in Cocker Spaniels with IMHA does not differ from that of other breeds.

FELINE IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Cats with primary IMHA tend to be younger than dogs, with a median age of 2 years. Males are slightly overrepresented, with no influence of neuter status. Secondary causes for antierythrocyte antibody formation are identified more frequently in cats, with feline leukemia virus and *Mycoplasma haemofel*is being common infections associated with IMHA. Primary IMHA in cats is more likely to present with a nonregenerative anemia, accounting for about 50% of cases.

Most cats with IMHA respond to prednisolone alone, and the adverse effects of glucocorticoids are less severe. In cats that need an additional immunosuppressive drug to treat IMHA, treatment with chlorambucil, cyclosporine, or mycophenolate should be considered. Not enough published information exists to recommend one drug over another. *Azathioprine is not recommended in cats because of the risk of unacceptable adverse effects* (see Chapter 72). The authors typically use chlorambucil or cyclosporine in cats that need an additional immunosuppressive drug. There is an increased risk of diabetes mellitus in cats treated with glucocorticoids; in these cats a second immunosuppressive drug should be added to allow tapering and ultimately discontinuation of glucocorticoids.

PURE RED CELL APLASIA

PRCA is a rare disorder characterized by severe, nonregenerative anemia with marked depletion or absence of erythroid precursors in the bone marrow. In some cases, evidence of concurrent peripheral hemolysis is present on the basis of the presence of spherocytes and a positive direct Coombs test. Other cell lines are usually normal. The erythroid aplasia in PRCA is in contrast to the nonregenerative form of IMHA, in which there is erythroid hyperplasia or sometimes maturation arrest of the erythroid maturation sequence at the rubricyte or metarubricyte level. PRCA is likely one end of the spectrum of IMHA, with acute peripheral hemolysis at the other end of this spectrum (Table 73.4). The affinity of circulating antibody for different erythroid precursors likely influences the level at which damage occurs in the bone marrow. As with IMHA, both primary and secondary forms of PRCA are recognized. Secondary causes of PRCA include treatment with recombinant human erythropoietin and parvovirus infection in dogs. Infection with feline leukemia virus subtype C is a cause of PRCA in cats.

Dogs with PRCA have a similar signalment and present with similar clinical signs as dogs with IMHA. As is the case with primary IMHA, cats with primary PRCA are typically younger than dogs, with an age range of 8 months to 3 years. Dogs and cats with PRCA have severe, nonregenerative anemia, whereas the platelet count and leukogram are typically normal. In contrast to IMHA, the biochemical panel and urinalysis are also usually unremarkable, with no evidence of peripheral hemolysis or inflammation. Low numbers of spherocytes are sometimes present in dogs with PRCA. The Coombs test is usually negative.

Diagnosis of PRCA is made by evaluation of a bone marrow aspirate and bone marrow core biopsy. In PRCA, erythroid precursors are rare or absent and the M/E ratio is high (>99:1). In contrast to nonregenerative IMHA, severe myelofibrosis is rare.

Treatment of PRCA is similar to IMHA. In the authors' experience, most dogs with PRCA respond to prednisolone alone; however, other drugs are commonly added to the treatment protocol because of the length of time it takes to see a response in some dogs. Adjunctive immunosuppressive medications have been used with success in dogs that have an incomplete response to prednisolone alone. These adjunctive medications include azathioprine, cyclophosphamide, cyclosporine, and mycophenolate. The time taken to achieve complete remission (2-6 months) is longer in dogs with PRCA compared with IMHA, and it is sometimes difficult to judge whether a particular protocol is failing or whether inadequate time has been allowed for the bone marrow to respond to treatment and begin to produce and release RBCs into the circulation. Sequential bone marrow evaluations should ideally be used to determine when to change the treatment protocol. A repeat bone marrow aspirate should be considered after 2 months of treatment if no improvement in the anemia is observed. Repeated transfusion of pRBCs or whole blood is necessary while waiting for a response to

TABLE 73.4

Comparison of Regenerative IMHA, Nonregenerative IMHA, and PRCA in Dogs

	RATE OF DECREASE OF HEMATOCRIT	RETICULOCYTE COUNT	COOMBS TEST (% POSITIVE)	EVIDENCE OF INFLAMMATION ON CBC	THROMBOCYTOPENIA	BONE MARROW EVALUATION
Regenerative hemolytic anemia	Fast	High	60%-80%	Severe inflammatory leukogram in most dogs	Yes (60%)	Erythroid hyperplasia, myelofibrosis in some cases
Nonregenerative anemia	Variable	Low	57%	Mild inflammation in 50% of dogs only	Rare	Erythroid hyperplasia, myelofibrosis common
PRCA	Slow	Low	Rarely positive	No	No	Erythroid hypoplasia, myelofibrosis uncommon

CBC, Complete blood count; *IMHA,* immune-mediated hemolytic anemia; *PRCA,* pure red cell aplasia.

treatment. Dogs with PRCA do not typically have evidence of systemic inflammation and are not at increased risk of TE, so anticoagulant treatment is not indicated. The prognosis for PRCA in dogs is better than for IMHA, with a mortality of less than 20%. The major cause of death is euthanasia because of the high cost of supportive care. Response to treatment and mortality rates in cats with PRCA appears to be similar to dogs, although cats respond to treatment more quickly (1.5-5 weeks) and are more likely to relapse if treatment is discontinued. Cyclophosphamide and cyclosporine have been used in cats that do not respond to glucocorticoids alone. See Chapter 80 for additional information on PRCA.

IDIOPATHIC APLASTIC ANEMIA

Aplastic anemia (aplastic pancytopenia) is characterized by cytopenia of all three marrow-derived cell lines and a hypocellular/acellular bone marrow, with the marrow elements replaced by adipose tissue. Reported causes of aplastic anemia in dogs and cats include infectious agents (*Ehrlichia* spp., parvovirus, sepsis, feline leukemia virus, feline immunodeficiency virus); hormonal (estrogens); drug associated; radiation associated; and idiopathic. By definition, the cause of idiopathic aplastic anemia is unknown; however, evidence in humans suggests that it may be immune mediated. Although an immune-mediated cause has not been established for idiopathic aplastic anemia in dogs and cats, trial therapy with prednisone, cyclosporine, or both may be considered once other causes of aplastic anemia, most notably infectious agents, have been ruled out. An immune-mediated cause for idiopathic anemia is currently difficult to prove but should be suspected in cases that respond to immunosuppressive therapy. The prognosis for idiopathic aplastic anemia is generally guarded to poor. See Chapter 86 for more information on this topic.

IMMUNE-MEDIATED THROMBOCYTOPENIA

Classification/Etiology

Immune-mediated thrombocytopenia (idiopathic thrombocytopenic purpura [ITP]) is a clinical syndrome in which thrombocytopenia results from antibody-mediated accelerated destruction of platelets. Immune-mediated thrombocytopenia is diagnosed in approximately 5% of cases of thrombocytopenia and is the most common cause of severe thrombocytopenia in dogs (Table 73.5). In primary thrombocytopenia (true autoimmune thrombocytopenia), antibodies are directed against platelet antigens, presumably because of an underlying defect in immune regulation. Antibodies directed against platelet membrane glycoproteins IIb/IIIa have been identified as target antigens in dogs, although others may be important as well. Primary ITP is a common cause of thrombocytopenia in dogs but is rare in cats. Environmental factors suspected to precipitate ITP in some cases include stress, changes in environmental temperature, hormonal changes, vaccination, and surgery. A recent retrospective study of 48 dogs with immune mediated thrombocytopenia was unable to document a temporal association between vaccination and development of thrombocytopenia.

In secondary ITP, antibody-mediated platelet destruction occurs as a result of an underlying inflammatory or neoplastic disease. Causes of secondary immune-mediated thrombocytopenia in dogs and cats are listed in Table 73.5. Immune-mediated thrombocytopenia may be a component of SLE and may occur in conjunction with IMHA (Evans syndrome).

Clinical Features

Dogs with primary ITP range in age from 8 months to 15 years, with a median age of 6 years. Females are affected twice as often as males; although any breed can be affected, the Cocker Spaniel, Poodle (all varieties), German Shepherd dog, and Old English Sheepdog are overrepresented. Common findings include sudden onset of petechial and ecchymotic hemorrhages in the skin and mucous membranes, epistaxis, hematochezia, hematemesis, easy bruising, lethargy, weakness, and anorexia. Additional findings on physical examination may include evidence of melena or hematochezia, hematuria, hyphema, retinal hemorrhage, and pale mucous membranes (Fig. 73.4). Neurologic signs and blindness may occur from bleeding into the central nervous system (CNS) and eye, respectively. Because rapid-onset, life-threatening hemorrhage is rare in dogs with ITP, anemia is usually initially mild and slowly progressive unless IMHA is concurrent. As affected dogs become moderately to severely anemic, lethargy, exercise intolerance, tachypnea, tachycardia, and a heart murmur may develop. In some dogs with ITP, clinical signs of hemorrhage are not present and thrombocytopenia is an incidental finding on a CBC performed for another reason. The platelets present in dogs with ITP are often larger and may be hemostatically more competent, which may explain why not all dogs with severe ITP bleed spontaneously. Platelet dysfunction (impaired aggregation) has been documented in normal canine platelets after incubation with serum from dogs with ITP, suggesting that antibodies or other factors in the serum impair platelet function in some dogs with ITP. Certain breeds such as the Greyhound are known to have lower platelet counts than other dogs and do not appear to have increased risk of bleeding. Macrothrombocytopenia is a disorder associated with low platelet counts and increased mean platelet volume (MPV) reported to be caused by a β1-tubulin mutation in Cavalier King Charles Spaniels; platelet counts as low as 30,000/μL have been reported in otherwise healthy dogs. Similar conditions have been reported in other breeds such as the Norfolk Terrier. Affected dogs do not have a bleeding diathesis, and treatment is not required.

Diagnosis

Because ITP can occur in association with many other disorders (see Table 73.5 and Chapter 86), a diagnosis of

TABLE 73.5

Causes of Thrombocytopenia in Dogs and Cats

CAUSE	MECHANISM	DOGS	CATS
Immune-mediated disease	Antibody mediated	Primary ITP Secondary ITP	Secondary ITP Primary ITP
Neoplasia	Antibody mediated Bone marrow suppression Myelophthisis	Lymphoma Hemangiosarcoma Leukemia Malignant histiocytosis Histiocytic sarcoma Unclassified carcinoma/sarcoma Many others	Lymphoma Leukemia Hemangiosarcoma Many others

ITP, Immune-mediated thrombocytopenia.

primary ITP can only be made by ruling out other causes of thrombocytopenia. In primary ITP, thrombocytopenia is usually severe (<50,000 platelets/μL). Dogs with ITP confirmed by the presence of platelet-bound antibody have lower platelet counts than dogs with non–immune-mediated thrombocytopenia, and dogs with primary ITP have lower platelet counts than those with secondary ITP. Platelet fragments (microthrombocytosis) may be identified on blood smears and are caused by immune injury or because larger platelets are preferentially removed from circulation. Platelet fragments are considered to be a specific but insensitive indication of immune platelet destruction. The presence of large platelets on the blood smear has been reported to support the presence of increased bone marrow production of platelets, but this is not specific for a regenerative response because bone marrow injury may also cause enlarged platelets. Paradoxically a recent study reported that MPV in dogs with primary ITP is lower than MPV in other causes of thrombocytopenia. Potential explanations for this finding may be that large platelets with a higher density of bound antibody are more likely to be destroyed; large platelets may also be preferentially removed from circulation because they are more active and adherent. The presence of platelet fragments (microparticles) may falsely decrease the MPV.

Diagnosis of ITP is confirmed by ruling out other causes of severe thrombocytopenia (see Table 73.5 and Chapter 86). Spurious thrombocytopenia from platelet clumping, other technical problems, and breed-related thrombocytopenia should be considered in dogs that do not have clinical signs of bleeding. In dogs with thrombocytopenia,

FIG 73.4
Photographs of three dogs with immune-mediated thrombocytopenia and ecchymotic hemorrhage. **(A)** Note the ecchymotic hemorrhages in the skin of the abdomen. **(B)** Note the hemorrhage into the anterior chamber of the eye. **(C)** Note petechial hemorrhage in the oral mucous membranes.

examination of a bone marrow aspirate is the most reliable method for differentiating lack of platelet production from increased platelet consumption or destruction. A bone marrow evaluation should ideally be performed early in the diagnostic workup of cases with severe thrombocytopenia (<20,000/μL) and evidence of other hematologic abnormalities, especially other cytopenias. In these cases, evaluation of bone marrow is helpful to rule out disorders such as myelophthisis, neoplasia, megakaryocytic aplasia, and aplastic anemia (see Chapter 86). Megakaryocytic aplasia is a rare disorder in which aplasia of the megakaryocytic cell line results in severe thrombocytopenia. This disease may be a primary immune-mediated disease or secondary to infections such as *Ehrlichia canis* and *Borrelia burgdorferi*. Immune-mediated megakaryocytic aplasia will look similar to primary immune-mediated thrombocytopenia on presentation but has a more severe clinical course and a poorer prognosis. Bone marrow aspiration and biopsy can be safely performed even in severely thrombocytopenic dogs because hemorrhage can be controlled with local pressure. In most dogs with ITP, normal to increased numbers of megakaryocytes are present on a bone marrow aspirate. Decreased numbers of megakaryocytes in the bone marrow have been associated with a poorer prognosis in dogs with ITP. In dogs with severe thrombocytopenia (<20,000/μL) and no evidence of other hematologic abnormalities, the results of a bone marrow examination rarely reveal nonmegakaryocytic bone marrow abnormalities or result in a definitive diagnosis, so this procedure has a relatively low diagnostic yield in this subset of patients.

The presence of a positive assay for platelet-bound antibody (see Chapter 71) is highly sensitive but not specific for a diagnosis of ITP. A diagnosis of ITP is unlikely if the test result is negative. Prior immunosuppressive therapy may result in a negative test. A positive test result is not specific for ITP because immune-mediated mechanisms are responsible for many causes of thrombocytopenia in dogs, including thrombocytopenia due to neoplasia, inflammation, drug reactions, and infectious causes. In summary the diagnostic approach to a dog with suspected ITP includes a thorough history and physical examination; a minimum database (CBC, serum biochemical profile, urinalysis); evaluation of coagulation status (platelet count, aPTT, partial thromboplastin time [PTT], FDPs); diagnostic imaging (thoracic radiographs, abdominal ultrasound); infectious disease titers (depending on geographic location); plus or minus bone marrow cytology; and histopathology. Although the majority of cases of ITP will have megakaryocytic hyperplasia, the rare case of megakaryocytic aplasia or hypoplasia can only be diagnosed by examination of the bone marrow; if a bone marrow examination is not performed at the time of diagnosis, it should definitely be performed in any dog with suspected ITP that does not respond to routine immunosuppressive treatment.

IMMUNOSUPPRESSION

Treatment

Immunosuppressive drugs are the key to treating ITP; however, because results of serology for infectious causes of immune-mediated thrombocytopenia may be delayed, concurrent treatment with doxycycline is often initiated with immunosuppressive drugs. High doses of corticosteroids block macrophage-mediated destruction of platelets and are the first line of treatment. Prednisolone or prednisone at a dose of 2-4 mg/kg/day PO is the corticosteroid of choice. Dexamethasone (0.25-0.6 mg/kg intravenous [IV] q24h) is an acceptable alternative in dogs that do not tolerate oral glucocorticoids. Treatment with one dose of vincristine (0.02 mg/kg IV) should be considered early in the course of treatment for dogs with severe ITP (platelet count < 15,000/μL) or those showing evidence of active hemorrhage. Dogs treated with vincristine have a more rapid increase in platelet count and shortened duration of hospitalization compared with untreated dogs (see Chapter 72).

A prospective study in 18 dogs with ITP demonstrated that adjunctive treatment with hIVIG shortens platelet recovery time compared with treatment with glucocorticoids alone. In another prospective study comparing platelet recovery times in dogs treated with hIVIG versus vincristine as adjunctive therapy for ITP, recovery times were similar for dogs treated with hIVIG compared with vincristine. Because hIVIG is much more expensive than vincristine, its use in dogs with ITP should be limited to patients that fail to respond to glucocorticoids and vincristine. The median platelet recovery time in dogs treated with prednisone and either vincristine or hIVIG is 3 days (range 1-10 days). Once the platelet count is in the reference range, the dose of prednisone can be slowly tapered. Because of the risk of relapse, the dose should not be tapered more rapidly than 20% to 30% per month over a 3- to 6-month period. If after 6 months the prednisone dose has been tapered to a low every-other-day dose and the disease is in remission, discontinuation of medication should be attempted.

In dogs that do not respond to glucocorticoids and vincristine, bone marrow aspiration cytology and biopsy should be performed, if not already done, to rule out megakaryocytic hypoplasia, which has a much poorer prognosis. Adjunctive immunosuppressive medications should be considered in dogs that do not have an adequate response to prednisone alone (platelet count <100,000 per μL) or when the dose of prednisone cannot be decreased low enough to manage the adverse effects of glucocorticoids. Azathioprine, cyclosporine, and mycophenolate have all been described as appropriate adjunctive immunosuppressive medications for dogs with ITP. At the authors' institution, azathioprine and mycophenolate are used most commonly as adjunctive immunosuppressive medications for dogs with ITP. In a recent study, survival of dogs on prednisolone and cyclosporine was similar to that of dogs receiving prednisolone and mycophenolate, but the cost of therapy and side effects were fewer in the dogs receiving mycophenolate. If the adjunctive immunosuppressive medication is tolerated, it should be continued at an unchanged dose while the prednisone is being tapered. Once the prednisone has been discontinued, the adjunctive medication is then tapered slowly. If a relapse occurs, lifelong therapy with prednisone and/or the adjunctive immunosuppressive medications should be continued at the lowest dose that maintains the platelet count within the reference range. A platelet count should be performed before and 2 weeks after any change in immunosuppressive therapy. In some dogs with ITP, maintaining the platelet count within the reference range is not possible without incurring severe glucocorticoid side effects. In these dogs, maintaining the platelet count greater than 100,000 per μL is acceptable because this degree of thrombocytopenia does not cause increased risk of bleeding. Splenectomy may be indicated in dogs with ITP that have chronic relapses while tapering prednisone and azathioprine therapy (see Chapter 72).

SUPPORTIVE CARE

Supportive care for dogs with ITP is critical to a positive outcome. Cage rest and exercise restriction to prevent trauma, minimizing venipuncture, and eliminating all except absolutely necessary diagnostic procedures decrease risk of hemorrhage. A balance between appropriate monitoring and minimizing blood collection is important. Patients should be frequently monitored for development of clinical signs that could be the result of new hemorrhage, especially evidence of neurologic or ophthalmologic bleeding. Patients with clinically relevant anemia and those that are actively bleeding require blood transfusion. Blood products that provide clinically significant platelet activity are fresh whole blood, platelet-rich plasma, platelet concentrate, and frozen platelet concentrate (see Chapter 82). Platelet-rich plasma or platelet concentrates are the ideal products for administration to actively bleeding patients before they become anemic; however, availability and cost limit their use in most hospitals. In the authors' experience fresh whole blood often provides enough platelets to stop an episode of clinical bleeding, although a measurable increase in the platelet count is not expected. The authors have found that the beneficial effect of a fresh whole blood transfusion typically lasts approximately 48 hours. Blood typing of the donor and crossmatching of the recipient should be performed as described in Chapter 82. Administration of gastric protectants such as H_2 blockers (e.g., famotidine) or proton pump inhibitors (e.g., omeprazole) and sucralfate may help prevent adverse effects of glucocorticoid treatment on the gastrointestinal tract, especially in dogs with gastrointestinal bleeding. Administration of desmopressin (1 μg/kg SC q24h for 3 doses) was associated with control of spontaneous bleeding and increased platelet counts in three dogs with secondary immune-mediated thrombocytopenia. This approach requires further study.

Evans syndrome (concurrent IMHA and ITP) should be treated aggressively by starting glucocorticoids and an

adjunctive immunosuppressive medication concurrently. One dose of vincristine should be considered if the thrombocytopenia is severe (platelet count < 15,000/μL). Whole blood transfusion rather than pRBCs should be administered in dogs with Evans syndrome that are actively bleeding. Dogs with Evans syndrome should not be treated with heparin because of the risk of exacerbating hemorrhage due to thrombocytopenia.

Prognosis

The prognosis for dogs with ITP is good to guarded, with a short-term survival rate of 74% to 93%. Most dogs respond to medical treatment, although relapse occurs in 9% to 58% of dogs as drug dosages are reduced. Dogs with megakaryocytic hypoplasia have a poor prognosis. The prognosis for dogs with concurrent IMHA and ITP is also poor, with reported mortality rates as high as 80%, although in one study, mortality in dogs with Evans syndrome was similar to that of dogs with IMHA alone. See Chapter 82 for more information on this topic.

FELINE IMMUNE-MEDIATED THROMBOCYTOPENIA

Most cats with thrombocytopenia have an underlying cause identified, and primary feline immune-mediated thrombocytopenia is an extremely rare disorder. The clinical presentation and response to treatment is similar to that of dogs. Spontaneous bleeding due to thrombocytopenia is less common. In the rare cases that do not respond to glucocorticoids alone, chlorambucil is recommended as an adjunctive immunosuppressant. Practitioners should be aware that platelet clumping leading to marked pseudothrombocytopenia (i.e., <30,000/μL) is more common in cats than in dogs, so a blood smear for semiquantitative platelet estimation or a platelet count performed in citrate or heparin tubes should always be evaluated in asymptomatic thrombocytopenic cats.

IMMUNE-MEDIATED NEUTROPENIA

Etiology

Immune-mediated neutropenia (IMN) is rare in dogs and cats, accounting for approximately 0.4% of cases of neutropenia (see Chapter 85). In IMN (also called *idiopathic neutropenia* or *steroid-responsive neutropenia*), serum antineutrophil IgG antibodies can be detected by flow cytometry in the serum. Antibody and complement directed against myeloid cells within the bone marrow have also been identified; however, because these tests are rarely done, the term is primarily used for dogs and cats with "idiopathic" neutropenia that responds to steroids. As with other immune-mediated disorders, IMN may be a primary disorder or may occur secondary to drug therapy, neoplasia, or other immune-mediated disorder (Table 73.6). The majority of canine cases reported in the literature have been primary. Only one case of suspected IMN in a cat has been reported.

TABLE 73.6

Causes of Severe Neutropenia in Dogs and Cats

ETIOLOGY	EXAMPLE
Infection	Parvovirus, ehrlichiosis, bacterial sepsis
Drug associated	Chemotherapeutic agents, cytotoxic drugs, vincristine, estrogens, trimethoprim/sulfadiazine, phenobarbital
Bone marrow suppression	Aplastic anemia, *Ehrlichia canis* infection, myelodysplasia, myeloid hypoplasia, leukemia
Immune mediated	Primary immune-mediated neutropenia

Clinical Features

In the largest retrospective report of 35 dogs with suspected IMN, a variety of breeds were represented and 22/35 cases were female. Affected dogs were typically young, with a median age of 5 years. Clinical signs included fever, lameness, anorexia, and lethargy, and the duration of clinical signs ranged from 3 to 180 days. Common abnormalities detected on CBC, serum biochemistry panel, and urinalysis included severe neutropenia (median 110 cells/μL), thrombocytopenia, mild anemia, hyperglobulinemia, and increased alkaline phosphatase activity. It has been proposed that up to 25% of dogs diagnosed with IMN have concurrent ITP. In the large retrospective study, 25% of dogs had thrombocytopenia, with 14% having platelet counts of <99,000/μL. Further evaluation of affected dogs with bacterial culture, infectious disease serology, and imaging did not reveal a cause for the neutropenia. Bone marrow cytology and histopathology revealed myeloid hyperplasia in two thirds of affected dogs and myeloid hypoplasia in the other one third of dogs, with maturation arrest identified in 20%.

Diagnosis and Treatment

A clinical diagnosis of IMN is made by exclusion of other causes of neutropenia. Additionally, antineutrophil antibodies can be detected by flow cytometry. Blood samples can be submitted to the University of Tennessee Diagnostic Immunology Laboratory (UTCVM Immunology Service, 2407 River Dr, Knoxville, TN 37996; immunology@utk.edu). Presumptive diagnosis may be made by rapid response to treatment with glucocorticoids at an initial dose of 2-4 mg/kg/day of oral prednisone. In dogs who do not initially respond to prednisone or those who relapse during prednisone tapering, addition of an adjunctive immunosuppressive medication is appropriate. Azathioprine and cyclosporine have been described for the treatment of IMN. Gradual withdrawal of corticosteroid therapy is conducted in a similar way as described for IMHA and ITP. Some dogs require long-term immunosuppression. Routine monitoring is important to

detect recurrence of neutropenia and monitor for infection. See Chapter 85 for more information on this topic.

POLYARTHRITIS

Etiology

Immune-mediated polyarthritis is defined as chronic synovial inflammation in two or more joints, failure to isolate an organism from the joint fluid, and a positive response to immunosuppressive therapy. Immune-mediated polyarthritis is primarily a type III immune complex hypersensitivity disorder (see Chapter 70) in which immune complexes are deposited in the synovial membrane, initiating local inflammation and release of proteolytic enzymes and cytokines, with resultant cartilage degeneration. In rheumatoid arthritis, type IV hypersensitivity may also be present with perivascular infiltration of mononuclear cells into the synovial membrane (see Chapter 70). Immune-mediated polyarthritis may be classified as primary or secondary. In secondary polyarthritis, immune complex deposition in the joints is secondary to an underlying inflammatory or neoplastic disease. Infectious agents are an important cause of secondary polyarthritis. Chronic bacterial infections may cause secondary or reactive polyarthritis, and *Anaplasma* spp., *Ehrlichia* spp., and *B. burgdorferi* also cause polyarthritis, although they cannot usually be visualized in or cultured from affected joints. Administration of live calicivirus vaccine also causes transient polyarthritis in cats.

In primary immune-mediated polyarthritis, no underlying cause of polyarthritis can be identified. This form of polyarthritis is believed to be attributable to an underlying immune system dysfunction or imbalance (true autoimmunity).

The most commonly recognized forms of polyarthritis in the dog and cat are idiopathic nonerosive polyarthritis; reactive nonerosive polyarthritis secondary to underlying inflammatory disease (gastrointestinal disease, chronic inflammation, neoplasia, or infection); and rheumatoid arthritis. A number of breed-specific syndromes are also recognized in dogs (Table 73.7). Nonerosive polyarthritis is also one of the most common clinical signs in dogs with SLE. See Chapter 69 for a more detailed discussion of the various forms of polyarthritis.

Clinical Features

The clinical hallmark of immune-mediated polyarthritis is the presence of nonseptic inflammation within the synovial membrane of two or more joints. Consequently, the diagnosis is made by analysis of synovial fluid collected from joints suspected to be affected. Common clinical signs are listed in Box 73.5. In some cases, neurologic disease is initially suspected because the animal is unable to ambulate; however, the neurologic examination in dogs with polyarthritis is normal. Many dogs and cats with polyarthritis have clinical signs of systemic illness, including fever, anorexia, and lethargy. In some cases, joint pain and swelling may be mild or not clinically detected, and fever is the only clinical sign. Polyarthritis is one of the most common causes

TABLE 73.7

Forms of Polyarthritis Recognized in Dogs and Cats

SYNDROME	CLINICAL MANIFESTATIONS	BREED PREDISPOSITION
Idiopathic nonerosive	Small distal joints	Large-breed dogs, rarely cats
Secondary nonerosive	Similar to idiopathic but clinical signs of underlying disease also present	Any breed
Breed-specific idiopathic nonerosive	Similar to idiopathic but more severe and often concurrent meningeal inflammation	Akitas, Weimaraners, Newfoundlands
Familial Shar-Pei fever	Recurrent fever, soft tissue swelling around affected joints, predisposition to systemic amyloidosis	Shar Peis
Lymphoplasmacytic synovitis	No sign of systemic illness, cranial cruciate rupture, lymphocytes and plasma cells in synovial fluid	Rottweilers, Labrador Retrievers, Newfoundlands, Staffordshire Terriers
SLE	Multisystemic immune disease	German Shepherd dogs, rarely cats
Rheumatoid arthritis	Initially similar to nonerosive form but progresses to joint crepitus, laxity, luxation, and deformity of affected joints (carpi, hocks, phalanges)	Small and toy breeds, rarely cats
Erosive polyarthritis of Greyhounds	Erosive changes in phalanges, carpi, hocks, elbow, stifles; lymphoplasmacytic inflammation in synovial fluid	Young Greyhounds

SLE, Systemic lupus erythematosus.

BOX 73.5

Clinical Signs of Polyarthritis in Dogs and Cats

Dogs

Palpable joint swelling
Distention of joint capsule
Shifting leg lameness
Unwillingness to rise
Hesitant or "walking on eggshells" gait
Joint pain
Fever
Anorexia
Lethargy
Cervical pain

Cats

Palpable joint swelling
Distention of joint capsule
Joint pain
Fever
Anorexia
Lethargy
Generalized hyperesthesia
Decreased activity/hiding

of unexplained fever in dogs. Joint pain from polyarthritis may also cause cervical pain, and concurrent meningeal inflammation has been reported in dogs with polyarthritis. Polyarthritis should therefore be considered in any dog or cat presenting with cervical pain without neurologic deficits. Cats with polyarthritis may appear to have generalized hyperesthesia and be resistant to handling. Cats may also present for decreased activity, and the owners often note that the animal has become withdrawn, often hiding in inaccessible locations. In the less-common erosive forms of polyarthritis, affected joints may become distorted or collapsed as the disease progresses, resulting in a severe gait abnormality. These changes are typically irreversible.

Diagnosis

Diagnosis of immune-mediated polyarthritis is made by documentation of inflammation within the synovial fluid, synovial membrane, or both (Fig. 73.5). Synovial fluid for cytologic evaluation and culture should be collected from at least three and preferably four joints. Synovial fluid should be collected from the more distal joints (carpus, tarsus, stifle) because these are the most commonly affected. The approach to joint fluid collection is discussed in Chapter 68. Joint fluid may be grossly turbid, with decreased viscosity and increased volume. Cytologic evaluation reveals neutrophilic and/or lymphocytic inflammation with no evidence of sepsis. Fluid should always be collected for bacterial culture and sensitivity to rule out an occult infection (especially likely if the animal has been previously treated with antibiotics). Once inflammation within multiple joints has been documented, the next step is to identify the type of polyarthritis

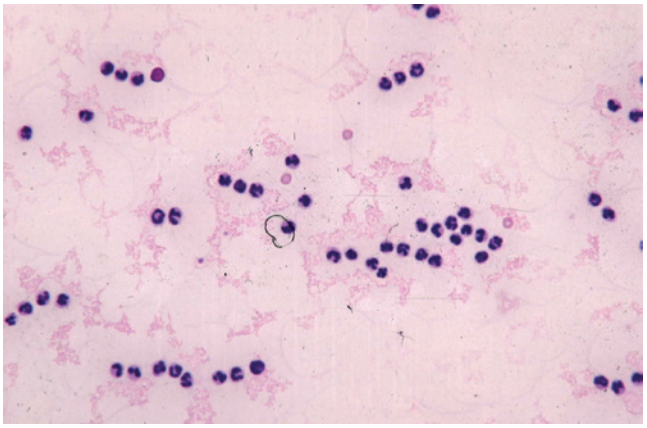

FIG 73.5
Direct smear of synovial fluid from a dog with idiopathic immune-mediated polyarthritis. Note the presence of increased numbers of nondegenerate neutrophils.

(see Table 73.7) and whether it is from a primary autoimmune disease or secondary to underlying inflammation, infection, or neoplasia. Diagnostic tests should include a CBC, biochemistry profile, urinalysis, urine culture, thoracic radiographs, abdominal ultrasound, and infectious disease titers or SNAP test *(E. canis, Anaplasma phagocytophilum, Anaplasma platys, Ehrlichia ewingii, Ehrlichia chaffeensis, B. burgdorferi)* (SNAP 4DX Plus, IDEXX, Westbrook, Maine). Because polyarthritis is usually a component of the acute form of ehrlichiosis or anaplasmosis, affected dogs may have negative SNAP results; convalescing test results (i.e., 10-14 days later) are usually positive in those patients. In some cases, blood cultures may also be indicated. In suspected erosive arthritis, radiographs of the joints are useful to assess severity of joint destruction. In dogs with suspected rheumatoid arthritis, a rheumatoid factor test should be performed (see Chapter 68). In dogs and cats with evidence of multiple organ involvement, an antinuclear antibody (ANA) titer is indicated to investigate for SLE (see Chapter 71). C-reactive protein (CRP), a positive acute phase protein and nonspecific marker of inflammation, has been shown to be increased in dogs with immune-mediated polyarthritis. CRP should not be used to diagnose IMPA but may be useful to monitor response to therapy in lieu of repeat arthrocentesis.

Treatment

Treatment of secondary immune-mediated polyarthritis depends on identification of an underlying cause. Secondary polyarthritis usually resolves with appropriate treatment and use of antiinflammatory doses of glucocorticoids or nonsteroidal antiinflammatory drugs. In areas endemic for infectious causes of polyarthritis (see previous discussion), empirical treatment with doxycycline should be instituted while awaiting the results of preliminary diagnostic testing for infectious agents. Dogs with infectious causes of polyarthritis typically show rapid clinical improvement after treatment with appropriate antibiotics.

In dogs with primary (autoimmune) polyarthritis, immunosuppressive dosages of prednisone/prednisolone are the initial treatment of choice (2-4 mg/kg/day PO). More aggressive immunosuppression is usually necessary in polyarthritis associated with SLE, in the breed-specific polyarthritis of Akitas, and in rheumatoid arthritis. Due to the fact that long-term glucocorticoid therapy can have deleterious effects on the musculoskeletal system (e.g., muscle atrophy, ligamentous laxity), several studies have investigated treating IMHA with nonglucocorticoid immunosuppression. Cyclosporine and leflunomide have both shown success in small studies as monotherapy for canine IMPA. Remission rates were similar when compared with treatment with prednisone, but clinical signs improved more slowly. Nonsteroidal antiinflammatory drugs can be added to address pain and inflammation while waiting for the onset of immune suppression when relying on nonglucocorticoid immunosuppressive medications.

Response to treatment should be monitored by assessment of clinical signs and cytologic changes within the joint fluid. Joint fluid should be cytologically normal before tapering immunosuppressive therapy. Failure to establish cytologic remission in addition to clinical remission may result in disease relapse or progressive injury to the joints that ultimately results in degenerative joint disease. Approximately 80% of dogs with idiopathic nonerosive polyarthritis treated with prednisone alone respond well to initial treatment, and half of these dogs can be weaned off therapy after 3 to 4 months. The prognosis for idiopathic nonerosive polyarthritis is good, with a mortality/euthanasia rate of less than 20%. Relapses are common, however, and some dogs require lifelong therapy. The prognosis for other forms of immune-mediated polyarthritis varies with the different forms of the disease. See Chapters 68 and 69 for more information on this topic.

SYSTEMIC LUPUS ERYTHEMATOSUS

Etiology

SLE is a multisystemic immune disorder in which antibodies to specific tissue proteins (type II hypersensitivity) and immune complex deposition (type III hypersensitivity) result in immune-mediated damage to multiple organs. Type IV mechanisms (delayed hypersensitivity) may also contribute to tissue damage. The underlying cause of SLE is still poorly understood, but an increased CD4/CD8 ratio, increased expression of a T-cell activation marker, and marked lymphopenia have been reported in dogs with active disease. These findings suggest that T-suppressor cells may be defective in dogs with SLE. The disease is heritable, although not by simple autosomal mechanisms. Breeds that are predisposed include the German Shepherd dog, Shetland Sheepdog, Collie, Beagle, and Poodle. Several colonies of dogs with a high predisposition toward SLE have been established, and an association with certain major histocompatibility complex (MHC) (dog leukocyte antigen [DLA]) types exists. Other risk factors likely include environmental factors and exposure to certain infectious agents and drugs.

Clinical Features

The disease is uncommon in dogs and rare in cats. In dogs SLE most commonly occurs in middle-aged dogs (age range, 1-11 years), and there is no sex predisposition. Because any organ system may be affected in SLE, a wide range of clinical signs is possible. The most common signs are fever (100%), lameness or joint swelling due to nonerosive polyarthritis (91%), dermatologic manifestations (60%), and signs of renal failure such as weight loss, vomiting, polyuria, and polydipsia. Proteinuria from glomerulonephritis (GN) is detected in 65% of patients. The dermatologic lesions often involve areas of skin exposed to sunlight; photosensitization is common. The dermatologic manifestations are highly variable and may include alopecia, erythema, ulceration, crusting, and hyperkeratosis. Mucocutaneous lesions may also occur. Other possible clinical manifestations of SLE are hemolytic anemia, PRCA, thrombocytopenia, leukopenia, myositis, pleuropericarditis, laryngeal paralysis, and CNS dysfunction. A similar spectrum of disease manifestations has been reported in cats with SLE, with dermatologic lesions being the most common. SLE typically has a relapsing and remitting course, and different organ systems may be involved with subsequent relapses. For example, a dog initially presenting with clinical signs predominantly relating to the neuromuscular system (polyarthritis or myositis) may later relapse with signs of IMHA or ITP.

Diagnosis

A diagnosis of SLE should be suspected when evidence of involvement of more than one organ system is present in a dog or cat with immune-mediated disease. Because of the large number of organ systems that may be involved, the diagnostic testing required varies widely from patient to patient. Diagnostic tests that should be performed in all dogs and cats with suspected SLE include a CBC, serum biochemical profile, urinalysis, urine protein quantification (provided the urine sediment is inactive), collection of synovial fluid for cytology and culture, and fundic examination. Additional tests that may be indicated include thoracic and abdominal radiographs (investigating fever); abdominal ultrasonography (investigating renal dysfunction); infectious disease titers (investigating fever, thrombocytopenia, hemolytic or nonregenerative anemia, proteinuria, or polyarthritis); Coombs test (in patients with hemolytic anemia); bone marrow aspirate and core (in cases of cytopenia); and skin or kidney biopsy if dermatologic or renal lesions are present. The extent of diagnostic testing for infectious disease will depend on the species and geographic location. For example, testing for feline leukemia virus, feline immunodeficiency virus, and feline infectious peritonitis should be considered in any cat with suspected SLE. In dogs in Europe, testing for leishmaniasis should be strongly considered because this infection can mimic SLE.

Numerous criteria for the diagnosis of SLE in dogs have been extrapolated from the literature in humans. The most commonly accepted and clinically applicable criteria are shown in Table 73.8. Measurement of serum ANA titer is a relatively sensitive test to confirm the diagnosis of SLE, although the sensitivity reported in the literature ranges from 50% to 100% (see Chapter 71). The variability in diagnostic sensitivity probably arises from variation in the diagnostic criteria for confirming the diagnosis, as well as variations in the populations of dogs tested. When used in dogs that have appropriate clinical criteria for SLE, the ANA test is an excellent test; however, false-positive results can occur in dogs and cats with other inflammatory or infectious disorders or neoplasia. ANAs are detected in 10% to 20% of dogs with seroreactivity to *Bartonella vinsonii*, *E. canis*, and *Leishmania infantum*. Dogs with seroreactivity to multiple pathogens are more likely to be ANA positive. A recent study of 120 dogs in which an ANA titer was measured emphasized the importance of appropriate patient selection for testing. In this study, measurement of an ANA titer was not a useful diagnostic test in dogs without any major clinical or clinicopathologic abnormalities suggestive of SLE. Only 1 of 47 dogs tested that did not have any major signs of SLE had immune-mediated disease, and this dog was seronegative for ANA. Ten (21%) of 47 dogs were seropositive for ANA. Conversely, 13 of 16 dogs with two major signs compatible with SLE had immune-mediated disease, and ANA was positive in 10 of these dogs. These results emphasize that the positive predictive value of a diagnostic test is lower in a population of animals in which the disease prevalence is low.

The LE test is rarely used clinically for diagnosis of SLE because of very low sensitivity. A number of other antibody tests have been investigated in groups of dogs with SLE, including antinative DNA antibodies, antiextractable nuclear antigen antibodies, and antihistone antibodies. None of these tests has been extensively evaluated in dogs, and none is currently commercially available.

Treatment

Immunosuppressive therapy for SLE begins with high doses of prednisone/prednisolone (1-2 mg/kg PO q12h). The dose is then tapered if disease remission is achieved. Addition of

TABLE 73.8

Criteria for Diagnosis of SLE

MAJOR SIGNS	MINIMUM DIAGNOSTIC TESTING NECESSARY TO SUBSTANTIATE MAJOR SIGN	MINOR SIGNS	DIAGNOSTIC TEST NEEDED TO SUBSTANTIATE
Polyarthritis	Synovial fluid analysis and culture	Fever of unknown origin	Abdominal radiographs, urine culture, no response to antibiotics
Dermatologic lesions (consistent with SLE)	Skin scraping, skin biopsy	CNS signs	CT or MRI scan, CSF tap with infectious disease serology
GN	Urine protein/creatinine ratio >2, renal biopsy useful but not required	Oral ulceration	Biopsy of lesions
Polymyositis	Increased creatine kinase or muscle biopsy demonstrating inflammation	Lymphadenopathy	Lymph node aspirate
Hemolytic anemia	Regenerative anemia, positive Coombs test, bone marrow aspirate if anemia not regenerative, negative infectious disease testing	Pericarditis	Echocardiography
Immune-mediated thrombocytopenia	Bone marrow aspirate, negative infectious disease testing	Pleuritis	Thoracic radiographs, thoracocentesis
Immune-mediated leukopenia	Bone marrow aspirate, negative infectious disease testing		

A diagnosis of SLE is considered confirmed if there are two major signs compatible with SLE and the antinuclear antibody (ANA) titer or LE test is positive or if there is one major sign and two minor signs and the ANA test or LE test is positive. A diagnosis is considered probable if there is only one major sign or two minor signs and a positive ANA titer (or LE test) or if there are two major signs and a negative ANA titer. Immune-mediated hemolytic anemia in conjunction with immune-mediated thrombocytopenia (Evans syndrome) is not considered to be a diagnosis of SLE unless there is an additional major or minor sign. Not all testing listed in the table is necessary in all cases. Specific diagnostic tests will depend on the individual case presentation and geographic location.

CNS, Central nervous system; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *GN,* glomerulonephritis; *LE,* lupus erythematosus; *MRI,* magnetic resonance imaging; *SLE,* systemic lupus erythematosus.

Modified from Marks SL, Henry CJ: CVT update: diagnosis and treatment of systemic lupus erythematosus. In Bonagura JD, ed.: *Kirk's current veterinary therapy XIII: small animal practice,* ed 13, Philadelphia, 2000, WB Saunders, p 514.

other adjunctive immunosuppressive drugs (e.g., azathioprine, cyclosporine, mycophenolate) is usually necessary to induce or maintain remission. Little information is available on the efficacy of drug protocols for treating SLE. The prognosis for dogs with SLE is guarded to poor. Relapse is common regardless of the drug protocol used, and long-term and often lifelong immunosuppressive therapy is necessary to control the disease. Relapses may involve different organ systems and clinical signs than at initial presentation (e.g., hemolytic anemia initially and polyarthritis at relapse).

GLOMERULONEPHRITIS

Etiology

Acquired GN is more common in dogs than cats and results from the presence of immune complexes within the glomerular capillary walls (see Chapter 40). Immune complexes may be circulating antigen-antibody complexes that are deposited or trapped in the glomerulus or may form in situ when circulating antibodies react with either endogenous glomerular antigens or nonglomerular antigens within the glomerular capillary wall. Soluble circulating immune complexes formed in the presence of mild antigen excess, or when both antigen and antibody are present in approximately equal quantities, may be deposited along capillary walls, resulting in a granular pattern observed on immunofluorescent or immunoperoxidase staining. Infectious and inflammatory diseases are common identifiable causes for deposition of immune complexes within the glomerulus (Box 73.6). Unfortunately, in the majority of cases of GN, an underlying cause is not identified. When immune complexes form in situ, a smooth linear pattern is observed with immunofluorescent or immunoperoxidase staining. Causes of in situ deposition of immune complexes may be either true autoimmune disease when antibodies are directed against the basement membrane of the glomerular capillaries or when antigen becomes localized in the glomerular capillary wall. For example, in dogs with heartworm disease, soluble *Dirofilaria immitis* antigens have been shown to adhere to the glomerular capillary wall by a carbohydrate-glycoprotein interaction.

Whatever the cause of immune complex deposition, the consequences are similar (see Chapter 40) and ultimately lead to severe proteinuria, systemic hypertension, renal failure, and predisposition to thromboembolism.

BOX 73.6

Infectious and Inflammatory Diseases Implicated in Pathogenesis of Glomerulonephritis in Dogs

Ehrlichiosis
Dirofilariasis
Leptospirosis
Borreliosis
Brucellosis
Endocarditis
Pyelonephritis
Prostatitis

Clinical Features

The hallmark of GN is proteinuria, which is readily detected on routine urinalysis. In many cases proteinuria is initially identified as an incidental finding, and the animal may have no obvious clinical signs or only subtle abnormalities (e.g., weight loss, lethargy, decreased appetite). In other cases, animals present with clinical signs of renal failure (e.g., anorexia, weight loss, vomiting, polyuria, polydipsia), and proteinuria is identified in the course of the evaluation. In nephrotic syndrome, which is defined as the presence of proteinuria, hypoalbuminemia, hypercholesterolemia, and either peripheral edema or ascites, the clinical signs are more severe and often rapidly progressive. Other clinical signs in dogs with GN may relate to the presence of hypertension or hypercoagulability. Hypertension may result in retinal changes and blindness, whereas TEs may occur as a result of the hypercoagulable state.

Diagnosis

A diagnosis of protein-losing nephropathy (PLN) is made by documentation of persistent proteinuria that cannot be explained by inflammation of the lower urinary tract or blood contamination of the urine. Initial dipstick estimates of urine protein should be evaluated in the light of the urine sediment and specific gravity of the urine. The severity of protein loss should then be quantitated by measurement of a protein-to-creatinine ratio, preferably on a urine sample with no inflammation or hematuria. A protein-to-creatinine ratio greater than 0.5 is abnormal; most dogs and cats with PLN have a ratio greater than 2.0. Once persistent proteinuria has been documented, further testing is necessary to determine whether evidence of tubular dysfunction also exists and to investigate for the presence of underlying infectious or inflammatory diseases implicated as causes of GN. Diagnostic tests that should be performed include a CBC, serum biochemical profile, urinalysis and urine culture, blood pressure, and radiographs of the thorax and abdomen. Ultrasonography of the kidneys is useful to investigate for evidence of pyelonephritis, nephroliths, or other underlying renal disease, but it rarely detects changes associated with GN. An occult heartworm test should be performed and serum titers submitted for the infectious diseases listed in Box 73.6. Testing for hyperadrenocorticism should be considered in dogs if the appropriate signalment and clinical signs are present. Renal biopsy should be considered if an underlying cause for the proteinuria cannot be identified. Tissue samples should be submitted for routine histopathology, electron microscopy, and immunopathology. Goals of renal biopsy should be to confirm the underlying disease process (specific type of GN, hereditary nephritis,

glomerulosclerosis, amyloidosis); determine severity of the disease; and, if possible, determine a prognosis and guide specific therapy.

Treatment

Therapy for immune-mediated GN should be directed at treating the underlying disease (if identified), decreasing protein loss in the urine, decreasing the likelihood of thromboembolism, and initiating appropriate dietary therapy and supportive care. Angiotensin-converting enzyme inhibitors (ACEIs) (e.g., enalapril 0.5-1.0 mg/kg PO q12h-24h) are currently the most effective treatment for proteinuria. Angiotensin receptor blockers (e.g., telmisartan 0.5-1.0 mg/kg PO q24) can be used in cases where proteinuria is refractory to traditional ACEI therapy. Anticoagulation is recommended to decrease the likelihood of thromboembolism in dogs with GN, especially in those with documented antithrombin deficiency (<70%). Low-dose aspirin (0.5 mg/kg PO q24h) or clopidogrel (1.0-2.0 mg/kg PO q24h) may be beneficial for their anticoagulant effects. Other supportive measures include control of hypertension (if not controlled by ACEI alone); dietary sodium restriction; a low-protein, high-quality protein diet with n-3 fatty acid supplementation; and control of ascites and edema if present. Therapy for overt renal failure may also be necessary. See Chapter 41 for further details on general management of renal failure.

In theory, immunosuppression should be useful in idiopathic immune-mediated GN; however, the use of corticosteroids may exacerbate rather than ameliorate proteinuria. Corticosteroid therapy is indicated when GN occurs as part of an immune-mediated disease known to respond to corticosteroids such as SLE. Mycophenolate is recommended as the first choice for treatment of dogs with rapidly progressive glomerular disease of an apparent immune-mediated pathogenesis (10 mg/kg PO q12). GN secondary to *Borrelia burgdorferi* may benefit from immunosuppressive therapy with mycophenolate as well. Other indications for immunosuppressive treatment are currently poorly defined in dogs.

Careful monitoring of response to therapy with monthly measurement of urine protein-to-creatinine ratio; biochemical profile (blood urea nitrogen, creatinine, electrolytes, albumin); and blood pressure is important to assess adequacy of therapy. Prognosis for GN varies depending on the severity of disease, underlying histopathology, and response to treatment. In general, the prognosis is guarded in animals that initially present with concurrent azotemia. The outcome is best in dogs with reversible causes of immune complex deposition and those that respond to diet and medications to control proteinuria. See Chapter 40 for more information on this topic.

ACQUIRED MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a disorder of neuromuscular transmission resulting from deficiency or dysfunction of the nicotinic acetylcholine receptor (AChR) on the postsynaptic membrane. Acquired MG is an autoimmune disease in which antibodies directed against the AChR interfere with the interaction between acetylcholine and its receptor. Antibodies also cross-link AChR and cause receptor internalization. Complement-mediated damage to the postsynaptic membrane also contributes to neuromuscular blockade. As with other immune-mediated diseases, MG may be a primary autoimmune disorder or may occur in association with other disorders, such as thymoma, and other neoplasms. Hypothyroidism and hypoadrenocorticism, which are also immune-mediated disorders, may also occur in association with MG. A breed predisposition exists for MG in dogs, with the Akita, various Terrier breeds, and German Shorthaired Pointer being at increased risk. Abyssinian and Somali cats also have an increased risk of MG compared with other breeds.

The most common clinical presentation of MG is generalized weakness, either with or without concurrent megaesophagus. In focal MG, in which signs of generalized weakness are absent, the most common clinical sign is regurgitation because of megaesophagus, but dysphagia, dysphonia, and cranial nerve dysfunction may also occur. An acute fulminating form of MG is characterized by severe weakness, sometimes with loss of spinal reflexes and usually in conjunction with megaesophagus and aspiration pneumonia. In cats, the two most common clinical presentations are generalized weakness without megaesophagus and generalized weakness associated with a cranial mediastinal mass (i.e., thymoma).

Definitive diagnosis of MG is by measurement of serum autoantibodies against AChR by immunoprecipitation radioimmunoassay. The assay is sensitive and specific, and false-positive results are rare. Seronegative MG occurs in only 2% of dogs with MG. Canine- and feline-specific assay systems should be used. Immunosuppressive doses of corticosteroids lower the antibody concentration and can interfere with testing. Because antibodies are not the cause of congenital MG, results of antibody testing will be negative. Other useful tests in diagnosis of MG include evaluation of the response of clinical signs to a short-acting anticholinesterase drug (edrophonium chloride [Tensilon]) and electrodiagnostic testing. Once a diagnosis of MG has been confirmed, additional testing is necessary to investigate for the presence of other underlying disorders that may lead to secondary MG or occur concurrently.

The first line of treatment for MG is oral or injectable anticholinesterase inhibitors such as neostigmine or pyridostigmine (Table 73.9). These drugs act by prolonging the action of acetylcholine at the neuromuscular junction. Immunosuppression with glucocorticoids should be considered in patients that do not respond well to anticholinesterase inhibitors alone. The advantages of the immunosuppressive effects of glucocorticoids in MG are often outweighed by adverse effects such as worsening of muscle weakness and muscle atrophy. Corticosteroids may also be problematic in animals with aspiration pneumonia, diabetes mellitus, and

TABLE 73.9

Drug Regimens and Doses Used for Routine Management of MG in Dogs and Cats

DRUG	DOGS	CATS
Pyridostigmine	0.5-3 mg/kg PO q8-12h	0.25-3 mg/kg PO q8-12h (start at low end of dose)
Neostigmine (use to bypass gastrointestinal tract in presence of severe regurgitation)	0.04 mg/kg IM q6h	0.04 mg/kg IM q6h
Prednisone	0.5 mg/kg PO q48h to 2 mg/kg/day PO	0.5 mg/kg PO q48h to 2 mg/kg/day PO
Azathioprine	2 mg/kg PO q24h Dose can be decreased to every other day to reduce risk of toxicity	Do not use in cats
Cyclosporine	5-10 mg/kg q12-24h	3-5 mg/kg PO q12h
Mycophenolate mofetil	10 mg/kg PO q12h	

MG, Myasthenia gravis.

gastrointestinal ulceration; if corticosteroids are necessary for MG, care should be used to avoid excessive doses. Therapeutic approaches include starting glucocorticoids at the low end of the immunosuppressive range (prednisone 2 mg/kg/day PO) or starting glucocorticoids at an even lower dose (prednisone 0.5 mg/kg PO every other day) and slowly increasing the dose after 2 weeks if a satisfactory response is not seen. Other immunosuppressive drugs that have been used for adjunctive management of MG include azathioprine, cyclosporine, leflunomide, and MMF. Drug regimens and doses used in the routine management of MG are given in Table 73.9. Thymectomy should be considered in dogs and cats with MG associated with thymoma; good long-term outcomes have been reported in the majority of dogs and cats following resection of thymoma. However, MG does not consistently resolve after surgery, and some cats may develop MG postoperatively.

Spontaneous remission of acquired MG is common in dogs. Clinical remission is accompanied by a decrease of the AChR antibody titer into the reference range. Repeated measurement of the AChR titer is a useful guide for identifying when clinical remission is occurring and when adjustments to therapy may be indicated. The majority of dogs that do not go into remission have underlying neoplasia. See Chapter 66 for more information on this topic.

PERIANAL FISTULA

Etiology

Perianal fistula, also called anal furunculosis, is a chronic inflammatory disease described in dogs. It is characterized by the formation of one or more ulcerations around the circumference of the anus. These ulcerations cause significant pain and can lead to hematochezia, tenesmus, fecal incontinence, and rectal stricture.

The etiology is not fully understood, but the majority of evidence supports an immune-mediated mechanism. Histologically, affected tissues are infiltrated by lymphocytes and plasma cells (primarily secreting IgA and IgG), as well as eosinophils and macrophages. The lymphocytes in these tissues are predominantly T cells, with high concentrations of IL-2 and tumor necrosis factor-α present, indicating a cell-mediated immune response. German Shepherds are the most common breed to be diagnosed with perianal fistulas, and this breed is known to have an impairment in cell-mediated immunity, further supporting an immune-mediated etiology.

Clinical Features

Middle-aged to older German Shepherds are most commonly affected by this disease, although it has been reported in other large-breed dogs (e.g., Labrador Retrievers). Clinical signs usually involve excessive grooming of the perianal region or self-mutilation. Tenesmus, hematochezia, dyschezia, and fecal incontinence can occur as well. The pain associated with this disease tends to be severe and can lead to systemic signs like lethargy, inappetance, and weight loss.

The most important part of the physical examination is the rectal examination, which may require sedation because of the painful lesions. One or more ulcerated draining tracts are typically identified in the perianal region and often a malodorous, mucopurulent discharge is noted. These draining tracts should be cleaned and probed to evaluate how far they extend, as some can extend into the rectal lumen.

Signalment, history, and physical examination typically provide enough evidence to make a diagnosis of perianal fistula. If clinical signs include diarrhea or significant constipation or change in fecal consistency, proctoscopy and/or colonoscopy should be used to evaluate for colitis or rectal abnormalities.

Treatment

Perianal fistula was previously thought to be a surgical disease, but medical management has been shown to be more successful, especially with the evidence of an underlying immune-mediated mechanism.

Cyclosporine treatment has shown the most success for treatment of perianal fistula (5.0-7.5 mg/kg PO q12), with remission rates of 60% to 100%. Cyclosporine treatment should be continued until the fistula(s) have resolved and, at this point, a taper of this medication can be considered. Perianal fistulas do commonly recur, and, even with cyclosporine, recurrence rates have been reported from 30% to 60%. In the literature, up to 30% of cases require some degree of long-term immunosuppression. Prednisone and azathioprine have also been described for treatment of perianal fistula, though their success rates were less than those of cyclosporine, but they are both less costly.

Tacrolimus, a topical immunosuppressant, has also shown success in treating perianal fistula. Caution should be taken when using tacrolimus topically as it is a potent immunosuppressant and should not be ingested. Additionally, use of tacrolimus may be cost prohibitive.

Supportive care and daily cleaning of the perianal region is very important for the treatment of perianal fistula. Stool softeners (e.g., lactulose) and pain relief are helpful for alleviating some of the most severe clinical signs, if present. Perianal fistulas have a guarded prognosis due to the fact that the disease is rarely cured, and recurrence is common. Treatment has improved with the advent of immunosuppressive therapies but still requires long-term, and costly, therapy.

IMMUNE-MEDIATED MYOSITIS

MASTICATORY MYOSITIS

Masticatory myositis is a focal myositis affecting the muscles of mastication (temporalis, masseter, digastricus). Masticatory muscles contain a unique muscle fiber type (type 2M) that differs histopathologically, immunologically, and biochemically from fiber types in limb musculature. Antibodies directed against this unique muscle fiber type are present in more than 80% of dogs with masticatory myositis. The major antigen recognized by the antibodies is masticatory myosin binding protein C, which is localized near the cell surface in masticatory muscle fibers, perhaps making it accessible as an immunogen.

Masticatory myositis is the most common form of myositis in dogs; it has not been reported in cats. Young large-breed dogs are overrepresented, and there is no breed or gender predisposition; although a syndrome of juvenile-onset masticatory myositis has been reported in Cavalier King Charles Spaniels. Clinical signs include inability to open the mouth (trismus), swelling and/or pain of the masticatory muscles, and severe muscle atrophy. In some dogs, an acute phase is recognized in which muscle swelling and pain predominate. If untreated this acute phase progresses to a chronic phase characterized by severe muscle atrophy and trismus. In many affected dogs, the acute phase is not recognized, and the first recognized clinical signs are severe muscle atrophy and inability to open the jaws. In severe cases the jaws can only be separated by a few centimeters, and the affected animal is unable to eat or drink. Less severely affected dogs may be able to use the tongue to lick up fluids or liquidized food. Other clinical signs include fever, depression, weight loss, dysphagia, dysphonia, and exophthalmos from swelling of the pterygoid muscles.

Diagnosis of masticatory myositis is made on the basis of characteristic clinical signs and presence of antibodies against type 2M fibers. This test is positive in greater than 80% of cases and has a specificity approaching 100%. Muscle biopsy is useful to determine the degree of fibrosis and likelihood of return to normal function with treatment, as well as to confirm the diagnosis in dogs in which the antibody test is negative. Multifocal infiltration with lymphocytes, histiocytes, and macrophages, with or without eosinophils, is found on histopathology. Moderate to severe muscle fiber atrophy, fibrosis, and sometimes complete loss of muscle fibers with replacement by connective tissue may be present. Other adjunctive tests that may be useful include measurement of creatine kinase, which is increased in some but not all dogs with masticatory myositis, and electrodiagnostic testing, which allows identification of the most severely affected muscles. Typical electrodiagnostic findings include presence of fibrillation potentials and positive sharp waves.

Treatment of masticatory myositis relies on the use of immunosuppressive doses of corticosteroids (prednisone 2-4 mg/kg PO q24h). Under no circumstances should force be used to open the jaws because fracture or luxation of the temporomandibular joint may result. Once resolution of clinical signs is achieved with corticosteroids, the dose should then be slowly tapered over several months. Disease activity and progression should be monitored by clinical signs (especially range of motion) and measurement of creatine kinase (if elevated at presentation). Long-term treatment with prednisone or an additional immunosuppressive drug such as azathioprine is required in dogs that relapse when prednisone is tapered. Tapering of prednisone too quickly increases the chance of relapse. The goal of therapy is a return to normal muscle function and a normal quality of life. In many cases, especially in the presence of severe fibrotic changes, muscle atrophy persists and is exacerbated by glucocorticoid therapy. Prognosis for return to function is good in most cases. See Chapter 67 for more information on this topic.

POLYMYOSITIS

Polymyositis is characterized by multifocal or diffuse infiltration of skeletal muscle by lymphocytes and negative serology for infectious disease. Although most cases are primary autoimmune, paraneoplastic immune-mediated myositis may be associated with malignancies such as lymphoma (particularly in Boxers), bronchogenic carcinoma, myeloid leukemia, tonsillar carcinomas in dogs, and thymoma in cats. The specific inciting antigen is not known, although the

mechanism of injury is believed to be mediated by cytotoxic T cells (type IV delayed-type hypersensitivity).

Polymyositis is uncommon in dogs and rare in cats. The disease is most common in young large-breed dogs, and Boxers, Newfoundlands, and Vizslas are overrepresented. Clinical signs include generalized weakness that worsens with exercise and a characteristic stiff gait. Cervical ventriflexion may occur, especially in cats. Most animals show pain on palpation of affected muscles, particularly the proximal muscle groups. Dysphagia, generalized muscle atrophy, dysphonia, tongue atrophy, and fever may also be present. Megaesophagus has been reported in 15% of cases. Some dogs with polymyositis also have signs of masticatory myositis, and these dogs are positive for antibodies against type 2M fibers. Polymyositis may also occur in SLE and in canine polyarthritis/myositis syndrome.

Diagnosis of polymyositis is based on characteristic clinical signs, presence of an elevated creatine kinase level (more commonly increased in polymyositis than in masticatory myositis), electrophysiologic testing abnormalities consistent with myositis, serology for infectious causes of myositis (Box 73.7), and muscle biopsy. It is important to rule out infectious causes of myositis in dogs with polymyositis (see Box 73.7). Muscle biopsies in dogs with polymyositis have similar changes to those described for dogs with masticatory myositis; however, the presence of eosinophils in dogs with polymyositis increases the index of suspicion for an infectious cause. A diagnosis of polymyositis has been made in dogs, particularly Boxers, that months later are diagnosed with lymphoma. Potential reasons for this association include paraneoplastic syndrome, malignant transformation of lymphocytes, or misdiagnosis of polymyositis. A complete evaluation for neoplasia should be part of the diagnostic evaluation of dogs with polymyositis, especially if there is lymphadenopathy.

Treatment of polymyositis is similar to treatment of masticatory myositis. Prognosis for return to function is good in most cases. See Chapter 67 for more information on this topic.

DERMATOMYOSITIS

Dermatomyositis is an uncommon immune-mediated disorder affecting the skin, skeletal muscle, and vasculature of Collies and Shetland Sheepdogs. The disorder has an autosomal-dominant pattern of inheritance, and the pathogenesis is suspected to be immune complex deposition, although the target antigen is not known.

In dermatomyositis, cutaneous lesions develop between 2 and 4 months of age, with signs of myositis developing later. The temporalis muscle is most commonly affected, and clinical signs include dysphagia and muscle atrophy. More severe signs may include megaesophagus and generalized polymyositis with diffuse muscle atrophy, especially of the distal appendicular muscles. Diagnosis of dermatomyositis is based on the classic signalment (age, breed, presence of cutaneous signs). The creatine kinase activity is usually only minimally increased. Definitive diagnosis is based on skin and muscle biopsy.

Treatment of dermatomyositis relies on symptomatic care of cutaneous lesions and immunosuppression. The protocol for corticosteroid therapy is similar to that used for polymyositis, but prolonged therapy is necessary and relapses are common. Additional recommendations include avoidance of exposure to sunlight, neutering of sexually intact dogs, and vitamin E supplementation. Pentoxifylline has also been shown to be of some benefit in affected dogs (see Chapter 72). The prognosis depends on severity, being good for mild cases and poor for severely affected dogs. See Chapter 67 for more information on dermatomyositis.

BOX 73.7

Infectious Causes of Polymyositis in Dogs

Toxoplasma gondii
Neospora caninum
Borrelia burgdorferi
Clostridial myositis
Ehrlichia canis
Rickettsia rickettsii
Hepatozoon americanum
Leishmania infantum
Leptospirosis (icterohaemorrhagiae)

Drugs Used to Treat Immune-Mediated Diseases of Dogs and Cats and General Dosing Guidelines

GENERIC NAME (TRADE NAME)	PURPOSE	RECOMMENDED DOSE	
		DOG	CAT
Aspirin	Prevent thromboembolic complications of IMHA or PLN	0.5 mg/kg PO q24h	NA
Azathioprine (Imuran)	Immunosuppression	2 mg/kg/day initially. Dose can be decreased to every other day to reduce risk of toxicity	Not recommended
Chlorambucil (Leukeran)	Immunosuppression	0.1-0.2 mg/kg PO q24h initially, then taper to every other day once a response is seen	0.1-0.2 mg/kg PO q24h initially, then q24-72h
Clopidogrel (Plavix)	Prevent thromboembolic complications of IMHA or PLN	1-2 mg/kg PO q24h	1-2 mg/kg PO q24h, or 18.75 mg/cat PO q24h
Cyclosporine (Atopica, Neoral)	Immunosuppression	5-10 mg/kg PO q12-24h Recommend using only Atopica® due to concerns for bioavailability of other products Lower doses of 1-2.5 mg/kg q12h if in conjunction with ketoconazole	3-5 mg/kg PO q12h Recommend using only Atopica® due to concerns for bioavailability of other products
Dexamethasone	Immunosuppression	0.25-0.5 mg/kg PO q24h	0.25-1 mg/kg PO q24h
Enalapril (Enacard)	Treatment of proteinuria	0.5-1.0 mg/kg q12-24h	NA
Famotidine (Pepcid)	Treatment and prevention of gastric ulceration	0.5-mg/kg PO/IM/SC q12-24h	0.5 mg/kg PO/IM/SC q12-24h
Heparin (unfractionated)	Anticoagulation	200-300 U q6h as initial dose. Adjust on basis of measurement of aPTT or anti-Xa activity	NA
hIVIG	Immunosuppression	0.25-1.5 g/kg as an IV infusion over 6-12 hours (one dose only)	NA
Leflunomide (Arava)	Immunosuppression	2-4 mg/kg PO q24h	NA
Mycophenolate mofetil (CellCept)	Immunosuppression	10 mg/kg q12h	10 mg/kg q12h
Neostigmine (Prostigmin)	Anticholinesterase inhibitor	0.04 mg/kg IM q6h	0.04 mg/kg IM q6h

CHAPTER 74

Cytology

GENERAL CONSIDERATIONS

Evaluation of a cytologic specimen obtained by fine-needle aspiration (FNA) in small animals with suspected neoplastic lesions often yields information that can be used to make a definitive diagnosis, thereby circumventing the immediate need to perform a surgical biopsy. At the authors' hospitals, almost every mass or enlarged organ is evaluated cytologically before a surgical biopsy is performed because the risks and costs associated with FNA are considerably lower than those associated with surgical biopsy. Frequently, a definitive cytologic diagnosis allows the clinician to institute a specific treatment (i.e., multicentric lymphoma treated with chemotherapy) and spares the patient the need for a surgical biopsy.

In a study of 269 cytologic specimens from dogs, cats, horses, and other animal species, the cytologic diagnosis completely agreed with the histopathologic diagnosis in approximately 40% of cases and partially agreed in 18% of the cases; complete agreement ranged from 33% to 66%, depending on the lesion and location, and was highest for skin/subcutaneous lesions and for neoplastic lesions (Cohen et al., 2003). Interestingly, in the author's experience, the cytologic and histopathologic diagnoses agree in more than 70% of the cases. When a clinician with experience on cytology evaluates a cytologic specimen, the bias experienced after obtaining a history and performing a physical examination is beneficial in the cognitive processing of information. For example, being fairly certain that a dog has multicentric lymphoma (on the basis of the history and physical examination) makes specimen interpretation easier.

Clinically applicable diagnostic cytologic techniques are summarized in this chapter, with emphasis on sample collection and the cursory interpretation of the specimens. Although some clinicians can obtain sufficient diagnostic information, a board-certified veterinary clinical pathologist should always evaluate a cytologic specimen before any prognostic or therapeutic decisions are made.

FINE-NEEDLE ASPIRATION

In FNA, a single cell suspension is obtained using a small-gauge needle (i.e., 23-25 gauge) of the appropriate length for the desired target organ or mass; this needle can be coupled to a 6-, 12-, or 20-mL sterile, dry plastic syringe, but frequently this is not necessary; the size of the syringe is based on how comfortable it is for the operator. Although the technique is still referred to as "FNA," in most cases no aspiration is performed with the syringe (see later). Tissues easily accessible using this technique include the skin and subcutis, deep and superficial lymph nodes, spleen, liver, kidneys, lungs, thyroid, prostate, and intracavitary masses (e.g., mediastinal mass).

If the clinician is sampling superficial masses, sterile preparation of the site is not necessary. However, clipping and sterile surgical preparation should always be done when aspirating organs or masses within body cavities. Once the mass or organ has been identified by palpation or radiography, it should be manually isolated, if feasible; manual isolation is not necessary when performing ultrasonography-, computed tomography (CT)–, or fluoroscopy-guided FNAs. A needle, either by itself or coupled to a syringe, is then introduced into the mass or organ; if the "needle-alone" technique is used, the needle is reinserted into the tissue/mass several times; this can be referred to as the "woodpecker technique" due to the repeated puncturing motion that mimics a woodpecker at work. This allows the clinician to core out small samples, which will be completely contained within the hub of the needle. Once a sample has been obtained, a clean disposable syringe is loaded with air and coupled to the needle. The specimen is then gently expelled onto slides, as described later in this chapter. If the needle-syringe technique is used, suction is applied to the syringe three or four times. If the size of the mass or lesion allows it, the needle is then redirected two or three times and the procedure is repeated. Before withdrawing the needle and

syringe, the clinician should release the suction to avoid aspirating blood that would contaminate the sample or air that would make the sample irretrievable from the barrel of the syringe. The needle is then detached, air is aspirated into the syringe, the needle is recoupled, and the sample is expelled onto a glass slide. It is important to do this in a gentle fashion; loading the whole syringe with air and expelling the sample abruptly will result in "aerosolization" of the sample. In that case, each droplet will dry instantly upon touching the glass slide; because the cells will not spread out, they will be difficult to identify. Instead, the clinician should apply gentle pressure in the plunger of the syringe until a minuscule droplet appears in the tip of the syringe, and then touch the glass slide with it and make the smears immediately. In most cases, no material is seen in the syringe, but the amount of cells present within the hub of the needle is usually adequate to obtain four to eight good-quality smears.

Rarely, tumor cells can be transplanted along the needle tract. This occurs more frequently in dogs with transitional cell carcinomas of the urinary bladder or prostate but has also been documented in dogs with primary pulmonary, intestinal, and prostatic adenocarcinomas. Hence, if a dog has a potentially resectable apical bladder mass, we do not do percutaneous FNAs but rather transurethral, ultrasonography-guided catheter aspirates.

Superficial ulcerated masses can easily be sampled by scraping their surface with a sterile scalpel blade, wooden tongue depressor, or gauze. Smears are then made by either touching a glass slide onto the ulcerated lesion (see the following section, Impression Smears) or further scraping the surface with a tongue depressor and transferring the material thus obtained onto the slide. "Pull" smears made using two glass slides are preferable over "push" smears. Once the smears have been made, they are air-dried and stained using any of the techniques described in the next section.

IMPRESSION SMEARS

Impression smears of surgical specimens or open lesions are commonly used in practice. When making impression smears from surgical specimens, the clinician first gently blots the tissue onto a gauze pad or paper towel to remove any blood or debris and then gently grasps it with forceps from one end. When making impression smears of endoscopic gastrointestinal or urinary bladder lesions, it is important, if possible, to orient the sample in such fashion that the deep aspect of the lesion is used for the smears; this avoids nondiagnostic samples obtained by applying the surface (i.e., epithelium) onto the glass slides. Touch imprints are made on a glass slide by gently touching the slide with the tissue specimen. We make two or three rows of impressions along the slide and then stain them. It is advisable to submit a different tissue specimen for histopathologic evaluation. IMPORTANT: Do not make the smears next to the formalin vial or the fumes will irreversibly damage the cells!

STAINING OF CYTOLOGIC SPECIMENS

Several staining techniques are practical for in-office use, including rapid Romanowsky (e.g., Diff-Quik; various manufacturers) and new methylene blue (NMB) stains. Most commercial laboratories use Romanowsky stains, such as Wright or Giemsa.

These staining techniques have some differences. Romanowsky stains are slightly more time consuming, but they produce better cellular detail and offer worse contrast between nucleus and cytoplasm; moreover, the smears can be permanently archived. NMB, on the other hand, is a quick stain (it takes literally seconds to stain a smear), but it is not permanent, which means that slides cannot be saved for consultation; moreover, cellular details are not as sharp as they are on Romanowsky-stained smears. In addition, because nuclear DNA and RNA stain extremely well with this technique, most cells appear to be malignant. We routinely use Diff-Quik stain on the clinic floor. The main difference between rapid hematologic stains (e.g., Diff-Quik) and Giemsa or Wright-Giemsa stains is that, in a small proportion of canine mast cell tumors (MCTs), the former do not stain the granules. It was suggested that the lack of staining of MCT granules with Diff-Quik was due to the relatively short fixation recommended by the manufacturer and that more prolonged fixation (e.g., minutes) would result in the granules staining. A study revealed that longer fixation does not improve the staining of mast cell granules (Jackson et al., 2013). In addition, rapid hematologic stains do not stain granules in some large granular lymphocytes (LGLs) or in eosinophils from Greyhounds, other sighthounds, and some Golden Retrievers.

INTERPRETATION OF CYTOLOGIC SPECIMENS

Although the clinician should strive to evaluate cytologic specimens proficiently, a board-certified veterinary clinical pathologist should always make the ultimate cytologic diagnosis. The following are guidelines for cytologic interpretation. As a general rule, cytologic specimens are classified into one of the following six categories: normal tissue, hyperplasia/dysplasia (difficult to diagnose), inflammation, neoplasia, cystic lesions (contains fluid of various types), or mixed cellular infiltrate. The latter is usually either a malignant tumor with ongoing inflammation (e.g., squamous cell carcinoma with neutrophilic inflammation) or a hyperplastic tissue secondary to chronic inflammation (e.g., chronic cystitis with epithelial hyperplasia/dysplasia). Cytology of cystic lesions is not discussed in this chapter.

NORMAL TISSUES

Epithelial Tissues

Most epithelial cells, particularly those of the glandular or secretory epithelium, tend to cling together (i.e., they have

desmosomes), forming clusters or sheets. Individual cells are easily identifiable and are round or polygonal; both nucleus and cytoplasm are well differentiated (i.e., the nucleus is small and has heavily clumped chromatin). Most cells in Romanowsky-stained smears have blue cytoplasm and round to oval nuclei.

Mesenchymal Tissues

Cells from mesenchymal tissues (e.g., fibroblasts, fibrocytes, chondroblasts) are difficult to obtain in routine FNA material or tissue scrapings because they are usually surrounded by intercellular matrix. Mesenchymal cells are typically spindle-shaped, polygonal, or oval and have irregular nuclei; cytoplasmic boundaries are usually indistinct, and cell clumps are seen rarely.

Hematopoietic Tissues

A detailed morphologic description of circulating blood cells is beyond the scope of this chapter. Briefly, however, most cells from hemolymphatic organs are round, individual cells (with no tendency to clump); they have a blue cytoplasm on Romanowsky-stained smears and a variable nuclear size. Most nuclei are round or kidney-shaped. Tissue such as bone marrow has cells in different stages of development (i.e., from blasts to well-differentiated circulating cells).

HYPERPLASTIC PROCESSES

Hyperplasia commonly results in enlargement of glandular organs and lymphoid structures. The cytologic features of epithelial and lymphoid hyperplasia differ; lymphoid hyperplasia is discussed later in this chapter. Cytologically, epithelial hyperplastic changes may be difficult to recognize because they can mimic either normal or neoplastic tissues (i.e., the morphologic features are in between those of normal and neoplastic tissues). Care should be taken when evaluating specimens from organs such as enlarged prostates or thickened urinary bladders because the high degree of hyperplasia and dysplasia frequently suggests malignancy; abundance of inflammatory cells suggests that the changes are due to chronic irritation (i.e., hyperplasia).

INFLAMMATORY PROCESSES

Most inflammatory reactions are characterized cytologically by the presence of inflammatory cells and debris in the smear. The type of cell present depends on the etiologic agent (e.g., neutrophils in pyogenic infections, eosinophils in parasitic or allergic reactions) and the duration of the inflammatory process (i.e., acute processes are usually characterized by a predominance of granulocytes, whereas macrophages and lymphocytes predominate in chronic processes). BEWARE: Chronic inflammation frequently results in hyperplasia of fibroblasts and angioblasts, which can mimic a malignant mesenchymal tumor (sarcoma) (Fig. 74.1). The following pathogens are frequently identified in cytologic specimens: *Histoplasma, Blastomyces, Sporothrix, Cryptococcus, Coccidioides, Aspergillus/Penicillium, Toxoplasma, Leishmania,*

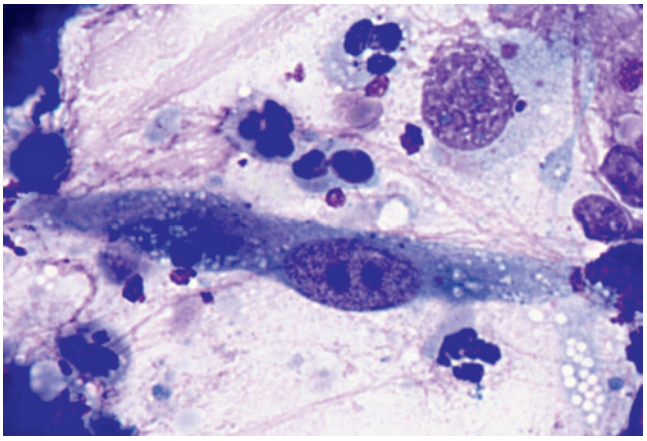

FIG 74.1
Photomicrograph of a fine-needle aspirate of a vaccine reaction in a 2-year-old, castrated, mixed-breed dog; note spindle cell with cytologic features of malignancy (likely a fibroblast) (×1000).

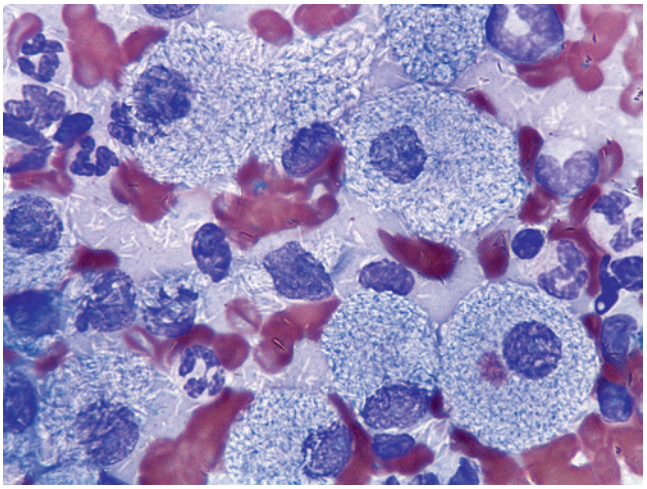

FIG 74.2
Photomicrograph of a splenic fine-needle aspirate of a 2-year-old Schnauzer with tuberculosis. The rod-shaped nonstaining inclusions in the macrophages are *Mycobacterium avium* (×1000).

Mycobacterium, other rickettsial agents, bacteria, and *Demodex* (Fig. 74.2).

MALIGNANT CELLS

The cells that make up most normal organs and tissues (with the exception of bone marrow precursors) are well differentiated, in that most of them are similar in size and shape, they have a normal nuclear-to-cytoplasmic (N:C) ratio, the nuclei usually have condensed chromatin and no nucleoli, and the cytoplasm may exhibit features of differentiation (e.g., keratin formation in squamous epithelium).

Malignant cells have one or more of the following features (Box 74.1): a high N:C ratio (i.e., larger nucleus and smaller cytoplasm); a delicate chromatin pattern; nucleoli (usually multiple); anisokaryosis (i.e., cells have nuclei of different

sizes); nuclear molding (i.e., a nucleus in a multinucleated cell is compressed by a neighboring one); morphologic homogeneity (i.e., all cells look alike); pleomorphism (i.e., cells in different stages of development); vacuolization (primarily in malignant epithelial tumors); anisocytosis (i.e., cells are of different sizes); multinucleated giant cells; and, occasionally, phagocytic activity. Another feature of malignancy is heterotopia (i.e., the presence of a given cell type where it is not found anatomically); for example, relevant numbers of epithelial cells can appear in a lymph node only as a consequence of metastasis from a carcinoma. In addition, malignant cells tend to be morphologically different from the progenitor cell population (see Box 74.1). On the basis of the predominant cytologic features, malignancies can be classified as carcinomas (epithelial), sarcomas (mesenchymal), or round (or discrete) cell tumors (Fig. 74.3).

BOX 74.1

Cytologic Characteristics of Malignant Neoplasms

Large nuclei
Fine chromatin pattern
One or more nucleoli
Anisokaryosis
Nuclear molding
Monomorphism
Pleomorphism
Anisocytosis
Cytoplasmic vacuolization
Cytoplasmic basophilia
Multinucleated giant cells
Phagocytosis
Heterotopia

Carcinomas

Most carcinomas are composed of round or polygonal cells that tend to cling together, forming clusters or large sheets. Their cytoplasms are usually deep blue, and in most adenocarcinomas vacuolization is evident. Cytoplasmic boundaries are difficult to recognize, and the cells resemble a mass of protoplasm rather than a sheet of individual cells. In squamous cell carcinomas, cells usually appear individualized, can be irregular or polygonal, have a deep blue cytoplasm (with an occasional eosinophilic fringe), and have large vacuoles; neoplastic cells in squamous cell carcinomas frequently exhibit leukophagia. Nuclei in both adenocarcinomas and squamous cell carcinomas are large, with a fine chromatin pattern and evident nucleoli (Fig. 74.4).

Sarcomas

The cytologic features of sarcomas vary according to the histologic type. As a general rule, sarcomas do not exfoliate well; however, hemangiopericytomas and other spindle cell sarcomas exfoliate so well that the clinician's first impression on evaluating a smear may be that of a carcinoma (i.e., the cells appear to be in groups) (Fig. 74.5). Most mesenchymal tumors have spindle-shaped, polygonal, polyhedral, or oval cells, with a reddish-blue to dark blue cytoplasm and irregularly shaped nuclei. Most cells are individualized, although clumping may occur (particularly in impression smears or when a large-bore needle is used for sample collection). The

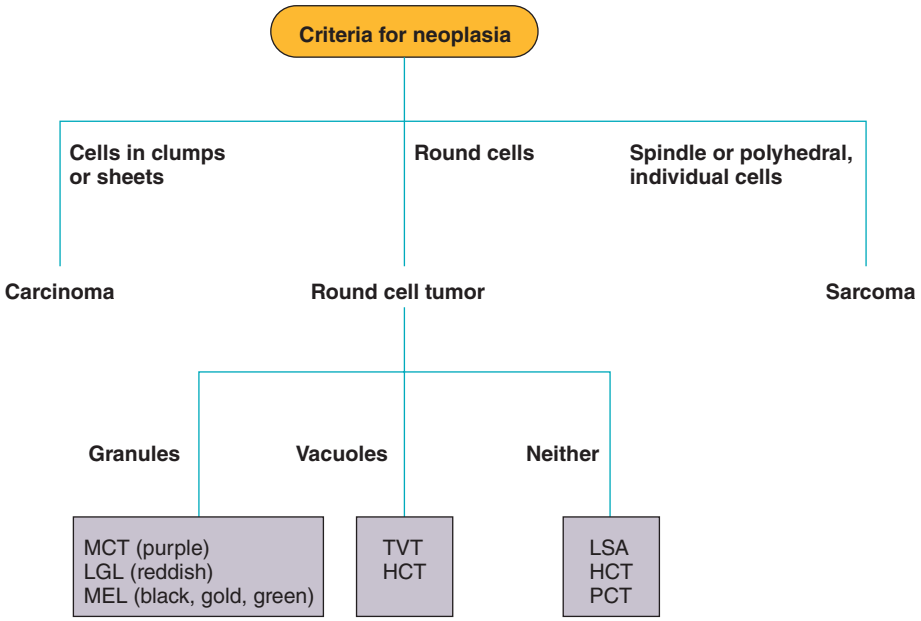

FIG 74.3

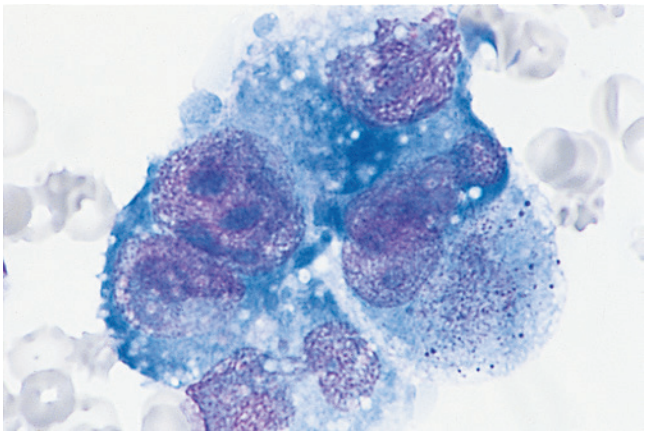

FIG 74.4
Photomicrograph of pleural fluid from an older female Irish Setter showing a cluster of deeply basophilic cells, with vacuolated cytoplasm, anisocytosis, anisokaryosis, and prominent nucleoli. The cytologic diagnosis was carcinomatosis (i.e., metastatic adenocarcinoma of unknown origin) (×1000).

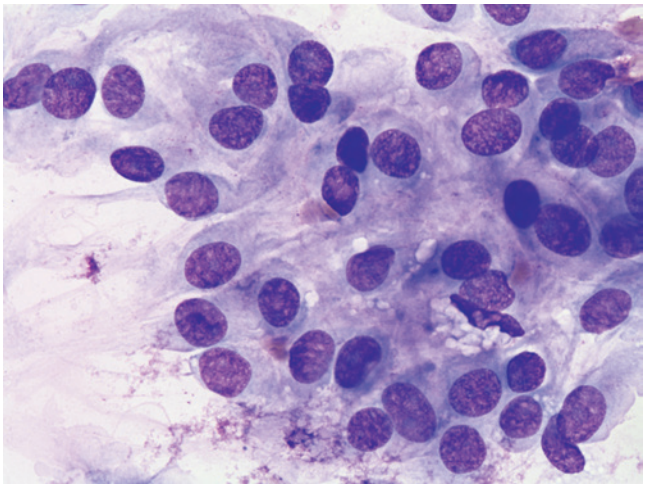

FIG 74.5
Photomicrograph of a fine-needle aspirate of a firm, lobulated, subcutaneous mass in an older dog. The cells appear to be in clusters, but closer inspection reveals that it is an aggregate of spindle cells consistent with spindle cell sarcoma. The clinical diagnosis was hemangiopericytoma (×500).

cells in most sarcomas tend to form "tails," and the nuclei protrude from the cytoplasm (Fig. 74.6). The presence of spindle-shaped or polygonal cells with a vacuolated blue-gray cytoplasm is highly suggestive of hemangiosarcoma (Fig. 74.7). Intercellular matrix (e.g., osteoid, chondroid) is found occasionally in osteosarcomas (OSAs) and chondrosarcomas (CSAs), respectively; in these two tumor types the cells are usually round or ovoid. The preferred approach to lytic bone lesions in our clinics is to perform an FNA (see Chapter 81); the probability of obtaining a definitive diagnosis is higher than when doing a bone biopsy, with significantly lower cost,

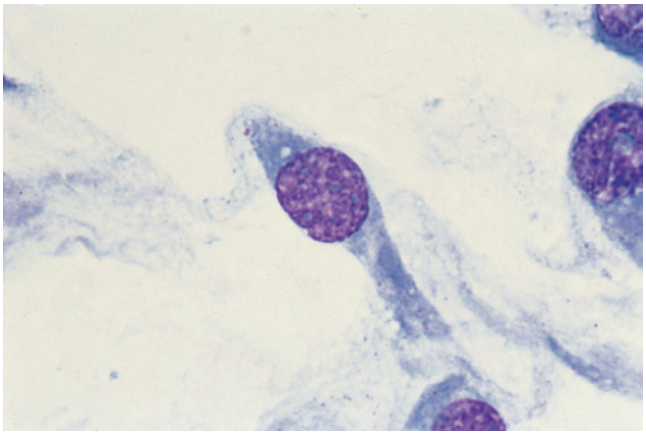

FIG 74.6
Photomicrograph of a fine-needle aspirate of a firm, lobulated, subcutaneous mass in an older dog. The cells are spindle-shaped, have "tails," and do not associate with other cells. The nuclei appear to be protruding from the cytoplasm (×1000). The cytologic diagnosis is spindle cell sarcoma. Histopathologic findings were diagnostic for fibrosarcoma.

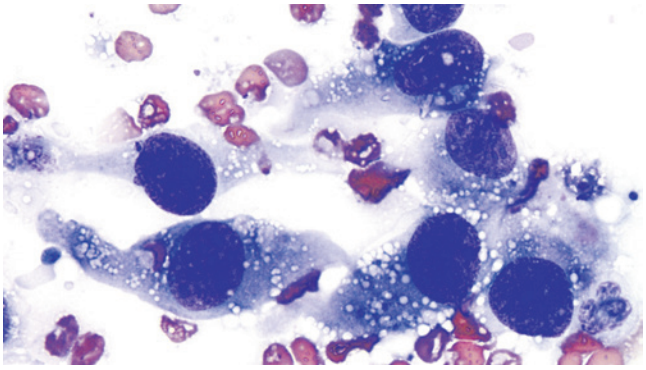

FIG 74.7
Photomicrograph of one of several purple cutaneous nodules in a dog with a primary splenic hemangiosarcoma. The polygonal to spindle-shaped cells with blue-gray cytoplasm and vacuoles are characteristic of hemangiosarcoma (the lesions were metastases from the primary tumor) (×1000). (Courtesy Dr. S. M. Nguyen.)

and minimal discomfort to the patient. Multinucleated giant cells are common in some sarcomas in cats.

As discussed earlier, because sarcoma cells usually do not exfoliate well, aspirates may yield false-negative results. Therefore, if a mass is clinically suspected to be a sarcoma and FNA findings are negative, a core biopsy specimen of the mass should be obtained because it is likely to be a sarcoma.

Round (Discrete) Cell Tumors

Tumors composed of a homogeneous population of round (or discrete) cells are referred to as *round* (or *discrete*) *cell tumors* (RCTs). These tumors are common in dogs and cats and include lymphoma (LSA), histiocytoma (HCT), MCT, transmissible venereal tumor (TVT), plasma cell tumor

(PCT), and malignant melanoma (MM); as discussed earlier, OSAs and CSAs can be composed of round cells, so they are included within this category. RCTs are easily diagnosed on the basis of cytology; the presence or absence of cytoplasmic granules or vacuoles and the location of the nucleus aid in the classification of RCTs (see Fig. 74.3).

Cells in MCTs (Fig. 74.8), LGL LSAs (Fig. 74.9), and MMs (Fig. 74.10) usually have cytoplasmic granules; cells in neuroendocrine tumors (i.e., thyroid carcinomas) can also have granules. When hematologic stains are used, the granules are purple in MCTs; red in LGL LSAs; and black, green, brown, or yellow in MMs. Lymphomas (Fig. 74.11), HCTs (Fig. 74.12), PCTs, and TVTs do not have cytoplasmic granules. Cells in OSA occasionally have small to large pink cytoplasmic granules (osteoid) (see Fig. 81.6 in Chapter 81). Cytoplasmic vacuoles are common in TVTs and HCTs.

Briefly, large cell LSAs are characterized by a monomorphic population of individual poorly differentiated round cells with large nuclei, a coarse chromatin pattern, and one or two nucleoli; occasional cells may be vacuolated (see Fig. 74.11). Small and intermediate cell lymphomas may be difficult to recognize cytologically because the neoplastic population may resemble normal lymphocytes. Cells in HCTs are similar to those in lymphomas except that the chromatin pattern is fine rather than coarse, they have more abundant cytoplasm, and they are frequently vacuolated (see Fig.

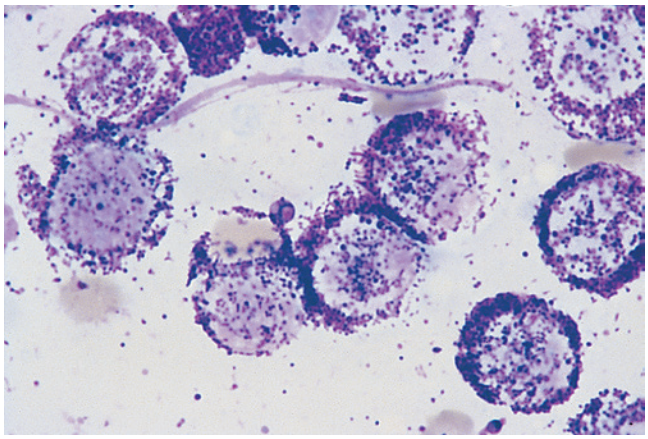

FIG 74.8
Photomicrograph of a fine-needle aspirate from a subcutaneous mass in an older Boxer with multiple dermoepidermal and subcutaneous masses and marked multifocal lymphadenopathy. Note the monomorphic population of round cells containing purple granules. The cytologic diagnosis was mast cell tumor (×1000).

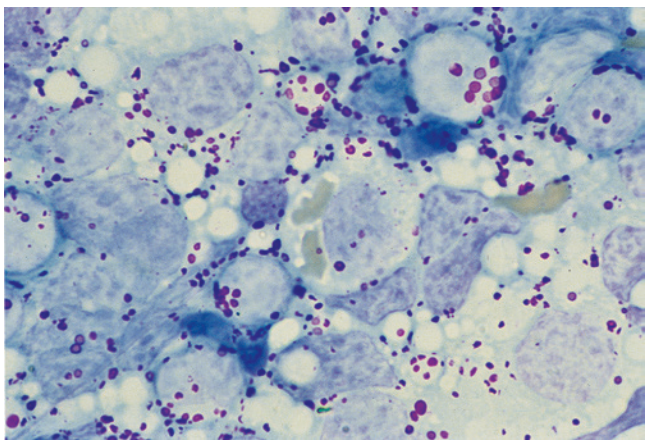

FIG 74.9
Photomicrograph of an impression smear from a mesenteric lymph node in an old cat evaluated because of vomiting and diarrhea. Note the large round cells with red, large cytoplasmic granules. The diagnosis was lymphoma of large granular lymphocytes (×1000).

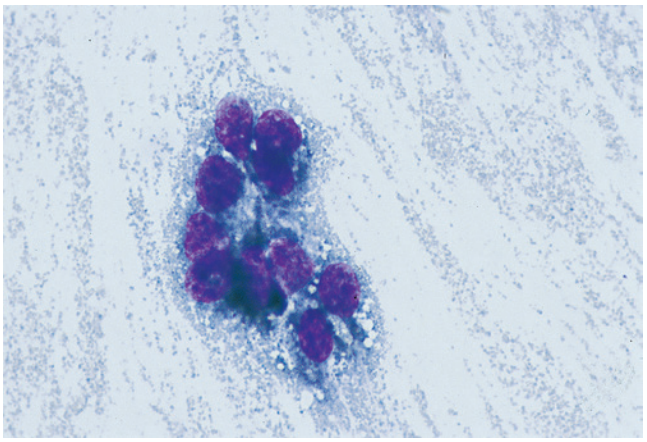

FIG 74.10
Photomicrograph of a fine-needle aspirate from a mass in the oral cavity of a 10-year-old Schnauzer. Note the dark, fine granules in the cytoplasm. The diagnosis was melanoma (×400).

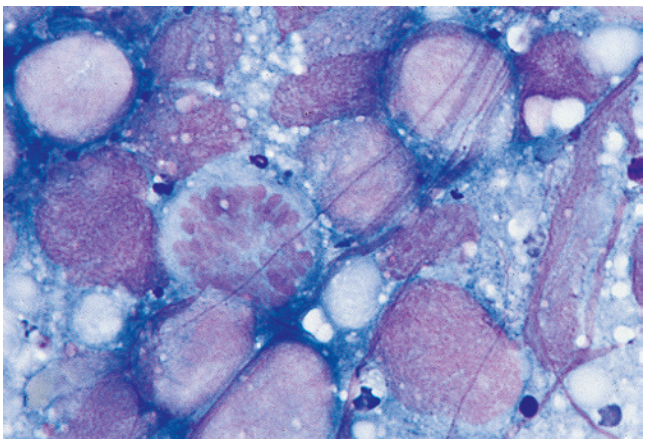

FIG 74.11
Photomicrograph of a fine-needle aspirate from the kidney of a middle-aged Boxer with bilateral renomegaly. Note the monomorphic population of round cells, with large nuclei, prominent nucleoli, and no cytoplasmic granules or vacuoles. A mitotic figure is seen in the center. The cytologic diagnosis was lymphoma (×1000).

74.12). Because inflammation is an important component of HCTs, inflammatory cells (i.e., neutrophils, lymphocytes) are commonly found in these tumors. MCTs are distinctive in that the cytoplasm of the neoplastic cells contains purple (metachromatic) granules, which can be so numerous as to obscure the nuclear features; eosinophils are also a common feature in these tumors. Mast cell granules may be absent in poorly differentiated tumors or in tumors stained with Diff-Quik (Fig. 74.13).

LYMPH NODES

Cytologic evaluation of lymph node aspirates is commonly done in practice. In our clinics, a cytologic diagnosis is obtained in approximately 90% of dogs and 60% to 70% of cats with lymphadenopathy. If the cytologic findings of an enlarged lymph node are inconclusive, the node should be surgically excised and submitted for histopathologic evaluation.

When evaluating cytologic specimens prepared from lymph node aspirates or impression smears, the clinician should keep in mind that these organs react to a variety of stimuli following a distinct pattern. In general, four cytologic patterns are recognized: normal lymph node, reactive or hyperplastic lymphadenopathy, lymphadenitis, and neoplasia.

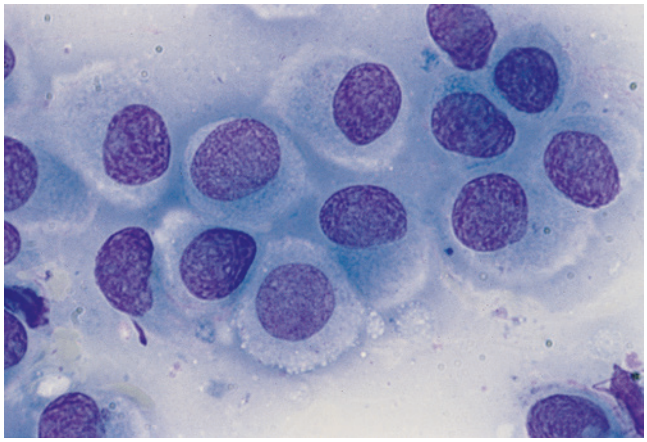

FIG 74.12
Photomicrograph of a fine-needle aspirate from a small, round, dermoepidermal mass in the head of a 1-year-old dog. Note the large round cells with abundant clear cytoplasm and fine chromatin pattern. The diagnosis was histiocytoma (×1000).

Normal Lymph Node

Cytologic specimens from normal nodes are composed predominantly (≈70% to 90%) of small lymphocytes; thus they are monomorphic. These cells are approximately 7 to 10 µm in diameter (1-1.5 times the diameter of a red blood cell and smaller than a neutrophil) and have a dense chromatin pattern and no nucleoli. The remaining cells are macrophages, lymphoblasts, plasma cells, and other immune cells.

Reactive or Hyperplastic Lymphadenopathy

Lymphoid tissues reacting to different antigenic stimuli (e.g., bacterial, fungal, neoplastic) are cytologically similar in that the cell population is composed of a mixture of small, intermediate, and large lymphocytes; lymphoblasts; plasma cells; and macrophages (Fig. 74.14). In addition, other cell types may be present, depending on the specific agent (e.g., eosinophils in parasitic or allergic reactions). The first impression when evaluating a reactive or hyperplastic node cytologically is that of a heterogeneous population of cells. The presence of cells in different stages of development indicates that the lymphoid tissue is undergoing polyclonal expansion (i.e.,

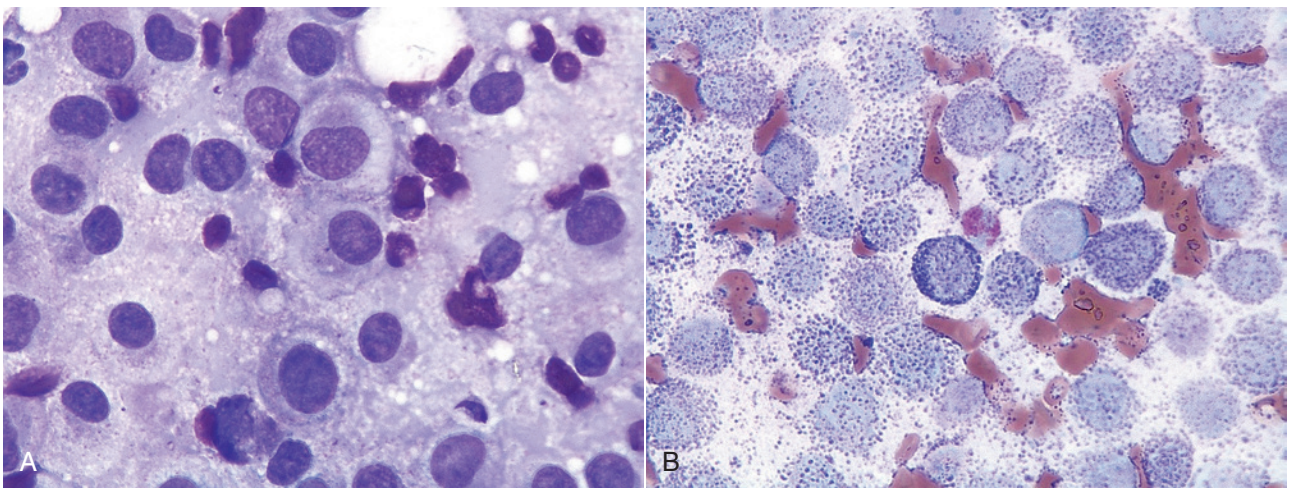

FIG 74.13
Photomicrograph of a fine-needle aspirate of a dermoepidermal mass in a Shar-Pei. Diff-Quik stain **(A)** does not reveal cytoplasmic granules; counterstaining the same slide with Wright-Giemsa **(B)** reveals typical cytoplasmic granules of mast cells. Final diagnosis: mast cell tumor (×1000).

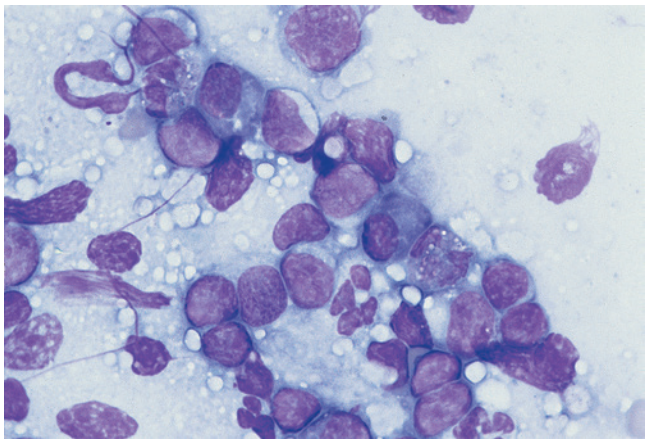

FIG 74.14
Photomicrograph of a fine-needle aspirate from a reactive lymph node in a dog. Note the heterogeneous population of lymphoid cells (small, medium, and large), plasma cells, and macrophages (×1000).

response to multiple antigens). Reactive lymph nodes in cats frequently lack plasma cells but contain large numbers of lymphoblasts, so they may be difficult to distinguish from lymphoma.

Lymphadenitis

Inflammatory processes affecting the lymph nodes produce cytologic changes similar to the ones seen in reactive lymphadenopathy, although there is a profusion of bloodborne inflammatory cells (e.g., neutrophils in suppurative infections) and degenerative changes (e.g., pyknosis, karyorrhexis) in most cell lines. The etiologic agents may be visualized.

Neoplasia

Neoplastic cells can appear in a lymph node either as a result of lymphatic or vascular dissemination (i.e., metastasis from a primary tumor draining into the lymph node) or as a primary process affecting these structures (i.e., lymphomas). Cytologic features of metastatic lymph node lesions consist of a reactive pattern and the presence of neoplastic cells; in advanced metastatic lesions it is frequently difficult to identify normal lymphoid cells because the node architecture is effaced by the tumor. The morphology of the metastatic cells depends on the primary tumor type. As discussed in the preceding section, lymphomas are characterized by a monomorphous population of large, immature lymphoid cells; these cells are usually large and have an abnormally low N:C ratio, coarse chromatin, and evident nucleoli. As discussed previously, small cell lymphomas are difficult to diagnose cytologically.

Decision Making in Lymph Node Cytologic Evaluation

From our perspective, the easiest approach to classifying a lymph node cytologically is to first determine whether the cell population is homogeneous (i.e., >70% of the cells resemble one another) or heterogeneous. If the population is homogeneous, it is either a normal node (i.e., the cells are normal lymphocytes) or it is neoplastic (lymphoma or metastasis); if it is heterogeneous, it is either reactive, inflammatory, or early neoplastic.

CHAPTER 75

Principles of Cancer Treatment

GENERAL CONSIDERATIONS

Cancer remains the main cause of death in dogs and possibly cats as well. In some dog breeds, including Golden Retrievers and retired racing Greyhounds, 60% of the deaths are due to cancer. For years, a variety of therapeutic modalities have been used in dogs and cats with cancer (Box 75.1). However, until 2 or 3 decades ago, surgery remained the mainstay of cancer treatment for pets. Today, nonresectable or metastatic malignancies can be treated with varied degrees of success, using some of the modalities listed in Box 75.1.

When evaluating a pet with cancer, the clinician should bear in mind that, in most cases, if given the option, owners will elect to treat their pets. Although euthanasia still remains a reasonable choice in some small animals with cancer, every effort should be made to investigate treatment options. More than 60% of human cancer patients have a life expectancy of at least 5 years, and a sizable portion of cancer patients, including those with high-grade lymphoma, some acute leukemias, and some carcinomas and sarcomas, are cured. Although such numbers are not available for dogs and cats with cancer, in the author's clinic, the proportion of cancer patients evaluated for 2- to 5-year follow-up is increasing.

A major philosophical difference when treating cancer in humans versus pets is the concept of cure. Although cure is a laudable goal in people, the price paid in terms of toxicity (and the expenses) makes it difficult to justify such an approach in pets. In the author's clinic, quality of life (QOL) drives the treatments of choice (see later).

Depending on the tumor type, biologic behavior, and clinical stage, a clinician may recommend one or more of the treatments listed in Box 75.1. However, in addition to tumor-related factors, many other factors influence the selection of the optimal treatment for a pet with cancer. These include patient-related, family-related, and treatment-related factors.

PATIENT-RELATED FACTORS

It is important to remember that the best treatment for a particular tumor does not necessarily constitute the best treatment for a particular patient or the best treatment from the family's perspective. The most important patient-related factor to be considered is the animal's general health and activity or performance status (Table 75.1). For example, a cat or dog with markedly diminished activity and severe constitutional signs (i.e., poor performance status) may not be a good candidate for aggressive chemotherapy or the repeated anesthetic episodes required for external beam radiotherapy. Age by itself is not a factor that should be considered when discussing cancer therapy with the owner; the author believes that "age is not a disease." For example, a 14-year-old dog in excellent health is a better candidate for chemotherapy or radiotherapy than a 9-year-old dog with chronic kidney disease or decompensated congestive heart failure. Patient-related factors should be addressed before instituting specific cancer treatment (e.g., correct the azotemia, improve the nutritional status with enteral feeding).

FAMILY-RELATED FACTORS

Family-related factors play an important role in determining the treatment to be implemented in pets with cancer. Every clinician is aware of the impact of the owner-pet bond; this bond is so important that it often dictates the treatment approach used in a given patient. For example, owners may be so apprehensive about having their dog with lymphoma receive chemotherapy that they refuse such treatment; thus the optimal treatment is denied to this patient.

In the author's experience, pet owners should be made a part of the medical team. If they are assigned tasks to perform at home such as measuring the tumor to monitor the response to treatment, taking their pet's temperature daily, and monitoring their pet's performance status, they

Unconventional (alternative)

TABLE 75.1

Modified Karnovsky's Performance Score for Dogs and Cats

GRADE	ACTIVITY/PERFORMANCE
0—Normal	Fully active, able to perform at predisease level
1—Restricted	Restricted activity from predisease level but able to function as an acceptable pet
2—Compromised	Severely restricted activity level; ambulatory only to the point of eating but consistently defecating and urinating in acceptable areas
3—Disabled	Completely disabled; must be force-fed; unable to confine urinations and defecations to acceptable areas
4—Dead	

Modified from Beveridge IB, Sobin LH: International histological classification of tumors of domestic animals, *Bull World Health Organ* 53:145, 1976.

assume responsibility for the fate of their pet and are therefore quite cooperative. The clinician should always be available to answer concerned pet owners' questions and guide them through difficult times. We always discuss all potential treatment options with the owner, emphasizing the pros and cons of each (e.g., beneficial effects and potential for adverse effects of treatment A versus B versus C versus no treatment). The authors also clearly explain what will (or should) happen during the pet's treatment, including a thorough description of the potential adverse effects by presenting different case scenarios (i.e., best-case scenario versus worst-case scenario). By observing these easy steps, the clinician usually cultivates realistic expectations on the part of the owner and ensures that the interaction with the owner is smooth and uneventful. As discussed in later paragraphs, the option of euthanasia may also be addressed at this time, either as an immediate option or eventual option if treatments fail.

Another important owner-related factor is finances. In general, the treatment of a cat or dog with disseminated or metastatic malignancy is relatively expensive, as judged by the average clinician. However, it is the owner who should determine whether this treatment is indeed too costly. It is relatively common for an owner to spend $5000 to $10,000 to treat a dog or cat with surgery, radiotherapy, or chemotherapy. In contrast, a common orthopedic surgical procedure (e.g., tibial plateau leveling osteotomy) costs $2500 to $4000. Therefore all treatment options should be described and offered to the pet family, regardless of their cost. Occasionally, families spend what most people consider to be exorbitant amounts of money to treat their pet with cancer or other diseases. As numerous owners explain, this is their family member, and it is their money!

TREATMENT-RELATED FACTORS

Several important treatment-related factors must be considered when planning cancer therapy. First, the specific indication should be considered. Surgery and radiotherapy are treatments aimed at eradicating a locally invasive tumor with a low metastatic potential (and potentially curing the patient), although they can be used palliatively in dogs or cats with extensive (bulky) disease or in those with metastatic disease. On the other hand, chemotherapy usually does not constitute a curative treatment, although palliation of advanced disease can easily be accomplished for several tumor types. Immunotherapy (the use of biologic response modifiers) also constitutes an adjuvant or palliative approach (i.e., tumors are rarely cured by immunotherapy alone). Recently, targeted molecular therapy has been aimed at blocking specific pathways present in neoplastic but not normal cells. In general, it is best to use an aggressive treatment when the tumor is first detected (because this is when the chances of eradicating every single tumor cell are the highest) rather than to wait until the tumor is in an advanced stage (i.e., to "treat big when the disease is small"). Removing "only" 99% of the tumor cells will not lead to a cure.

In some cases, the highest success rates are obtained by combining two or more treatment modalities. For example, the combination of surgery and chemotherapy has resulted in a significant prolongation of disease-free survival in dogs with osteosarcoma of the appendicular skeleton (4 months with surgery alone versus 12-18 months with surgery and chemotherapy).

The complications and adverse effects of different treatments also constitute treatment-related factors to be considered when planning therapy. Complications of chemotherapy are addressed in Chapter 77. As discussed later, the patient's QOL should be maintained (or improved) during cancer treatment. At the authors' clinic, this is the priority in a cat

or dog with cancer receiving treatment. Our motto is "The patient should feel better with the treatment than with the disease."

Cancer treatment can be either palliative or curative. Given the current paucity of information regarding specific tumor types and treatments, these two approaches sometimes overlap (i.e., a treatment initially thought to be palliative may result in cure, or vice versa). As discussed earlier, every effort should be made to eradicate every single cancer cell in the body (i.e., obtain a cure) shortly after diagnosis, if "the price is right" (i.e., the cost and toxicity are not excessive and the patient's QOL will be good). This means taking immediate action rather than adopting a wait-and-see attitude. With few exceptions, malignant tumors do not regress spontaneously. In other words, by delaying treatment in a patient with confirmed malignancy, the clinician is only increasing the probability that the tumor will disseminate locally or systemically, thereby decreasing the likelihood of a cure. As discussed earlier, surgery and radiotherapy are potentially curative treatments, whereas chemotherapy and immunotherapy are usually palliative.

If a cure cannot be obtained, the two main goals of treatment used to be to induce remission while achieving a good QOL. The term *remission* refers to shrinkage of the tumor. When objectively evaluating the effects of therapy, the clinician should measure the tumor or tumors and assess the response using the criteria given in Box 75.2. Recently, veterinary oncologists adopted RECIST (response evaluation criteria in solid tumors), commonly used in people (Eisenhauer et al., 2009), and have adapted them to lymphomas (Vail et al., 2010).

A newer approach that may become more and more common as data are generated is the use of novel, low-dose treatment (metronomic chemotherapy) to "keep the tumor at bay" while preserving the patient's QOL. Most cancer patients are not symptomatic when they first present; hence keeping the tumor as-is while preserving the QOL is a viable (and attractive) option for an elder patient. Metronomic chemotherapy is discussed in detail in Chapter 76.

The QOL issue is important in small animal oncology (see preceding paragraphs). In a QOL survey of owners whose pets had undergone chemotherapy for nonresectable or metastatic malignancy conducted in the author's clinic, more than 80% responded that the QOL of their pets was maintained or improved during treatment. If a good QOL cannot be maintained (i.e., the patient's performance status deteriorates), the treatment should be modified or discontinued. Several useful QOL evaluation tools have been developed for use in pets with cancer (Lynch et al., 2011).

Palliative treatments are acceptable for small animals with cancer and to their owners. For example, even though chemotherapy rarely achieves a cure for most tumors, veterinarians can provide a cat or dog (and its family) with a prolonged, good-quality survival. Although these patients ultimately die of tumor-related causes, the owners are usually pleased to have a pet that is asymptomatic for a longer period of time. Another common example that is frequently forgotten is palliative surgery (e.g., in dogs or cats with ulcerated mammary carcinomas and small pulmonary metastases, euthanasia is frequently recommended because the primary lesion is draining and thus does not allow for the patient to be a "pet," as in sitting on the owners' lap or on the furniture). Clinicians now know that performing a mastectomy or lumpectomy (even if the owners decline chemotherapy) is likely to result in several months of good-quality survival, until the metastatic lesions finally cause respiratory compromise. In another example, dogs with apocrine gland

BOX 75.2

Criteria Used to Assess Tumor Response to Treatment in Pets With Lymphoma

Complete Response (CR):

Target lesions: Disappearance of all evidence of disease. All lymph nodes must be nonpathologic in size in the judgment of the evaluator(s).

Nontarget lesions: Any pathologic lymph nodes must be considered to have returned to normal size in the judgment of the evaluator(s), and no new sites of disease should be observed. Spleen and liver should be considered within normal limits by the evaluator(s).

Partial Response (PR):

Target lesions: At least a 30% decrease in the mean sum LD of target lesions taking as reference the baseline mean sum LD. Nontarget lesions: Not applicable.*

Progressive Disease (PD):

Target lesions: At least a 20% increase in the mean sum LD taking as reference the smallest mean sum LD at baseline or during follow-up (this includes the baseline mean sum LD if that is the smallest on study). The LD of at least one of the target lesions must demonstrate an absolute increase of at least 5 mm compared with its nadir for PD to be defined. For target lesions less than 10 mm at nadir, an increase in LD of any single previously identified target lesion to 15 mm or greater.

Nontarget lesions: unequivocal progression of existing nontarget lesions, in the judgment of the evaluator. (*Note:* The appearance of one or more new lesions is also considered progression.)

Stable Disease (SD):

Target lesions: Neither sufficient decrease to qualify for PR nor sufficient increase to qualify for PD. Nontarget lesions: Not applicable.*

LD, Longest diameter.
This is a modification of the RECIST criteria (Eisenhauer et al., 2009) and can be applied to pets with solid tumors.
Modified from Vail DM, et al.: Response evaluation criteria for peripheral nodal lymphoma in dogs (v1.0)—a Veterinary Cooperative Oncology Group (VCOG) consensus document, *Vet Comp Oncol* 8:28, 2010.
*Nontarget lesions will be assessed as "CR," "PD," "non-CR/non-PD," or, if there are no nontarget lesions, "None."

TABLE 75.2

Analgesics Commonly Used in Dogs With Cancer

DRUG	BRAND	DOSAGE
Nonsteroidal Antiinflammatories		
Carprofen	Rimadyl	1-2 mg/kg PO q12h
Deracoxib	Deramaxx	1 mg/kg PO q24h
Meloxicam	Metacam	0.1-0.2 mg/kg PO q24h
Firocoxib	Previcox	5 mg/kg PO q24h
Piroxicam	Feldene	0.3 mg/kg PO q24-48h
Opioids		
Tramadol	Ultram	1-4 mg/kg PO q8-12h
Buprenorphine	Buprenex	0.01-0.03 mg/kg PO or SC q8-12h

adenocarcinoma of the anal sac and metastatic sublumbar lymphadenopathy benefit from surgical resection of the primary tumor and/or metastatic nodes, even if adjuvant chemotherapy is not being considered. Removal of the primary mass improves clinical signs of straining in these patients; because the colon and rectum are compressed ventrally by the enlarged lymph nodes and laterally or dorsally by the primary mass, the removal of one of the lesions easily alleviates clinical signs. Sublumbar (or iliac) lymphadenectomy and chemotherapy in dogs with metastatic apocrine gland adenocarcinoma of the anal sacs in the author's clinic result in survival times of 1 to 3 years.

Needless to say, the clinician should also address the presence of paraneoplastic syndromes even if specific antineoplastic therapy is not contemplated. For example, treatment of hypercalcemia of malignancy with bisphosphonates causes remarkable improvement in the QOL of affected dogs. The authors' clinics have used pamidronate (at a dosage of 1-2 mg/kg, administered intravenously q6-8 weeks) or zoledronate (at a dosage of 0.1 mg/kg administered intravenously q3-8 weeks) in dogs with tumor-associated hypercalcemia in which the neoplastic disease could not be surgically removed or that had failed chemotherapy. In most dogs, serum calcium concentrations were maintained within normal limits, and no appreciable toxicity was detected. In addition, pain control has recently contributed markedly to improving the QOL in small animal cancer patients. Opioids, nonsteroidal antiinflammatories, and other drugs have resulted in excellent clinical results (Table 75.2).

Finally, most cats and dogs with cancer are treated using a team approach. This team includes the pet, family, medical oncologist, oncologic nurse, surgical oncologist, radiotherapist, clinical pathologist, and anatomic pathologist. A smooth interaction among the members of the team results in marked benefits for the pet and its owner.

CHAPTER 76

Practical Chemotherapy

CELL AND TUMOR KINETICS

To better understand the effects of chemotherapy on both neoplastic and normal tissues, it is necessary to have a basic understanding of cell biology and tumor kinetics. As a general rule, the biologic characteristics of neoplastic cells are similar to those of their normal counterparts; however, neoplastic cells usually do not undergo terminal differentiation or apoptosis (programmed cell death). Therefore the cell cycles of normal and neoplastic cells are similar.

Recently, Hanahan and Weinberg reviewed the original hallmarks of cancer (Hanahan and Weinberg, 2011); these hallmarks provide a framework to better understand cancer cell biology. They include sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis. Underlying these hallmarks is genome instability, which generates the genetic diversity that expedites their acquisition, and inflammation, which fosters multiple hallmark functions. Research in the past few years added two emerging hallmarks—reprogramming of energy metabolism and evading immune destruction. In addition to cancer cells, tumors exhibit another dimension of complexity: they contain a repertoire of recruited, ostensibly normal cells that contribute to the acquisition of hallmark traits by creating the "tumor microenvironment." Recognition of the widespread applicability of these concepts will increasingly affect the development of new means to treat human cancer.

The mammalian cell cycle has two apparent phases: mitosis and the resting phase. The resting phase is actually composed of four phases (Fig. 76.1):

1. Synthesis phase (S): DNA is synthesized.
2. Gap 1 phase (G1): RNA and the enzymes needed for DNA production are synthesized.
3. Gap 2 phase (G2): The mitotic spindle apparatus forms.
4. Gap 0 phase (G0): This is the true resting phase.

The mitosis phase is termed the *M phase.*

Oncogenes serve as checkpoints between different phases of the cell cycle.

Several terms must be defined before chemotherapy is discussed. The *mitotic index* (MI) refers to the proportion of cells in the process of mitosis within a tumor; the pathologist often provides information about the mitotic activity in a given tumor sample, reported as the MI or as the number of mitoses per high-power field (or per 10 high-power fields). The *growth fraction* (GF) refers to the proportion of proliferating cells within a tumor and cannot be quantified in a patient. The *doubling time* (DT) refers to the time it takes for a tumor to double in size; it can be calculated by using sequential measurements of the tumor volume [$V = p/6' (\text{mean diameter})^3$] seen on imaging or determined by direct palpation. In dogs the DT ranges from 2 days (for metastatic osteosarcoma) to 24 days (for metastatic melanoma), whereas in humans it ranges from 29 days (for malignant lymphomas) to 83 days (for metastases from breast cancer). The DT depends on the time spent in mitosis, the cell cycle duration, the GF, and the cell loss resulting from death or metastasis; as a general rule, the shorter the DT, the more aggressive the tumor (and the more likely to respond to conventional chemotherapy). Given our knowledge of tumor kinetics, by the time a pulmonary metastatic nodule is visualized on radiographs, it consists of more than 200 million cells, weighs less than 150 mg, and the cells have already divided 25 to 35 times. A 1-cm palpable nodule has 10^9 tumor cells (1 trillion) and weighs 1 g (Fig. 76.2). As a general rule, most nonneoplastic tissues (with the exception of bone marrow stem cells and intestinal crypt epithelium) have a low GF, low MI, and prolonged DT, whereas most neoplastic tissues have a high MI, high GF, and short DT (at least initially; see Fig. 76.2).

Surgical cytoreduction (debulking) of a tumor that has reached a plateau of growth decreases the total number of cells, thus increasing the MI and GF and shortening the DT through yet unknown mechanisms (Fig. 76.3). In theory, this renders the neoplasm more susceptible to chemotherapy or radiotherapy.

BASIC PRINCIPLES OF CHEMOTHERAPY

Chemotherapeutic agents predominantly kill cells in rapidly dividing tissues. To exploit the tumoricidal effect of different chemotherapeutic drugs, it is common practice to combine three or more drugs to treat a given malignancy. These drugs are selected on the basis of the following principles: Each should be active against the given tumor type, act by a different mechanism of action, and not have superimposed toxicities. It is customary to name the protocol after the first letters of each drug in the combination (e.g., *VAC* for *v*incristine, doxorubicin [or *A*driamycin], and *c*yclophosphamide). As a general rule, combination chemotherapy results in more sustained remissions and prolonged survival times than single-agent chemotherapy; this is thought to result from the fact that multiagent chemotherapy delays (or even prevents) the development of drug-resistant clones. In some cases, single-agent chemotherapy is as effective as

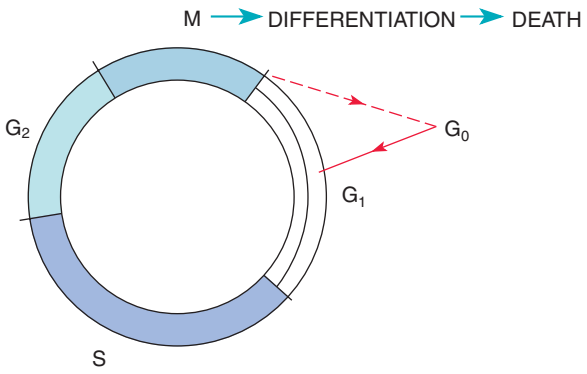

FIG 76.1
Mammalian cell cycle. Cells in mitosis *(M)* can differentiate and subsequently die (the rule in normal tissues); they can also progress to G_0 (true resting phase), from which they can be recruited by a variety of stimuli (see text). G_1, Gap 1; *S,* DNA synthesis; G_2, gap 2.

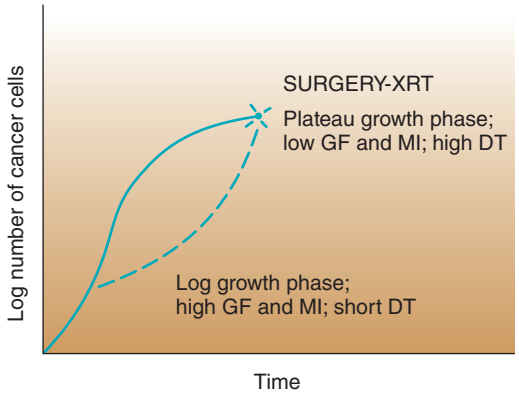

FIG 76.3
The effect of surgical or radiotherapeutic intervention on tumor kinetics. After cytoreduction, cells are recruited from the G_0 phase and the tumor returns to the exponential phase. *DT,* Doubling time; *GF,* growth factor; *MI,* mitotic index; *XRT,* radiation therapy. FIG 76.2
Tumor (cell) kinetics. Additional information on tumor kinetics can be found in the text. *GF,* Growth fraction; *MI,* mitotic index; *DT,* doubling time. (From Couto CG: Principles of chemotherapy. In *Proceedings of the tenth annual Kal Kan symposium for the treatment of small animal diseases: oncology,* Kalkan Foods, Inc, 1986, Vernon, Calif, p 37.)

multiagent chemotherapy and is associated with significantly less toxicity. Examples include using carboplatin or doxorubicin as single agents in dogs with osteosarcoma; chlorambucil alone for dogs with chronic lymphocytic leukemia; and vincristine alone in dogs with transmissible venereal tumors.

Another general concept of chemotherapy from the standpoint of cell kinetics is that it is more effective in a relatively small tumor than in a large one, even though the inherent sensitivity to the drug or drugs may be the same. As can be seen in Fig. 76.3, a small tumor (e.g., 10^6 cells) is more likely (e.g., 10^{11} cells) to be completely eradicated by the drugs than a larger one because the smaller mass has a higher MI, a higher GF, and consequently a shorter DT than the larger mass (i.e., more cells are actively dividing at a given time).

Despite continued controversy, the doses of most chemotherapeutic agents are still determined on a body surface area (BSA) basis; exceptions are listed later. This appears to provide a more constant metabolic parameter for comparing doses across species. It can be calculated using the following formula:

$$\frac{\text{Weight (g)}^{2/3} \times \text{K (constant)}}{10^4} = \text{m}^2 \text{ BSA}$$

The constant is 10.1 for the dog and 10 for the cat. Table 76.1 is a conversion table of weight (in kilograms) to BSA (in squared meters) for dogs. Table 76.2 is a conversion table for cats. When using drugs such as doxorubicin or carboplatin, doses determined on the basis of BSA usually lead to adverse effects in very small dogs (i.e., those <10 kg) and in cats. A dose determined on the basis of weight (e.g., 1 mg/kg for doxorubicin, 10 mg/kg for carboplatin) is more appropriate in such small patients, resulting in a relatively lower adverse effect profile.

INDICATIONS AND CONTRAINDICATIONS OF CHEMOTHERAPY

Chemotherapy is primarily indicated for animals with systemic (e.g., lymphoma, leukemias) or metastatic neoplasms, although it can also be used for the management of nonresectable, chemoresponsive neoplasms that have historically proved refractory to radiotherapy (primary chemotherapy). It can also be used as an adjuvant treatment after partial surgical debulking of a neoplasm (e.g., partial excision of an undifferentiated sarcoma) and is indicated for the control of micrometastatic disease after the surgical excision of some primary neoplasms (e.g., carboplatin or doxorubicin therapy after limb amputation in dogs with osteosarcoma; VAC or doxorubicin after splenectomy for dogs with hemangiosarcoma). Chemotherapy can also be administered intracavitarily in dogs and cats with malignant effusions or neoplastic involvement of the cavity/area in question (e.g., intrapleurally administered cisplatin or 5-fluorouracil in dogs with pleural carcinomatosis). Finally, neoadjuvant or primary chemotherapy is the approach used in animals with bulky tumors not amenable to surgical excision or radiotherapy. After the drugs cause the tumor to shrink, the tumor can be surgically excised; chemotherapy is then continued to eliminate any residual neoplastic cells (e.g., VAC chemotherapy for dogs with subcutaneous hemangiosarcomas, multiple chemotherapy protocols for dogs with mast cell tumors).

As a general rule, chemotherapy is considered to be palliative in pets with cancer. Although the cure rate of some human cancers treated with chemotherapy is high (e.g., >75% in high-grade lymphomas and pediatric acute lymphoid leukemias), the cost and toxicity associated with the high doses of chemotherapy is unacceptable in pets. For example, a dose of cyclophosphamide for a dog is rarely higher than 300 mg/m^2, whereas in humans doses of 2 to 3 g/m^2 are occasionally used. Similarly, we have used doses of 300 to 600 mg/m^2 of cytarabine once every 1 to 2 weeks in dogs, whereas in humans, some protocols call for 3 g/m^2 q12h for 6 or 7 days. Finally, conventional dosages of doxorubicin in dogs are 30 mg/m^2 q2 or 3 weeks, whereas some human protocols use 75 mg/m^2 q3 weeks.

Chemotherapy should not be used as a substitute for surgery or radiotherapy nor should it be used in animals with severe underlying multiple-organ dysfunction (or it should be used cautiously, with a dose modification) because this increases the risk of systemic toxicity.

MECHANISM OF ACTION OF ANTICANCER DRUGS

The effects of anticancer drugs on a neoplastic cell population follow first-order kinetic principles (i.e., the number of cells killed by a drug or drug combination is directly proportional to the dose used). These drugs kill a constant proportion of cells rather than a constant number of cells. Therefore the efficacy of a drug or drug combination depends on the number of cells in a given tumor (e.g., a drug combination that kills 99% of the cells in a tumor containing 100 million [10^9] cells leaves 1 million [10^6] viable cells).

As discussed in the following paragraphs, different types of anticancer drugs kill tumor cells by different mechanisms. Drugs that kill only dividing tumor cells (i.e., that do not kill cells in the G_0 phase) by acting on several phases of the cycle are termed *cell cycle phase-nonspecific drugs.* Alkylating agents belong to this group. Drugs that selectively kill tumor cells during a given phase of the cell cycle are termed *cell cycle phase-specific drugs.* Most antimetabolites and plant alkaloids are phase-specific drugs. Finally, drugs that kill neoplastic cells regardless of their cycle status (i.e., they kill both dividing and resting cells) are termed *cell cycle-nonspecific drugs.* These latter drugs are extremely myelosuppressive (e.g., nitrosoureas).

TYPES OF ANTICANCER DRUGS

Anticancer drugs are commonly classified into six categories (Box 76.1). Most of these drugs are currently available as generic products at a reasonable cost.

Alkylating agents cross-link DNA, thus preventing its duplication. Because they mimic the effects of radiotherapy, they are also referred to as *radiomimetics.* These drugs are active during several phases of the cell cycle (i.e., they are

Rabacfosadine

cell cycle phase-nonspecific) and are more active if given intermittently at high doses. The major toxicities of these drugs are myelosuppression and gastrointestinal. Alkylating agents commonly used in pets with cancer are listed in Box 76.1.

Antimetabolites exert their activity during the S phase of the cell cycle (cell cycle phase-specific) and are more active if given repeatedly at low doses or as continuous intravenous infusions. These drugs are structural analogs of naturally occurring metabolites (fake metabolites) that substitute for normal purines or pyrimidines. The major toxicities of these drugs are myelosuppression and gastrointestinal. Box 76.1 lists the antimetabolites commonly used in small animals with cancer.

Antitumor antibiotics act by several mechanisms (i.e., cell cycle phase-nonspecific), the most important of which appears to be DNA damage produced by free radicals or by a topoisomerase-II–dependent mechanism. There are now several synthetic or semisynthetic antibiotics, such as mitoxantrone. The major toxicities of these drugs are myelosuppression and gastrointestinal; doxorubicin and actinomycin D are extremely caustic if given perivascularly, resulting in severe extravasation injuries. Additionally, doxorubicin has cumulative cardiotoxic effects in dogs and may cause renal tubular damage with repeated dosing in cats. Antitumor antibiotics are listed in Box 76.1.

Plant alkaloids are derived from the periwinkle plant *(Vinca rosea)* and the May apple plant *(Podophyllum peltatum)*. Vinca derivatives disrupt the mitotic spindle and are therefore cell cycle phase-specific (active during M phase), whereas *Podophyllum* derivatives cross-link DNA. The major toxicity is perivascular sloughing if the agent extravasates. Although traditionally etoposide was not given intravenously because the vehicle (Tween 80) causes anaphylaxis, a recent study in 27 dogs with lymphoma using etoposide phosphate, a water-soluble derivative, reported no cases of anaphylaxis. Paclitaxel has also been recently used in dogs with neoplasia, primarily carcinomas; however, after conditional USDA approval for dogs, the drug was taken off the market. Box 76.1 lists selected plant alkaloids.

Hormones (corticosteroids) are commonly used for the treatment of hemolymphatic malignancies, mast cell tumors, and brain tumors (where they result in clinical improvement due to decrease in tumor-associated edema). Box 76.1 lists the most commonly used hormone.

Miscellaneous agents consist of drugs with a mechanism of action that is either unknown or differs from those of agents already described. Box 76.1 lists miscellaneous agents commonly used in small animals with cancer.

A novel approach to anticancer chemotherapy is to exploit the use of inhibitors of molecular targets such as the tyrosine kinase (TK) family receptors. These include vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), fibroblast growth factor receptor (FGFR), and Tie1/2, among others. Kit is a receptor found on mast cells, and Kit signaling is required for the differentiation, survival, and function of mast cells. Kit mutations are commonly identified in human chronic myelogenous leukemia; imatinib (Gleevec, Novartis, East Hanover, NJ) selectively blocks this TK pathway and induces apoptosis of neoplastic (but not normal) cells. Mutations of Kit are also common in canine mast cell tumors, where other small molecule TK inhibitors have been effective. Toceranib (Palladia, Zoetis, Madison, NJ), masitinib, and imatinib have been used extra-label in small animal patients for a variety of tumors (despite Palladia being approved for use in mast cell tumors); Palladia was the first FDA-approved drug for canine cancer.

METRONOMIC CHEMOTHERAPY

After Judah Folkman discovered tumor angiogenesis, several groups proposed that anticancer drugs may be able to target tumor vasculature because many of the endothelial cells that compose the wall of tumor blood vessels are immature

and constantly proliferating. Antiangiogenic drugs showed promise in mouse studies but not in human or spontaneous animal tumor patients.

Metronomic (from the Greek "metros," in small constant installments) chemotherapy is defined as the chronic administration of chemotherapeutic agents at relatively low, minimally toxic doses and with no prolonged drug-free breaks. It is proposed to inhibit tumor growth primarily through antiangiogenic mechanisms, while significantly reducing undesirable toxic adverse effects. Targeted molecular drugs such as toceranib (Palladia, Zoetis, Madison, NJ) and nonsteroidal antiinflammatory drugs (NSAIDs) appear to have antiangiogenic effects by targeting specific receptors.

Metronomic chemotherapy is thought to exert its anticancer activity mainly by inhibiting tumor angiogenesis. However, immunomodulation appears to play a role in tumor response. T-regulatory lymphocytes (T_{REG}) have been shown to be increased in several human, canine, and feline cancers, and appear to correlate with tumor progression and lack of treatment response. Several studies performed in tumor-bearing animals have shown that low-dose cyclophosphamide can increase antitumor immune response by decreasing numbers and inhibiting the suppressive functions of T_{REG} cells but also by increasing both lymphocyte proliferation and memory T cells. Low-dose cyclophosphamide also decreases numbers of circulating T_{REG} in dogs. A third mechanism that appears to contribute to the effectiveness of metronomic chemotherapy is the induction of tumor dormancy or tumor cell apoptosis.

The authors previously evaluated several metronomic chemotherapy protocols that combine an NSAID, low-dose alkylators, and toceranib (Palladia) in dogs with spontaneous neoplasms, which showed objective responses in patients with carcinomas and sarcomas. For metronomic chemotherapy protocols, please see the Cancer Chemotherapy Protocols table (p. 1337).

SAFE HANDLING OF ANTICANCER DRUGS

Cytotoxic drugs have narrow therapeutic indices, with toxic effects occasionally noted at the standard therapeutic dosages. Occupational exposure, as might occur in personnel who commonly administer these drugs, has been documented in the literature; adverse effects, including headache, nausea, liver disease, and reproductive abnormalities, have been reportedly associated with this exposure. As such, no safe exposure level has been identified, and all possible measures to limit personnel exposure to cytotoxic drugs must be taken during their preparation and administration.

Reconstitution of cytotoxic drugs for administration must be performed in a biosafety level II vertical laminar airflow hood. Although the cost for this equipment is not prohibitively expensive for a large veterinary hospital (≈$6000-$10,000), this cost is currently not justified by the frequency of use. Closed system transfer devices (CSTDs) are practical and relatively inexpensive (PhaSeal, Carmel Pharma, Columbus, OH, and EquaShield, Port Washington, NY), which limit operator and environmental drug exposure to almost zero. If containment devices are not available, cytotoxic drugs can be reconstituted at a human hospital or pharmacy, or at a nearby small animal clinic with a sufficiently large oncology caseload. Care should be taken to respect the storage half-life of reconstituted drugs, and they should be administered to the patient as soon as possible after reconstitution. A recent literature review (Chan et al., 2017) described storage recommendations for various chemotherapy agents and can be used as a resource for chemotherapeutic drug storage in practice. Drugs should be delivered in a clearly labeled, sealed plastic bag, and any handling of the drugs should be performed while wearing the appropriate personal protective gear.

Personal protective gear has been shown to all but eliminate detectable occupational exposure to cytotoxic drugs in human oncology nurses when combined with safe, conservative handling practices. All personnel present during chemotherapy administration to animal patients, including veterinarians, technicians, and ward staff, must wear thick latex chemotherapy gloves or two pairs of regular latex examination gloves. The thickness of the gloves is more important than the composition for barrier protection. Ideally, personnel should also wear impermeable disposable gowns, eye protection, and particle-filtering face masks. All fluid lines should be primed before addition of cytotoxic drugs to reduce environmental contamination, and all potentially contaminated supplies, including gowns, gloves, fluid bags, lines, and so forth, should be disposed of in properly labeled biohazard bags or plastic sharps containers. Disposal of material potentially contaminated with cytotoxic drugs may be arranged through a local human hospital; alternatively, an Environmental Protection Agency–approved disposal facility should be located. Materials used in the preparation and administration of chemotherapy should not be reused. Patient waste, including urine and feces, should be disposed of similarly 24 to 48 hours after chemotherapy administration, and personnel involved in the husbandry of these patients should wear the previously recommended personal protective gear when attending patients.

Protocols for handling spills should be prepared in advance and posted in areas where patients may be receiving chemotherapy. This area should be a designated area of the hospital with low traffic and minimal drafts; a stall may be selected for this purpose in equine hospitals. Isolation stalls will minimize exposure of personnel to chemotherapeutic agents. Once the patient has received chemotherapy, its cage should be clearly identified with a notice that contains information about precautions to be taken during handling of the animal and its wastes.

CHAPTER 77

Complications of Cancer Chemotherapy

GENERAL CONSIDERATIONS

Because most anticancer agents are relatively nonselective, they kill not only rapidly dividing neoplastic cells but also some of the rapidly dividing normal cells in the host (e.g., villus epithelium, bone marrow cells). In addition, similar to other commonly used agents (e.g., digitalis glycosides), most anticancer agents have low therapeutic indices (i.e., narrow therapeutic-to-toxic ratios).

Because anticancer agents follow first-order kinetic principles (i.e., the fraction of cells killed is directly proportional to the dose used), increasing the dose of a particular drug increases the proportion of the neoplastic cells killed, but it also enhances its toxicity. This is commonly seen when a tumor relapses and higher doses of a previously prescribed chemotherapeutic agent are administered.

Because toxicity generally tends to affect rapidly dividing cells, given the short doubling times of the bone marrow and villal epithelial cells, myelosuppression and gastrointestinal signs are the most common toxicities encountered in practice. Other rare complications of chemotherapy include anaphylactoid (or anaphylactic) reactions, dermatologic toxicity, pancreatitis, cardiotoxicity, pulmonary toxicity, neurotoxicity, hepatopathies, and urotoxicity. Table 77.1 lists anticancer drugs commonly used in small animals and their toxicities.

Several factors can potentiate the effects of anticancer agents and thereby enhance their toxicity. For example, drugs that are excreted primarily through the kidneys (e.g., platinum compounds, methotrexate) are more toxic to animals with renal disease; thus a dose reduction or the use of an alternative drug is usually recommended in such patients.

In addition to the direct effects of some drugs on different organ systems, rapid killing of certain neoplastic cells (i.e., lymphoma cells) can lead to sudden metabolic derangements that result in acute clinical signs mimicking those of drug toxicity (i.e., depression, vomiting, diarrhea). This syndrome is referred to as *acute tumor lysis syndrome* (ATLS) (see p. 1286) and is extremely rare.

In general, cats appear to be more susceptible than dogs to some of the adverse effects of chemotherapy (e.g., anorexia, vomiting) but not to others (e.g., myelosuppression). Certain breeds of dogs, including Collies and Collie crosses, Old English Sheepdogs, Cocker Spaniels, and West Highland White Terriers, also appear to be more prone to some of the acute adverse reactions to chemotherapy (i.e., gastrointestinal signs, myelosuppression) than the general dog population. Interestingly, only some of these breeds (e.g., Collie, Sheltie) have mutations of the *ABCB1* (formerly *MDR1*) gene that encodes for P-glycoprotein, an efflux pump that rapidly eliminates chemotherapeutic agents from the cytoplasm of the cells, so alternative mechanisms of toxicity must be sought.

The overall prevalence of toxicity of different chemotherapy protocols is considerably lower in dogs and cats (≈5%-40%) than in humans (75%-100%) treated with similar drugs or combinations. A survey of owners whose pets had been treated with a variety of chemotherapy protocols at The Ohio State University Veterinary Medical Center revealed that more than 80% considered their pets' quality of life to be as good as or better than that before the institution of chemotherapy. Additionally, a similar study performed at North Carolina State University revealed that 77% of dogs and 66% of cats experienced no negative impact on their quality of life while undergoing chemotherapy, and 65% of dogs and 44% of cats handled chemotherapy better than the owners were expecting.

Recently, the Veterinary Cooperative Oncology Group updated the terminology for adverse events after chemotherapy in dogs and cats (Table 77.2).

HEMATOLOGIC TOXICITY

The high mitotic rate and growth fraction (i.e., 40%-60%) of the bone marrow cells predispose this organ to relevant toxicity from anticancer drugs. Hematologic toxicity constitutes the most common complication of chemotherapy, and often the severe and potentially life-threatening cytopenias that

occur necessitate the temporary or permanent discontinuation of the offending agent or agents. Table 77.1 lists agents commonly implicated in this type of toxicity.

It is easy to anticipate the cell line that will be affected on the basis of the bone marrow transit times and circulating half-lives of blood-formed elements. For example, the bone marrow transit time and circulating half-life of red blood cells in the dog are approximately 7 and 70 to 120 days, those of the platelets are 3 to 5 days and 4 to 6 days, and those of neutrophils are 5 to 6 days and 4 to 8 hours, respectively. On the basis of this, neutropenia usually occurs first, followed by thrombocytopenia. Chemotherapy-induced anemia is rare in dogs and cats and, if it occurs, is of late onset (3-4 months after initiation of therapy); in some dogs on chemotherapy, iron deficiency anemia is due to chronic gastrointestinal bleeding from gastroduodenal ulcers or erosions (see Chapters 30 and 82). Other patient-related factors (e.g., malnutrition, old age, concurrent organ dysfunction, prior extensive chemotherapy) and tumor-related factors (e.g., bone marrow infiltration, widespread parenchymal organ metastases) can also affect the degree of myelosuppression.

Although thrombocytopenia is probably as common as neutropenia, it is rarely severe enough to cause spontaneous bleeding, and therefore it is not discussed at length here. In general, in most dogs with chemotherapy-induced thrombocytopenia, the platelet counts remain above 50,000 cells/μL; spontaneous bleeding usually does not occur until platelet counts are below 30,000/μL. Some drugs and protocols are associated with predictable thrombocytopenia, including doxorubicin and dacarbazine (ADIC), D-MAC (see the table on cancer chemotherapy protocols in page 1337), lomustine, and melphalan in dogs; platelet counts associated with these protocols can be lower than 50,000/μL. Chemotherapy-induced thrombocytopenia is extremely rare in cats; however, because platelet clumping is common in cats, pseudothrombocytopenia (i.e., low platelet "count" but platelet aggregates on the analyzer graphics or blood smear) is seen frequently. Thrombocytosis is common in cats and dogs receiving vincristine or corticosteroids.

Neutropenia usually constitutes the dose-limiting cytopenia and occasionally leads to life-threatening sepsis in dogs; although neutropenia does occur in cats receiving chemotherapy, it rarely leads to the development of clinically recognizable sepsis. The nadir (i.e., lowest point in the curve) of neutropenia for most drugs usually occurs 5 to 7 days after treatment, and the neutrophil counts return to normal within 36 to 72 hours of the nadir. With certain drugs, the nadir of neutropenia is delayed (i.e., ≈3 weeks for carboplatin in dogs and cats). Dogs with neutrophil counts less than 2000 cells/μL should be closely monitored for the development of sepsis, although overwhelming sepsis rarely occurs in animals with neutrophil counts of more than 1000 cells/μL. As reported in a recent study, the development of sepsis in neutropenic cats is extremely rare or may go unrecognized. In this collaborative study from 8 institutions where patients were selected based on the authors' recall, only 20 cats with febrile neutropenia while undergoing chemotherapy were identified. Most cats had lymphoma and were receiving either lomustine and/or vinca alkaloids (Pierro et al., 2016). We have also observed severe, long-lasting myelosuppression associated with administration of lomustine in a limited number of cats (Fig. 77.1).

The pathogenesis of sepsis in neutropenic animals is as follows: First, the chemotherapy-induced death and desquamation of gastrointestinal crypt epithelial cells occur simultaneously with myelosuppression; next, enteric bacteria are translocated through the damaged mucosal barrier into the systemic circulation; and, finally, because the number of neutrophils in the circulation is not sufficient to phagocytose and kill the invading organisms, multiple organs become colonized with the bacteria and death ensues, unless the animal is treated appropriately.

It is important to identify the septic neutropenic patient using laboratory means due to the fact that the cardinal signs of inflammation (i.e., redness, swelling, increased temperature, pain, abnormal function) may be absent because there are not enough neutrophils to participate in the inflammatory process. The same holds true for radiographic changes

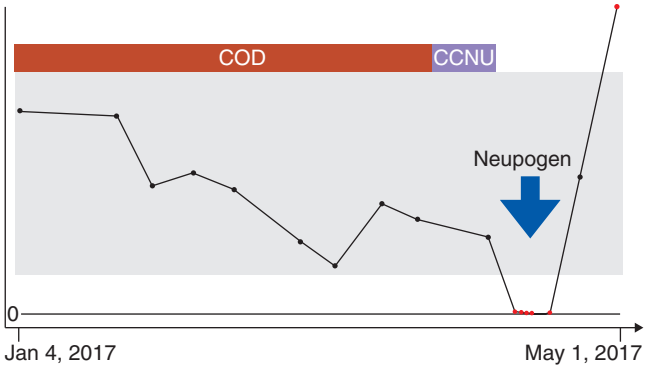

FIG 77.1
Leukocyte count in a Siamese cat with multicentric lymphoma who had a severe, long-lasting myelosuppressive event associated with lomustine administration. *COD,* Cyclophosphamide, vincristine, dexamethasone; *CCNU,* lomustine; *NEUPOGEN,* granulocyte colony-stimulating factor. The grey zone represents the reference interval for the white blood cell count.

compatible with inflammation; for example, dogs with neutropenia and bacterial pneumonia diagnosed on the basis of cytologic and microbiologic findings in transtracheal wash material often have normal thoracic radiographic findings (Fig. 77.2). As a general rule, if a severely neutropenic animal (neutrophil count <500/µL) is evaluated because of pyrexia (>104° F [>40° C]), the fever should be attributed to bacterial pyrogens until proved otherwise, and the patient should be treated aggressively with antimicrobial therapy (see following paragraphs). Neutropenic septic patients can also be hypothermic.

All dogs and cats undergoing chemotherapy should be up to date on their vaccines; it is controversial whether the use of modified-live vaccines should be avoided because of the potential for inducing illness in immunosuppressed animals. Recent evidence suggests that vaccinated dogs with cancer undergoing chemotherapy have protective serum antibody titers for commonly used vaccines.

Hematologic monitoring of the patient receiving chemotherapy constitutes the most effective way to prevent (or anticipate) severe, life-threatening sepsis or bleeding secondary to myelosuppression. Complete blood counts (CBCs) should be obtained weekly or every other week (depending on the treatment protocol), and the myelosuppressive agent or agents should be temporarily discontinued (or the dose decreased) if the neutrophil count decreases to fewer than 1000 cells/µL or if the platelet count decreases to fewer than 50,000 cells/µL. Discontinuing the offending agent or agents for two or three administrations usually allows sufficient time for the cell counts to return to normal. When therapy is reinstituted, it is recommended that only 75% of the initial dose be given and the doses increased during the next 2 to 3 weeks until the initially recommended dose (or a dose that does not produce marked cytopenias) is reached. Obviously, the drawback of discontinuing chemotherapy is the potential for tumor relapse, so the clinician

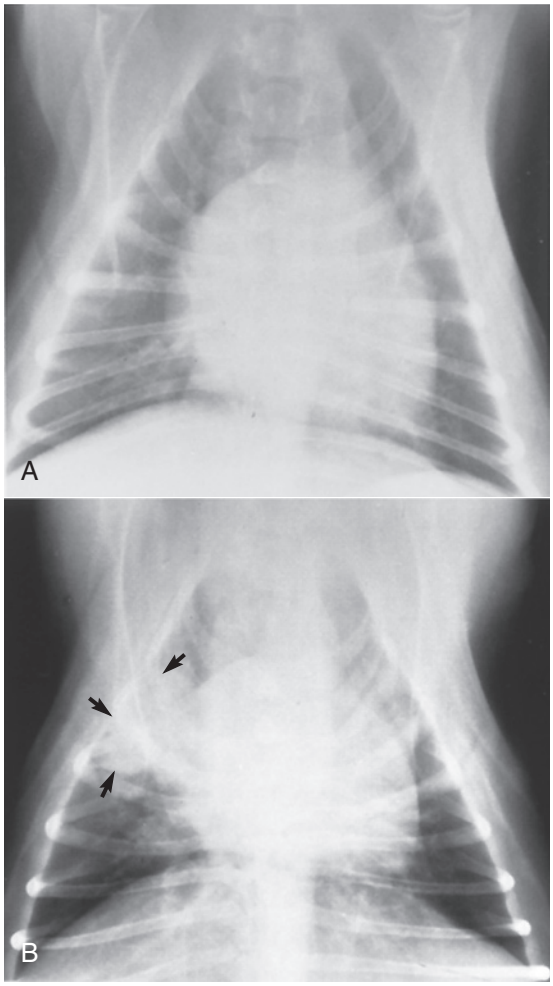

FIG 77.2
Thoracic radiographs from a 5-year-old male, castrated Boston Terrier with multicentric lymphoma treated with doxorubicin and dacarbazine (ADIC) chemotherapy. This dog presented as an emergency because of depression, fever, and mild bilateral nasal discharge. The neutrophil count on admission was 1500/µL. **(A)** Thoracic radiograph findings were considered normal at the time, but a transtracheal wash specimen contained bacteria. **(B)** Two days later, when the neutrophil count increased to 16,300/µL, focal areas of pneumonia became evident. (From Couto CG: Management of complications of cancer chemotherapy, *Vet Clin North Am* 20:1037, 1990.)

and owner must weigh the pros and cons of temporarily discontinuing treatment.

Clinically, neutropenic patients are classified as febrile or afebrile. Neutropenic, febrile patients should be managed aggressively because they are usually septic; thus fever in a neutropenic patient constitutes a medical emergency. The following protocol is the one currently used in such patients at our clinic. First, a thorough physical examination is performed to search for a septic focus, an indwelling intravenous (IV) catheter is placed aseptically, and IV fluids are administered as required. All anticancer agents are discontinued immediately, with the exception of corticosteroids,

which should be discontinued gradually, if at all, because acute hypoadrenocorticism can develop in animals receiving steroid therapy if the drug is abruptly discontinued. Blood samples for a CBC and serum biochemical profile are obtained immediately. A urine sample for urinalysis and bacterial culture may also be obtained, unless the patient is thrombocytopenic, in which case cystocentesis should be avoided to prevent intravesical bleeding. Two or three sets of aseptically collected blood samples can be obtained at 30-minute intervals for aerobic and anaerobic bacterial cultures and antibiotic susceptibility tests, although this is usually not necessary because the bacterial isolates are quite predictable (see following paragraph) and because the results of these tests will not be available for several days. After the second set of samples for blood cultures is collected (if doing so), therapy with an empirical bactericidal antibiotic combination is instituted. The authors use a combination of enrofloxacin (5-10 mg/kg IV q24h) and ampicillin (22 mg/kg IV q8h) or ampicillin/sulbactam (30 mg/kg IV q8h) because most bacterial isolates in such animals are Enterobacteriaceae and staphylococci, organisms commonly susceptible to these agents. Once the neutrophil count returns to normal and the patient's condition is clinically normal (usually within 72-96 hours), the antibiotic combination is discontinued and the animal is allowed to go home, with instructions to the owner to administer sulfadiazine-trimethoprim (ST) at a dosage of 13 to 15 mg/kg by mouth (PO) q12h, amoxicillin-clavulanic acid (CLAV) at a dosage of 13.75 to 20 mg/kg PO q12h, or enrofloxacin at a dosage of 5 to 10 mg/kg PO q24h for 5 to 7 days. When the patient returns for additional chemotherapy, the dose of the offending agent or agents should be decreased by 15% to 20% to prevent an additional occurrence.

In an unpublished study by one of the authors (GC), the yield for three sets of blood cultures in dogs with cancer, fever, and normal-to-high neutrophil counts is approximately 40%, whereas it is approximately 20% in dogs with cancer, fever, and neutropenia. Isolates in the former group usually include *Streptococcus* spp., *Staphylococcus* spp., *Enterobacter* spp., *Klebsiella* spp., and *Escherichia coli,* in decreasing order of frequency. In neutropenic febrile dogs, the isolates include mainly *Klebsiella* spp. and *E. coli; Staphylococcus* spp. is isolated in less than 20% of the dogs.

In a recent study (Shaffer et al., 2016) of 57 neutropenic episodes in 55 dogs undergoing chemotherapy, the prevalence of bacteremia when using 2 sets of blood cultures was 12.3% (7/57) and that of bacteriuria was 7.5%. The prevalence of bacteremia was similar between febrile and afebrile dogs, and most isolates were gram-positive organisms.

Neutropenic, afebrile, asymptomatic patients can be treated as outpatients by discontinuing the drug or drugs as described earlier and administering ST (13-15 mg/kg PO q12h), CLAV (13.75-20 mg/kg PO q12h), or enrofloxacin (5-10 mg/kg PO q24h). The patient that is afebrile but has constitutional signs should be considered to be septic and treated as described in previous paragraphs. If the neutropenia is not severe (i.e., >1000 cells/μL), no therapy is required and the patient should only be observed by the owner. Owners should be instructed to take their pet's rectal temperature twice daily and to call the veterinarian if pyrexia develops, in which case the patient is treated as neutropenic and febrile. ST and fluoroquinolones eliminate the aerobic intestinal flora but preserve the anaerobic bacteria, which are an important component of the local defense system because of their ability to produce local antibiotic factors and for this reason may be considered over CLAV. In addition, ST and fluoroquinolones are active against many pathogens isolated from animals with cancer, and they achieve therapeutic blood and tissue concentrations and also high intragranulocytic concentrations. Recent studies suggest that the use of antibiotics against gram-positive bacteria may shorten survival time in humans with lymphoma or chronic lymphocytic leukemia (Pflug et al., 2016), and that the microbiome composition predicts risk of sepsis in children with acute leukemia (Hakim et al., 2018), thus highlighting the role of the intestinal microbiome on tumor immunomodulation. Moreover, recent studies suggest that chemotherapy modifies the intestinal microbiome in some species and may decrease immunologic response against tumor antigens (Viaud et al., 2013).

Myelosuppression in dogs may be alleviated through the use of lithium carbonate (10 mg/kg PO q12h) or, in dogs and cats, recombinant human granulocyte colony–stimulating factor (G-CSF; Neupogen; 5 μ g/kg subcutaneously q24h). Although several studies have reported the beneficial role of G-CSF or granulocyte-macrophage colony–stimulating factor (GM-CSF) in dogs and cats, it is unlikely that these agents will find their way into the clinic owing to their high cost (≈$70-$150/day) and the fact that dogs and cats can mount an antibody response to this protein of human origin and inactivate it; moreover, in dogs with chemotherapy-induced neutropenia, the activity of endogenous G-CSF is extremely high, and neutrophil counts return to normal within 36 to 72 hours, the same interval reported for "response" to G-CSF. For this reason, G-CSF is typically reserved for patients that received accidental chemotherapy overdoses and in which the predicted duration of neutropenia is unknown.

GASTROINTESTINAL TOXICITY

Although less common than myelosuppression, gastrointestinal toxicity is a relatively common complication of cancer chemotherapy in pets. From a clinical standpoint, two major types of gastrointestinal complications can occur: the combination of anorexia, nausea, vomiting, and gastroenterocolitis.

Although results of controlled studies are not available, nausea and vomiting are not apparently as common in pets as they are in humans receiving similar drugs and dosages. Drugs associated with nausea and vomiting include dacarbazine (DTIC), cisplatin, doxorubicin (primarily in cats), methotrexate, actinomycin D, cyclophosphamide, and 5-fluorouracil (5-FU; see Table 77.1).

Acute anorexia, nausea, and vomiting caused by injectable drugs are usually prevented by administering the offending agents by slow IV infusion. If these problems persist despite this approach, antiemetics such as metoclopramide can be given at a dosage of 0.1 to 0.3 mg/kg IV, subcutaneously, or PO every 8 hours. Other antiemetics effective in dogs with chemotherapy-induced emesis are butorphanol (Torbugesic, Fort Dodge Labs, Fort Dodge, IA) at a dosage of 0.1 to 0.4 mg/kg intramuscularly or intravenously every 6 to 8 hours; ondansetron (Zofran, GlaxoSmithKline, Research Triangle Park, NC) at a dosage of 0.1 to 0.3 mg/kg immediately before chemotherapy and every 6 hours thereafter; or maropitant (Cerenia, Zoetis, Madison, NJ) at a dosage of 2 mg/kg, PO every 24 hours. (For additional information on this subject, see Chapter 28.) Our preferred approach is to use maropitant in these situations.

Methotrexate and cyclophosphamide, two drugs commonly administered PO, can also cause anorexia, nausea, and vomiting. Methotrexate commonly causes anorexia and vomiting 2 or 3 weeks after the start of therapy in dogs; these adverse effects are usually controlled with antiemetics as described earlier. If these problems persist, it may be necessary to discontinue methotrexate treatment. Cyclophosphamide tends to induce anorexia or vomiting in some cats. Cyproheptadine (Periactin, Merck Sharp & Dohme, West Point, PA) at a dosage of 1 to 2 mg (total dose) PO q8-12h is quite effective as an appetite stimulant and antinausea agent in cats; an alternative option is mirtazapine (3.75 mg PO q24h for cats; 3.75-30 mg PO q24h for dogs).

In our experience, chemotherapy-associated anorexia in dogs is more difficult to manage because nonspecific appetite stimulants such as cyproheptadine and mirtazapine do not seem to be effective. In these cases, oral antiemetics can be considered, mainly ondansetron and maropitant, which can be beneficial to decrease the duration of anorexia in some dogs. The novel Entyce (capromorelin oral solution, Aratana Therapeutics, Leawood, KS) is also an appetite stimulant in both dogs and cats with chemotherapy or cancer-induced anorexia (3 mg/kg PO q24h).

Gastroenterocolitis is uncommon in patients receiving anticancer agents. Drugs that occasionally cause this include methotrexate, 5-FU, actinomycin D, and doxorubicin. It occurs rarely in association with other alkylating agents such as cyclophosphamide. Of the drugs mentioned in the previous paragraphs, only doxorubicin and methotrexate appear to be of clinical relevance. On the basis of the author's experience, Collies and Collie crosses, Old English Sheepdogs, Cocker Spaniels, and West Highland White Terriers appear to be extremely susceptible to doxorubicin-induced enterocolitis, independently of *ABCB1* mutations.

Doxorubicin-induced enterocolitis is characterized by the development of hemorrhagic diarrhea (with or without vomiting), primarily of large bowel type, 3 to 7 days after the administration of the drug; it is more common in dogs than in cats. Supportive fluid therapy (if necessary) and treatment with therapeutic doses of bismuth subsalicylate–containing products (Pepto-Bismol, 3-15 mL or 1-2 tabs PO q8-12h) are generally effective in controlling the clinical signs in dogs, which usually resolve in 3 to 5 days. The administration of Pepto-Bismol from days 1 to 7 of the treatment may alleviate or prevent these signs in dogs at risk for gastroenterocolitis (i.e., one of the breeds mentioned, a patient with a history of this toxicity). The use of bismuth subsalicylate should be avoided in cats. Gastroenteritis associated with the PO administration of methotrexate usually occurs after 2 weeks of administration; the treatment is the same as that used for doxorubicin-induced enterocolitis.

HYPERSENSITIVITY REACTIONS

Acute type I hypersensitivity reactions occasionally occur in dogs receiving parenteral L-asparaginase or doxorubicin and are common in dogs treated with IV etoposide or taxol derivatives; in the latter two, there is a reaction to the solubilizing agent (Tween 80, Cremophor EL). As discussed earlier, a water-soluble form of etoposide is now available. The reaction to doxorubicin does not appear to be a true hypersensitivity reaction, however, because this agent can induce direct mast cell degranulation independently of immunoglobulin E (IgE) mediation. Etoposide can be safely administered to dogs PO. Hypersensitivity reactions to anticancer agents are extremely rare in cats and thus are not discussed.

Clinical signs in dogs with hypersensitivity reactions to anticancer agents are similar to those in dogs with other types of hypersensitivity reactions (i.e., they are primarily cutaneous and gastrointestinal). Typical signs appear during or shortly after administration of the agent and include head shaking (caused by ear pruritus), generalized urticaria and erythema, restlessness, occasionally vomiting or diarrhea, and rarely collapse caused by hypotension.

Most systemic anaphylactic reactions can be prevented by pretreating the patient with H_1 antihistamines (i.e., intramuscular diphenhydramine, 1-2 mg/kg 20-30 minutes before administration of the drug) and by administering certain drugs (e.g., L-asparaginase) subcutaneously or intramuscularly rather than through an IV route. If the agent cannot be given by any other routes (i.e., doxorubicin), it should be diluted and administered by slow IV infusion.

The treatment of acute hypersensitivity reactions includes immediate discontinuation of the agent and the administration of H_1 antihistamines (i.e., diphenhydramine, 0.2-0.5 mg/kg by slow IV infusion), dexamethasone sodium phosphate (1-2 mg/kg IV), and fluids if necessary. If the systemic reaction is severe, epinephrine (0.1-0.3 mL of a 1:1000 solution intramuscularly or intravenously) should be used. Once the reaction subsides (and if it was mild), the administration of certain drugs such as doxorubicin may be continued. Injectable H_1 antihistamines should be used with caution in cats (if at all) because they can cause acute central nervous system depression leading to apnea.

DERMATOLOGIC TOXICITY

It is rare for anticancer agents to cause dermatologic toxicity in small animals. However, three types of dermatologic toxicities can occur: local tissue necrosis (caused by extravasation), delayed hair growth and alopecia, and hyperpigmentation. More recently, the newest chemotherapeutic agent that is conditionally approved for use in dogs with lymphoma, rabacfosadine (Tanovea, VetDC, Fort Collins, CO) has been reported to have a unique dermatologic toxicity discussed later.

Local tissue necrosis resulting from the extravasation of vincristine, vinblastine, actinomycin D, doxorubicin, or Tanovea is occasionally seen in dogs receiving these drugs but is extremely rare in cats. Indeed, according to anecdotal reports, cats have accidentally received full doses of doxorubicin perivascularly without developing tissue necrosis. The pathogenesis of this toxicity is poorly understood, but it is thought to be mediated by release of free radicals. Every effort should be made to ensure that these drugs are administered intravascularly. In addition to this complication, some retrievers (e.g., Labrador and Golden Retrievers) appear to experience pruritus or discomfort around the site of the IV injection even when the drug is known to have been administered intravascularly. This pain and discomfort frequently lead to licking and the development of a pyotraumatic dermatitis ("hot spot") within hours of the injection. In these dogs, applying a bandage over the injection site or placing an Elizabethan collar prevents this type of reaction.

To prevent or minimize the probability of extravascular injection of caustic drugs, they should be administered through small-gauge (22- to 23-gauge), indwelling, IV, over-the-needle catheters or through 23- to 25-gauge butterfly catheters. We use the former to administer doxorubicin and the latter to administer the vinca alkaloids and actinomycin D. Caustic drugs should be properly diluted before administration (i.e., vincristine to a final concentration of 0.1 mg/mL and doxorubicin to a concentration of 0.5 mg/mL) and the patency of the intravascular injection site ensured by intermittently aspirating until blood appears in the catheter. In the authors' clinics, doxorubicin is not administered by IV constant-rate infusion because such patients are more likely to undergo extravasation. If the site is not patent, the catheter should be placed in another vein. Recommendations for the management of extravascular injections are controversial; other than cold-packing the area for a few days, authors cannot agree as to whether diluting the extravasated drug with saline solution is a good or bad idea. For the management of perivascular doxorubicin, see next paragraph.

If, despite these precautions, a local tissue reaction occurs, it develops approximately 1 to 7 days after the perivascular injection of vinca alkaloids or actinomycin D and 7 to 15 days after doxorubicin extravasation. Tissue necrosis resulting from doxorubicin extravasation is far more severe than that associated with the extravasation of other agents because the drug is extremely caustic and persists in tissues for up to 16 weeks. If perivascular administration of doxorubicin has occurred (and the clinician has recognized it during or immediately after the administration), dexrazoxane (Zinecard, Pfizer) can be administered at 5 to 10 times the dose of doxorubicin given (i.e., for 30 mg of doxorubicin, 150-300 mg of dexrazoxane should be given). Dexrazoxane is rather expensive, so it is not routinely used in small animal patients. One of the authors has evaluated carvedilol (Coreg, GlaxoSmithKline) in a limited number of dogs that received perivascular doxorubicin. In three dogs that received treatment immediately after drug extravasation (at a dosage of 0.1-0.4 mg/kg q12-24h), there were no visible signs of necrosis. In three dogs that developed necrosis after perivascular doxorubicin administration, carvedilol resulted in rapid healing of the area (i.e., within 2-3 weeks). Clinical signs of extravasation include pain, pruritus, erythema, moist dermatitis, and necrosis of the affected area; severe tissue sloughing may occur (Fig. 77.3). If local tissue reactions develop, they can be treated as shown in Box 77.1.

In dogs and cats undergoing chemotherapy, delayed hair growth is more common than alopecia. This is in contrast to the situation in human patients, in whom severe scalp alopecia is a predictable complication of therapy. Because most chemotherapeutic agents affect rapidly dividing tissues, cells in the anagen (growth) phase of the hair cycle are usually affected. Therefore hair is slow to regrow in areas that were clipped or shaved before or during chemotherapy. Excessive shedding is also common.

Alopecia occurs predominantly in woolly-haired (coarse-haired) dogs such as Poodles, Schnauzers, and Kerry Blue

FIG 77.3
Tissue necrosis after extravascular injection of doxorubicin in a dog. Note the full-thickness sloughing of the area.

BOX 77.1

Treatment of Local Tissue Reactions

1. Apply an antibiotic ointment (with or without corticosteroids) to the affected area and start systemic antibiotics (amoxicillin/clavulanic acid).
2. Bandage the area (and replace bandages daily).
3. Prevent self-mutilation by placing an Elizabethan collar or a muzzle.
4. If there is no bacterial contamination (ruled out on the basis of negative bacterial cultures), 10 to 20 mg of methylprednisolone acetate (Depo-Medrol, Zoetis, Madison, NJ) can be injected subcutaneously in the affected area to alleviate pruritus and inflammation.
5. If severe necrosis or gangrene caused by anaerobic contamination occurs, the area should be surgically debrided.
6. In the event of severe doxorubicin-induced soft tissue necrosis, the affected limb may need to be amputated.

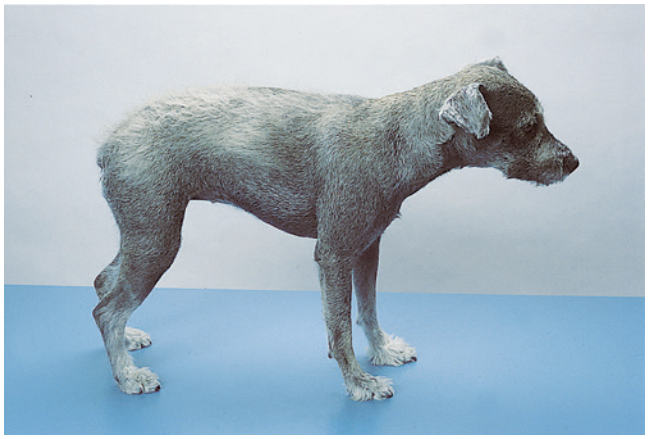

FIG 77.4
Alopecia in a 7-year-old Schnauzer undergoing doxorubicin and dacarbazine (ADIC) chemotherapy. Note the short and light-colored haircoat.

Terriers (Fig. 77.4). It primarily affects the tactile hairs in short-haired dogs and cats. Although the exact reason that chemotherapy-induced alopecia occurs in woolly-haired dogs is unknown, a prolonged anagen phase and synchronous hair growth, comparable with those occurring in human scalp hair, may make these dogs prone to this toxic effect. Drugs commonly associated with delayed hair growth and alopecia include cyclophosphamide, doxorubicin, 5-FU, 6-thioguanine, and hydroxyurea (Hydrea, E.R. Squibb & Sons, Princeton, NJ). Alopecia and delayed hair growth usually resolve shortly after discontinuation of the offending agent.

Hyperpigmentation is uncommon in dogs and extremely rare in cats receiving chemotherapy. Cutaneous hyperpigmentation affecting the face, ventral abdomen, and flanks is common in dogs receiving doxorubicin- and bleomycin-containing protocols. Occasionally, dogs on hydroxyurea develop generalized erythema.

Dermatologic toxicity has been identified in multiple cohorts of dogs receiving Tanovea; this dermatopathy develops in up to 45% of dogs, and generally consists of pruritic, focal otitis externa or focal erythemic skin lesions on the dorsum and in the inguinal region. This generally resolves with the institution of supportive treatments (antibiotics for dermatitis, corticosteroids) and treatment interruption.

PANCREATITIS

Pancreatitis is a well-recognized entity in human patients undergoing chemotherapy. Offending drugs in humans include corticosteroids, azathioprine, 6-mercaptopurine, L-asparaginase, cytosine arabinoside, and combination chemotherapy. Sporadic reports of pancreatitis in dogs (but not in cats) receiving chemotherapeutic and immunosuppressive agents have also appeared in the literature.

The author has documented acute pancreatitis in several dogs receiving L-asparaginase or combination chemotherapy. Dogs in the latter group were receiving COAP (cyclophosphamide, vincristine, cytosine arabinoside, prednisone); ADIC (doxorubicin, DTIC); or VAC (vincristine, doxorubicin, cyclophosphamide) chemotherapy. Clinical signs developed 1 to 5 days after the start of chemotherapy and consisted of anorexia, vomiting, and depression. Physical examination findings in these dogs were unremarkable, and abdominal pain was rare. The patients were treated with IV fluids, and the clinical signs resolved within 3 to 10 days in most dogs.

It is difficult to prevent chemotherapy-induced pancreatitis because it is not a predictable complication. As a further precaution, dogs receiving drugs with the potential to cause pancreatitis may be fed a low-fat diet.

CARDIOTOXICITY

Cardiotoxicity is a relatively uncommon complication of doxorubicin therapy in dogs; it is extremely rare in cats (one author has personally given cats more than 20 doses of doxorubicin without signs of cardiotoxicity). Two types of doxorubicin-induced cardiac toxicities are observed in dogs: an acute reaction occurring during or shortly after administration and a chronic cumulative toxicity. Acute doxorubicin toxicity is characterized by cardiac arrhythmias (mainly sinus tachycardia) that develop during or shortly after administration. This phenomenon is thought to stem from doxorubicin-induced histamine-mediated catecholamine release because the sinus tachycardia and hypotension can be prevented by pretreatment with H_1 and H_2 antihistamines. Several weeks or months after repeated doxorubicin injections, persistent arrhythmias, including ventricular premature contractions, atrial premature contractions, paroxysmal

ventricular tachycardia, second-degree atrioventricular blocks, and intraventricular conduction defects, can develop. These rhythm disturbances are usually associated with the development of a dilated cardiomyopathy, similar to that which occurs spontaneously in Doberman Pinschers and Cocker Spaniels.

The hallmark of chronic doxorubicin toxicity is a dilated cardiomyopathy that allegedly develops after a total cumulative dose of approximately 240 mg/m^2 is exceeded in the dog; however, we have administered higher cumulative doses without overt cardiac problems in a large number of dogs (see later). The histologic lesions seen in dogs with doxorubicin-induced cardiomyopathy consist of vacuolation of myocytes, with or without myofibril loss. Clinical signs of toxicity in dogs are those of congestive heart failure (usually left-sided). Therapy consists of discontinuation of the offending drug and the administration of cardiac drugs such as digitalis glycosides or nonglycoside inotropic agents (e.g., pimobendan). Once cardiomyopathy develops, the prognosis is poor because the myocardial lesions are irreversible.

It is critical to monitor patients receiving doxorubicin to prevent potentially fatal cardiomyopathy. In this respect, dogs (and possibly cats) with underlying rhythm disturbances or impaired myocardial contractility, as shown by decreased fractional shortening on echocardiogram, should not receive doxorubicin. It is also recommended that high-risk dogs receiving doxorubicin undergo echocardiographic evaluation every three doxorubicin cycles (9 weeks) to assess myocardial contractility and that the drug be discontinued if decreased fractional shortening occurs. Endomyocardial biopsy specimens are commonly obtained in people receiving doxorubicin in an effort to detect submicroscopic lesions, but this is impractical in dogs. The value of serum cardiac troponin I concentrations to detect early myocardial damage from doxorubicin is questionable in dogs.

Several protocols have been devised in an attempt to minimize doxorubicin-induced cardiomyopathy in dogs. Administering the doxorubicin slowly in a diluted solution (≈0.5 mg/mL over 30 minutes) seems to be the most effective; one of the authors (GC) has administered 8 to 10 doses of doxorubicin to a large number of dogs without obvious cardiotoxicity. This is due to the fact that cardiotoxicity of doxorubicin is directly related to the peak plasma concentration of the drug.

Dexrazoxane (Zinecard, Pfizer) offers a promising means of reducing the chronic cardiotoxicity induced by doxorubicin; doxorubicin doses in excess of 500 mg/m^2 have been administered to dogs receiving the agent without causing significant cardiotoxicity. Recently, carvedilol (0.1-0.4 mg/kg PO q12-24h) has been used successfully to prevent or decrease the probability of developing doxorubicin-associated cardiomyopathy in people (Kalay et al., 2006); one of the authors (GC) has successfully used carvedilol in dogs with subclinical myocardial dysfunction that needed doxorubicin.

UROTOXICITY

The urinary tract in small animals is rarely affected by adverse reactions to anticancer agents. Only two specific complications are of clinical importance in pets with cancer: nephrotoxicity and sterile hemorrhagic cystitis. Transitional cell carcinomas of the urinary bladder associated with chronic cyclophosphamide therapy have also been reported in dogs.

Nephrotoxicity is rarely observed in dogs and cats undergoing chemotherapy. Although several potentially nephrotoxic drugs are commonly used in these species, only doxorubicin (primarily in cats), cisplatin (in dogs), and intermediate to high doses of methotrexate (in dogs) are of concern to clinicians. The author's clinic does not use cisplatin frequently because of its potential to induce nephrotoxicity.

Doxorubicin may be a nephrotoxin in cats, and the limiting cumulative toxicity in this species may be renal rather than cardiac. This is generally seen after repeated doses of doxorubicin in cats, and for this reason, the authors commonly monitor kidney values and urine specific gravities in cats receiving repeated doxorubicin. If increases in creatinine and/or SDMA concentrations, or decreases in urine specific gravity develop, doxorubicin discontinuation should be considered. Doxorubicin may cause nephrotoxicosis in dogs with preexisting renal disease and in those concomitantly receiving other nephrotoxins such as aminoglycoside antibiotics or cisplatin. The administration of cisplatin using forced diuresis protocols minimizes the prevalence of nephrotoxicity in dogs. Due to its potential for nausea/vomiting and nephrotoxicity, the authors' clinics do not use cisplatin.

Sterile hemorrhagic cystitis (SHC) is a relatively common complication of long-term cyclophosphamide therapy in dogs; rarely, it may also occur acutely after a single dose of cyclophosphamide. This toxicity is not clinically relevant in cats. Acute clinical signs and urinalysis changes compatible with SHC developed after the first injection in three dogs treated at one clinic with IV cyclophosphamide, 100 mg/m^2, and four dogs receiving PO cyclophosphamide, 300 mg/m^2. SHC results from the caustic effects of one of the cyclophosphamide metabolites (acrolein) on the bladder epithelium. It develops in approximately 5% to 25% of dogs treated with cyclophosphamide, usually after an average of 18 weeks of therapy. Subjectively, it appears that the prevalence of SHC is higher when using cyclophosphamide in metronomic protocols. Furosemide or prednisone administered concomitantly with cyclophosphamide appears to decrease the prevalence of cystitis.

Forced diuresis appears to minimize the severity of this complication or prevent it. The authors usually recommend administering the cyclophosphamide in the morning, allowing the pet to urinate frequently (if it is an indoor dog), and administering prednisone on the same day that the animal receives the cyclophosphamide (if the protocol calls for prednisone administration). In addition, if giving bolus doses of cyclophosphamide to dogs, furosemide should be used to decrease the potential for SHC. An alternative method for

decreasing the risk of SHC is calculating the total dose of cyclophosphamide for a dog to receive (i.e., 200-250 mg/m^2 in the typical multiagent protocol for lymphoma) and splitting administration over 2-4 days. In a recent study, splitting administration of cyclophosphamide over 3 days without concurrent furosemide administration in dogs with lymphoma, 0/57 dogs to develop SHC (these dogs also experienced an 82% complete remission, suggesting that the efficacy was likely not affected by this dosing regimen) (Best et al., 2013). Additionally, a recent study evaluating the use of concurrent furosemide during metronomic administration of cyclophosphamide also subjectively decreased the prevalence of SHC to 3.6% (versus up to 32%) (Chan et al., 2016).

Clinical signs of sterile hemorrhagic cystitis are similar to those of other lower urinary tract disorders and include pollakiuria, hematuria, and dysuria. Urinalysis typically reveals blood and mildly to moderately increased numbers of white blood cells but no bacteria. Treatment of this complication consists of discontinuing the cyclophosphamide, forcing diuresis, diminishing the inflammation of the bladder wall, and preventing secondary bacterial infections. The cystitis resolves in most dogs within 1 to 4 months after the cyclophosphamide is discontinued. The author administers furosemide at a dosage of 2 mg/kg PO every 12 hours for its diuretic effects, prednisone at a dosage of 0.5 to 1 mg/kg PO every 24 hours for its antiinflammatory (and diuretic) effect, and an ST combination at a dose of 13 to 15 mg/kg PO every 12 hours to prevent secondary bacterial contamination. If the clinical signs worsen despite this approach, the instillation of 1% formalin solution in water into the bladder can be attempted. Gross hematuria resolved within 24 hours and did not recur in two dogs thus treated. The intravesical infusion of a 25% to 50% dimethylsulfoxide solution may also alleviate the signs of cystitis in dogs.

HEPATOTOXICITY

Chemotherapy-induced hepatotoxicity is extremely rare in dogs and cats. With the exception of the hepatic changes induced by corticosteroids in dogs, methotrexate, cyclophosphamide, lomustine, and azathioprine (Imuran, Burroughs Wellcome, Research Triangle Park, NC) have been implicated as or confirmed to be hepatotoxins in dogs. In our experience, the hepatotoxicity caused by anticancer drugs in small animals is of little or no clinical relevance, with the exception of lomustine.

A recent report describes a low prevalence of hepatotoxicity (<10%) in dogs receiving lomustine (CCNU) for lymphoma or mast cell tumors. The authors clinics have documented marked increases in alanine transaminase (ALT) activities (>1000 IU/L) and mild increases in alkaline phosphatase (ALP) activities (<500 IU/L) within 3 weeks of starting lomustine therapy in several dogs. Most dogs had decreases in the ALT and ALP concentrations after lengthening the dosing interval, decreasing the individual dosage, or both. In a recent study of 50 dogs receiving CCNU, increased liver enzyme activity occurred in 84% of dogs receiving CCNU alone and in 68% of dogs on concurrent Denamarin (Nutramax, Lancaster, SC) at therapeutic doses. Dogs receiving CCNU alone had significantly greater increases in ALT, aspartate aminotransferase, alkaline phosphatase, and bilirubin, and a significantly greater decrease in serum cholesterol concentrations than dogs receiving concurrent Denamarin. Dogs receiving CCNU alone were significantly more likely to have treatment delayed or discontinued because of increased ALT activity (Skorupski et al., 2011). For this reason, Denamarin should be used concurrently with CCNU when possible.

Dogs with immune-mediated disorders receiving chronic azathioprine therapy rarely develop increases in liver enzyme activities that respond to discontinuation of the drug.

NEUROTOXICITY

Anticancer agent–induced neurotoxicity is also extremely rare in dogs and cats. Neurotoxicosis occurs infrequently in dogs receiving 5-FU, although it is common in cats (for this reason, this drug should not be used in cats). Neurotoxicity can also occur in dogs and cats that ingest 5-FU intended for human use (i.e., prescribed for the owners). Clinical signs occur shortly (3-12 hours) after ingestion of the drug and consist primarily of excitation and cerebellar ataxia, resulting in death in approximately one third of the dogs and in most cats. Neurotoxicity was also documented in 25% of dogs receiving a combination of actinomycin D, 5-FU, and cyclophosphamide (the CDF protocol) for the management of metastatic or nonresectable carcinomas at one of the authors' clinics. This prevalence is considerably higher than that seen in association with the use of 5-FU in combination with other drugs and may be a result of drug interactions.

PULMONARY TOXICITY

Chemotherapy-induced pulmonary toxicity appears to be a rare adverse effect in dogs and cats. Lomustine has been associated with the development of pulmonary fibrosis in cats. This was seen after a high cumulative dose; however, it was associated with death after an episode of acute respiratory distress in one patient.

Similarly, there are multiple reports of pulmonary fibrosis in 5% to 15% of dogs treated with Tanovea; in most patients, it was fatal. Anecdotally, the concurrent use of prednisone may help decrease this specific toxicity. For this reason, we recommend not using Tanovea in breeds predisposed to development of pulmonary fibrosis, mainly West Highland White Terriers and other terrier breeds; we also recommend having baseline thoracic radiographs on dogs receiving this agent.

Bleomycin has also been associated with pulmonary toxicity in humans, leaving this as a potential concern for

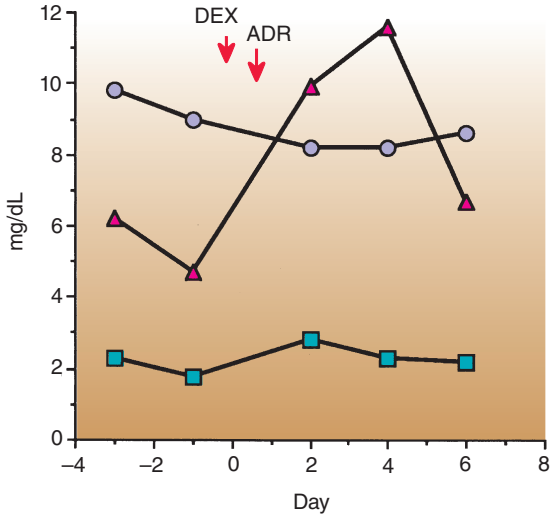

FIG 77.5
Serum phosphorus (Δ), calcium (○), and creatinine (□) concentrations in a dog with acute tumor lysis syndrome after chemotherapy for a primary pulmonary lymphoma. Note the increase in the serum phosphorus concentrations, with a mild decrease in the calcium concentrations and minor increases in the serum creatinine concentrations. *ADR,* Doxorubicin; *DEX,* dexamethasone. (From Couto CG: Management of complications of cancer chemotherapy, *Vet Clin North Am* 20:1037, 1990.)

veterinary use. Lastly, cisplatin can cause fatal pulmonary hypertension and edema in cats, and for this reason, is contraindicated for use in this species.

ACUTE TUMOR LYSIS SYNDROME

In human patients, the rapid lysis of certain tumor cells (e.g., lymphoma cells) shortly after chemotherapy may lead to a syndrome of hyperuricemia, hyperphosphatemia, and hyperkalemia, either singly or in combination. This clinical entity is referred to as *acute tumor lysis syndrome* and is thought to be secondary to the release of high quantities of intracellular phosphate, uric acid, and nucleic acid metabolites. The intracellular concentration of phosphorus in human lymphoma and leukemic cells is 4 to 6 times higher than that in normal lymphocytes, and the same appears to be true for dogs.

In dogs ATLS has been reported to occur only in association with lymphomas treated with chemotherapy, radiation therapy, or both, and is characterized by hyperphosphatemia, with or without azotemia, hyperkalemia, hypocalcemia, metabolic acidosis, and hyperuricemia. It is rare in cats. Clinical signs include depression, vomiting, and diarrhea, and occur within hours of the start of chemotherapy.

At one author's clinic, 10 cases of canine ATLS were documented in dogs with lymphoma during a period in which approximately 2000 dogs with lymphoma were treated with chemotherapy. In most dogs, the pretreatment serum creatinine concentrations or the tumor burden was high; one of the dogs had high liver enzyme activities. Within 1 to 7 days of the start of chemotherapy, lethargy, vomiting, and bloody diarrhea developed in affected dogs, and the serum phosphorus concentrations increased markedly (Fig. 77.5). Aggressive fluid therapy and the correction of acid-base and electrolyte disturbances resulted in resolution of the clinical signs within 3 days in 6 dogs; the remaining 2 dogs died as a result of ATLS.

CHAPTER 78

Approach to the Patient With a Mass

APPROACH TO THE CAT OR DOG WITH A SOLITARY MASS

It is common for the practicing veterinarian to evaluate a clinically healthy dog or cat in which a single mass is found during a routine physical examination or in which the owner has detected a mass and is concerned about it. The mass can be superficial (e.g., enlarged prescapular lymph node, dermal mass, or subcutaneous mass) or deep (e.g., splenic mass, enlarged mesenteric lymph node), and often the clinician wonders how to proceed and what to recommend to the owner.

In this situation, there are several possible approaches:

1. Do nothing and see if the mass "goes away."
2. Evaluate the mass cytologically.
3. Evaluate the mass histopathologically.
4. Do a complete workup, including complete blood count (CBC), serum biochemistry profile, radiography, abdominal ultrasonography, and urinalysis.

The first option (i.e., do nothing and see if the mass goes away) is not really an option because the presence of any mass is abnormal, and it should therefore be evaluated. As a general rule, most masses, with the notable exception of inflammatory lesions, histiocytomas in young dogs, and transmissible venereal tumors, do not regress spontaneously.

At our clinics, the typical first step in evaluating a solitary mass is to perform a fine-needle aspiration (FNA) to obtain material for cytologic evaluation (see Chapter 74). Using this simple, relatively atraumatic, quick, and inexpensive procedure, the clinician can arrive at a highly presumptive or definitive diagnosis in the vast majority of animals. After identifying the nature of the mass (i.e., benign neoplastic, malignant neoplastic, inflammatory, or hyperplastic), the clinician can recommend additional tests to the owner.

Performing a biopsy for histopathology constitutes another valid alternative. However, the cost, the trauma to the patient, and the time it takes for the pathologist's report to become available make biopsy a less-attractive option than FNA. An intensive workup of a cat or dog with a solitary mass (i.e., option 4) may not be warranted because additional diagnostic information regarding the mass is rarely gained from these procedures. However, the presence of metastatic lesions on thoracic radiographs may suggest that the mass in question is a malignant tumor.

If a cytologic diagnosis of a benign neoplasm is made (e.g., lipoma), the clinician faces two options: to do nothing and observe the mass or surgically excise it. Because benign neoplasms in cats and dogs are rarely premalignant (with the notable exception of solar dermatitis/carcinoma in situ preceding the development of squamous cell carcinomas), if a benign neoplasm is definitively diagnosed, a sound approach is to recommend a wait-and-see attitude. In those cases, the mass should be measured using calipers and recorded in the medical record; if the mass enlarges, becomes inflamed, or ulcerates, then surgical excision is recommended. However, the clinician should keep in mind that most benign neoplasms are more easily excised when they are small (i.e., it is not advisable to wait until the mass becomes quite large). To some owners, the option of surgically excising the mass shortly after diagnosis is more appealing; this can be scheduled at the same time of a dental prophylaxis, for example.

If a cytologic diagnosis of malignancy is obtained (or if the findings are suggestive of or compatible with malignancy), additional evaluation is warranted. Different approaches are indicated, depending on the cytologic diagnosis (i.e., carcinoma versus sarcoma versus round cell tumor), the patient, the family, and the clinician. However, with the exception of mast cell tumors (i.e., pulmonary metastases are extremely rare in dogs and cats with this tumor type), thoracic radiographs should be obtained to search for metastatic disease in dogs and cats with most types of malignant neoplasms. Two lateral views (i.e., right and left) and a ventrodorsal (or dorsoventral) view are recommended to increase the likelihood of detecting metastatic lesions. If available, a computed tomography (CT) can detect masses smaller than those detectable on plain radiography; however, this has not yet become a routine staging diagnostic at the authors' clinics due to the fact that this procedure

requires general anesthesia and is more expensive. Plain radiographs of the affected area may also be indicated to look for soft tissue and bone involvement. Abdominal ultrasonography or CT may be indicated for further staging in patients with certain neoplasms (e.g., hemangiosarcoma, intestinal neoplasms, mast cell tumors). A minimum database consisting of a CBC, serum biochemistry profile, and urinalysis may provide additional clinical information (e.g., paraneoplastic syndromes, concurrent organ failure), and assess the general health of the patient in preparation for potential treatment.

If the mass is malignant and there is no evidence of metastatic disease, surgical excision is usually recommended. If there are systemic or metastatic lesions, the pathologist feels comfortable with the cytologic diagnosis, and the tumor is likely to respond to chemotherapy (e.g., lymphoma, hemangiosarcoma), chemotherapy constitutes the best viable option (see Chapter 75). However, as discussed in Chapter 75, surgical resection of the primary mass (e.g., mammary carcinoma) in a patient with metastatic lesions may provide considerable palliation and prolong good-quality survival. If an assertive diagnosis cannot be made on the basis of the cytologic findings, an incisional or excisional biopsy of the mass is advisable. The authors' clinics almost never recommend euthanasia in dogs and cats with metastatic lesions and good quality of life because survival times in excess of 6 months (without chemotherapy) are common in animals with most metastatic neoplasms. Metronomic chemotherapy may result in long-standing stable or slowly progressive metastatic disease (Fig. 78.1).

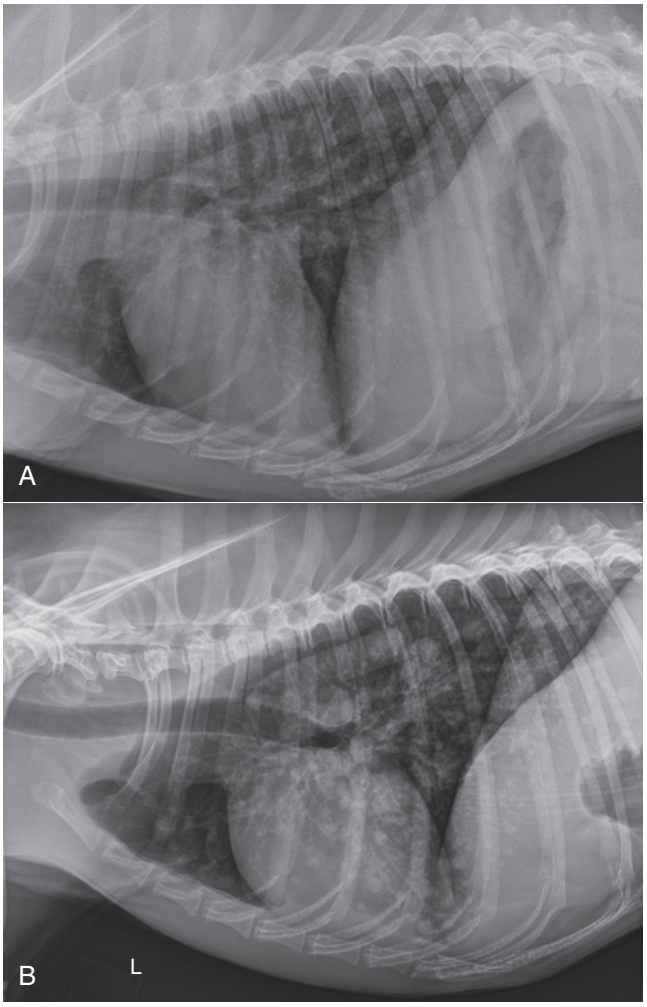

FIG 78.1
Thoracic radiographs in a 10-year-old, mixed-breed dog with a nonresectable thyroid carcinoma before **(A)** and after 756 days of metronomic chemotherapy **(B).**

APPROACH TO THE PATIENT WITH METASTATIC LESIONS

Radiographic or ultrasonographic evidence of metastatic cancer is occasionally found during the routine evaluation of an animal with a suspected or confirmed malignancy, or during the evaluation of a cat or dog with obscure clinical signs. In such instances, the clinician should be familiar with both the biologic behavior of the common neoplasms and with their characteristic radiographic and ultrasonographic patterns (Table 78.1). Suter et al. (1974) described the typical radiographic appearances of various metastatic malignancies. In addition, the owner should be questioned regarding any prior surgeries in the pet (e.g., excision of a mass that was thought to be benign but may have been the primary malignancy).

If a cytologic or histopathologic diagnosis of malignancy has already been made and the metastatic lesions are detected while staging the patient, treatment options can be discussed with the owner at this point (assuming that the metastatic lesions have arisen from the previously diagnosed primary tumor). As a general rule, cytologic or histopathologic evaluation of one or more of these lesions should be performed so that the clinician can best advise the owner as to the appropriate course of action.

A cytologic diagnosis of metastatic lung lesions can usually be obtained through blind or ultrasonography-, fluoroscopy-, or CT-guided percutaneous FNA of the lungs. To do this, the area to be aspirated (i.e., the one with the highest density of lesions radiographically or the easily identified and accessible lesions) is clipped and aseptically prepared. For blind percutaneous lung aspirates, the patient should be in sternal recumbency or standing; a 25- or 27-gauge, 2- to 3-inch (5- to 7.5-cm) needle (depending on the size of the animal) coupled to a 12- to 20-mL syringe is rapidly advanced through an intercostal space along the cranial border of the rib to the depth required (previously determined on the basis of the radiographs), and suction is applied two or three times and then released; the needle is then withdrawn. Smears are made as described in Chapter 74. When aspirating lungs, the clinician is likely to obtain a fair amount of air or blood (or both) in the syringe. Rare complications associated with this technique include pneumothorax (patients should be closely observed for 2-6 hours after the procedure and dealt with accordingly if pneumothorax develops) and bleeding. As a

general rule, FNA of the lungs should not be performed in cats or dogs with coagulopathies. In most patients, metastatic lesions are easily diagnosed using this simple approach.

If an FNA of the lungs fails to yield a diagnostic sample, a lung biopsy performed with a biopsy needle (under ultrasonographic, fluoroscopic, or CT guidance) or through a thoracotomy or thoracoscopy should be contemplated. This procedure is associated with an extremely low morbidity and should be recommended if owners are considering treatment.

Metastatic lesions in other organs or tissues (e.g., liver, bone) can also be diagnosed on the basis of FNA findings.

TABLE 78.1

Metastatic Behavior of Some Common Neoplasms in Dogs and Cats

NEOPLASM	SPECIES	COMMON METASTATIC SITES
HSA	D	Liver, lungs, omentum, kidney, eye, CNS
OSA	D	Lungs, bone
SCC—oral	C, D	Lymph nodes, lungs
aCA—mammary	C, D	Lymph nodes, lungs
aCA—anal sac	D	Lymph nodes
aCA—prostate	D	Lymph nodes, bone, lungs
TCC—bladder	D	Lymph nodes, lungs, bone
MEL—oral	D	Lymph nodes, lungs
MCT	D	Lymph nodes, liver, spleen
MCT	C	Spleen, liver, bone marrow

aCa, Adenocarcinoma; *C,* cat; *CNS,* central nervous system; *D,* dog; *HSA,* hemangiosarcoma; *MCT,* mast cell tumor; *MEL,* malignant melanoma; *OSA,* osteosarcoma; *SCC,* squamous cell carcinoma; *TCC,* transitional cell carcinoma.

The clinician should remember that nodular lesions of the liver or spleen in dogs with a primary malignancy should not necessarily be considered metastatic. FNA or biopsies of such lesions frequently reveal normal hepatocytes (i.e., regenerative hepatic nodule) or extramedullary hematopoiesis/lymphoreticular hyperplasia.

In addition, an ultrasonographically "normal" liver or spleen in a patient with suspected metastases may contain abundant malignant cells. For example, in dogs with lymphoma and increased ALT activity, FNA of ultrasonographically normal liver oftentimes yields neoplastic lymphoid cells. The authors occasionally find large (i.e., 4-6 cm) metastatic lesions in the liver of dogs with normal ultrasonographic appearance. Ultrasonographic features of internal lymph nodes may assist in classifying the lymphadenopathy as metastatic or reactive; for example, it has been reported that the resistive index (RI) and pulsatility index (PI) were significantly higher in neoplastic than in reactive medial iliac and mesenteric lymph nodes (Prieto et al., 2009).

Primary bone lesions or bone metastases can easily be aspirated using a hypodermic needle (20- to 22-gauge) that is inserted blindly or under ultrasonographic guidance; if this fails to yield cells, a 16- or 18-gauge bone marrow aspiration needle can be used. If a cytologic diagnosis cannot be made, a core (needle) biopsy can be performed.

As discussed in Chapter 75, cats and dogs with metastatic neoplasms can now be treated fairly successfully using conventional or metronomic chemotherapy. To do this, however, it is necessary to know the histologic (or cytologic) tumor type. The clinician should always bear in mind that euthanasia is a viable option for some owners.

APPROACH TO THE PATIENT WITH A MEDIASTINAL MASS

Several lesions are found as anterior mediastinal masses (AMMs) during physical examination or plain thoracic radiography (Table 78.2). Some of these lesions are malignant neoplasms; therefore diagnosis and treatment should be approached aggressively in such animals.

TABLE 78.2

Anterior Mediastinal Masses in Cats and Dogs

Thymic hematomas	?	Rare	Traumatic, rodenticides?
Heart base tumors	?	Rare	Brachiocephalic breeds

?, Questionable.

Clinicopathologic Features and Diagnosis

When evaluating a cat or dog with an AMM, the clinician should consider several issues before recommending a specific treatment. As discussed previously (see Chapter 75), the treatment recommended depends on the specific tumor type (i.e., surgical excision may be curative for dogs and cats with thymomas, whereas chemotherapy is indicated for those with lymphoma). Because lymphomas and thymomas are the most common AMMs in small animals, the ensuing discussion is limited to these two neoplasms. Other neoplasms that originate in anterior mediastinal structures include chemodectomas (heartbase tumors), ectopic thyroid carcinomas, and lipomas, among others. Nonneoplastic lesions of the mediastinum include mainly thymic or mediastinal hematomas, granulomatous lymphadenitis (e.g., blastomycosis), and ultimobranchial cysts.

Paraneoplastic syndromes such as generalized or focal myasthenia gravis, polymyositis, exfoliative dermatitis, lymphocytosis, neutropenia, and second neoplasms have been well characterized in cats and dogs with thymoma. Aplastic anemia, a paraneoplastic syndrome common in humans with thymoma, is uncommon in small animals with this tumor type. Hypercalcemia is a common finding in dogs with mediastinal lymphoma, but it can also occur in dogs with thymoma.

In cats, the age at the time of presentation points to a specific diagnosis. In other words, anterior mediastinal lymphomas are more common in young cats (1-3 years old), whereas thymomas are more common in older cats (>8 years old). It is also important to know the feline leukemia virus (FeLV) status in this species because most cats with mediastinal lymphomas are viremic (i.e., FeLV positive), whereas most cats with thymoma are not. FeLV-negative mediastinal lymphomas have been described in young to middle-age Siamese cats and can occasionally be seen in other cats.

In dogs most AMMs are diagnosed in older animals (older than 5-6 years of age); therefore age cannot be used as a means of distinguishing between lymphomas and thymomas. However, a large proportion of dogs with mediastinal lymphoma are hypercalcemic, whereas most dogs with thymomas are not (although hypercalcemia can also occur in dogs with this neoplasm). Peripheral blood lymphocytosis can be present in dogs and cats with either lymphoma or thymoma; in most dogs with lymphoma, the circulating lymphocytes are morphologically abnormal. The presence of neuromuscular signs in a dog or cat with an AMM suggests the existence of a thymoma or of lymphoma with central nervous system involvement.

Thoracic radiographs are of little help in differentiating thymomas from lymphomas. The two neoplasms are similar in appearance, although lymphomas appear to originate more frequently in the dorsal anterior mediastinum, whereas thymomas originate more often in the ventral mediastinum (Fig. 78.2). Thymomas also occasionally "hug" the heart in the ventrodorsal radiographic view and can have sharp or irregular edges. The prevalence of pleural effusion in dogs and cats with either thymoma or lymphoma is similar; thus the finding cannot be used as a means to distinguish between these two tumor types. However, neoplastic cells are often seen in the pleural effusion in dogs and cats with lymphoma but are typically absent in those with thymoma.

FIG 78.2
Typical radiographic features of thymoma *(arrows)* in a dog. The mass originates in the ventral mediastinum, unlike most lymphomas, which usually originate in the dorsal mediastinal region. Percutaneous fine-needle aspiration of this mass yielded findings diagnostic for thymoma, and the dog underwent a thoracotomy with complete resection of the mass.

Ultrasonographic evaluation of the AMM should be attempted before more invasive diagnostic techniques are used. Ultrasonographically, most thymomas have mixed echogenicity, with discrete hypoechoic to anechoic areas that correspond to true cysts on cross section (Patterson and Marolf, 2014). The lack of a supporting stroma in lymphomas usually confers a hypoechoic to anechoic density to the mass, which therefore may look diffusely cystic. In addition to aiding in the presumptive diagnosis of a given tumor type, ultrasonography may provide information regarding the resectability of the mass and assists in obtaining a specimen for cytologic evaluation (see next paragraph). In patients with thymoma, a thoracic CT scan may help in planning surgery.

Transthoracic FNA of AMMs constitutes a relatively safe and reliable evaluation technique. After sterile preparation of the thoracic wall overlying the mass (see Chapter 74), a 2- to 3-inch (5- to 7.5-cm), 25-gauge needle is used to sample the mass. This can be done blindly (if the mass is so large that it is pressing against the interior thoracic wall) or guided by radiography (using three views to establish a three-dimensional location), fluoroscopy, ultrasonography, or CT. Despite the fact that there are large vessels within the anterior mediastinum, postaspiration bleeding is extremely rare if the animal remains motionless during the procedure. Alternatively, if the mass is large enough to be in close contact with the internal thoracic wall, a transthoracic needle biopsy can be performed to allow histopathologic evaluation.

Cytologically, mediastinal lymphomas are composed of a monomorphic population of lymphoid cells that are mostly immature (i.e., low nuclear-to-cytoplasmic ratio, dark blue cytoplasm, clumped chromatin pattern, and nucleoli); in cats, most cells in anterior mediastinal lymphomas are heavily vacuolated and resemble human Burkitt lymphoma cells (Fig. 78.3). Thymomas are cytologically heterogeneous and composed primarily of a population of small lymphocytes (although large blasts are sometimes present) and occasionally a distinct population of epithelial-like cells that are usually polygonal or spindle-shaped, which can be identified either as individual cells or in sheets. Hassall corpuscles are rarely seen in Wright-stained cytologic preparations. Plasma cells, eosinophils, neutrophils, mast cells, macrophages, and melanocytes are all occasionally seen (Fig. 78.4). Flow cytometry can also be used to help differentiate mediastinal lymphoma from thymomas in dogs. The presence of >10% lymphocytes that are CD4+/CD8+ is characteristic for thymomas, whereas mediastinal lymphomas generally contained <2% CD4+CD8+ lymphocytes (Lana et al., 2006).

Treatment

As discussed in preceding paragraphs, anterior mediastinal lymphomas are best treated with chemotherapy (see Chapter 79). Radiotherapy can also be used in conjunction with chemotherapy to induce a more rapid remission. A recent publication on canine mediastinal lymphoma reported that two dogs that did undergo radiotherapy in addition to their chemotherapy protocol had prolonged progression-free survival and overall survival compared with the rest of the dogs in the study that did not undergo radiation (Moore et al., 2018). However, the animal must be deemed an appropriate candidate for anesthesia before consideration of radiotherapy, because chemical restraint in patients exhibiting severe respiratory compromise can further compound their clinical status.

Because most thymomas are benign, surgical excision is usually curative. Although in some reports the perioperative morbidity and mortality of this procedure are high (Atwater et al., 1994), in the authors' experience, most patients that undergo thoracotomies for removal of a thymoma do well and are released from the hospital in 3 to 4 days. In a review of the surgical outcome in 9 cats and 11 dogs with thymomas (Zitz et al., 2008), 8 out of 9 cats and 8 out of 11 dogs survived the immediate postoperative period and had median survival times of 30 and 18.5 months, respectively. Two cats and one dog had late recurrences.

Radiotherapy can successfully induce remission in patients with thymoma, although complete, long-lasting remission is rarely achieved. This may be due to the fact that radiotherapy eliminates only the lymphoid component of the neoplasm, whereas the epithelial component remains unchanged. Chemotherapy may be beneficial in selected cats and dogs with nonresectable thymomas or in those in which repeated anesthetic episodes or a major surgical procedure poses a severe risk. One author's clinic has used combination chemotherapy protocols commonly used for dogs and cats with lymphoma (i.e., cyclophosphamide, vincristine, cytosine arabinoside, and prednisone [COAP]; cyclophosphamide, vincristine, and prednisone [COP]; and cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]; see Chapter 79) in a limited number of cats and dogs with cytologically diagnosed thymomas. As with radiotherapy, however, chemotherapy may only eliminate the lymphoid cell population, thus rarely resulting in complete or long-lasting remissions.

If a definitive diagnosis of thymoma or lymphoma cannot be obtained preoperatively, the clinician has two therapeutic

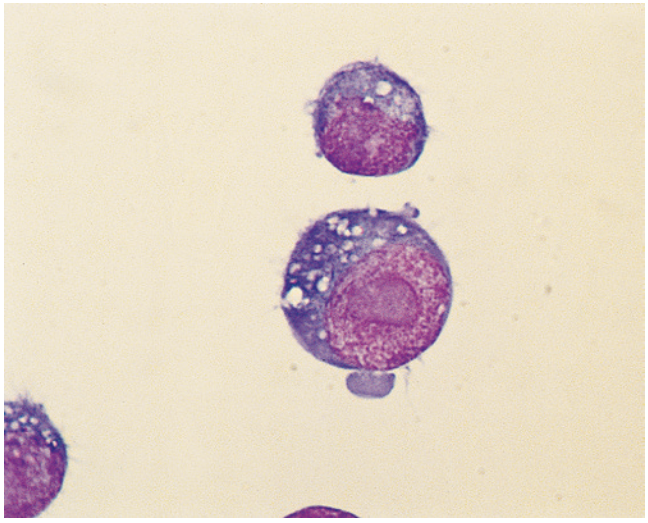

FIG 78.3

options: (1) perform a thoracotomy and excise the mass or (2) initiate chemotherapy for lymphoma (COP, COAP, or CHOP). In the latter case, if no remission (or only a partial remission) is observed 10 to 14 days after the start of chemotherapy, the mass is most likely a thymoma, and surgical resection should be considered.

CHAPTER 79

Lymphoma

Lymphoma (i.e., malignant lymphoma, lymphosarcoma) is a lymphoid malignancy that originates from solid organs or tissues (e.g., lymph nodes, liver, spleen, eye); this distinguishes lymphomas from lymphoid leukemias, which originate in the bone marrow (see Chapter 80).

Etiology and Epidemiology

Early reports stated that approximately 70% of cats with lymphoma are persistently infected with feline leukemia virus (FeLV) (Table 79.1). Although the prevalence of viremia in cats with lymphoma varies with the anatomic form of presentation (see later discussion), young cats with lymphoma are generally FeLV positive, whereas older cats are FeLV negative. Over the past few years, the prevalence of FeLV infection in cats with lymphoma in the United States has been decreasing, so we tend to see predominantly FeLV-negative cats with lymphoma. Feline immunodeficiency virus (FIV) infection increases the risk of developing lymphoma in cats; cats infected with FIV are almost six times more likely to develop lymphoma than noninfected cats, whereas cats coinfected with FeLV and FIV are more than 75 times more likely to develop lymphoma than noninfected cats (Shelton et al., 1990). Louwerens et al. (2005) reported an increase in the prevalence of feline lymphoma despite the decrease in the prevalence of FeLV infection; this increase was associated primarily with the gastrointestinal form, extranodal or atypical forms, and FeLV-negative mediastinal forms in young to middle-aged Siamese and oriental breeds. *Helicobacter* spp. may play a role in the development of gastric lymphoma in cats (Bridgeford et al., 2008). *Borrelia* spp. infection has been linked to the development of non-Hodgkin lymphoma in people and in a horse (Ferreri et al., 2009); however, this has not been described in dogs. A T-cell multicentric lymphoma associated with infection with a novel *Ehrlichia* spp (Panola Mountain *Ehrlichia*) that responded to doxycycline was recently reported (Qurollo et al., 2013).

In dogs, the etiology of lymphomas is considered multifactorial because no single etiologic agent has been identified. However, a genetic component is evident in that the neoplasm is highly prevalent in certain breeds and bloodlines (Modiano et al., 2005). For example, Boxers, Shih Tzus, and Siberian Huskies have primarily T-cell tumors, whereas Cocker Spaniels and Basset Hounds have predominantly B-cell lymphoma; B- and T-cell tumors are almost equally distributed in Golden Retrievers.

The age of cats with lymphoma at the time of presentation is bimodal, with the first peak occurring in cats that are approximately 2 years of age and the second peak in cats that are approximately 10 to 12 years of age. The cats that make up the first peak are mainly FeLV positive, whereas those that make up the second peak are predominantly FeLV negative. As mentioned earlier, the prevalence of FeLV-positive cats with lymphoma in the United States continues to decrease. Most dogs with lymphoma are middle-aged or older (6-12 years of age); however, lymphoma can occur in dogs of any age (even in puppies).

Clinical Features

Four anatomic forms of presentation occur in dogs and cats with lymphoma:

1. *Multicentric,* characterized by generalized lymphadenopathy; hepatic, splenic, or bone marrow involvement; or a combination of these
2. *Mediastinal,* characterized by mediastinal lymphadenopathy, with or without bone marrow infiltration
3. *Alimentary,* characterized by solitary, diffuse, or multifocal gastrointestinal tract infiltration, with or without intraabdominal lymphadenopathy
4. *Extranodal,* affecting any organ or tissue (e.g., renal, neural, ocular, cutaneous)

The distribution of the different anatomic forms differs between cats and dogs. The multicentric form is the most common in dogs, accounting for more than 80% of all the lymphomas in this species. In cats, the alimentary form is the most common, representing more than 70% of the cats with this neoplasm.

The clinical findings in dogs and cats with lymphoma are related to the anatomic form of presentation. Patients with

TABLE 79.1

Prevalence of Feline Leukemia Virus Infection in Cats With Lymphoma

ANATOMIC FORM	FeLV POSITIVE (%)
Alimentary	30
Mediastinal	90
Multicentric	80
Cutaneous	0

the multicentric form are evaluated because of vague, nonspecific clinical signs, or more frequently, the owners detect one or more subcutaneous masses (i.e., enlarged lymph nodes, Fig. 79.1) during grooming or petting in an otherwise healthy pet, and this prompts them to seek veterinary care. Occasionally, dogs and cats with lymphoma are evaluated because of nonspecific clinical signs such as weight loss, anorexia, and lethargy. If the enlarged lymph nodes mechanically obstruct lymphatic drainage, edema can occur; if they compress the airway, coughing may occur. Dogs with lymphoma and hypercalcemia (see later) frequently present for polyuria and polydipsia, and are often times clinically unwell.

Physical examination of dogs and cats with multicentric lymphoma usually reveals marked to massive generalized lymphadenopathy, with or without hepatomegaly, splenomegaly, or extranodal lesions (e.g., ocular, cutaneous, renal, neural). The affected lymph nodes are enlarged, painless, and freely movable. A syndrome of reactive (hyperplastic) lymphadenopathy that occurs in cats can mimic the clinicopathologic features of multicentric lymphoma but is usually easily distinguished cytologically.

Cats and dogs with mediastinal lymphoma are usually evaluated because of dyspnea, coughing, or dysphagia/regurgitation (the latter is more common in cats) of recent onset. Polyuria and polydipsia are also common presenting complaints in dogs with mediastinal lymphoma and hypercalcemia; tumor-associated hypercalcemia is rare in cats with lymphoma. The respiratory and upper digestive tract signs are caused by compression from enlarged anterior mediastinal lymph nodes, although malignant pleural effusion can contribute to the severity of the respiratory tract signs. On physical examination, the abnormalities are usually confined to the thoracic cavity and consist of decreased bronchovesicular sounds, normal pulmonary sounds displaced to the dorsocaudal thoracic cavity, a dull sound heard on percussion of the ventral thoracic cavity, and a noncompressible anterior mediastinum (in cats). Unilateral or bilateral Horner syndrome may occur in cats (and occasionally dogs) with mediastinal lymphoma. Some dogs with mediastinal lymphoma have marked head and neck edema caused by compression from enlarged lymph nodes (anterior vena cava syndrome).

Cats and dogs with alimentary lymphoma usually display gastrointestinal tract signs such as anorexia, vomiting, diarrhea, or weight loss. Occasionally, signs compatible with an intestinal obstruction or peritonitis (caused by rupture of a lymphomatous mass) can occur. Physical examination typically reveals an intraabdominal mass or masses (e.g., enlarged mesenteric or ileocecocolic lymph nodes or intestinal masses) and thickened bowel loops (in patients with diffuse small intestinal lymphoma). Rarely, polypoid lymphomatoid masses can protrude through the anus in dogs with colorectal lymphoma.

The clinical signs and physical examination findings in cats and dogs with extranodal lymphomas are extremely variable and depend on the location of the lesions. In general, the clinical signs stem from the compression or displacement of normal parenchymal cells in the affected organ (e.g., anterior uveitis or hyphema in ocular lymphoma, variable neurologic signs in central nervous system [CNS] lymphoma). The typical clinical signs and physical examination findings in cats and dogs with extranodal lymphomas are summarized in Table 79.2. Common extranodal forms in dogs include cutaneous and ocular lymphomas; in cats they include nasopharyngeal, ocular, renal, and neural lymphomas.

Cutaneous lymphoma is one of the most common extranodal forms of lymphoma in dogs but is rare in cats. The clinical signs and characteristics of the lesions are extremely variable, and they can mimic any primary or secondary skin lesion. Dogs with mycosis fungoides (an epitheliotropic T-cell lymphoma) are usually first evaluated because of chronic alopecia, desquamation, pruritus, and erythema, eventually leading to plaque and mass formation (Fig. 79.2). Mucocutaneous and mucosal lesions are relatively common, but generalized lymph node involvement may not occur initially. A characteristic lesion in dogs with this form of lymphoma is a circular, raised, erythematous, donut-shaped, dermoepidermal mass that contains normal skin in the center (Fig. 79.3). Diffuse swelling and erythema are also common (Fig. 79.4, *A*). Most of the cats with cutaneous

lymphoma reported in the literature and seen by the authors have been negative for FeLV viremia.

Ocular lymphoma occurs in both dogs and cats. In dogs, it is commonly associated with the multicentric form, whereas both primary ocular involvement and ocular involvement associated with the multicentric form are common in cats. A variety of signs and lesions may be present in these patients, including photophobia, blepharospasm, epiphora, hyphema, hypopyon, ocular masses, third eyelid infiltration, anterior uveitis, chorioretinal involvement, and retinal detachment.

Nasopharyngeal lymphoma is relatively common in cats but is extremely rare in dogs. Clinical signs are similar to those seen in cats with any upper respiratory tract disorder and include sneezing, unilateral or bilateral nasal discharge (ranging from mucopurulent to frankly hemorrhagic), stertorous breathing, exophthalmos, and facial deformity (Fig. 79.5); this is one of the most common forms of extranodal lymphoma seen in cats at the authors' clinics.

Renal lymphoma is relatively common in cats but uncommon in dogs. Cats with this anatomic form are first evaluated because of vague clinical signs, usually secondary to azotemia. On physical examination, the cat is often emaciated, typically has pale mucous membranes from anemia, and has large, irregular, and firm kidneys; both kidneys are commonly affected. There is a purported association between

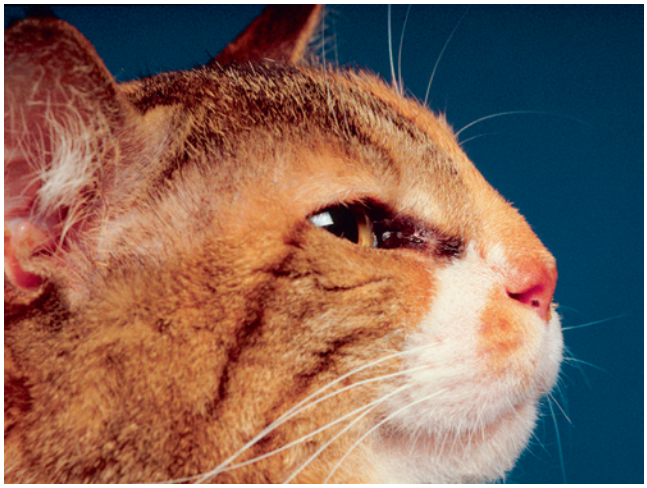

FIG 79.5
Facial deformity and nasal discharge associated with intranasal lymphoma in a 6-year-old cat.

renal and CNS lymphoma in cats, so some oncologists recommend using antineoplastic drugs that achieve high CNS concentrations (i.e., cytosine arabinoside, lomustine) in the treatment of cats with renal involvement in an attempt to prevent secondary CNS dissemination (see later).

Dogs and cats with neural lymphoma are evaluated because of a variety of neurologic signs that reflect the location and extent of the neoplasm. Although CNS signs are most common, peripheral nerve involvement may occur occasionally in cats. Three forms of presentation are clinically recognized: solitary epidural lymphoma, neuropil (intracranial or intraspinal) lymphoma (also called *true CNS lymphoma*), and peripheral nerve lymphoma. Solitary epidural lymphoma is common in young FeLV-positive cats. Neural lymphomas can be primary (e.g., epidural lymphoma), or they may be secondary to the multicentric form; as discussed earlier, secondary CNS involvement may occur in cats with renal lymphoma. Additionally, dogs that have been receiving chemotherapy for multicentric lymphoma can develop late CNS relapse; these patients develop acute onset of neurologic signs, usually while the multicentric neoplasm is still in remission. This late CNS relapse is likely related to the fact that most drugs used to treat lymphoma do not cross the blood-brain barrier when used at standard doses; thus the CNS becomes a sanctuary for tumor cells. In our clinics, CNS signs in any dog with lymphoma before or during treatment are attributed to this neoplasm (and treated accordingly) until proven otherwise.

A variety of differential diagnoses should be considered in a dog or cat with suspected lymphoma. The clinician should always bear in mind that lymphomas are great imitators; they can mimic numerous different neoplastic and nonneoplastic disorders. The differential diagnoses for cats and dogs with lymphoma are similar to those in patients with leukemia (see Chapter 80).

Occasionally, dogs with lymphoma are evaluated because of clinical signs secondary to a paraneoplastic syndrome (i.e., molecularly mediated distant effects of the neoplasm). Paraneoplastic syndromes that have been encountered in dogs with lymphoma include hypercalcemia, monoclonal and polyclonal gammopathies, immune-mediated cytopenias (typically immune-mediated hemolytic anemia or immune-mediated thrombocytopenia), polyneuropathy, and hypoglycemia. Only hypercalcemia and gammopathies have been documented in cats with this neoplasm, although they are considerably less frequent than in dogs. Of all these syndromes, humoral hypercalcemia of malignancy in dogs is of main clinical relevance and typically resolves with the treatment. Most paraneoplastic syndromes resolve when patients are treated with chemotherapy.

Hematologic and serum biochemical features

A variety of nonspecific hematologic and serum biochemical abnormalities can be detected in patients with lymphoma. The hematologic abnormalities result from infiltration of the bone marrow with neoplastic cells, splenic hypofunction or hyperfunction (caused by neoplastic infiltrates), chronic disease, or paraneoplastic immune-mediated abnormalities. Certain hematologic abnormalities (i.e., monocytosis, eosinophilia, leukemoid reactions) may result from the local or systemic production of bioactive substances by the tumor cells (e.g., hematopoietic growth factors, interleukins). With the new flow cytometry (FCM)-based hematology analyzer, neoplastic cells in circulation are often "counted" as monocytes, so monocytosis should always prompt careful evaluation of the graphics or a blood smear review. Given the fact that these analyzers evaluate 10,000 to 15,000 leukocytes per run, it is common to identify neoplastic cells in circulation in dogs with lymphoma (Fig. 79.6).

The serum biochemical abnormalities result from either the production of bioactive substances by the tumor cells or from organ failure secondary to neoplastic infiltration. In general, the complete blood count (CBC) and biochemical profile are not diagnostic in cats and dogs with lymphoma, unless there are unclassified cells identified as abnormal lymphoid cells on evaluation of the blood smear or the graphics from the analyzer.

Common hematologic abnormalities include nonregenerative anemia, leukocytosis, neutrophilia (with or without a left shift), monocytosis, eosinophilia (usually in cats), abnormal lymphoid cells in peripheral blood (i.e., leukemic phase of lymphoma), thrombocytopenia, isolated or combined cytopenias, and leukoerythroblastic reactions, among others. Lymphocytosis is rare in dogs and cats with lymphoma; when present, it is usually of low magnitude (i.e., <10,000-12,000/μL). Erythrocytosis occurs in approximately half of the dogs with renal lymphoma, but it is extremely uncommon in cats (see Chapter 84).

Serum biochemical abnormalities are more common in dogs than in cats with lymphoma and consist mainly of hypercalcemia or gammopathies. Hypercalcemia is one of the most common paraneoplastic abnormalities in dogs with lymphoma, occurring in approximately 20% to 40% of the patients; it is extremely rare in cats, and it is more prevalent

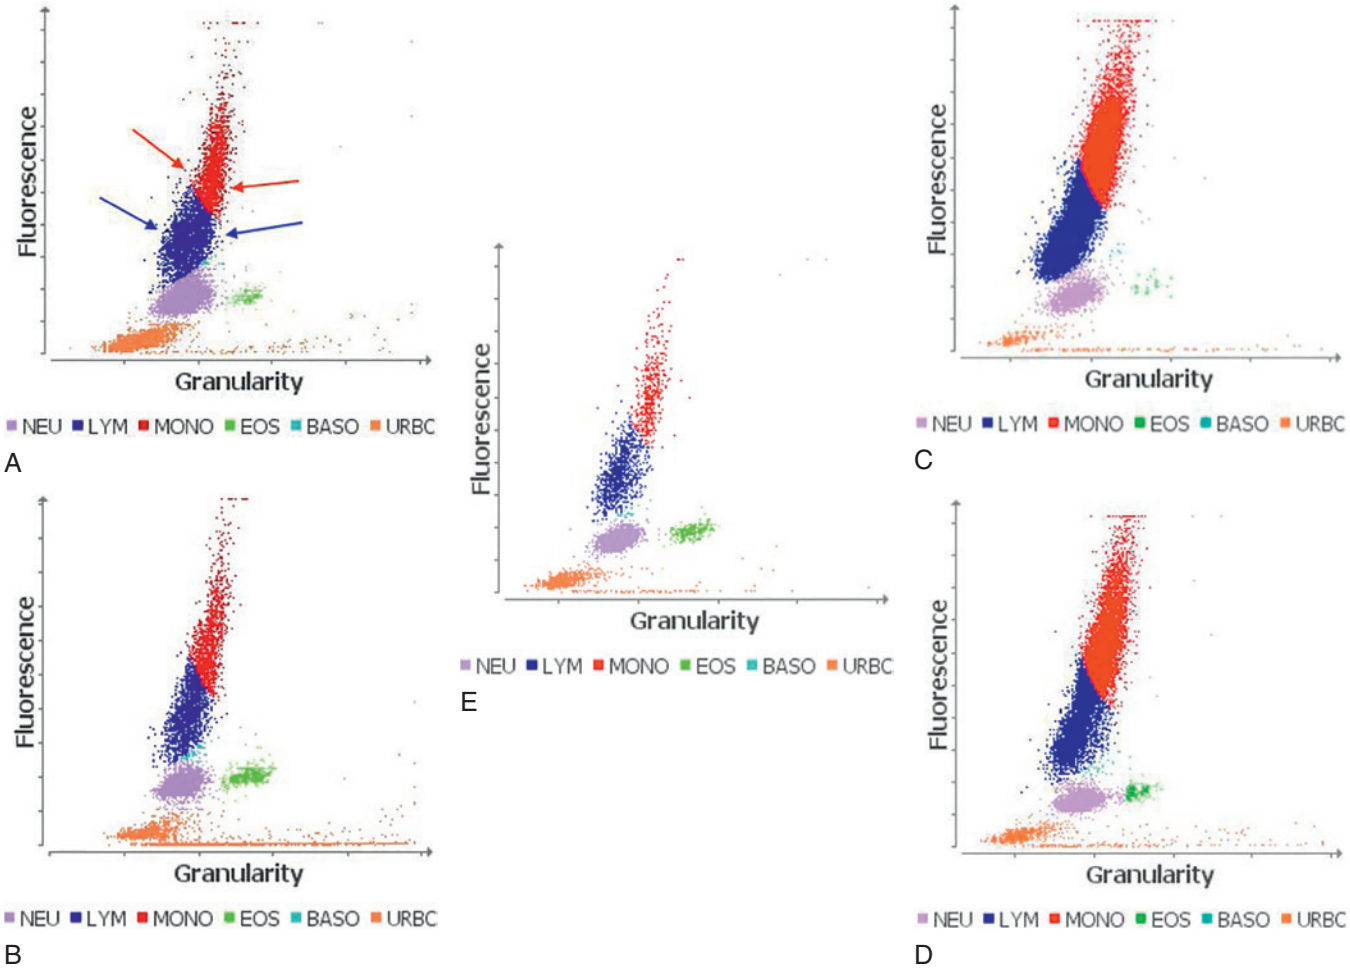

FIG 79.6
Leukocyte graphics (dot plots) from four dogs with lymphoma obtained with a ProCyteDx (Idexx Laboratories, Westbrook, ME). Note the difference in the lymphocyte (*blue arrrows*) and monocyte (*red arrows*) clouds when compared with a normal dog, and the straight line between both populations. *Panels A and B,* small and intermediate cell lymphomas; *panels C and D,* large cell lymphomas; *panel E,* normal dog.

in dogs with mediastinal lymphoma than in those with the multicentric, alimentary, or extranodal forms. In most dogs with lymphoma and hypercalcemia, the tumor is of T-cell origin.

Numerous molecular mechanisms underlie hypercalcemia in dogs with lymphoma, but in most cases, hypercalcemia is thought to occur as a result of the production of a parathyroid hormone-like protein, called *PTHrP (PTH-related protein),* by the neoplastic cells. Markedly increased serum concentrations of 1,25-vitamin D have been documented in dogs with lymphoma and hypercalcemia by one of the authors (GC).

Hyperproteinemia is another paraneoplastic abnormality that occurs rarely in cats and dogs with lymphoma. It may be secondary to the production of a monoclonal protein by the lymphoma cells and can result in the development of hyperviscosity syndrome. In a recent study of serum protein electrophoresis in 155 cats, only one cat had a monoclonal gammopathy associated with lymphoma (Taylor et al., 2010). Polyclonal gammopathies may also be present in cats and dogs with lymphoma. Recently, we identified high serum SDMA concentrations in some dogs and cats with lymphoma or lymphoid leukemia.

Imaging

Radiographic abnormalities in cats and dogs with lymphoma vary with the different anatomic forms but in general are secondary to lymphadenopathy or organomegaly (i.e., hepatomegaly, splenomegaly, renomegaly); occasionally, the infiltration of other organs (e.g., lungs) may lead to the appearance of additional radiographic abnormalities.

Radiographic changes in cats and dogs with multicentric lymphoma include sternal or tracheobronchial lymphadenopathy or both (Fig. 79.7); interstitial, bronchoalveolar, or mixed pulmonary infiltrates; pleural effusion (rare); intra-abdominal lymphadenopathy (e.g., mesenteric or iliac); hepatomegaly; splenomegaly; renomegaly; or intraabdominal masses. Rarely, lytic or proliferative bone lesions are identified on plain abdominal or thoracic radiographs.

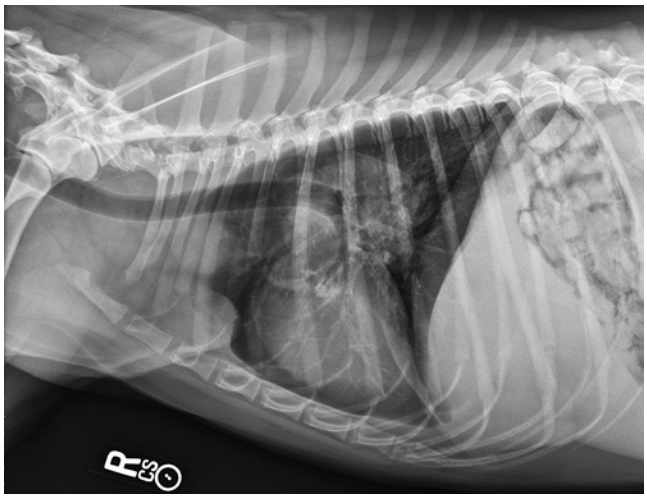

FIG 79.7
Mediastinal, hilar, and sternal lymphadenopathy in a dog with multicentric lymphoma.

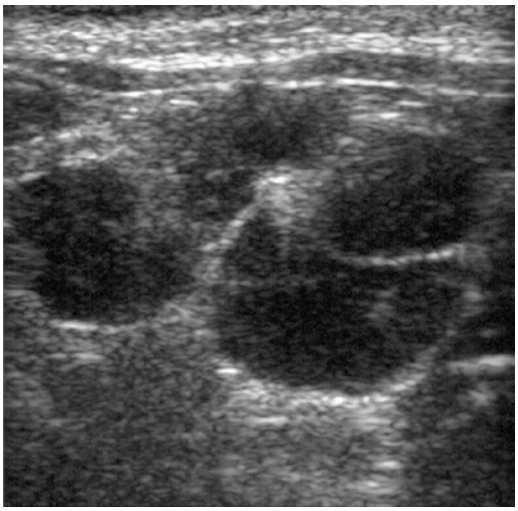

FIG 79.8
Mesenteric lymphadenopathy in a 12-year-old cat with diarrhea associated with an intestinal small cell lymphoma. Note the marked enlargement of the affected lymph node (3 × 5 cm).

In cats and dogs with mediastinal lymphoma, radiographic changes are usually limited to the finding of an anterior (or, more rarely, posterior) mediastinal mass, with or without pleural effusion. In cats and dogs with alimentary lymphoma, abnormalities are rarely detected on plain abdominal radiographs (<50%). When present, they vary in nature but include mainly hepatomegaly, splenomegaly, and midabdominal masses. Positive contrast–enhanced radiography of the upper gastrointestinal tract usually reveals abnormalities in most animals. In a series of dogs with alimentary lymphoma evaluated at one authors' clinic (GC), abnormalities were found in all dogs that underwent positive contrast–enhanced radiography of the upper gastrointestinal tract and included mucosal irregularities, luminal filling defects, and irregular thickening of the wall, suggestive of infiltrative mural disease.

Ultrasonography constitutes an invaluable tool for evaluating cats or dogs with suspected or confirmed intraabdominal lymphoma. The technique is also helpful in the evaluation of mediastinal masses in both species (see Chapter 78). Changes in the echogenicity of parenchymal organs (i.e., liver, spleen, kidneys) detected by this technique usually reflect changes in organ texture secondary to neoplastic infiltration. In addition, enlarged lymphoid structures or organs can easily be identified using this technique. Several abnormalities are commonly detected ultrasonographically in cats and dogs with intraabdominal lymphoma, including hepatomegaly; splenomegaly; changes in the echogenicity of liver or spleen (mixed echogenicity or multiple hypoechoic areas); diffuse, focal, or multifocal intestinal thickening; lymphadenopathy (Fig. 79.8); splenic masses; and effusion. Cats with lymphoma of the small intestine are more likely to have thickening of the muscularis when compared with cats with inflammatory bowel disease (Zwingenberger et al., 2010). Fine-needle aspiration (FNA) and needle biopsy can also be easily performed using this technique to guide the placement of the needle. Ultrasonography is neither sensitive nor specific for the evaluation of liver lesions; a high proportion of dogs with hepatic lymphoma have normal ultrasonographic appearance. Therefore obtaining a sample for cytology in patients with ultrasonographically normal liver is recommended in dogs with lymphoma or suspected lymphoma.

Diagnosis

The clinical signs and physical examination findings described in preceding paragraphs are usually suggestive of lymphoma. However, before instituting therapy, the clinician must confirm the diagnosis cytologically, histopathologically, or, less frequently, using molecular techniques. In addition, a minimum database consisting of a CBC, serum biochemistry profile, and urinalysis should be obtained if the owners are contemplating treatment.

From a cytologic standpoint, lymphomas can be classified as small-, intermediate-, or large-cell types. As a general rule, small-cell lymphomas are slowly progressive (i.e., indolent), whereas large-cell lymphomas are more aggressive. Intermediate-cell lymphomas can be indolent or aggressive. In most dogs and cats with large-cell multicentric, superficial extranodal, mediastinal, or alimentary lymphoma, a diagnosis can easily be obtained by cytologic evaluation of FNA of the affected organs or lymph nodes. The techniques for FNA and the cytologic features of lymphoma are described in detail in Chapter 74 (Fig. 79.9).

In the authors' practices, lymphomas can be diagnosed cytologically in over 90% of dogs and 70% to 75% of cats evaluated. In other words, in only 10% of the dogs and 25% to 30% of the cats is it necessary to perform a histopathologic,

TABLE 79.3
TNM Staging System for Dogs and Cats With Lymphoma

STAGE	CLINICAL FEATURES
I	Solitary lymph node involvement
II	More than one lymph node enlarged but on one side of the diaphragm (i.e., cranial or caudal)
III	Generalized lymph node involvement
IV	Stage III findings, plus hepatomegaly and/or splenomegaly
V	Any of the above, plus bone marrow or extranodal involvement Substage a: asymptomatic Substage b: sick

TNM, Tumor, node, metastasis.

flow cytometric, or molecular evaluation of a lymph node or mass to establish a diagnosis.

Pathologists have advocated the use of an adaptation of the human World Health Organization's histopathologic classification of non-Hodgkin lymphomas for several decades. Recently, Valli et al. (2013) proposed a modified system that may have prognostic implications. However, it includes more than 30 different categories of tumors, usually requires histopathologic evaluation of an entire lymph node, and specific diagnoses may not be consistent among pathologists. In this scheme, the authors (and others) recognized a subset of multicentric indolent lymphomas, in which survival times with minimal treatment (see later) are common. These subtypes include mainly mantle zone lymphoma (MZL-intermediate cell, B-cell) and T zone lymphoma (TZL-small cell, T-cell) (Deravi et al., 2017; Flood-Knapik et al., 2013; Valli et al., 2013). Most dogs with TZL are Golden Retrievers, Shih Tzus, and Labrador Retrievers. The combination of cytologic appearance and FCM allows for classification of these tumors as indolent (Deravi et al., 2017; Flood-Knapik et al., 2013). There is also a specific splenic indolent lymphoma in dogs, termed marginal zone lymphoma; this tumor usually presents as a solitary splenic mass (as opposed to diffuse splenomegaly) and can be effectively treated with splenectomy alone, resulting in prolonged survival times (O'Brien et al., 2013).

Until there is conclusive evidence that the histopathologic classification of canine and feline lymphomas offers conclusive prognostic or therapeutic information, the surgical removal of a lymph node or extranodal mass for histopathologic evaluation in a patient with a cytologic diagnosis of lymphoma is not generally indicated. A diagnosis based on cytologic findings rather than histopathologic findings yielded by an excisional lymph node biopsy also offers two major benefits: (1) It is associated with minimal or no morbidity, and (2) it is financially acceptable to most owners (i.e., approximate cost of a lymph node aspirate is $200-$300; the cost for biopsy and histopathologic evaluation is $500-$700).

New diagnostic methodologies commonly used in patients with lymphoma in our clinics include immunophenotyping by FCM and clonal analysis by polymerase chain reaction (PCR). In the former, a sample of the affected organ/tissue is obtained by FNA and placed in appropriate transport media. In the laboratory, these cells are incubated with specific antibodies that recognize epitopes specific for T or B cells. FCM evaluation of the sample allows to immunophenotype the cell population as T or B cell derived. Immunophenotyping by FCM is now performed by some diagnostic reference laboratories. Immunophenotyping can also be carried out on lymph node or tissue biopsies immunohistochemically or previously submitted cytology slides by immunocytochemistry. Clonal analysis by PCR (or PCR for antigen receptor rearrangement [PARR]) also requires an FNA or a small biopsy specimen. Specific laboratories will evaluate the population of cells in question by PCR to determine if they are monoclonal or polyclonal. This technique has high sensitivity and specificity for distinguishing reactive lymphadenopathy from lymphoma in dogs and cats. As a general rule, the authors use FCM to immunophenotype lymphomas and PARR when the diagnosis of lymphoma is in question (i.e., to confirm or rule out lymphoma).

After a diagnosis of lymphoma is confirmed, it is customary to stage the disease to obtain a prognosis. A staging system devised by the World Health Organization has been used routinely for the staging of cats and dogs with lymphoma (Table 79.3). In this system, derived from the tumor, node, metastasis (TNM) staging system for neoplasms in humans, clinical and clinicopathologic information from the

patient is used in an attempt to determine the extent of disease and correlate it with the prognosis. Unfortunately, it has little prognostic value (i.e., animals with stage I disease have survival times similar to those of animals with stage IV disease). The only prognostic information of clinical relevance in this system is the fact that asymptomatic (i.e., substage a) dogs with lymphoma have a better prognosis than "sick" (i.e., substage b) dogs. As discussed earlier, with the novel FCM analyzer's use for in-house CBCs, circulating neoplastic cells are frequently identified in the graphics; therefore these patients who would have previously been classified as stage III, now undergo "stage migration" to stage V disease.

A staging system that takes into account tumor bulk and FeLV status in cats with lymphoma provides some prognostic information. Until a new system is devised, it is advisable to determine the prognosis on the basis of the patient's overall clinical condition, the FeLV status (in cats), and any constitutional signs or severe hematologic and biochemical abnormalities the patient may have. Another important issue is that, even though a specific staging protocol may be of some prognostic value in patients treated with a given chemotherapy protocol, it may not be so when a different drug combination is used. Moreover, at this time the effectiveness of more aggressive protocols in dogs and cats with advanced-stage lymphoma is unknown.

At least a CBC, a serum biochemistry profile, and a urinalysis should be performed in all cats and dogs with lymphoma whose owners are contemplating therapy. In addition, FeLV and FIV tests should be performed in cats. The resulting minimum database can provide a wealth of information that can help the owner (and clinician) decide whether the patient should be treated. In addition, once a decision to treat the pet has been made, the nature of any clinicopathologic abnormalities usually dictates the treatment or treatments used. For example, in a dog with pronounced cytopenias caused by lymphomatous infiltration of the bone marrow, a highly myelosuppressive chemotherapy combination will almost certainly result in severe neutropenia and sepsis; it should therefore be avoided. L-asparaginase is a useful initial treatment in this situation, as it does not have myelosuppressive effects.

In cats and dogs with suspected CNS lymphoma, it is advisable to perform cerebrospinal fluid (CSF) analysis and advanced imaging (i.e., computed tomography [CT] scan or magnetic resonance imaging [MRI]). The finding of high numbers of neoplastic lymphoid cells and an increased protein concentration in a CSF sample is diagnostic for lymphoma. Because of their poor accessibility, the diagnosis of extradural masses usually requires the collection of a surgical specimen for cytologic or histopathologic evaluation. As discussed earlier, the authors' clinics assume that any dog or cat with lymphoma and central neurologic signs has CNS involvement until proven otherwise, and it is treated appropriately (see later).

As previously discussed, immunophenotyping of canine and feline lymphoma has become routine for most oncologists. This can be done by immunocytochemistry, immunohistochemistry, FCM, or PARR. But the main question is: Should every dog or cat with lymphoma be immunophenotyped before initiating therapy? The blanket answer is "no." Phenotype has been shown to change the prognosis, mainly in dogs with multicentric lymphoma; however, in our experience, it rarely changes the initial treatment approach. In dogs, a T-cell phenotype is quite likely if the patient is a Boxer, has hypercalcemia or a mediastinal mass, or has cutaneous involvement.

Although multiple previously published reports suggest that dogs with large-cell T-cell lymphoma treated with standard combination chemotherapy have a worse prognosis for remission and survival than dogs with B-cell tumors; in one of the author's experience (GC), this is not the case. In a previous study, T-cell phenotype was not a negative prognostic factor in dogs with lymphoma treated with COP- or CHOP-based protocols (Hosoya et al., 2007). This is likely because most dogs with T-cell lymphoma received lomustine (CCNU), a drug that may be more effective in patients with T-cell phenotype.

Treatment

Once a diagnosis of lymphoma is established, the prognosis and potential therapeutic options should be discussed with the pet's family. Remission rates in cats and dogs with lymphoma treated with various chemotherapy protocols are approximately 65% to 75% and 80% to 90%, respectively. Most cats with multicentric or mediastinal lymphoma treated with multiple-agent chemotherapy protocols are expected to live 6 to 9 months; approximately 20% to 30% of the cats live more than 1 year. Cats with small cell intestinal lymphoma typically live in excess of 2 years, with response rates of >90%. Most dogs with lymphoma treated with multiagent chemotherapy are expected to live 8 to 16 months; approximately 20% to 30% of the dogs are alive 2 years after diagnosis. The approximate survival time in untreated cats and dogs with lymphoma is 4 to 8 weeks. The reasons for the shorter survival times in cats as compared with dogs with lymphoma is that their initial response rates (especially, the complete response rates) are lower, and along with this, remissions appear to be difficult to reinduce once their disease has relapsed. In addition, the retrovirus-associated nonlymphomatous disorders that affect cats with lymphoma lead to shortened survival times (i.e., FeLV infection is a negative prognostic factor in cats with lymphoma).

In our experience, even if a patient has stage I nodal or extranodal lymphoma at the time of presentation, systemic dissemination of the disease usually occurs within weeks to months of diagnosis. However, occasionally solitary oral or cutaneous lymphomas may behave as true stage I diseases (i.e., there is no systemic dissemination). Therefore the mainstay of treatment for patients with lymphoma is chemotherapy, given the fact that lymphomas are (or will become) systemic neoplasms. Surgery, radiotherapy, or both can be used to treat localized lymphomas before or during chemotherapy. Half-body irradiation and bone marrow

transplantation have been used to some degree in dogs with lymphoma, and radiotherapy can also be a useful technique for treating cats with nasal or solitary epidural lymphoma (see Suggested Readings). General guidelines for the management of patients with lymphoma are presented here, although each author has a different mainstay protocol.

There are two main chemotherapeutic approaches in dogs and cats with lymphoma: induction chemotherapy, followed by maintenance (and reinduction) or more aggressive chemotherapy for a finite period of time, at the end of which no maintenance chemotherapy is used. The former is usually done with a less aggressive COP (cyclophosphamide, vincristine, and prednisone)–based protocol, whereas the latter is usually based on CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone)–type protocols. An example of the latter is one of several University of Wisconsin (UW) protocols. CHOP-based protocols are similar to those used in people with high-grade lymphomas.

COP-Based Protocols

One of the authors (GC) favors COP-based protocols in dogs and cats with large-cell lymphoma. The treatment is divided into several phases, or strategies: induction of remission, intensification, maintenance, and reinduction of remission or "rescue" (Box 79.1). Immediately after diagnosis, a relatively "nonaggressive" multiple-agent COP-based chemotherapy protocol is used to *induce remission.* During this phase, which lasts 6 to 8 weeks, patients are evaluated weekly by a veterinarian, at which time they receive an intravenous (IV) injection of an antimitotic agent (vincristine) in addition to

BOX 79.1

Chemotherapy Protocols Used by the Author to Treat Dogs and Cats* With Lymphoma

1. Induction of Remission

a. COP protocol

Cyclophosphamide: 200-300 mg/m^2 BSA, PO, every 3 weeks (dogs or cats)‡
Vincristine: 0.5 mg/m^2 BSA, IV, once a week
Prednisone: 40-50 mg/m^2 BSA, PO, q24h for a week; then 20-25 mg/m^2 BSA, PO, every other day or dexamethasone 4-5 mg total dose, PO, q1-3 weeks (in cats only)

b. COAP protocol †

Cyclophosphamide: 200-300 mg/m^2 PO q3 weeks
Vincristine: 0.5 mg/m^2 IV weekly
Cytosine arabinoside: 100 mg/m^2 daily as an IV drip or SC for only 2 days in cats and 4 days in dogs
Prednisone: 50 mg/m^2 PO q24h for 1 week; then 20 mg/m^2 PO q48h or dexamethasone 4-5 mg total dose, PO, q1-3 weeks (in cats only)

c. UW-25 protocol (This protocol uses no maintenance chemotherapy—for additional information see text.)

Week 1: Vincristine 0.5-0.75 mg/m^2 IV; Asparaginase 400 IU/kg, IM or SC; Prednisone 2 mg/kg PO q24h
Week 2: Cyclophosphamide 200-250 mg/m^2 IV; Prednisone 1.5 mg/kg PO q24h
Week 3: Vincristine 0.5-0.75 mg/m^2 IV; Prednisone 1 mg/kg PO q24h
Week 4: Doxorubicin 30 mg/m^2 (or 1 mg/kg if <10 kg) IV; Prednisone 0.5 mg/kg PO q24h
Week 5: **No treatment**
Week 6: Vincristine 0.5-0.75 mg/m^2 IV
Week 7: Cyclophosphamide 200-250 mg/m^2 IV
Week 8: Vincristine 0.5-0.75 mg/m^2 IV
Week 9: Doxorubicin 30 mg/m^2 (or 1 mg/kg if <10 kg) IV
Week 10: **No treatment**
Week 11: Vincristine 0.5-0.75 mg/m^2 IV
Week 13: Cyclophosphamide 200-250 mg/m^2 IV
Week 15: Vincristine 0.5-0.75 mg/m^2 IV
Week 17: Doxorubicin 30 mg/m^2 (or 1 mg/kg if <10 kg) IV
Week 18: **No treatment**
Week 19: Vincristine 0.5-0.75 mg/m^2 IV
Week 21: Cyclophosphamide 200-250 mg/m^2 IV
Week 23: Vincristine 0.5-0.75 mg/m^2 IV
Week 25: Doxorubicin 30 mg/m^2 (or 1 mg/kg if <10 kg) IV

2. Intensification

Dogs

L-Asparaginase: 10,000-20,000 IU/m^2 SC or IM (one or two doses)
or
Vincristine: 0.5-0.75 mg/m^2 IV q1-2 weeks

Cats

Doxorubicin: 1 mg/kg IV q3 weeks
or
Mitoxantrone: 4-6 mg/m^2 IV q3 weeks

3. Maintenance§

a. LMP protocol

Chlorambucil: 20 mg/m^2 PO q2 weeks
Methotrexate: 2.5 mg/m^2 PO two or three times per week
Prednisone: 20 mg/m^2 PO q48h or dexamethasone 4-5 mg total dose PO q1-3 weeks (in cats only)

b. Lomustine/prednisone protocol

Lomustine: 60-70 mg/m^2 PO q3 weeks in dogs or 10 mg total dose q3 weeks in cats
Prednisone: 2 mg/kg PO q24h, taper when remission obtained or dexamethasone 4-5 mg total dose, PO, q1-3 weeks (in cats only)

c. COP protocol

Use as previously discussed every other week for six treatments, then every third week for six additional treatments, then try to maintain the animal on one treatment every fourth week. Maintenance therapy is continued until the tumor relapses.

BOX 79.1

Chemotherapy Protocols Used by the Author to Treat Dogs and Cats* With Lymphoma—cont'd

4. Rescue

Dogs

a. D-MAC protocol (14-day cycle)
   Dexamethasone: 0.5 mg/lb (1 mg/kg) PO or SC on days 1 and 8
   Actinomycin D: 0.75 mg/m^2 as IV push on day 1
   Cytosine arabinoside: 200-300 mg/m^2 as IV drip over 4 hours *or* SC on day 1
   Melphalan: 20 mg/m^2 PO on day 8‖
b. AC protocol (21-day cycle)
   Doxorubicin: 30 mg/m^2 (or 1 mg/kg for dogs <10 kg) IV on day 1
   Cyclophosphamide: 100-150 mg/m^2 PO on days 15 and 16
c. Rescue CHOP-based protocol (21-day cycle)
   Cyclophosphamide: 200-300 mg/m^2 PO on day 10
   Doxorubicin: 30 mg/m^2 (or 1 mg/kg for dogs <10 kg) IV on day 1
   Vincristine: 0.75 mg/m^2 IV on days 8 and 15
   Prednisone: 20-25 mg/m^2 PO q48h
d. MOPP protocol (28-day protocol; repeat continuously until relapse)
   Mechlorethamine: 3 mg/m^2 IV on day 0, 7
   Vincristine: 0.7 mg/m^2 IV on days 0,7
   Procarbazine: 50 mg/m^2 PO q24h for days 0-13
   Prednisone: 30-40 mg/m^2 PO q24h for days 0-13
e. Combination L-asparaginase, lomustine, and prednisone
   Lomustine: 60-70 mg/m^2 PO q3 weeks
   L-asparaginase: 400 u/kg SC or IM q3 weeks
   Prednisone: 2 mg/kg PO q24h, taper when remission obtained
f. Dacarbazine: 800-1000 mg/m2 q14-21d
g. Lomustine: 60-80 mg/m^2 q21d
h. Rabacfosadine: 0.82-1 mg/kg IV over 30 minutes q3 weeks

Cats

a. ACD protocol (21-day cycle)
   Doxorubicin: 1 mg/kg IV on day 1
   Cyclophosphamide: 200-300 mg/m^2 PO on day 10 or 11
   Dexamethasone (4-5 mg total dose q1-2 weeks can be added to this protocol)
b. MiCD protocol (21-day cycle)
   Mitoxantrone: 4-6 mg/m^2 as IV drip over 4-6 hours on day 1
   Cyclophosphamide: 200-300 mg/m^2 PO on day 10 or 11
   Dexamethasone (4-5 mg total dose q1-2 weeks can be added to this protocol)
c. MiCA protocol (21-day cycle)
   Mitoxantrone: 4-6 mg/m^2 in IV drip over 4-6 hours on day 1
   Cyclophosphamide: 200-300 mg/m^2 PO on day 10 or 11
   Cytosine arabinoside: 200 mg/m^2 in IV drip over 4-6 hours (mixed in the same bag with mitoxantrone) on day 1
   Dexamethasone (4-5 mg total dose q1-2 weeks can be added to this protocol)

5. "Low-Budget" Protocols

Prednisone: 50 mg/m^2 PO q24h for 1 week; then 25 mg/m^2 PO q48h
Chlorambucil: 20 mg/m^2 PO q2 weeks
Lomustine: 60 mg/m^2 PO q3 weeks in dogs; 10 mg (total dose) q3 weeks in cats
Prednisone and chlorambucil: doses as above
Prednisone and lomustine: doses as above

*Unless otherwise specified, protocols can be used in both dogs and cats.
†Use for 6-10 weeks, then use LMP.
‡The duration of chemotherapy using this protocol is variable.
§Use until relapse occurs, then go to "rescue."
‖After four doses, substitute chlorambucil (20 mg/m^2 PO q2 weeks) for melphalan.
BSA, Body surface area; *IM,* intramuscular; *IV,* intravenous; *PO,* by mouth; *SC,* subcutaneous.

undergoing a routine physical examination (with or without a CBC). If at the end of this phase, the patient is considered to be in complete remission (CR; i.e., all neoplastic masses have completely disappeared), the *maintenance* phase is initiated. During this phase, a multiple-agent chemotherapy protocol consisting of three drugs (chlorambucil [Leukeran], methotrexate, and prednisone [LMP]) administered orally is used so that the patient requires less intensive monitoring (once every 6-8 weeks). The owners are then instructed to closely monitor the size of the lymph nodes in their pets; when the nodes start enlarging (i.e., relapse), a fourth drug is added to the LMP protocol (usually vincristine, at a dosage of 0.5-0.75 mg/m^2 IV q1-2 weeks). This usually suffices to reinduce remission and maintain it for several weeks or months. Alternatively, in suspected or confirmed T-cell tumors (in dogs), a maintenance protocol consisting of lomustine (60-70 mg/m^2 orally [PO] q3-6 weeks) and prednisone can be used, utilizing the same strategy for relapse as in dogs on LMP.

The maintenance or modified maintenance phase continues until the tumor relapses (i.e., is out of remission), at which time the *reinduction* phase begins. This phase is similar to the induction phase in that intensive treatments are used. Once remission is obtained, the patient is started

again on a modified maintenance protocol. If at the end of the induction phase the patient is not in a CR, the author recommends that *intensification* with L-asparaginase be done before the maintenance phase is initiated. In addition to the chemotherapeutic approach discussed in this section, a variety of protocols have been used successfully in the treatment of cats and dogs with lymphoma. (See Suggested Readings for additional information.)

Induction of remission

As previously discussed, one author's (GC) protocol of choice for the induction of remission is COP. The agents in this protocol consist of cyclophosphamide, vincristine, and prednisone; these drugs are currently available as generic products and are relatively inexpensive. The dosages are specified in Box 79.1. These drugs belong to three different categories, have different mechanisms of action, and do not have superimposed toxicities. In dogs or cats with CNS or ocular involvement, cytosine arabinoside can be added by the subcutaneous (SC) route or as a continuous rate infusion for 6 to 8 hours (COAP protocol); given its short half-life and S-phase–specific mechanism of action, an IV bolus injection results in minimal cell kill. SC administration of this drug is painful in cats (and in some dogs). The induction phase lasts 6 to 8 weeks, and weekly chemotherapy visits are necessary during this time.

During the induction phase, toxicity is minimal (<15%) and client compliance is high because most of the toxic signs are hematologic (i.e., cytopenias) and usually do not result in clinical signs that can be detected by the owners. The dose-limiting toxicity of this induction protocol is hematologic (i.e., myelosuppression leading to neutropenia), and it occurs in less than 10% of the patients; the neutrophil nadir usually occurs around day 7 or 8 because two myelosuppressive agents (i.e., cyclophosphamide and cytosine arabinoside) are given during the initial 2 to 4 days of treatment in the COAP protocol. In most cases, the neutropenia is mild (2000-3500 cells/μL). The neutropenia can be severe if the animals have neoplastic bone marrow infiltration before the initiation of treatment, have FeLV- or FIV-associated myelodysplasia or other retrovirus-associated bone marrow disorders, or receive the cytosine arabinoside by constant-rate IV infusion rather than by the SC route. Also, anecdotally, neutropenia appears to be common in Cocker Spaniels and West Highland White Terriers receiving this protocol. Dosage adjustments in cats and dogs that develop neutropenia are described in Chapter 77. Gastrointestinal toxicity is minimal to nonexistent; however, cats receiving cyclophosphamide can occasionally become anorectic. Consequently, this drug should be administered once every 3 weeks in cats (as opposed to every other day as in dogs; see Box 79.1). If anorexia develops, treatment with cyproheptadine, an antiserotonin drug, at a dosage of 1 to 2 mg per cat PO every 12 h or mirtazapine at a dosage of 1.875 to 3.75 mg per cat PO every 1 to 3 days is indicated. Capromorelin, is a novel appetite stimulant (Entyce, Aratana Therapeutics, Leawood, KS) given at a dosage of 3 mg/kg PO every 24 h. Hair loss is also minimal, and it occurs primarily in woolly-haired dogs (e.g., Poodle, Bichon Frise); cats (and some dogs) may also shed their tactile hairs during treatment.

During this phase, owners are instructed to monitor their pet's appetite and activity level, measure their lymph nodes (if peripheral lymphadenopathy was present initially), and take their pet's rectal temperature if they are unwell (pyrexia is usually secondary to neutropenia and bacteremia or sepsis). If pyrexia develops, owners are instructed to contact their veterinarian immediately so that their pet can undergo a complete physical examination and CBC (for additional information, see Chapter 77). Treatment with COP results in CR within 1 to 14 days of the start of therapy in most animals (>85% in dogs, >70% in cats) (Figs. 79.9 and 79.10, *A* and *B*). This remission is usually maintained throughout the induction phase.

In dogs with diffuse large-cell alimentary lymphoma, the authors both use a CHOP-based protocol (see Box 79.1) because, on the basis of experience, the response rate to COP is low. This protocol is more expensive and slightly more likely to cause adverse effects than the COP protocol.

FIG 79.10
Mixed-breed dog with multicentric lymphoma before **(A)** and 7 days after initiating chemotherapy **(B).** Note complete disappearance of mandibular lymphadenopathy and ventral facial edema.

Lomustine (CCNU) is typically used in dogs with epitheliotropic T-cell lymphoma (see Box 79.1) and, as discussed earlier, for one of the authors (GC), as part of the maintenance or reinduction protocol in dogs with other large-cell T-cell lymphomas.

In dogs and cats with multicentric lymphoma (or any other anatomic form) coexisting with neurologic or ocular signs, one author (GC) usually uses the COAP protocol but administers the cytosine arabinoside as a continuous IV infusion (200-400 mg/m^2 as an IV infusion over 24 hours for 1-4 days) to attain high concentrations of this drug in the CNS. This protocol tends to cause marked myelosuppression in cats, so cytosine arabinoside is typically administered as a 12- to 24-hour infusion (200 mg/m^2) in this species. More information on the treatment of dogs and cats with suspected or confirmed CNS lymphoma is given later in this chapter.

Maintenance

The protocol recommended by one of the authors (GC) for the maintenance phase of treatment is LMP ("lump"), which consists of chlorambucil, methotrexate, and prednisone (see Box 79.1). These drugs also act by three different mechanisms of action and have differing toxicities. The advantages of this protocol include its reduced cost compared with the cost of the induction phase; its ease of administration (all the drugs are administered orally by the owners); its minimal toxicity; and the fact that intensive monitoring by a veterinarian is not necessary.

The toxicities associated with LMP maintenance chemotherapy are minimal. Of the three drugs in this protocol, methotrexate is the only one associated with moderate to severe toxicity. Approximately 25% of dogs and cats receiving methotrexate develop gastrointestinal tract signs consisting of anorexia, vomiting, or diarrhea. Anorexia and vomiting are more common than diarrhea, and usually occur after the patient has been receiving the drug for more than 2 weeks. In these cases, treatment with an antiemetic such as metoclopramide on the days the animal receives the methotrexate, at a dosage of 0.1 to 0.3 mg/kg PO q8h, alleviates or eliminates the upper gastrointestinal tract signs. Use of maropitant (Cerenia, Pfizer Animal Health, Kalamazoo, Mich) at a dosage of 2 mg/kg PO q24h for dogs, and 1 mg/kg PO q24h for cats can also be considered to prevent chemotherapy-associated nausea and vomiting. Gastroprotectants such as famotidine (0.5-1 mg/kg PO q12h) may also be effective in preventing or minimizing this adverse effect. In cases of methotrexate-associated diarrhea, treatment with a bismuth subsalicylate–containing product (Pepto-Bismol) may also alleviate or eliminate the signs; however, it may be necessary to discontinue the drug. Hematologic toxicity associated with LMP therapy is minimal to nonexistent. In a small proportion of cats (i.e., <5%) receiving chlorambucil for weeks to months, serum biochemical abnormalities consistent with cholestasis that resolve with discontinuation of the drug may develop. Tonic or tonic-clonic convulsions can also rarely occur in cats receiving chlorambucil.

During this phase the patient is examined every 6 to 8 weeks, at which time a complete physical examination and a CBC are performed. As with the induction protocols, owners are instructed to monitor their pet's activity, appetite, behavior, and lymph node size. As discussed previously, is it recommended that the owners of pets with multicentric lymphoma are instructed to closely monitor the size of the lymph nodes; when the nodes start enlarging (i.e., relapse), a fourth drug can be added to the LMP protocol (usually vincristine, at a dosage of 0.5-0.75 mg/m^2 IV q1-2 weeks). This usually suffices to reinduce remission and maintain it for several weeks or months.

Most patients treated with this protocol remain in remission for approximately 3 to 6 months. If a relapse occurs, reinduction of remission (as discussed next) is instituted. After remission is reinduced, animals can be treated with a modified maintenance protocol, as described in previous paragraphs.

CHOP-Based Protocols

When using CHOP-based protocols (favored by one of the authors—KC), a 4 to 6 month protocol without long-term maintenance is used. Typically, weekly to twice monthly chemotherapy with a combination of cyclophosphamide, doxorubicin, vincristine, and prednisone is used for a total of 4 cycles; the main difference between the UW-19 and UW-25 protocol are a longer interval between treatments during the second half of the protocol. As stated earlier, these drugs have differing mechanisms of action and do not have superimposed toxicities, again fulfilling the criteria for traditional multiagent chemotherapy described in Chapter 76. Doxorubicin can be associated with a slightly higher risk of gastrointestinal adverse effects than the other drugs in this protocol, and the author (KC) generally uses Cerenia after each dose of doxorubicin to help limit this toxicity. Fasting before doxorubicin administration has also been associated with a lower frequency of delayed vomiting, so this should also be considered. During treatment, similarly to the previously described recommendations, owners are instructed to monitor their pet's appetite, activity level, lymph node size (if peripheral lymphadenopathy was present initially), and take their pet's rectal temperature if they are unwell. Additionally, the patient is examined every 1 to 2 weeks, at which time a complete physical examination and CBC are performed. After completion of the 4 to 6 month protocol, patients are examined every 4 to 6 weeks, to assess for relapse of their lymphoma, and if any overt abnormalities were present on CBC or chemistry panel before diagnosis (i.e., circulating neoplastic cells, liver enzyme elevation, etc.), this bloodwork is repeated. If no previous abnormalities were present, then full bloodwork is rechecked every 3 months to assess for development of any concerning findings related to relapse of lymphoma.

These conventional CHOP-based chemotherapy protocols have been associated with remission rates of approximately 85% to 95% in dogs with high-grade lymphoma, and 60% to 70% in cats with high-grade lymphoma. The typical

MSTs reported for dogs with multicentric lymphoma are 10 to 12 months. Cats treated with CHOP-based protocols for high-grade lymphoma experience overall lower MSTs than dogs; however, approximately 30% of cats have long-term survivals of over 1 to 2 years.

Should You Use COP-Based or CHOP-Based Protocols?

Clinicians have been debating the relative merits of COP- and CHOP-based protocols for several years. However, due to the fact that most institutions or clinicians prefer one protocol over the other (illustrated by the differing protocols used in this chapter by both authors), most reports on COP-based protocols are 10 to 20 years old, and most reports of COP- or CHOP-based chemotherapy studies have remission times as endpoints rather than survival times, a definitive answer is not readily available. There is no clear advantage of one protocol over the other, so it is recommended that the clinician make decisions based on various factors (e.g., the owner's perception, the patient's clinical signs, other concurrent illnesses, the veterinarian's "comfort" with a given protocol or drug, etc.). See Figures 79.12 and 79.13.

Intensification

If a dog with large-cell lymphoma is undergoing induction therapy (with either COP- or CHOP-based protocols), but only partial remission (PR) is obtained, intensification with one or two doses of L-asparaginase (10,000-20,000 IU/m^2 intramuscular [IM] or SC, repeated once at a 2- to 3-week interval) may be indicated. This drug can rapidly induce CR in most dogs with lymphoma that have shown only PR while receiving COP or CHOP. Additionally, in patients that are unwell or have cytopenias, we frequently induce the initial remission, before initiation of either COP or CHOP, with L-asparaginase, given the lack of adverse effects and the high probability of response. This can be quite beneficial for dogs that are sick from their lymphoma and cannot tolerate traditional chemotherapy. Caution is recommended in dogs with a history of pancreatitis or in those that are at high risk for acute pancreatitis (i.e., obese, middle-aged female dogs), as asparaginase can cause pancreatitis; however, in our experience, this is an uncommon adverse effect. L-asparaginase appears to be less effective in cats than in dogs, only inducing remission in approximately 30% of cats.

Reinduction of remission or rescue

Virtually every dog and cat with lymphoma treated with either COP- or CHOP-based chemotherapy protocols will eventually relapse; this generally occurs 3 to 6 months after the start of induction therapy with COP (median: ≈4 months), and 8 to 9 months after initiation of the CHOP. At this time, reinduction of remission is indicated. In our experience, remission can be reinduced one to four additional times in most dogs with relapsing lymphoma. Reinduction of remission is usually not as successful in cats (i.e., remission is difficult to reinduce in most cats with relapsing lymphoma). Therefore the following discussion on "rescue" pertains mostly to dogs with lymphoma.

Numerous "rescue" protocols have been described in the literature, and as a general rule, the practitioner may have difficulty deciding what protocol to choose since the final decision is frequently based on personal experience. Typically, if a patient has completed the induction phase of COP or the entirety of the CHOP protocol before relapse, reinduction with one of these protocols is considered the most likely to induce another remission. There are also alternative rescue chemotherapy options consisting of multi- or single-agent protocols that can be considered for use if the COP or CHOP protocol is unsuccessful at reinducing remission, or the owner opts to proceed with an alternative protocol.

One author (GC) currently uses the D-MAC protocol (see Box 79.1) as the first alternative to COP, which consists of dexamethasone, melphalan, cytosine arabinoside, and actinomycin D (Alvarez et al., 2006). This protocol results in a greater than 70% remission rate in dogs with relapsing lymphoma; it has a relatively low toxicity compared with that of doxorubicin-containing protocols, and it is necessary for the owner to go to the veterinarian only once every 2 weeks (instead of every week). The median duration of remission using the D-MAC protocol was 61 days (range 2-467+ days) in a previous study (Alvarez et al., 2006). Previous use of doxorubicin and failure to induce remission with the induction protocol were negative prognostic factors for response to this protocol. Thrombocytopenia occurred in 56% of the dogs, neutropenia in 17%, and gastrointestinal toxicity in 22%; 3 of the 56 dogs required hospitalization because of toxicity. Because the long-term use of melphalan is associated with severe chronic thrombocytopenia, chlorambucil, 20 mg/m^2, is substituted for melphalan after four cycles. If complete or partial remissions are achieved after the administration of four to six cycles of D-MAC, the patient can be started on a maintenance protocol again. If the response to D-MAC is poor (i.e., the disease progresses), GC then pursues the CHOP protocol (see Box 79.1). This protocol calls for two or three cycles of CHOP; if CR is obtained, the patient is started on maintenance chemotherapy at the end of the second or third CHOP cycle. The maintenance protocol in these animals also includes LMP, with the possible addition of vincristine (0.5-0.75 mg/m^2 IV once weekly to every other week, alternating weeks with the chlorambucil) or cytosine arabinoside (200-400 mg/m^2 SC every other week, alternating weeks with the chlorambucil). After a second relapse occurs, GC generally proceeds with an additional D-MAC or CHOP protocol for two additional cycles, as described in the preceding paragraph.

If a CHOP-based protocol is unsuccessful at reinducing a remission, or owners opt to not proceed with another CHOP-based protocol, KC generally discusses different rescue options with owners to decide which protocol is most suitable. The main considerations include whether the owners are able to commit to weekly or every other week office visits, finances, and the health of the patient at relapse. The protocols commonly considered are listed in Box 79.1, with the single-agent protocols (e.g., dacarbazine, CCNU) having response rates of approximately 30% to 40% and the

combination protocols (e.g., MOPP, L-asparaginase/CCNU/prednisone, DMAC) having response rates of 60% to 80%. One exception, single-agent rabacfosadine, has recently been evaluated for the use of dogs with relapsed B-cell lymphoma, and an overall response rate of 74% was reported (Saba et al., 2018).

After the second and third relapses, the percentage of patients in which remission can be easily reinduced decreases with each subsequent cycle. This likely stems from the development of multiple-drug resistance by the tumor cells. The authors usually advise owners that after each subsequent relapse, the probability and duration of remission are about half of those in the previous one. Other protocols that have been successful in reinducing remission in dogs with lymphoma are listed in Box 79.1. Although the probability of reinducing remission is considerably lower in cats than in dogs, one of the protocols listed in Box 79.1 can be used for this purpose.

In cats, the authors generally consider doxorubicin- or mitoxantrone-containing protocols, as well as CCNU, which have shown some degree of success (see Box 79.1); asparaginase-containing protocols may also be used but are generally not as effective as in dogs.

Management of dogs with indolent lymphomas

A diagnosis of indolent lymphoma can be made on the basis of histopathology or using a combination of historical, physical examination, cytologic, and FCM findings. For example, a middle-aged Shih Tzu with long-standing mild to moderate generalized lymphadenopathy and a small-cell lymphoma based on cytology likely has a TZL. We manage these patients either with chlorambucil and prednisone (see earlier), with or without vincristine, or with a short course of COP followed by chlorambucil and prednisone. Survival times of 1 to 2 years are common. In one study, the use of CHOP in these patients resulted in significantly shorter survival times (Flood-Knapik et al., 2013). As discussed before, splenectomy alone typically results in long-term survival in dogs with splenic indolent lymphoma (O'Brien et al., 2013).

Management of solitary and extranodal lymphomas

The clinician faces a dilemma when confronted with a dog or cat with a solitary lymphoma, regardless of whether it is nodal (i.e., stage Ia disease) or extranodal (i.e., a solitary cutaneous or oral mass). Should the mass (or lymph node) be treated in the same manner as other solitary malignancies (i.e., by wide surgical excision)? Should the patient be treated primarily with chemotherapy? Should the patient be treated with a combination of surgery, irradiation, and chemotherapy? Unfortunately, there are no correct answers to these questions.

In our experience, seemingly solitary lymphomas become (or already are) systemic in most animals. Exceptions include some oral and some cutaneous solitary T-cell lymphomas. Although cures have been achieved through surgical excision or irradiation of solitary lymphomas, they are extremely rare. Therefore it is important not to underestimate the malignant behavior of this neoplasm by treating the patient with only localized treatment modalities such as surgery or radiotherapy. The following guidelines can be used in this subset of patients. As a general rule, these patients should be thoroughly staged before consideration of any localized therapy to ensure that visible systemic disease is not present before local therapy:

1. If the tumor is easily resectable (e.g., cutaneous mass, superficial lymph node, intraocular mass) and the surgical procedure does not pose a considerable risk to the patient, the mass should be resected and the animal treated with chemotherapy.
2. If the mass is difficult or impossible to resect or if a major surgical procedure would pose an undue risk for the patient, then systemic chemotherapy with or without radiotherapy of the primary lesion should be pursued.

Radiotherapy constitutes an excellent treatment modality for dogs and cats with solitary lymphomas because the tumor cells are extremely radiosensitive. Marked responses (CR or PR) can be seen within hours or days of the start of such treatment. Different sources and protocols have been used in cats and dogs with lymphoma, but in general 3 to 5 Gy per fraction is delivered daily or three times weekly for a total of 6 to 10 fractions (total dose, 30-50 Gy). One of the authors has successfully used coarse fractionation radiotherapy (7 Gy once a week for 4 treatments) followed by maintenance chemotherapy (discussed later) in dogs with solitary oral T-cell lymphomas. A previous study supports a major role for radiotherapy of oral mucocutaneous lymphomas, where median survival times in excess of 2 years were obtained (Berlato et al., 2012). Additionally, special settings in which radiotherapy may be beneficial include CNS lymphomas (see following paragraphs) and upper airway lymphomas that cause respiratory compromise.

Another decision the clinician must make if chemotherapy is to be used is which protocol to use and for how long. There are also no specific guidelines for this. Generally, the authors use similar protocols for the more typical lymphomas in this situation (e.g., COP, CHOP-based protocols).

Central nervous system lymphoma

The treatment of choice for cats and dogs with primary or secondary epidural lymphoma is multiple-agent chemotherapy with or without radiotherapy. If radiotherapy facilities are not available, multiple-agent chemotherapy alone is an effective approach. It is our clinical impression that the surgical excision of such masses does not provide a therapeutic advantage over chemotherapy alone or radiotherapy plus chemotherapy, given the fact that the latter two forms of treatment can consistently induce rapid remissions (i.e., within 12-36 hours of the initiation of therapy, see Fig. 79.11). However, because surgery may be necessary to confirm the diagnosis, surgical excision of the mass may be attempted at that time. If radiotherapy is available, it is quite effective. The COAP protocol alone can also be effective in inducing remission in cats with epidural lymphoma. One of the authors (KC) has also used CHOP-based

FIG 79.11
Cat with retroorbital and intranasal lymphoma before **(A)** and 24 hours after administration of asparaginase, cytosine arabinoside, and dexamethasone **(B).**

protocols with cytarabine arabinoside used in place of cyclophosphamide.

In cats and dogs with lymphoma of the neuropil (i.e., true CNS lymphoma), chemotherapy with or without radiotherapy is the preferred protocol. Intrathecal chemotherapy can be used in cats and dogs with confirmed or highly likely neuropil lymphoma. The drug of choice is cytosine arabinoside because it is almost nontoxic, it is inexpensive, and it is easy to administer. However, IV administration of this drug as a constant rate infusion (CRI) at dosages of 200 to 600 mg/m^2 over 24 to 72 hours achieves similar results and is the preferred approach. Responses to intrathecal or IV CRI cytosine arabinoside are usually quite spectacular. Dogs and cats that are tetraparetic, demented, or comatose usually regain normal neurologic status within 6 to 48 hours of receiving the first dose of this agent. In addition, disappearance of the neoplastic cells from the CSF occurs within hours of the injection.

The authors frequently induce clinical and cytologic remission (i.e., normal neurologic status and disappearance of neoplastic cells from CSF) in cats and dogs with primary or secondary CNS lymphoma treated with COAP (using cytosine arabinoside as an IV infusion) or CHOP with cytosine arabinoside as an IV infusion in place of cyclophosphamide. As previously discussed, an alternative drug that crosses the blood-brain barrier and is effective in eliminating lymphoma cells is lomustine (CCNU; see Box 79.1) administered at a dosage of 60-70 mg/m^2 PO every 3 weeks in dogs and at a dosage of 10 mg/cat every 3 to 6 weeks in cats; the authors have seen marked improvement or disappearance of neurologic signs in dogs and cats with lymphoma treated with this drug and corticosteroids.

Despite the fact that remissions are easily attained in dogs and cats with CNS lymphoma, they are often relatively short in duration compared with disease in other anatomic locations. Most dogs and cats with CNS lymphoma relapse within

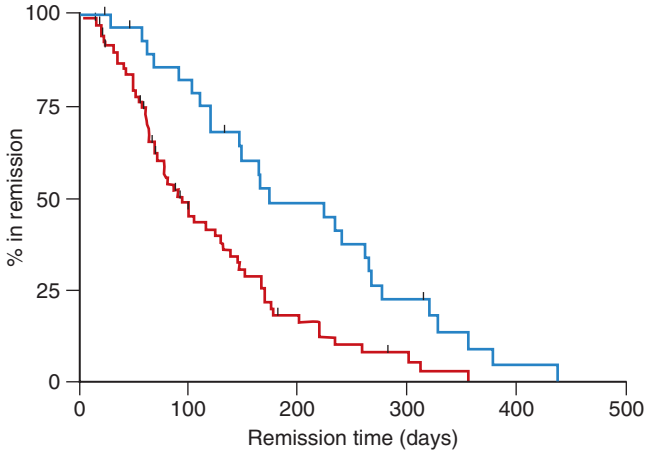

FIG 79.12
Kaplan-Meier curves for duration of first remission in dogs with multicentric lymphoma treated with COAP *(red line)* or CHOP *(blue line)*. The median duration of remission was significantly longer in dogs treated with CHOP chemotherapy (P <0.01). (From Hosoya et al., 2007.)

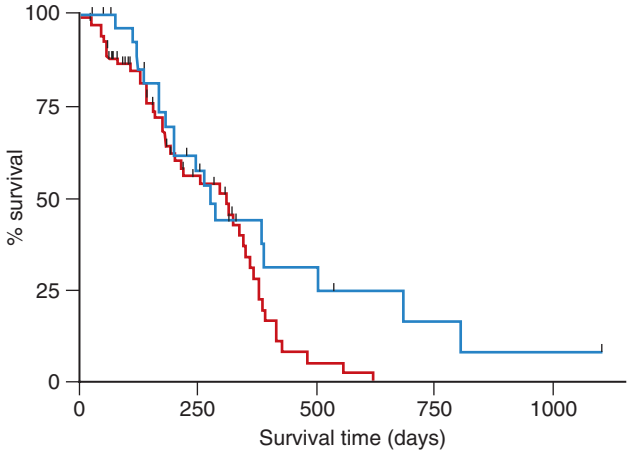

FIG 79.13

2 to 4 months of diagnosis; however, prolonged remissions (i.e., 6-12 months) are possible.

Ocular lymphoma

Ocular lymphoma can be treated using a variety of modalities. However, the eye behaves similarly to the blood-brain barrier in that adequate intraocular concentrations of chemotherapeutic agents are usually difficult to attain. If the clinician and owner want to try to preserve the animal's eye, there are several alternatives to enucleation. As in animals with CNS lymphoma, the administration of cytosine arabinoside as a slow IV drip usually results in remission of the tumor (see Fig. 79.11). Lomustine is also effective in dogs and cats with intraocular lymphoma.

Cutaneous lymphoma

Cutaneous lymphoma is the one of the most common extranodal form of lymphoma in dogs seen in most clinics in the United States. In dogs with cutaneous involvement secondary to multicentric lymphoma, the authors use a standard chemotherapy protocol (i.e., COP- or CHOP-based protocols). In dogs with epitheliotropic T-cell lymphomas, we use lomustine (CCNU)-containing protocols. Two studies have evaluated the use of lomustine for epitheliotropic cutaneous T-cell lymphoma, reporting an overall response rate of approximately 80%, with 20% to 30% attaining CR and 50% to 60% attaining PR. The overall median duration of response in these studies was approximately 90 days, with most dogs experiencing progressive disease resulting in death. More recently, rabacfosadine has also been used for epitheliotropic cutaneous lymphoma, which resulted in a response rate of 45%, and a progression free-survival of 37.5 days (Morges et al., 2014). This is an alternative treatment option if lomustine has been unsuccessful, or if there are contraindications for its use. As discussed earlier, radiotherapy is effective in localized cutaneous/mucocutaneous T-cell lymphomas. Fig. 79.4 depicts a cat with cutaneous lymphoma before and after chemotherapy.

Alimentary lymphoma

Both authors use standard chemotherapy protocols (i.e., COP or COAP, CHOP-based protocols) in dogs and cats with solitary mural or nodal (e.g., mesenteric or ileocecocolic lymph node) involvement of large-cell lymphoma. Even though surgery is not necessarily indicated for these dogs and cats, a fair number are referred after exploratory surgery and an incisional or excisional biopsy has been performed. In general, the response in these animals is good; however, it can be short-lived. Dogs and cats with diffuse large-cell intestinal lymphoma usually respond poorly to chemotherapy. Responses to doxorubicin-containing protocols (i.e., CHOP) appear to be better than those to COP, although survival times are overall short (4-6 months). Dogs with colorectal lymphoma and cats with gastric lymphoma tend to respond extremely well to COP- or CHOP-based chemotherapy, with documented remission times in excess of 3 years in these subsets of patients. Recently, a study of 31 dogs with colorectal lymphoma reported a progression free-survival of 1318 days and a disease-related MST of 1845 days. These dogs underwent chemotherapy, and a portion of them also underwent either radiation therapy or surgical resection (Desmas et al., 2017). In cats with gastric lymphoma, prolonged survival may be related to the fact that *Helicobacter* spp. may play a role in the development of gastric lymphoma, as *H. pylori* does in people; all cats with gastric lymphoma should be treated with combination chemotherapy and antibiotics proven effective in cats with *Helicobacter* infection.

In cats with epitheliotropic intestinal lymphoma, a common, small lymphocytic form of the disease in older individuals, a more conservative approach is recommended, which has been associated with excellent results. A combination of chlorambucil (20 mg/m^2 PO q2 weeks) plus prednisolone (1-2 mg/kg PO q24-48h) or dexamethasone (4 mg/cat PO q1-2 weeks) is administered; if clinical signs do not improve within 3 or 4 weeks, vincristine can be added (0.5 mg/m^2 IV q1-2 weeks). Most cats treated with this protocol have marked improvement of the clinical signs and typically gain weight; survival times of 1 to 2 years are common with treatment. Interestingly, some of the cats exhibit no appreciable decrease in mesenteric lymph node size, despite the remarkable clinical improvement. For these cats, the author uses the approach of "treating the patient, not the disease" (i.e., as long as the patient feels well and is free of clinical signs, the current treatment is continued). Recently, this disease entity has also been documented in dogs by one of the authors (KC), and similar to cats, treatment with a combination of chlorambucil and prednisone may results in long-term survivals (Couto et al., 2018).

"Low-Budget" Lymphoma Protocols

Quite frequently, the clinician is evaluating a dog or cat with lymphoma that should benefit from chemotherapy, but because of finances or other issues (e.g., time commitment), the owners are not interested in the standard multiagent chemotherapy approach. The authors have used one of the following quite successfully: prednisone alone, prednisone and chlorambucil, chlorambucil alone, lomustine alone, or prednisone and lomustine. Although the duration of remission is shorter than when using COP- or CHOP-based protocols, most of these patients (and their owners) can enjoy prolonged (i.e., months), good-quality survival times. These protocols are listed in Box 79.1.

CHAPTER 80

Leukemias

DEFINITIONS AND CLASSIFICATION

Leukemias are malignant neoplasms that originate from hematopoietic precursor cells in the bone marrow. Because these cells are unable to undergo terminal differentiation or apoptosis, they self-replicate as a clone of usually immature (and nonfunctional) cells. The neoplastic cells may or may not appear in peripheral circulation; thus the confusing terms *aleukemic* and *subleukemic* are used to refer to leukemias in which neoplastic cells proliferate within the bone marrow but are absent or scarce in the circulation.

Leukemias can be classified into two broad categories according to the cell line of origin: *lymphoid* and *myeloid* (or nonlymphoid; Table 80.1). The term *myeloproliferative disease* has also been used to refer to myeloid leukemias (particularly in acute forms in cats), but we will use *myeloid leukemias* throughout this chapter. On the basis of their clinical course and the cytologic features of the leukemic cell population, leukemias are also classified as *acute* or *chronic*. Acute leukemias are characterized by an aggressive biologic behavior (i.e., death ensues shortly after diagnosis, sometimes even if the patient is treated) and by the presence of immature (blast) cells in bone marrow or blood. Chronic leukemias have a protracted, often indolent course, and the predominant cell in the blood is a well-differentiated, late precursor (i.e., lymphocyte in chronic lymphocytic leukemia [CLL] and neutrophil in chronic myeloid leukemia [CML]). In dogs (and possibly in cats) CML can undergo *blast transformation* (blast crisis), during which the disease behaves like an acute leukemia and is usually refractory to therapy. Additionally, CLL can transform into an aggressive high-grade lymphoma, referred to as Richter syndrome; this has recently been described in dogs, where it carries a poor prognosis, with a median survival time (MST) of 41 days reported in a small cohort of dogs (Comazzi et al., 2017).

As opposed to humans, acute leukemias in dogs and cats may be difficult to classify morphologically as myeloid or lymphoid on the basis of the evaluation of Giemsa-, Wright-, or Diff-Quik–stained blood or bone marrow smears because poorly differentiated blasts look similar under the light microscope. In veterinary medicine, cytochemical stains are used in some diagnostic laboratories to establish whether the blasts are lymphoid or myeloid and also to subclassify myeloid leukemias, as described later (i.e., myeloid versus monocytic versus myelomonocytic). These cytochemical stains reveal the presence of different enzymes in the cytoplasm of the blasts, which aids in establishing their origin (Table 80.2); however, in most diagnostic laboratories immunophenotyping (see next paragraph) is the standard for diagnosis.

Immunophenotyping of canine and feline leukemic cells using monoclonal antibodies via immunocytochemistry or flow cytometry is now available in teaching institutions and most commercial diagnostic laboratories; however, although there are several validated antibodies for lymphoid cells, there is a paucity of myeloid markers that work consistently in dogs and cats. In most laboratories CD3, CD4, CD5 (in cats), and CD8 are used as T-lymphocyte markers, whereas CD21 and CD79a are B-lymphocyte markers. Acute myeloid leukemias (AMLs) are diagnosed in dogs with cells negative for lymphoid markers and positive for CD45 (panleukocyte marker) and CD34 (stem cell marker). Monocytic/monoblastic leukemias are diagnosed if cells are negative for lymphoid markers and positive for CD45 and CD14. CD41 and CD61 are megakaryocyte markers. Recently, ALP cytochemical staining has been proposed to differentiate AML and acute lymphoid leukemia (ALL) (Stokol et al., 2014); AML cells have more intense ALP staining patterns than those in ALL. Fig. 80.1 depicts flow cytometry dot plots from a cat with CLL. Clinical correlations between immunophenotype and prognosis have been investigated in few studies; however, no definitive difference in prognosis has been established among phenotypes (Novacco et al., 2015a). It is still possible that, with additional investigation, especially with more frequent availability of flow cytometric analysis, specific phenotypes may be associated with different prognoses.

A classification scheme for acute leukemia in people was devised by a group of French, American, and British investigators (the FAB scheme) and was based on the morphologic

TABLE 80.1

Classification of Leukemias in Dogs and Cats

CLASSIFICATION	SPECIES
Acute Leukemias	
Acute myeloid (myelogenous) leukemia (AML)	
Undifferentiated myeloid leukemia (AML-M_0)	D, C
Acute myelocytic leukemia (AML-M_{1-2})	D, C
Acute progranulocytic leukemia (AML-M_3)	—
Acute myelomonocytic leukemia (AMML; AML-M_4)	D, C
Acute monoblastic/monocytic leukemia (AMoL; AML-M_5)	D, C
Acute erythroleukemia (AML-M_6)	C, D?
Acute megakaryoblastic leukemia (AML-M_7)	D, C
Acute lymphoblastic leukemia (ALL)	
ALL-L_1	D, C
ALL-L_2	D, C
ALL-L_3	C, D?
Acute leukemia of large granular lymphocytes (LGL)	D, C?
Subacute and Chronic Leukemias	
Chronic myeloid (myelocytic) leukemia (CML)	D > C
Chronic myelomonocytic leukemia (CMML)	D
Chronic lymphoid (lymphocytic) leukemia (CLL)	D > C
Large granular lymphocyte (LGL) variant	D

characterized by cytopenias and a hypercellular bone marrow and is more common in cats than in dogs. The clinical and hematologic features of dogs and cats with MDS are discussed at the end of this chapter.

LEUKEMIAS IN DOGS

In dogs, leukemias constitute less than 10% of all hemolymphatic neoplasms and are therefore considered rare. At one author's previous clinic, the leukemia-to-lymphoma ratio is approximately 1:7 to 1:10. However, this ratio is artificially high because many dogs with lymphoma may be treated by their family veterinarians, whereas most dogs with leukemia are referred for treatment. Although most leukemias in dogs are considered to be spontaneous in origin, radiation and viral particles have been identified as etiologic factors in some experimental dogs with this disease.

ACUTE LEUKEMIAS

Prevalence

In the United States, AML appears to be more common than ALL in dogs, constituting approximately three fourths of the cases of acute leukemia. However, in two studies from Italy, one reported that ALL was almost twice as common as AML (Tasca et al., 2009), and the other one reported similar prevalence of the two (Novacco et al., 2015a). However, morphologically (i.e., as determined by evaluation of a Wright- or Giemsa-stained blood or bone marrow smear), most acute leukemias are initially classified as lymphoid. After cytochemical or immunocytochemical staining of the smears, or immunophenotyping is performed, approximately one third to one half of them are then reclassified as myeloid. Approximately half of the dogs with AML have myelomonocytic differentiation when cytochemical staining or immunophenotyping is performed (see Table 80.2). With the advent of immunophenotyping, most laboratories are no longer doing cytochemical stains. There is a bimodal age of presentation, with most diagnosed at 1 to 3 years of age, whereas a small proportion develop AL as adults (>7 years).

Clinical Features

The clinical signs and physical examination findings in dogs with acute leukemia are usually vague and nonspecific (Table 80.3). Most owners seek veterinary care when their dogs become lethargic or anorectic, or when persistent or recurrent fever, severe weight loss, shifting limb lameness, or other nonspecific signs develop; neurologic or ocular signs occur occasionally. Some of these signs may be quite acute (e.g., days). Splenomegaly, hepatomegaly, pallor, fever, and mild generalized lymphadenopathy are commonly detected during routine physical examination. The spleen in these dogs is usually markedly enlarged, and it has a smooth surface on palpation. Inspection of the mucous membranes in dogs with acute leukemia often reveals pallor and petechiae, ecchymoses, or both. Icterus may also be detected if marked leukemic infiltration of the liver has occurred. The generalized lymphadenopathy seen in dogs with acute leukemia is usually mild in contrast to that seen in dogs with lymphoma, in which the lymph nodes are typically massively enlarged (Fig. 80.2). In other words, the hepatosplenomegaly is more striking than the lymphadenopathy in leukemic patients. Most dogs with leukemia also have constitutional signs (i.e., they are clinically ill), whereas most dogs with lymphoma are asymptomatic. Although it is usually impossible to distinguish between acute myeloid and ALL on the basis of physical examination findings alone, some subtle differences do exist; mainly, shifting limb lameness, fever, and ocular lesions (hyphema, hypopyon) are more common in dogs with AML, whereas neurologic signs are more common in dogs with ALL.

TABLE 80.3

Clinical Signs and Physical Examination Findings in Dogs and Cats With Acute Leukemias*

?, Unknown.
*Results are expressed as the approximate percentage of animals showing the abnormality.

Hematologic Features

Marked hematologic changes are usually present in dogs with acute leukemia. Couto (1985) and Grindem et al. (1985b) have published detailed reviews of the hematologic features of dogs with acute leukemia. Briefly, abnormal (leukemic) cells are observed in the peripheral blood of most dogs with AML and ALL, although this is slightly more common in the latter (i.e., circulating blasts are absent in some dogs with AML; Fig. 80.3). Isolated cytopenias, bicytopenias, or pancytopenia is present in almost all dogs with AML and ALL. Leukoerythroblastic reactions are detected in approximately half of dogs with AML but are rare in dogs with ALL. The total white blood cell (WBC) and blast counts

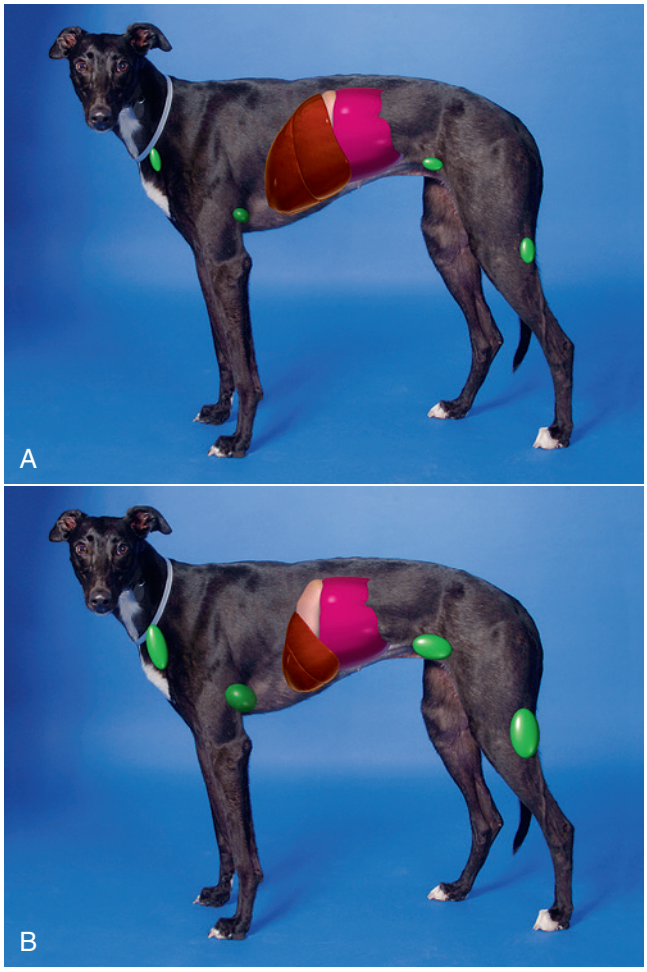

FIG 80.2
Hepatosplenomegaly and generalized lymphadenopathy in dogs with acute leukemia or multicentric lymphoma. Note the marked hepatosplenomegaly and mild lymphadenopathy in the leukemic patient **(A)** and the marked lymphadenopathy and mild hepatosplenomegaly in the dog with lymphoma **(B).** (Artwork by Tim Vojt. Reproduced with the permission of The Ohio State University.)

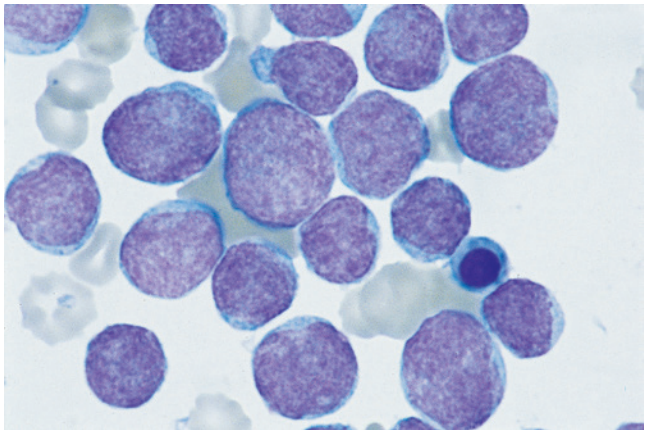

FIG 80.3
Blood smear from a dog with acute lymphoblastic leukemia and a white blood cell count of approximately 1 million/μL. Note the predominance of large, immature lymphoid cells with large nuclei, clumped chromatin, and nucleoli (×1000).

are highest in dogs with ALL (median, 298,200/μL; range, 4000-628,000/μL), and as a general rule, only dogs with ALL have WBC counts greater than 100,000/μL. Most dogs with AML and ALL are anemic, but dogs with acute monoblastic/monocytic leukemia (AMoL or AML-M_5) have the least severe anemia (packed cell volume of 30% versus 23% in all other groups). Most dogs with acute leukemias are also thrombocytopenic, although the thrombocytopenia also appears to be less severe in dogs with AML-M_5 (median, 102,000/μL; range, 39,000-133,000/μL).

With the advent of automated hematology analyzers based on flow cytometry and/or impedance, practitioners have access to "dot plots" or "cytograms" with some instruments. Visualization of dot plots in dogs with acute leukemias is helpful because some instruments "recognize" these leukemic cells as lymphocytes or monocytes (the analyzer "counts" >10,000 cells, whereas we only count 100 cells when we do a differential leukocyte count), but the shape of the "cloud" in the cytogram is quite unique (Fig. 80.4). In some dogs, the numerical values only indicate "monocytosis" or "lymphocytosis," but visualization of the dot plots is helpful from a diagnostic standpoint. In addition, in dogs with high leukemic cell counts, the abnormal cells may be counted as reticulocytes by the analyzer; this is important, because the anemia will then be classified as "regenerative" (Novacco et al., 2015b). However, all the reticulocytes are located in a relatively small area, as opposed to being widely distributed, as in dogs with true regenerative anemia.

Diagnosis

A presumptive diagnosis in dogs with acute leukemia is usually made on the basis of the history and physical examination findings; a complete blood count (CBC) is usually confirmatory, although the hematologic changes in dogs with "aleukemic leukemia" may resemble those of ehrlichiosis or other bone marrow disorders (e.g., bone marrow aplasia). Interestingly, as discussed earlier, some flow cytometry-based hematology analyzers allow for visualization of the abnormal cells in the leukocyte graphics (see Fig. 80.4); therefore the term *oligoleukemic leukemias* may be more appropriate than *aleukemic leukemia*.

To evaluate the extent of the disease, a bone marrow aspirate or biopsy may be indicated; if the patient has a high circulating blast count, a bone marrow aspirate is rarely necessary for diagnosis or prognosis. Splenic, hepatic, or lymph node aspirates for cytologic evaluation can also be obtained easily, although the information yielded may not help in establishing the diagnosis or prognosis. For example, if a dog has mild generalized lymphadenopathy and the only sample submitted to a laboratory is a lymph node, spleen, or liver aspirate, the finding of undifferentiated blasts in the smear points toward a cytologic diagnosis of either acute leukemia or lymphoma (i.e., the neoplastic lymphoid cells in lymphoma and leukemia are indistinguishable morphologically); indeed, it is quite common for the clinical pathologist to issue a diagnosis of lymphoma because it is the more common of the two diseases. In these cases, further clinical

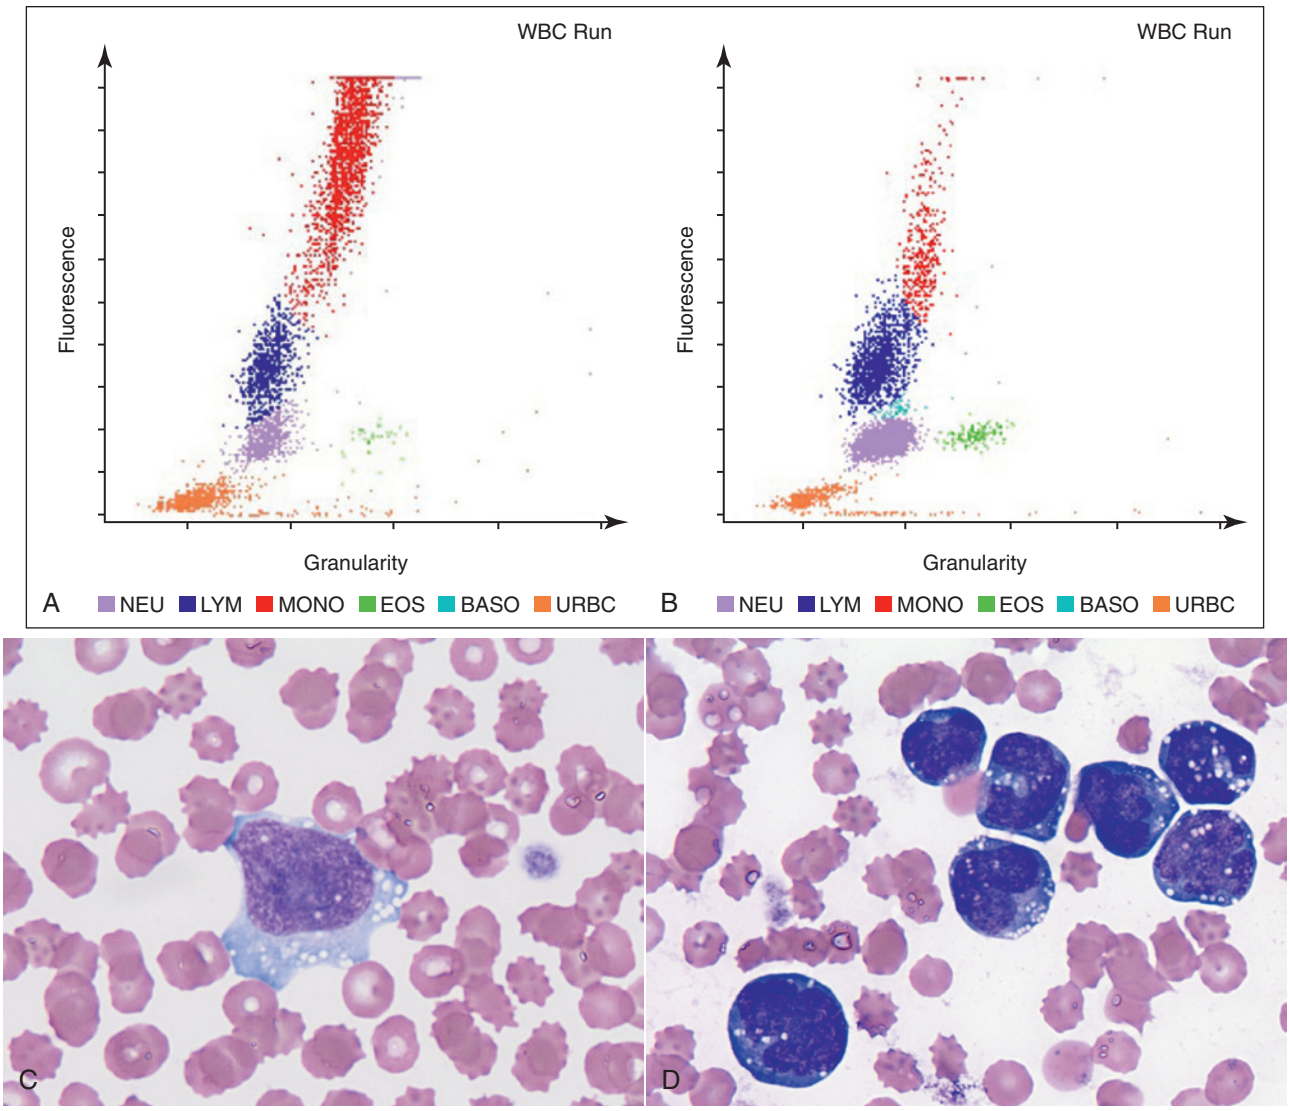

FIG 80.4
White blood cell dot plot from a ProCyte Dx in a dog with acute leukemia **(A)** compared with a normal dot plot **(B).** Note the funnel-shaped monocyte curve in red, in contrast with the well-defined, upward tapering cloud in B. The numeric values in this dog consisted of moderate neutropenia (0.96×10^9/L), mild monocytosis (2.5×10^9/L), and moderate thrombocytopenia (49×10^9/L). Monocytoid blast in peripheral blood **(C).** Bone marrow cytology reveals monocytoid precursors with a tendency toward myeloid/myelomonocytic differentiation **(D).** The final diagnosis was acute myeloid leukemia.

and clinicopathologic information (i.e., the degree and extent of lymphadenopathy, presence and degree of hepatosplenomegaly, hematologic and bone marrow biopsy, or aspiration findings) is required to establish a definitive diagnosis.

It may be difficult to diagnose the specific tumor type in a dog with generalized lymphadenopathy, hepatosplenomegaly, and a low number of circulating lymphoblasts. The main differential diagnoses are ALL and lymphoma with circulating blasts (leukemic phase of lymphoma). It is important to differentiate between these two disorders because the prognosis for dogs with lymphoma is considerably better than that for dogs with acute leukemia. These two entities may be difficult to distinguish on the basis of the clinical, hematologic, and cytologic information obtained, but the guidelines found in Box 80.1 can be used to try to arrive at a definitive diagnosis. Immunophenotyping can also be used to distinguish these two entities.

When the neoplastic cells are poorly differentiated, cytochemical staining or immunophenotyping is required to establish a definitive diagnosis (see Table 80.2). This is important if the owner is contemplating treatment because the therapy and prognosis for dogs with AML are different from those for dogs with ALL (i.e., the survival time in dogs with AML is shorter than that in dogs with ALL).

BOX 80.1

Acute Lymphoblastic Leukemia or Lymphoma With Circulating Blasts (Lymphosarcoma Cell Leukemia): Guidelines for a Clinical Diagnosis

1. If the lymphadenopathy is massive, the dog more likely has lymphoma (see Fig. 80.2).
2. If the dog is systemically ill, it is more likely ALL.
3. If bicytopenia or pancytopenia is present, ALL is the more likely diagnosis.
4. If the percentage of lymphoblasts in the bone marrow is more than 40% to 50%, the dog is more likely to have ALL.
5. If the cells are CD34 negative, it is more likely lymphoma.
6. If hypercalcemia is present, the more likely diagnosis is lymphoma.

ALL, Acute lymphoblastic leukemia.

BOX 80.2

Basic Diagnostic Principles for Dogs With Suspected Leukemia

1. If cytopenias or abnormal cells are present in peripheral blood, a bone marrow aspirate or biopsy specimen should be obtained.
2. If the spleen or liver is enlarged, a fine-needle aspirate of the affected organs should be obtained for cytologic evaluation.
3. If blasts are present, blood and bone marrow specimens should be submitted to a veterinary referral laboratory for cytochemical staining or immunophenotyping.
4. Other diagnostic tests (e.g., serologic tests or polymerase chain reaction [PCR] testing for *Ehrlichia canis*) should be performed if appropriate.

In addition to lymphoma, differential diagnoses in dogs with acute or chronic leukemias include other disorders of the mononuclear-phagocytic or hematopoietic systems, such as malignant or systemic histiocytosis; systemic mast cell disease (mast cell leukemia); and infectious diseases such as histoplasmosis, ehrlichiosis, anaplasmosis, bartonellosis, leishmaniasis, mycoplasmosis, and mycobacteriosis. Box 80.2 lists the basic principles of diagnosis that apply to all dogs with suspected leukemia.

The diagnosis of acute leukemia can be extremely straightforward (i.e., a dog that is evaluated because of weight loss, lethargy, hepatosplenomegaly, pallor, and central nervous system [CNS] signs and that has a WBC of >500,000/μL, most of which are blasts, is most likely to have ALL), or it may represent a challenge (i.e., a dog with unexplained cytopenias of prolonged duration in which aleukemic AML-M_1 subsequently develops).

Treatment

The treatment of dogs with acute leukemias is usually unrewarding. Most dogs with these diseases respond poorly to therapy, and prolonged remissions are rare. Treatment failure usually stems from one or more of the following factors:

1. Failure to induce remission (more common in AML than in ALL)
2. Failure to maintain remission
3. The presence or development of organ failure resulting from leukemic cell infiltration; this precludes the use of aggressive combination chemotherapy (i.e., because of enhanced toxicity)
4. The development of fatal sepsis, bleeding, or both caused by already existing or treatment-induced cytopenias

Prolonged remissions in dogs with AML treated with chemotherapy are extremely rare. In most dogs with AML, remissions in response to any of the protocols listed in Box 80.3 are uncommon. If patients do respond, the remission is usually extremely short-lived and survival rarely exceeds 3 months. In addition, more than half of the dogs die during induction as a result of sepsis or bleeding. In recent studies, the survival times in dogs with acute leukemias were 8 to 55 days (Bennett et al., 2016; Novacco et al., 2015a).

Furthermore, the supportive treatment required in these patients (e.g., blood component therapy, intensive care monitoring) is financially unacceptable to most owners, and the emotional strain placed on the owner is also quite high. In humans, it costs more than $1 million to treat a child with leukemia. Therefore owners should be aware of all these factors before deciding to treat their dogs.

The prognosis may be slightly better in dogs with ALL; however, responses to treatment and survival times in these patients are considerably lower than those in dogs with lymphoma. The remission rates in dogs with ALL are approximately 20% to 40%, in contrast to those in dogs with lymphomas, which approach 90%. Survival times with chemotherapy in dogs with ALL are also shorter (average, 1-3 months) than those in dogs with lymphoma (average, 12-18 months). Untreated dogs usually live less than 2 weeks. Chemotherapy protocols used in dogs with acute leukemia are listed in Box 80.3.

CHRONIC LEUKEMIAS

Prevalence

In dogs, CLL is far more common than CML; in addition, the latter is poorly characterized. One author's hospital evaluates approximately six to eight dogs with CLL a year, whereas approximately one dog with CML is evaluated every 3 to 5 years. CLL is one of the leukemias most commonly diagnosed at diagnostic referral laboratories. Small-breed dogs are more likely to develop B-cell CLL than large-breed dogs (Bromberek et al., 2016).

BOX 80.3

Chemotherapy Protocols for Dogs and Cats With Acute Leukemias

Acute Lymphoblastic Leukemia

1. OP protocol
Vincristine, 0.5 mg/m^2 IV once a week
Prednisone, 40-50 mg/m^2 PO q24h for a week; then 20 mg/m^2 PO q48h

2. COP protocol
Vincristine, 0.5 mg/m^2 IV once a week
Prednisone, 40-50 mg/m^2 PO q24h for a week; then 20 mg/m^2 PO q48h
Cyclophosphamide, 50 mg/m^2 PO q48h

3. LOP protocol
Vincristine, 0.5 mg/m^2 IV once a week
Prednisone, 40-50 mg/m^2 PO q24h for a week; then 20 mg/m^2 PO q48h
L-Asparaginase, 10,000-20,000 IU/m^2 IM or SC once every 2-3 weeks

4. COAP protocol
Vincristine, 0.5 mg/m^2 IV once a week
Prednisone, 40-50 mg/m^2 PO q24h for a week; then 20 mg/m^2 PO q48h
Cyclophosphamide, 50 mg/m^2 PO q48h
Cytosine arabinoside, 100 mg/m^2 SC daily for 2-4 days*

5. CHOP protocol
Vincristine 0.5-0.75 mg/m^2 IV week 1
Cyclophosphamide 200-250 mg/m^2 IV or PO week 2
Vincristine 0.5-0.75 mg/m^2 IV week 3
Doxorubicin 30 mg/m^2 (1 mg/kg if <10 kg) IV week 4

Acute Myelogenous Leukemia

1. Cytosine arabinoside, 5-10 mg/m^2 SC q12h for 2-3 weeks; then on alternate weeks
2. Cytosine arabinoside, 100-200 mg/m^2 in IV drip over 4 hours; repeat every 2-3 weeks
3. Mitoxantrone, 4-6 mg/m^2 in IV drip over 4 hours; repeat every 3 weeks

*The daily dose should be divided into two to four daily administrations.
IM, Intramuscular; *IV,* intravenous; *PO,* by mouth; *SC,* subcutaneous.

Clinical Features

Like their acute counterparts, the clinical signs in dogs with CLL or CML are vague and nonspecific; however, there is a history of chronic (i.e., months), vague clinical signs in approximately half of the dogs. Many cases of chronic leukemia are diagnosed incidentally during routine annual health checks or presurgical evaluations in asymptomatic dogs. Clinical signs in dogs with CLL may include lethargy, anorexia, vomiting, mildly enlarged lymph nodes, intermittent diarrhea or vomiting, and weight loss. As mentioned previously, more than half of the dogs with CLL are asymptomatic and are diagnosed serendipitously. Physical examination findings in dogs with CLL include mild generalized lymphadenopathy, splenomegaly, hepatomegaly, pallor, and pyrexia; the last two are uncommon. The clinical signs and physical examination findings in dogs with CML appear to be similar to those in dogs with CLL.

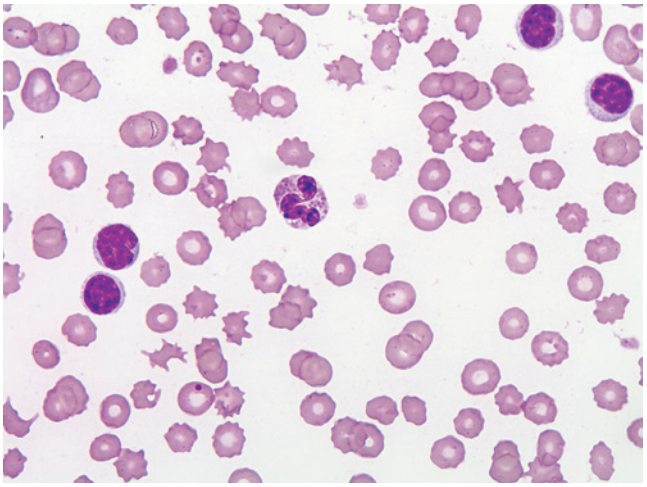

FIG 80.5
Diff-Quik–stained blood smear from a 14-year-old dog with CLL and chronic kidney disease. Note the predominance of well-differentiated small lymphocytes, smaller than the eosinophil in the center of the field, the low platelet number per field, and the presence of morphologic red blood cell changes (acanthocytes and keratoacanthocytes) (×1000).

A terminal event in dogs with CLL is the development of a diffuse large cell lymphoma, termed *Richter syndrome;* in humans Richter syndrome also includes prolymphocytic leukemia, acute leukemia, and Hodgkin lymphoma. In dogs, Richter syndrome is characterized by massive, generalized lymphadenopathy and hepatosplenomegaly. Once this multicentric lymphoma develops, chemotherapy-induced, long-lasting remissions are difficult to obtain and survival times are short. In a recent report, the MST in dogs with Richter syndrome was 41 days (Comazzi et al., 2017).

Blast crisis, which involves the appearance of immature blast cells in blood and bone marrow, occurs in humans and dogs with CML months to years after the initial diagnosis is made; in humans with CLL, acute leukemias are part of the Richter syndrome. In humans with blast crisis associated with CML, these blasts are of either myeloid or lymphoid phenotype; the origin of the blast cell in dogs with blast crises has not been determined. Blast crises in CML are uncommon.

Hematologic Features

The most common hematologic abnormality in dogs with CLL is a marked lymphocytosis resulting in leukocytosis (Figs. 80.5 and 80.6). The lymphocytes are usually morphologically normal (see Fig. 80.5), although large granular lymphocytes (LGLs) or "monocytoid" lymphocytes with abundant cytoplasm are occasionally present. The lymphocyte counts range from 8000/µL to more than 100,000/µL,

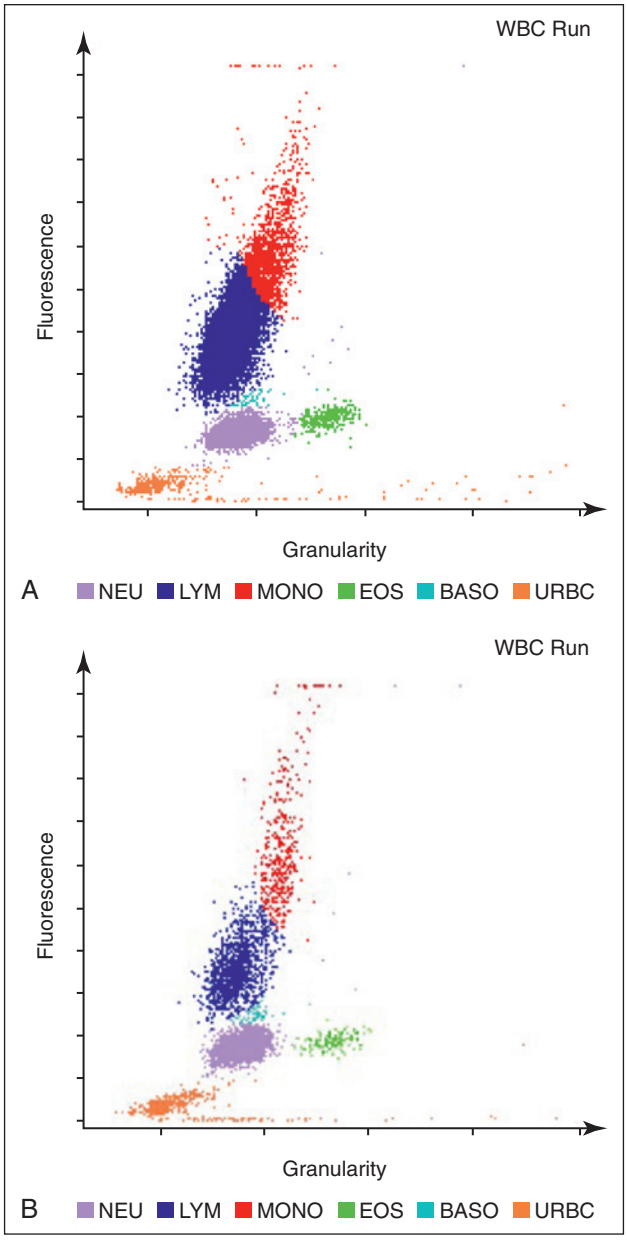

FIG 80.6
White blood cell dot plot from a ProCyte Dx in the dog with chronic lymphocytic leukemia depicted in Fig. 80.5 **(A)** compared with a normal dot plot **(B).** Note the larger, denser lymphocyte cloud in blue **(A),** positioned in the same location as that in normal dogs **(B),** suggesting that they are mature, well-differentiated lymphocytes. The straight line between the lymphocyte and monocyte clouds indicates that the instrument is "having trouble" differentiating some of the neoplastic cells from normal monocytes. The numeric values in this dog consisted of marked leukocytosis (53×10^9/L), marked lymphocytosis (39.2×10^9/L), moderate monocytosis (3.2×10^9/L), and moderate thrombocytopenia (84×10^9/L).

but lymphocyte counts of more than 500,000/μL are rare. In dogs with CLL, B-cell (i.e., CD21-positive) and T-cell (i.e., CD4/CD8-positive) CLLs were almost equally distributed (Comazzi et al., 2011). In addition to the lymphocytosis, which may be diagnostic in itself (e.g., a dog with a lymphocyte count of 100,000/μL most certainly has CLL and not an infectious disease), anemia and thrombocytopenia occur in approximately half of the dogs. Although cytologic evaluation of bone marrow aspirates in dogs with CLL usually reveals the presence of many morphologically normal lymphocytes, normal numbers of lymphocytes are occasionally detected. This is probably because the lymphocytosis in some animals with CLL, as in people, stems from disorders of recirculation rather than from the increased clonal proliferation of lymphocytes in the bone marrow. As in dogs with acute leukemias, in dogs with high-count CLL the neoplastic cells may be counted as reticulocytes by flow cytometry-based analyzers.

Monoclonal gammopathies have been reported in approximately two thirds of dogs with CLL in which serum was evaluated using protein electrophoresis. The monoclonal component is usually immunoglobulin M (IgM), but IgA and IgG components have also been reported. This monoclonal gammopathy can lead to hyperviscosity. Rarely, dogs with CLL have paraneoplastic, immune-mediated blood disorders (e.g., hemolytic anemia, thrombocytopenia, neutropenia). However, in our experience, monoclonal gammopathies are uncommon in dogs with CLL.

The hematologic features of CML in dogs are poorly characterized but include leukocytosis with a left-shift down to myelocytes (or occasionally myeloblasts), anemia, and possibly thrombocytopenia, although thrombocytosis can also occur. The hematologic findings seen during a blast crisis are indistinguishable from those seen in dogs with AML or ALL.

Diagnosis

Absolute lymphocytosis is the major diagnostic criterion for CLL in dogs. Although other diseases (e.g., ehrlichiosis, babesiosis, leishmaniasis, Chagas disease, Addison disease) should be considered in the differential diagnosis of dogs with mild lymphocytosis (i.e., 7000-20,000/μL), marked lymphocytosis (i.e., more than 20,000/μL) is almost pathognomonic for CLL. If the physical examination and hematologic abnormalities discussed in previous paragraphs (i.e., mild lymphadenopathy, splenomegaly, monoclonal gammopathy, anemia) are found, this may help establish a diagnosis of CLL in dogs with lymphocytosis, although all these changes can also be present in dogs with chronic ehrlichiosis (see Chapter 93). The phenotypic distribution after performing immunophenotyping may also establish if the cell population is monoclonal or polyclonal. In patients with lymphocytosis in which a confirmatory diagnosis of CLL cannot be made, a polymerase chain reaction (PCR) assay for clonality (PARR) will typically reveal if the cells are clonal in origin.

The diagnosis of CML may be challenging, particularly because this syndrome is poorly characterized in dogs. In our experience, most dogs with extreme neutrophilia have leukemoid reactions and not CML. Some of the markers used to diagnose CML in humans are of no use in dogs. For example, the Philadelphia 1 chromosome and the alkaline phosphatase score were originally used in humans to

differentiate CML from leukemoid reactions (i.e., CML cells have the Philadelphia 1 chromosome, and the alkaline phosphatase content of the neutrophils increases in the setting of leukemoid reactions and decreases in the setting of CML). Chromosomal analysis of the cells in question may reveal specific abnormalities that support a diagnosis of CML. As a general rule, a final diagnosis of CML should be made only after the clinical and hematologic findings have been carefully evaluated and the inflammatory and immune causes of neutrophilia have been ruled out.

Treatment

The clinician usually faces the dilemma of whether to treat a dog with CLL. If the dog is symptomatic, has organomegaly, or has concurrent hematologic abnormalities, treatment with an alkylator (with or without corticosteroids) is indicated. If there are no paraneoplastic syndromes (i.e., immune hemolysis or thrombocytopenia, monoclonal gammopathies), the authors use single-agent chlorambucil at a dosage of 20 mg/m^2 given orally (PO) once every 2 weeks (Box 80.4). If there are paraneoplastic syndromes, or the patient is symptomatic, the addition of corticosteroids (prednisone, 50-75 mg/m^2 PO q24h for 1 week, then 25 mg/m^2 PO q48h) may be beneficial.

Because the growth fraction of neoplastic lymphocytes in CLL appears to be low, a delayed response to therapy is common. In a high proportion of dogs with CLL treated with chlorambucil or chlorambucil and prednisone, it may take more than 1 month (and as long as 6 months) for the hematologic and physical examination abnormalities to improve. This is in contrast to dogs with lymphoma and acute leukemias, in which remission is usually induced in 2 to 7 days.

BOX 80.4

Chemotherapy Protocols for Dogs and Cats With Chronic Leukemias

Chronic Lymphocytic Leukemia

Chlorambucil, 20 mg/m^2 PO once every 2 weeks
Chlorambucil as above, plus prednisone, 50 mg/m^2 PO q24h for a week; then 20 mg/m^2 PO q48h

COP Protocol

Cyclophosphamide, 200-300 mg/m^2 IV or PO once every 2 weeks
Vincristine, 0.5-0.75 mg/m^2 IV once every 2 weeks (alternating weeks with the cyclophosphamide)
Prednisone as in protocol 2; this treatment is continued for 6-8 weeks, at which time protocol 1 or 2 can be used for maintenance

Chronic Myelogenous Leukemia

Hydroxyurea, 50 mg/kg PO q24h for 1-2 weeks; then q48h
Imatinib (Gleevec), 10 mg/kg PO q24h

IV, Intravenous; *PO,* by mouth.

The survival times in dogs with CLL are quite long. Indeed, even without treatment, survival times of more than 2 years are common. More than two thirds of the dogs with CLL treated with chlorambucil (with or without prednisone) at the authors' clinics have survived in excess of 2 years. In fact, most dogs with CLL do not die as a result of leukemia-related causes but rather of other senior disorders.

In a study of 202 dogs with neoplastic lymphocytosis, which likely included both dogs with CLL and dogs with leukemic phase of lymphoma, expression of CD34 on flow cytometry was associated with a negative prognosis (survival times of 16 days). Dogs with B-cell proliferation (CD21 positive) had shorter survival times than those with T-cell (CD8-positive) proliferations. Dogs with CD8-positive phenotype had longer survival times if the lymphocyte count was less than 30,000/μL (1100 days versus 131 days); among the dogs with B-cell phenotype, those with circulating small lymphocytes had a significantly longer survival than those with large lymphoid cells (MST not reached versus 129 days) (Williams et al., 2008).

Recently, Comazzi et al. (2011) reported that dogs with T-CLL that received chemotherapy had approximately 3-fold and 19-fold higher probability of surviving than dogs with B-CLL and atypical CLL, respectively. Old dogs with B-CLL survived significantly longer than did young dogs, and anemic dogs with T-CLL survived a significantly shorter time than dogs without anemia (Comazzi et al., 2011).

The treatment of dogs with CML using hydroxyurea (see Box 80.4) may result in prolonged remission, provided a blast crisis does not occur. However, the prognosis does not appear to be as good as that for dogs with CLL (i.e., survivals of 4-15 months with treatment). The treatment of blast crises is usually unrewarding. A novel therapeutic approach targeting tyrosine kinase in the neoplastic cells of humans with CML using imatinib (Gleevec) has shown to be beneficial in inducing remission; however, it is unknown if tyrosine kinase inhibitors are beneficial in dogs with this disease.

LEUKEMIAS IN CATS

ACUTE LEUKEMIAS

Prevalence

In the feline leukemia virus (FeLV)-free era, true leukemias are rare in the cat, constituting less than 15% of all hematopoietic neoplasms. Although exact figures regarding the incidences of leukemias and lymphomas are not available, these neoplasms are extremely rare in the authors' clinics.

If cytochemical staining or immunophenotyping is used to classify acute leukemias in cats, approximately two thirds are myeloid and one third are lymphoid. However, in contrast to dogs, myelomonocytic leukemias (M_4) appear to be rare in cats.

FeLV is commonly implicated as a cause of leukemias in cats; however, the role of feline immunodeficiency virus (FIV) in the pathogenesis of these neoplasms is still unclear.

Originally, it was reported that approximately 90% of cats with lymphoid and myeloid leukemias tested positive for FeLV p27 with enzyme-linked immunosorbent assay or immunofluorescence. As discussed in Chapter 78, because the prevalence of FeLV infection is decreasing, most cats with leukemia diagnosed in the authors' clinics have not been viremic for FeLV (i.e., they are FeLV negative).

Clinical Features

The clinical features and physical examination findings in cats with acute leukemias are similar to those in dogs and are summarized in Table 80.3. Shifting limb lameness and ocular or neurologic signs do not appear to be as common in cats as in dogs with myeloid leukemias.

Hematologic Features

More than three fourths of cats with AML and ALL have cytopenias; leukoerythroblastic reactions are common in cats with AML but extremely rare in those with ALL. In contrast to dogs, circulating blasts appear to be more common in cats with AML than in those with ALL.

Sequential studies of cats with myeloid leukemias have revealed that the cytomorphologic features can change from one cell type to another over time (e.g., sequential diagnoses of erythremic myelosis, erythroleukemia, and acute myeloblastic leukemia are common in a given cat). This is one of the reasons that most clinical pathologists prefer the term *myeloproliferative disorder* (MPD) to refer to this leukemia in cats.

Diagnosis and Treatment

The diagnostic evaluation of cats with suspected acute leukemia follows the same general sequence as that for dogs. If the changes in the CBC are not diagnostic, a bone marrow aspirate can provide information that may confirm the diagnosis (Fig. 80.7). In addition, cats with suspected or confirmed acute leukemias should be evaluated for circulating FeLV p27 and for serum antibodies against FIV.

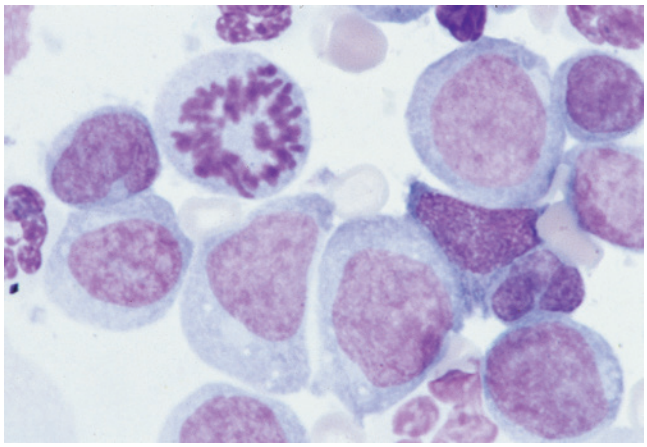

FIG 80.7
Bone marrow aspirate from a cat with peripheral blood cytopenias and absence of circulating blasts. Note the predominance of large immature myeloid cells, characterized by round to kidney-shaped nuclei. A mitotic figure is evident (×1000).

With treatment, cats with ALL apparently have better survival times than cats with AML. Survival times in cats with ALL treated with multichemotherapy range from 1 to 7 months.

There have been several published reports of cats with myeloid leukemias treated with single-agent or combination chemotherapy. The treatment protocols have included single-agent cyclophosphamide or cytosine arabinoside, as well as combinations of cyclophosphamide, cytosine arabinoside, and prednisone; cytosine arabinoside and prednisone; cyclophosphamide, vinblastine, cytosine arabinoside, and prednisone; and doxorubicin, cyclophosphamide, and prednisone. Survival times in these cats have usually ranged from 2 to 10 weeks, with a median of approximately 3 weeks. Therefore, as in dogs, intensive chemotherapy does not appear to be beneficial in cats with acute leukemias.

Low-dose cytosine arabinoside (LDA; 10 mg/m^2 subcutaneously q12h) has been used as an inductor of differentiation of the neoplastic clone. In several studies this treatment was observed to induce complete or partial remission in 35% to 70% of humans with MDS and MPD. Moreover, although myelosuppression was observed in some patients, the treatment was exceedingly well tolerated and associated with minimal toxicity.

One of the authors (GC) treated several cats with MPD using LDA and has observed in most complete or partial remissions, with transient hematologic improvement. Although no major toxicities were seen, the remissions were short-lived (3-8 weeks).

CHRONIC LEUKEMIAS

Chronic leukemias are becoming more common in cats; this may be due to the relative decrease in the prevalence of acute leukemias, or it may represent a true phenomenon. CLL is occasionally found incidentally during routine physical examination. More often, cats with CLL are seen by a veterinarian because of a protracted history of vague signs of illness, including anorexia, lethargy, and gastrointestinal tract signs.

One author's clinic (GC) previously evaluated seven FeLV-FIV–negative cats with CLL that presented primarily for anorexia and weight loss. Splenomegaly, hepatomegaly, and/or lymphadenopathy were present on physical examination in all cats. On initial evaluation, the average hematocrit was 26%, platelets averaged 258,000 cells/μL, and the total white cell count was 63,000 cells/μL. The mean lymphocyte count was 48,200 cells/μL (range, 10,000-104,000/μL) and were primarily small, well differentiated, with clumped chromatin and often a cleaved or irregular nuclear membrane (Fig. 80.8). Six of the seven cats had CD5+CD4+CD8– (T-helper cell) immunophenotype (see Fig. 80.1). Six of the seven cats (86%) responded to treatment with chlorambucil (20 mg/m^2, PO, q2 weeks) and dexamethasone (4 mg, PO, q1 week) or prednisolone (1 mg/kg, PO, q24 hours). MST was 14 months (range, 1-34 months). A recent report of

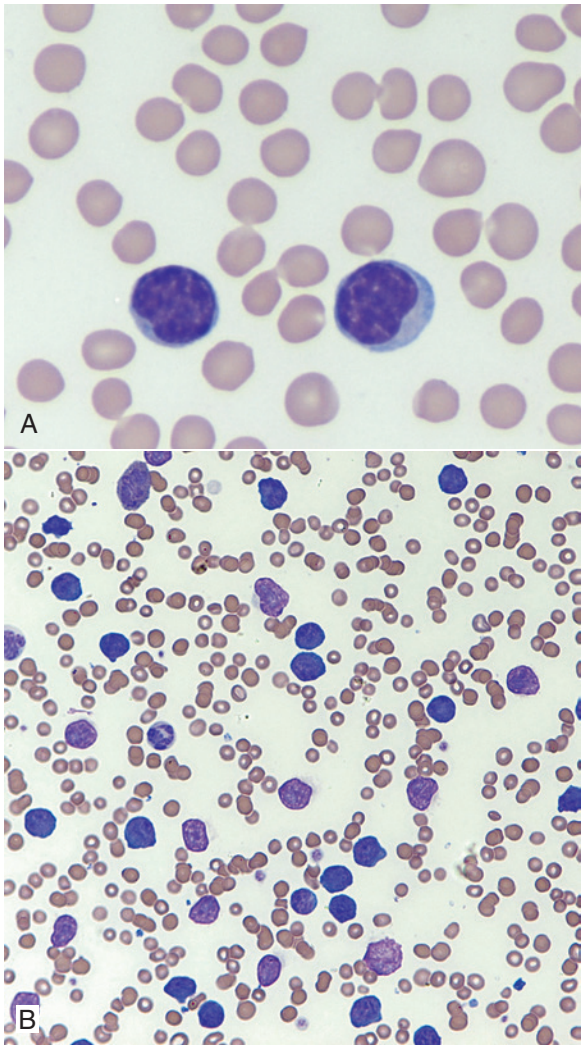

FIG 80.8

Wright-Giemsa stain; ×1000 **(A).** Blood smear showing increased number of lymphocytes per field. Wright-Giemsa stain; ×500 **(B).**

18 cats with CLL revealed similar findings (Campbell et al., 2012). Approximately 50% of the cats had clinical signs related to their disease, with the most common clinical sign being chronic weight loss. Various chemotherapy protocols were used, although chlorambucil and prednisolone were the most common; there was a response rate of 88%, with an MST of 14 months. As in dogs, CML is poorly characterized in cats.

CHAPTER 81

Selected Neoplasms in Dogs and Cats

HEMANGIOSARCOMA IN DOGS

Hemangiosarcomas (HSAs; hemangioendotheliomas, angiosarcomas) are malignant neoplasms that originate from the circulating endothelial cell precursors. They occur predominantly in older dogs (8-10 years of age) and in males; German Shepherd dogs and Golden Retrievers are at high risk for this neoplasm.

The spleen, right atrium, subcutis, and retroperitoneal space are common sites of involvement at the time of presentation; in Greyhounds, most HSAs originate in a muscle in the rear limb. Approximately 50% of the tumors originate in the spleen, 25% in the right atrium, 13% in subcutaneous tissue, 5% in the liver, 5% in the liver-spleen–right atrium, and 1% to 2% simultaneously in other organs (i.e., kidney, urinary bladder, bone, tongue, prostate). The latter are referred to as *multiple tumor, undeterminable primary.* In general, the biologic behavior of this neoplasm is highly aggressive, with most anatomic forms of the tumor infiltrating and metastasizing early in the disease. The exceptions are primary dermal and conjunctival or third eyelid HSAs, which have a low metastatic potential.

Clinical and Clinicopathologic Features

The owners' complaints and the clinical signs at presentation are usually related to the site of origin of the primary tumor; to the presence or absence of metastatic lesions; and to the development of spontaneous tumor rupture, coagulopathies, or cardiac arrhythmias. More than half of the dogs with HSA are evaluated because of acute collapse after spontaneous rupture of the primary tumor or a metastatic lesion. Some episodes of collapse may stem from ventricular arrhythmias, which are relatively common in dogs with splenic or cardiac HSA. In addition, dogs with splenic HSA are often seen because of abdominal distention secondary to tumor growth or hemoabdomen.

Dogs with cardiac HSA are usually presented for evaluation of right-sided congestive heart failure (caused by cardiac tamponade) or cardiac arrhythmias (see the chapters on cardiovascular system disorders for additional information). Dogs with cutaneous or subcutaneous neoplasms are usually evaluated because of a mass, which may be surrounded by hemorrhage. Greyhounds with intramuscular HSA typically present with a swollen and bruised rear limb; the tumor is frequently in the biceps femoris or quadriceps.

Two common problems in dogs with HSA, regardless of the primary location or stage, are anemia and spontaneous bleeding. The anemia is usually the result of intracavitary bleeding, microangiopathic hemolysis (MAHA), or both, whereas the spontaneous bleeding is usually caused by disseminated intravascular coagulation (DIC) or thrombocytopenia secondary to MAHA (see later discussion). HSA is so highly associated with clinical DIC (see Chapter 87) that when a dog with DIC of acute onset without an obvious primary cause is evaluated, HSA should be considered high on the list of differential diagnoses.

HSAs are usually associated with a wide variety of hematologic and hemostatic abnormalities. Hematologic abnormalities in dogs with HSA have been well characterized and include anemia; thrombocytopenia; the presence of nucleated red blood cells (RBCs), RBC fragments (schistocytes), and acanthocytes in the blood smear; and leukocytosis with neutrophilia, a left shift, and monocytosis. In addition, hemostatic abnormalities are also common in dogs with HSAs. However, these hematologic abnormalities are location dependent; for example, in our experience, anemia, thrombocytopenia, schistocytosis, and acanthocytosis are more common in dogs with splenic, right atrial, or visceral HSA than in dogs with subcutaneous or dermal HSA.

Most dogs with HSAs evaluated at the authors' clinics are anemic, and more than half have RBC fragmentation and acanthocytosis. The pretreatment hemostasis profiles are normal in less than 20% of the dogs; most dogs have thrombocytopenia. Approximately half of the hemostasis profiles may meet three or more criteria for diagnosis of DIC. Approximately 25% of these dogs can die as a result of their hemostatic abnormalities.

Diagnosis

HSAs can be diagnosed cytologically on the basis of the appearance of fine-needle aspirates (FNAs) or impression smears; however, the ability to identify these neoplastic cells in cytology samples may be impaired by blood contamination present, given this tumor's vascularity. When visible, the neoplastic cells are similar to those in other sarcomas in that they are spindle-shaped or polyhedral; however, they are quite large (40-50 μm), have large nuclei with a lacy chromatin pattern and one or more nucleoli, and a bluish gray, usually vacuolated cytoplasm (Fig. 81.1). Nucleated RBCs and acanthocytes/schistocytes can also be present in FNAs of HSAs, independently of the primary site. Although HSA cells are relatively easy to identify in tissue aspirates or impression smears, they are extremely difficult to identify in HSA-associated effusions. The probability of establishing a cytologic diagnosis of HSA after evaluating effusions is less than 25%. An additional problem with effusions is that they frequently contain reactive mesothelial cells that may resemble neoplastic cells, leading to a false-positive diagnosis of HSA.

In general, a presumptive clinical or cytologic diagnosis of HSA should be confirmed histopathologically, if feasible. Because of the large size of some splenic HSAs, however, multiple samples (from different morphologic areas) should be submitted in appropriate fixative, or ideally, the entire spleen should be submitted for the most thorough evaluation. Histochemically, HSA cells are positive for von Willebrand factor antigen in approximately 90% of the cases, and CD31, a novel marker, is positive in up to 100% of HSA cells. In practice, these are the two most routinely used histochemical stains that can be beneficial to help confirm a diagnosis of HSA.

Metastatic sites can be detected radiographically, ultrasonographically, or on computed tomography (CT). The staging diagnostics that should be considered for dogs with HSA include a complete blood count (CBC), serum biochemistry profile, hemostasis screen, urinalysis, thoracic radiographs, abdominal ultrasonography, and echocardiography. The latter is used to identify cardiac masses and determine the baseline fractional shortening before instituting doxorubicin-containing chemotherapy (see the section on treatment and prognosis). As mentioned earlier, concurrent splenic and right atrial masses can occur in dogs with HSA; in a recent study <10% of dogs initially diagnosed with splenic HSA had a right atrial mass on staging echocardiography, and 30% of dogs initially diagnosed with cardiac HSA had a splenic mass on staging ultrasonography (Boston et al., 2011). The number of dogs with concurrent right atrial masses on staging echocardiography may be falsely decreased, due to the fact that it can be more difficult to assess for cardiac masses in the absence of pericardial effusion; however, it does appear that concurrent cardiac HSA when splenic HSA is first diagnosed is less common.

Thoracic radiographs in dogs with metastatic HSA are typically characterized by the presence of interstitial or alveolar infiltrates, as opposed to the common "cannonball" metastatic lesions seen with other tumors. The radiographic pattern may be due to true metastases, DIC and intrapulmonary bleeding, or acute respiratory distress syndrome (ARDS).

Ultrasonography constitutes a reliable way to evaluate dogs with suspected or confirmed HSA for intraabdominal disease. Neoplastic lesions appear as nodules with variable echogenicity, ranging from anechoic to hyperechoic (Fig. 81.2). Hepatic metastatic lesions can often be identified using this imaging technique. However, the clinician should bear in mind that what appear to be metastatic nodules in the liver of a dog with a splenic mass may represent regenerative hyperplasia rather than true metastatic lesions. Contrast ultrasonography appears to enhance the operator's ability to detect hepatic metastatic nodules from HSA, but it is not easily available. Therefore we recommend using caution

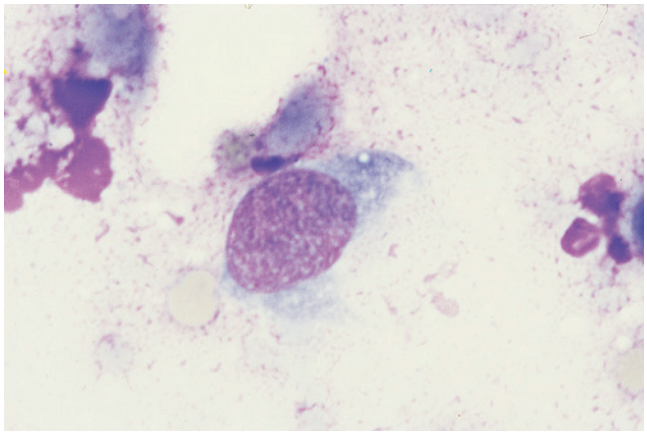

FIG 81.1
Cytologic features of canine hemangiosarcoma. Note the spindle-shaped cells, with a dark, vacuolated cytoplasm, and the fine nuclear chromatin pattern with prominent nucleolus (×1000).

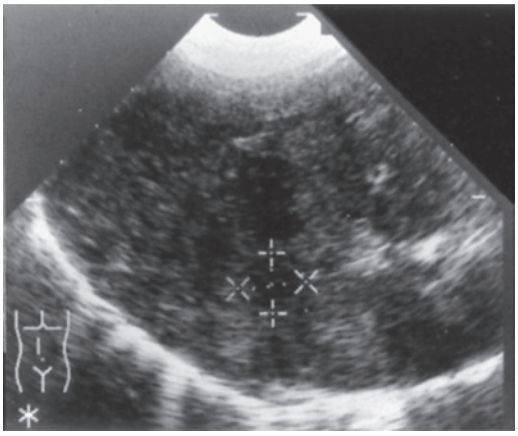

FIG 81.2
Ultrasonogram of an intraabdominal hemangiosarcoma.

when confirming hepatic metastasis only ultrasonographically, without the benefit of cytology or histopathology.

Overall, establishing a definitive diagnosis of HSA before surgical excision can be quite difficult, and for this reason, many clinicians will proceed with treatment (discussed later) without the benefit of a definitive diagnosis. Previous studies have reported the statistical likelihood of HSA in certain situations (mainly with splenic lesions), which can help clinicians discuss the probabilities with owners before consideration of surgery. If a dog presents with a splenic mass and a nontraumatic hemoabdomen, there is an approximately 50% to 75% possibility of a diagnosis of splenic HSA. However, a recent study has shown that, if only a splenic mass is present without a hemoabdomen, the possibility of HSA decreases to approximately 30% (meaning 70% of these lesions are benign). Extensive investigation into biomarkers of HSA (mainly splenic and cardiac) has been attempted; however, there is still no clear diagnostic test to differentiate a splenic or cardiac mass (unless cytologic analysis revealed enough neoplastic cells to determine the diagnosis) without full histopathology (and potentially the necessity for immunohistochemistry to confirm endothelial origin).

Treatment and Prognosis

Historically, the mainstay of treatment for dogs with HSA has been surgery, although the results have been poor. Survival times vary with the location and stage of the tumor, but in general (with the exception of dermal and conjunctival or third eyelid HSAs), they are quite short (approximately 20-60 days, with a 1-year survival rate of <10% after splenectomy alone). Results of treatment combining surgery and postoperative adjuvant chemotherapy with doxorubicin; doxorubicin and cyclophosphamide (AC protocol); and vincristine, doxorubicin, and cyclophosphamide (VAC protocol) are better than with surgery alone. Median survival times (MSTs) range from 4.5 to 8 months.

Clinical stage has been considered a negative prognostic factor for survival. The most routine staging system that is used in practice for dogs with splenic HSA is as follows:

- Stage I: disease confined to the spleen
- Stage II: ruptured splenic HSA
- Stage III: clinically detectable metastatic HSA; concurrent right atrial mass

Doxorubicin-based protocols are most commonly used in the adjuvant setting for HSA; we favor two typical protocols. As with most chemotherapy protocols, treatment choice depends on personal experience and preference. The first protocol, termed a *dose-intensified doxorubicin protocol* (see table on cancer chemotherapy protocols at the end of this chapter), involves 5 doses of doxorubicin delivered every 2 weeks (Sorenmo et al., 2004) and is quite suited for a general or referral practice. This protocol, when used in the adjuvant setting for splenic HSA, has been associated with an MST of 8.5 months for stage I disease, MST of 7 months for stage II disease, and MST of 3.5 months for stage III disease. The second protocol, termed the *VAC protocol*, involves a 21-day cycle repeated five or six times. In a previous study (Alvarez et al., 2013), the MST of dogs with stage III versus stage I/II HSA was compared in patients undergoing surgery and adjuvant VAC chemotherapy. Dogs with stage III disease had an MST of 6.5 months, and dogs with stage I/II HSA had an MST of 4.5 months (Figs. 81.3 and 81.4). In other words, dogs with metastatic disease did as well (or even better) than dogs without metastases. For this reason, in dogs with stage III disease, we generally discuss both the dose-intensified doxorubicin protocol and the VAC protocol; however, for stage I/II disease, one of us (KC) prefers the dose-intensified doxorubicin protocol. As discussed, dogs with visible metastatic disease at the time of diagnosis should not be denied treatment with this more aggressive chemotherapy protocol.

Neoadjuvant chemotherapy is also effective in dogs with soft tissue (e.g., subcutaneous, right atrial) HSA. Preoperative use of chemotherapy typically results in marked decrease in tumor size, thus making surgery easier. As discussed earlier, most dermal and conjunctival HSAs are cured by surgical excision and do not benefit from chemotherapy.

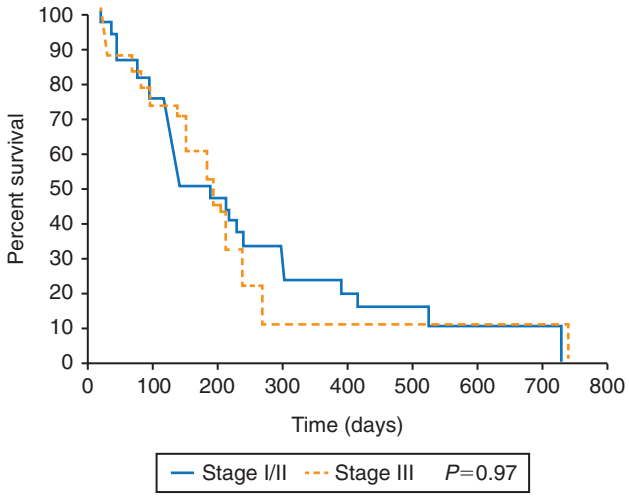

FIG 81.3
Survival times for dogs with stage III (195 days) and stage I/II HSAs (189 days) treated with VAC chemotherapy ($P = 0.97$).

There are two supplements that are also used to some degree in dogs with HSA. The first, Yunnan Baiyao, is a traditional Chinese herbal medicine that has been anecdotally reported to prolong survival time and help control bleeding in dogs with HSA. Additionally, more recently, in vitro effects of Yunnan Baiyao were investigated in canine HSA cells, and it was shown to cause dose and time-dependent HSA cell death through apoptosis (programmed cell death) (Wirth et al., 2016). The second, an extract from the common turkey tail mushroom (*Coriolous versicolor*), has been proposed to delay the progression of metastasis, affording a longer survival in dogs with HSA (Brown et al., 2012). This extract is found in the commercially available product, I'm-Yunity®, and additional investigation into this specific product is underway.

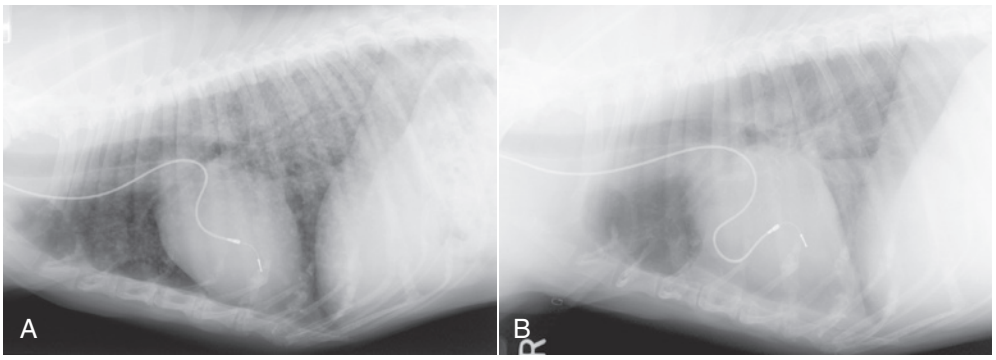

FIG 81.4
Thoracic radiographs of a 10-year-old, spayed female German Shepherd dog with pulmonary metastases from a primary splenic hemangiosarcoma before **(A)** and 9 weeks after initiating vincristine, doxorubicin, and cyclophosphamide chemotherapy **(B).** Notice the complete disappearance of the pulmonary nodules. The radiopaque line is the lead of a permanent pacemaker.

In summary, HSAs are usually diagnosed on the basis of historical, physical examination, and clinicopathologic findings, in conjunction with ultrasonographic and radiographic changes. A morphologic diagnosis can usually be made on the basis of cytologic findings, but histopathology may be necessary. Although surgery is the preferred treatment, survival times in such patients are short (except in dogs with dermal or conjunctival/third eyelid HSA), and for this reason, postoperative adjuvant chemotherapy using doxorubicin-based protocols is generally recommended, as it has been shown to prolong survival times in dogs with this malignancy.

OSTEOSARCOMA

Etiology and Epidemiology

Primary bone neoplasms are relatively common in dogs but rare in cats. Most primary bone tumors in dogs are malignant in that they usually cause death as a result of local infiltration (e.g., pathologic fractures or extreme pain leading to euthanasia) or metastasis (e.g., pulmonary metastases in osteosarcoma [OSA]). In cats, most primary bone neoplasms, although histologically malignant, can be cured by wide surgical excision (i.e., amputation). Neoplasms that metastasize to the bone are rare in dogs; some that occasionally metastasize to bones in dogs are transitional cell carcinoma of the urinary tract, OSA of the appendicular skeleton, mammary adenocarcinoma, and prostatic adenocarcinoma. Bone metastases are exceedingly rare in cats.

OSAs are the most common primary bone neoplasm in dogs. They can affect either the appendicular or axial skeletons, and they occur primarily in large- and giant-breed dogs and in Greyhounds; they are common in middle-aged to older dogs. In dogs weighing more than 40 kg, 95% of the tumors are appendicular (i.e., limbs), in contrast to dogs weighing less than 15 kg, where only 40% are appendicular. There is a distinct genetic predisposition to OSA in dogs; for example, in former racing Greyhounds, OSA is the most common cause of death (i.e., 25%), whereas OSAs are extremely rare in show Greyhounds in the United States. Due to the fact that canine OSA constitutes an excellent model for pediatric OSA, a large amount of research on the genetics of this tumor has been conducted in dogs (for a review, please see Rowell et al., 2011).

The biologic behavior of OSA is characterized by aggressive local infiltration of the surrounding tissues and rapid hematogenous dissemination (usually to the lungs). Although historically it was believed that OSAs of the axial skeleton had a low metastatic potential, it now appears that their metastatic rate is similar to that of the appendicular OSAs, with the exception of OSAs of the mandible, maxilla, or other calvarial locations, where the probability of metastases is lower (Selmic et al., 2014).

Clinical Features

Appendicular OSAs occur predominantly in the metaphyses of the distal radius, distal femur, and proximal humerus (i.e., *away from the elbow and toward the knee*), although other metaphyses can also be affected. OSA of the distal humerus or proximal radius is quite uncommon, so if an aggressive bone lesion is found in these locations, other diagnoses should also be considered. The location is also somewhat breed dependent; in Great Danes the most common site is the distal radius, whereas in Rottweilers and Greyhounds it is the distal femur. In Greyhounds, OSA of the femoral head or neck is a common cause of hip pain; therefore any Greyhound with hip pain should undergo radiographs (hip dysplasia leading to osteoarthritis is extremely uncommon in the breed). Owners seek veterinary care because of lameness or swelling of the affected limb. The pain and swelling can be acute in onset, leading to the presumptive diagnosis of a nonneoplastic orthopedic problem, and thus considerably delaying diagnosis and definitive therapy for the neoplasm while the dog is placed on nonsteroidal antiinflammatory drugs. A pathologic fracture at the time of diagnosis is

considered relatively rare and appears to be more common in Greyhounds, where approximately 15% of the patients present due to a pathologic fracture. Physical examination usually reveals a painful swelling in the affected area, with or without soft tissue involvement or pathologic fracture.

Diagnosis

Radiographically, OSAs exhibit a mixed lytic-proliferative pattern in the metaphyseal region of the affected bone (Fig. 81.5). Adjacent periosteal bone formation leads to the development of the so-called Codman triangle, which is composed of the cortex in the affected area and the periosteal proliferation. OSAs typically do not cross the articular space, but occasionally they can infiltrate adjacent bone (e.g., ulnar lysis resulting from an adjacent distal radial OSA). Because other primary bone neoplasms and some osteomyelitis lesions can mimic the radiographic features of OSAs, cytology or biopsy specimens of every lytic or lytic-proliferative bone lesion should be obtained before the owners decide on a specific treatment. An exception to this rule is an owner who has already decided that amputation is the initial treatment of choice for that lesion (i.e., the limb is amputated and the lesion submitted for histopathologic evaluation).

FIG 81.5
Radiographic appearance of an osteosarcoma in the distal tibia of a Greyhound; note the lytic and proliferative changes characteristic of this neoplasm **(A).** Radiographic appearance of a distal radial osteosarcoma with massive neoplastic new bone formation in a Mastiff **(B).**

Once a presumptive radiographic diagnosis has been established, and if the owners are contemplating treatment, thoracic radiographs or CT should be obtained to determine the extent of the disease. The authors generally obtain three radiographic views of the thorax and do not perform skeletal radiographic surveys (or radionuclide bone scan) unless there are clinical signs that warrant this investigation (i.e., lameness on a separate limb), as less than 10% of dogs with OSA have skeletal metastasis. Thoracic CT allows for detection of smaller nodules (Alexander et al., 2012), but to our knowledge, no correlations between dogs that had "negative" thoracic radiographs with pulmonary nodules on CT and survival have been established yet. Less than 10% of dogs with OSAs initially have radiographically detectable lung lesions; the presence of metastases is a strong negative prognostic factor.

When deemed necessary, the radiographic diagnosis can be confirmed before surgery (i.e., limb amputation or limb salvage) on the basis of the findings yielded either by FNA or by aspiration of the affected area using a bone marrow aspiration needle. In most cases, a blind percutaneous FNA can be performed with only manual restraint; if the operator cannot penetrate through the cortex, ultrasonographic guidance can help visualize a "window" through which the needle is inserted. OSA cells are usually round or oval; have distinct cytoplasmic borders; have a bright blue, granular cytoplasm; and have eccentric nuclei with or without nucleoli (Fig. 81.6). Osteoclast-like multinucleated giant cells are common, and there is frequently pink amorphous material (osteoid) in the background or in the cytoplasm of the osteoblasts. If the round cells cannot be convincingly identified as osteoblasts, most diagnostic laboratories can perform an alkaline phosphatase (ALP) cytochemical stain in unstained slides;

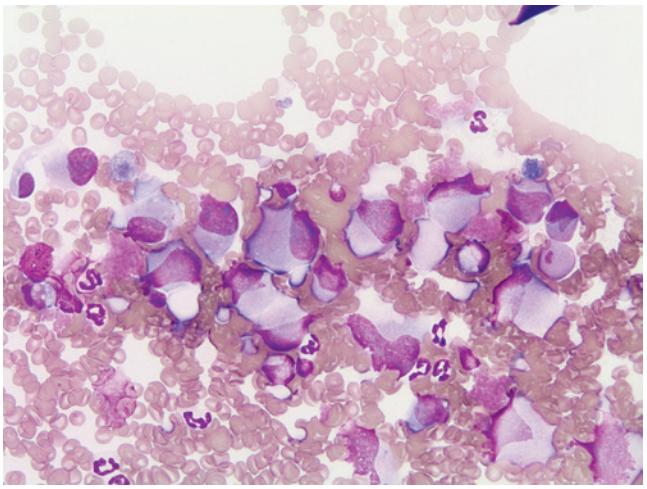

FIG 81.6
Characteristic cytologic features of osteosarcoma in a fine-needle aspirate of a lytic/proliferative lesion in the distal radius of a female Great Pyrenees. Note the round to oval eccentric nuclei with a fine chromatin pattern and prominent nucleoli, and the pink material (osteoid) in the cytoplasm of the neoplastic cells (×500).

osteoblasts are typically ALP positive. However, we have seen a fair number of histiocytic sarcomas that stain positive with ALP.

A preamputation diagnosis can also be made after histopathologic evaluation of core biopsy specimens from the affected areas. To obtain a bone biopsy, a 13- or 11-gauge Jamshidi bone marrow biopsy needle (Monoject, Covidien, Mansfield, MA) is used with the animal under general anesthesia, and a minimum of two (and preferably three) cores of tissue are obtained from both the center of the lesion and the area between affected and unaffected bone. Recently, a comparative assessment of the accuracy of cytologic and histopathologic biopsies on the diagnosis of canine bone lesions was performed, which revealed that the accuracy of cytology was similar to histopathology (approximately 80%), even in determination of tumor type. Typically, we recommend attempting to obtain a cytologic diagnosis (considering the use of ultrasound-guidance to increase potential yield), and only pursue bone biopsy if no cytologic diagnosis can be obtained and a diagnosis is required before consideration of treatment.

As long as the owners understand the biologic behavior of the neoplasm (i.e., the high likelihood of their dog dying of metastatic lung disease within 4-6 months of amputation if no chemotherapy is used) and as long as the clinical and radiographic features of the lesion are highly suggestive of OSA, the limb can be amputated in the absence of a histopathologic diagnosis. The amputated leg (or representative samples) and the regional lymph nodes should always be submitted for histopathologic evaluation. The presence of pulmonary or lymph node metastases, a high serum ALP activity, and the proximal humeral location are negative prognostic factors for survival in dogs with OSA.

Treatment and Prognosis

The standard of care for dogs with OSA is amputation and postoperative adjuvant single-agent or combination chemotherapy. The MST in dogs with appendicular OSA treated with amputation alone is approximately 4 to 6 months, whereas in dogs treated with amputation and cisplatin, carboplatin, doxorubicin, or combination chemotherapy the MST is 12 to 18 months; approximately 25% of the dogs live longer than 2 years. The dosages for chemotherapy in dogs with OSA are given in the table on cancer chemotherapy protocols at the end of this chapter and Box 81.1. The authors typically use carboplatin immediately after amputation (starting at the time of suture removal) for a total of six treatments.

An alternative therapeutic approach for dogs with distal radial or ulnar OSAs consists of sparing the affected limb. Instead of amputation, the affected bone is resected and an allograft from a cadaver or a prosthetic device is used to replace the neoplastic bone; novel biomaterials are also currently being investigated for this purpose. The dogs are also treated with chemotherapy and, in general, have almost normal limb function. Survival times in dogs treated with limb-sparing procedures are comparable with those in dogs that undergo amputation plus chemotherapy, with the added benefit to the owners of having a four-legged pet. The main complication is the development of osteomyelitis in the allograft, which occurs in up to 50% of patients; if that occurs, the limb frequently needs to be amputated. However, in patients with infected allografts that eventually undergo amputation, the survival times are significantly longer than in dogs that did not experience complications (Lascelles et al., 2005).

Recently, a novel form of irradiation (stereotactic radiation therapy) has been used for dogs with OSA. This approach allows for a high dose of radiation to be delivered to the primary tumor site, sparing the surrounding tissues of significant toxicity due to image guidance and stereotactic positioning, with the goal of affording dogs a similar survival time when compared with amputation or limb-sparing surgeries. The main complication in a relatively high percentage of dogs (up to 63%) undergoing this treatment is a pathologic fracture; in addition, skin necrosis appears to be common in Greyhounds undergoing this treatment. Pretreatment CT scans are being used to help predict which dogs may suffer a pathologic fracture, so that the best candidates for treatment can be chosen. These dogs should also be treated with postradiation chemotherapy, and bisphosphonates may be used to help strengthen the bone during the initial radiation series.

For owners who are not interested in limb amputation, limb-sparing surgeries, or stereotactic radiation therapy, more palliative intent treatments can be pursued, mainly to help with pain caused by the primary lesion. Another form of radiation therapy, termed *palliative radiation therapy*, can be used to help limit pain at the tumor site, and it is successful in approximately 75% of dogs for approximately 2 to 4

BOX 81.1

Chemotherapy Protocols and Palliative Treatment for Dogs With Osteosarcoma

Chemotherapy Protocols

1. Carboplatin: 300 mg/m^2, IV, q3-4 weeks for 4-6 doses
2. Doxorubicin: 30 mg/m^2, IV, q2 weeks, for 5 doses
3. Carboplatin: 300 mg/m^2, IV, on weeks 1 and 6, plus doxorubicin: 30 mg/m^2, IV, on weeks 3 and 9

Palliative Treatment

1. Zoledronate 0.1 mg/kg, IV, CRI in 0.9% saline, over 15 minutes, q3-4 weeks
2. Pamidronate: 1 mg/kg, IV, CRI in 0.9% saline, over 2 hours, q3-4 weeks
3. Tramadol: 3-5 mg/kg PO q8-12h
4. Deracoxib (Deramaxx): 1-2 mg/kg PO q24h*

CRI, Continuous rate infusion; *IV,* intravenous; *PO,* by mouth.
*Other nonsteroidal antiinflammatories are also effective.

months; the rate of pathologic fractures is approximately 40%. There is some information to suggest that adding chemotherapy to a course of palliative radiation therapy can enhance the analgesic effects and duration; however, doxorubicin should not be used in this setting because it acts as a radiation sensitizer and can cause severe local tissue reactions. Bisphosphonates (pamidronate 1 mg/kg, intravenous 2-hour constant rate infusion q3-4 weeks or zoledronate 0.1 mg/kg, intravenous 15-minute constant rate infusion q3-4 weeks) can be used concurrently with radiation therapy or as a sole therapy, and can improve pain in approximately 30% to 50% of dogs. Zoledronate, a newer generation bisphosphonate, is preferred by the author, as it has recently become less expensive and only requires a 15-minute infusion, in comparison to a 2-hour infusion necessary for pamidronate. Oral analgesics (see Box 81.1) are also used consistently in dogs that are not undergoing amputation or limb-sparing procedures.

Chemotherapy may modify the biologic behavior of the tumor, resulting in a higher prevalence of bone metastases and a lower prevalence of pulmonary metastases. Moreover, the doubling time (i.e., growth rate) of metastatic lesions appears to be longer than that in dogs that have not received chemotherapy, and there appear to be fewer metastatic nodules in treated than in untreated dogs. Therefore surgical removal of the metastatic nodules (i.e., metastasectomy) followed by additional chemotherapy may be recommended for a dog that has been treated with chemotherapy after amputation of the limb and in which one to two pulmonary metastatic lesions are detected (O'Brien et al., 1993). This is not recommended unless the dog has experienced a long relapse-free interval (>300 days), and the specific metastatic nodules have a long doubling time (>30 days).

Given the aggressive nature of OSA and its comparative value for pediatric OSA, there have been many attempts at novel medical therapy to help improve survival times of dogs with OSA. Recently, a multicenter, open label, prospective preclinical trial was conducted by the Comparative Oncology Trials Consortium (COTC) evaluating orally administered Rapamycin (Sirolomus) in the adjuvant setting for dogs with OSA. Dogs in this trial underwent amputation, received 4 doses of carboplatin, and were randomized to receive adjuvant Rapamycin or no additional treatment after finishing carboplatin chemotherapy. The results of this trial are not yet available; however, preliminary in vitro data suggest that Rapamycin can decrease the surviving tumor cell fraction in canine OSA cells. An additional ongoing COTC trial is currently evaluating immunotherapy using a recombinant, attenuated *Listeria monocytogenes* expressing chimeric human HER2/neu protein for dogs with OSA. Similar to the previous trial evaluating Rapamycin, dogs are undergoing amputation and receiving 4 doses of carboplatin, followed by 3 doses of the HER2/neu vaccine. In the first preliminary report of this study (Mason et al., 2016), dogs receiving this novel vaccine after amputation and carboplatin had significant longer survival times; however, only a small number of dogs was studied.

As discussed in previous paragraphs, the treatment of choice for OSAs in cats is limb amputation alone. Extremely long survival times (in excess of 2 years) are common in such cats. As discussed in Chapter 76, cisplatin is extremely toxic in cats and should therefore not be used in this species. If necessary, carboplatin or doxorubicin can be used instead.

MAST CELL TUMORS IN DOGS AND CATS

Not one of them is like another. Don't ask us why. Go ask your mother.
—From One Fish, Two Fish, Red Fish, Blue Fish, by Dr. Seuss

Mast cell tumors (MCTs) are among the most common skin tumors in dogs and are relatively common in cats. They originate from mast cells, which are intimately involved in the local control of vascular tone and which contain a large array of intracytoplasmic bioactive molecules, including heparin, histamine, leukotrienes, and several cytokines. Given their unpredictable biologic behavior, the term *mast cell tumor* is preferred to *mastocytoma* or *mast cell sarcoma.* Because of differences in the clinical and pathologic features of canine and feline MCTs, they are discussed separately.

MAST CELL TUMORS IN DOGS

Etiology and Epidemiology

MCTs constitute approximately 20% to 25% of the skin tumors seen by practicing veterinarians. Brachiocephalic breeds (Boxer, Boston Terrier, Bull Mastiff, English Bulldog) and Golden Retrievers are at high risk for MCTs. These tumors are also more common in middle-aged to older dogs (mean age, ≈8.5 years), and there is no gender-related predilection. MCTs have been found in sites of chronic inflammation or injury, such as burn scars.

Clinical and Pathologic Features

MCTs occur either as dermoepidermal masses (i.e., a superficial mass that moves with the skin) or subcutaneous/deep masses (i.e., the overlying skin moves freely over the tumor). Grossly, MCTs can mimic any primary or secondary skin lesion, including a macule, papule, nodule, tumor, or crust. Approximately 10% to 15% of all MCTs in dogs are clinically indistinguishable from the common subcutaneous lipomas. (Remember, a "lipoma"-feeling mass in the leg of a dog is almost always an MCT or a soft tissue sarcoma!) As a rule, an MCT cannot be definitively diagnosed until the lesion has been evaluated cytologically or histopathologically.

Most MCTs are solitary, although multifocal MCTs can occur. Regional lymphadenopathy caused by metastatic disease is also common in dogs with invasive MCTs or MCTs that have been present for a long period of time. Occasionally, splenomegaly or hepatomegaly is present in dogs with systemic dissemination.

Given the fact that mast cells produce a variety of bioactive (mainly vasoactive) substances, dogs with MCTs may be evaluated because of diffuse swelling (i.e., edema and inflammation around a primary tumor or its metastatic lesion), erythema, or bruising of the affected area. These episodes may be acute, and they may occur during or shortly after exercise or exposure to cold weather. Percutaneous FNA of an unexplained subcutaneous swelling in dogs should always be performed as part of the workup.

A "typical" MCT is a dermoepidermal, dome-shaped, alopecic, and erythematous lesion (Fig. 81.7). However, as discussed in previous paragraphs, MCTs rarely have a typical appearance. A clinical feature that may aid in the diagnosis of a MCT is the Darier sign, which is the erythema and wheal that form after the tumor is slightly traumatized (i.e., scraped, compressed, aspirated, etc.).

As discussed in Chapter 74, MCTs are easily diagnosed on cytology (see Fig. 74.8). Most dogs with MCTs have a normal, although eosinophilia (sometimes marked), basophilia, mastocythemia, neutrophilia, thrombocytosis, or anemia (or a combination of these) may be present. Serum biochemistry abnormalities are uncommon.

From a histopathologic standpoint, MCTs were traditionally classified using the Patnaik grading system into three categories: well differentiated (grade 1), moderately differentiated (grade 2), and poorly differentiated (grade 3). Several studies have shown that dogs with grade 1 tumors treated with surgery alone have longer survival times than identically treated dogs with grade 3 tumors, mainly because well-differentiated neoplasms are easier to resect and have a lower metastatic potential (i.e., most tumors in dogs with systemic mast cell disease are grade 3).

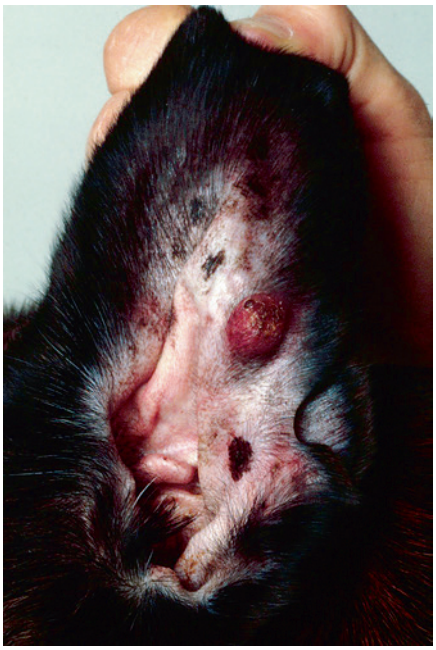

FIG 81.7
Dermoepidermal, dome-shaped lesion in the pinna of a Boxer. The cytologic diagnosis was mast cell tumor.

More recently, a group of pathologists proposed establishing a two-tier grading system for canine MCTs, using a low-grade and high-grade designation (Kiupel et al., 2011). A group of 28 pathologists from 16 institutions evaluated 95 MCTs from dogs treated by surgical resection alone. Interestingly, when grading the tumors using the original three-tier system, concordance among pathologists was approximately 60% to 65% for grades 1 and 2 tumors and 75% for grade 3 tumors. Using the newer two-tier grading system, there was a 98.6% consistency among six pathologists. Along with this, the MST for dogs with low-grade tumors was 23 months, compared with approximately 4 months for dogs with high-grade tumors. This newer grading scheme, overall, has been shown to decrease inter-pathologist variation as well as provide strong correlations with overall survival, MCT-associated mortality, and risk of metastasis. However, other authors have questioned whether this grading system correlates well with survival times (Stefanello et al., 2015).

In some cases, special stains may be required to identify the typical intracytoplasmic granules in poorly differentiated neoplasms. The mitotic index is of prognostic relevance in dogs with MCTs, so it should be provided by the pathologist (Romansik et al., 2007). In addition to the grading of the tumor, the pathologist should provide the clinician with information regarding the completeness of the excision. A dog with an incompletely excised MCT is rarely cured by the initial surgical procedure and requires either a second surgery, irradiation of the affected area, or chemotherapy.

Markers of proliferation, such as AgNOR (argyrophilic nucleolar organizing region) and Ki-67, have been used prognostically in some studies, and are now offered by several commercial laboratories. In these studies, high AgNOR and Ki-67 scores were associated with a shorter time to relapse and MSTs. We do not routinely use these stains to plan treatment of dogs with MCTs.

From a molecular standpoint, approximately 20% to 30% of canine MCTs have internal tandem duplications in exons 11 and 12 of c-kit; c-kit is the stem cell growth factor receptor, and its mutation results in immortalized clones that do not undergo apoptosis (Jones et al., 2004). Mutations in c-kit are more common in high-grade tumors and have been associated with decreased MST and disease-free interval (DFI), and a higher risk of local recurrence, metastasis, and MCT-related mortality.

Biologic Behavior

The biologic behavior of canine MCTs can be summed up in one word: unpredictable. Even though several criteria may help in establishing the biologic behavior of these neoplasms, they rarely apply to an individual dog (i.e., they may be meaningful from the statistical viewpoint; however, they are not always representative in a specific patient).

In general, solitary cutaneous MCTs that are termed low-grade (Kiupel) or grade 1 (Patnaik) have a low metastatic potential and low potential for systemic dissemination. However, the clinician may encounter a dog with several

dozen cutaneous MCTs, which on histopathologic evaluation are all considered low grade.

Grade 2 and 3 tumors have a higher metastatic potential and a higher potential for systemic dissemination than grade 1 MCTs. The newer Kiupel grading scheme helps clinicians determine how concerned to be about a specific MCT, which is especially helpful for MCTs with a grade 2 designation (under the Patnaik system), as some of these are categorized as low grade and some high grade. Grade 2, high-grade MCTs have a higher potential for metastasis and systemic dissemination than grade 2, low-grade MCTs. Metastases to the regional lymph nodes commonly occur (particularly in dogs with high-grade tumors), although occasionally a tumor "skips" the draining lymph node and metastasizes to the second or third regional node (e.g., a digital MCT in the rear limb metastasizing to the iliac or sublumbar node). Because nodal metastases can be present in normal-size lymph nodes, *every lymph node in the region of a MCT should be aspirated* before an aggressive surgery, regardless of whether it is enlarged or not. Pulmonary metastases are extremely rare. It also appears that MCTs in certain anatomic locations are more aggressive than tumors in other areas. For example, distal limb (e.g., toe), perineal, preputial, scrotal, inguinal, muzzle, and extracutaneous (e.g., oropharyngeal, intranasal) MCTs appear to have a higher metastatic potential than similarly graded tumors in other regions (e.g., trunk, neck).

Another biologic characteristic of canine MCTs is that they may become systemic, behaving like a hematopoietic malignancy (i.e., a lymphoma or leukemia). These dogs usually have a history of a high-grade or grade 3 cutaneous MCT that was excised, or a MCT in one of the locations described earlier. Most dogs with systemic mast cell disease (SMCD) are evaluated because of lethargy, anorexia, vomiting, and weight loss in association with splenomegaly, hepatomegaly, pallor, and (occasionally) detectable cutaneous masses. The CBC in affected dogs commonly reveals cytopenias, with or without circulating mast cells.

MCTs can release bioactive substances that may cause edema, erythema, or bruising of the affected area. Gastrointestinal tract ulceration may also occur as a result of hyperhistaminemia (≈80% of dogs euthanized because of advanced MCTs have gastroduodenal ulceration). Therefore any dog with an MCT should be considered to have an increased risk of gastroduodenal ulceration. Profuse intraoperative and postoperative bleeding and delayed wound healing occur in some dogs as a consequence of the bioactive substances released from mast cells.

A clinical presentation with a very distinctive biological behavior is the subcutaneous MCT (Thompson et al., 2011). Most dogs with subcutaneous MCT have a "lipoma"-feeling mass, usually in the leg (although other locations are possible). FNAs of these masses usually yield well-granulated mast cells, with no anisocytosis or mitotic figures. This clinical entity is very different than a "deep" dermal MCT, because most dogs with subcutaneous MCTs are cured by surgical excision alone, even when the tumor is incompletely excised.

Diagnosis

The evaluation of a dog with a suspected MCT should include FNA of the mass. MCTs are typically easy to diagnose cytologically. They consist of a monomorphic population of round cells with prominent intracytoplasmic purple granules; eosinophils are frequently present in the smear (see Fig. 74.8). In approximately one fourth to one third of MCTs, the granules do not stain with Diff-Quik; hence if agranular round cells are found in a dermal or subcutaneous mass resembling an MCT, the clinician should stain the slide with Giemsa or Wright stain to reveal the characteristic purple granules (see Fig. 74.13). A cytologic diagnosis of MCT allows the clinician to discuss treatment options with the owner and to plan therapeutic strategies (see the section on treatment and prognosis).

Although clinical pathologists frequently state the degree of differentiation of the cells in a cytologic specimen of an MCT, that scheme does not necessarily correlate with the histopathologic grading system. In other words, a cytologic diagnosis of a well-differentiated MCT does not necessarily imply that it will be a low-grade tumor when evaluated histopathologically (i.e., cytologic grading may not have the same prognostic implications as histopathologic grading). More recently, a variation of the Kiupel grading scheme was successfully applied to 152 cytologic specimens. Tumors were classified as high grade if the cells were poorly granulated or had at least two of four findings: mitotic figures, binucleated or multinucleated cells, nuclear pleomorphism, or >50% anisokaryosis. This cytologic grading scheme had 88% sensitivity and 94% specificity relative to histologic grading (Camus et al., 2016).

The clinical evaluation of a dog with a cytologically confirmed MCT should include careful palpation of the affected area and its draining lymph nodes; abdominal palpation, radiography, or ultrasonography to search for hepatosplenomegaly; a CBC, serum biochemistry profile, and urinalysis; and thoracic radiography if the neoplasm is in the cranial half of the body (i.e., to detect intrathoracic lymphadenopathy). Abdominal ultrasonography should be strongly considered in dogs with clinical negative prognostic factors, including an enlarged regional lymph node on physical examination, a MCT in any "high risk" location described earlier, an ulcerated MCT, history of rapid growth, known recurrence of a previous MCT, systemic signs that may indicate dissemination, or certain breeds. For example, in a recent study Shih Tzus and Rottweilers were reported to have a higher prevalence of high-grade MCTs (Mochizuki et al., 2017)

If lymphadenopathy, hepatomegaly, or splenomegaly is present, FNA of the enlarged lymph node or organ should be performed to detect mast cells (i.e., local neoplasm versus metastatic tumor versus SMCD); as discussed earlier, regional nodes should be aspirated, even if normal in size, before performing an aggressive surgery. Additionally, dogs with ultrasonographically normal liver and spleen can still have cytologic evidence of MCT metastasis, so aspirating these organs in dogs that have negative prognostic indicators (see previous discussion) is recommended.

Buffy coat smears to search for circulating mast cells are not clinically useful. Interestingly, circulating mast cells are more common in dogs with diseases other than MCTs; most dogs with mastocythemia have inflammatory disorders, regenerative anemia, tumors other than MCTs, or trauma. Circulating mast cells can frequently be recognized in the graphics of flow cytometry-based hematology analyzers (Fig. 81.8). Cytologic evaluation of a bone marrow aspirate may therefore be more beneficial for staging purposes, when deemed appropriate. On the basis of all these facts, the appropriate staging procedures in dogs with MCTs remain controversial. The authors do not use buffy coat smears or bone marrow aspirates routinely in dogs with MCT and a normal CBC; if cytopenias or leukoerythroblastic reactions are present, a bone marrow aspirate may be performed.

As a general rule, in dogs with solitary MCTs in a location amenable to wide surgical excision and no negative prognostic indicators, routine staging diagnostics (with the exception of regional lymph node aspiration) are not considered mandatory and can be performed postoperatively if there is indication of "aggressive" histopathology (i.e., high grade) (Table 81.1).

Treatment and Prognosis

As discussed previously, it is imperative to know whether the mass the clinician is preparing to excise is a MCT before surgery, because this information is useful when discussing treatment options with the family and when planning the treatment strategy. Dogs with MCT can be treated with surgery, radiotherapy, chemotherapy, molecular-targeted therapy, or a combination of these. However, the first two

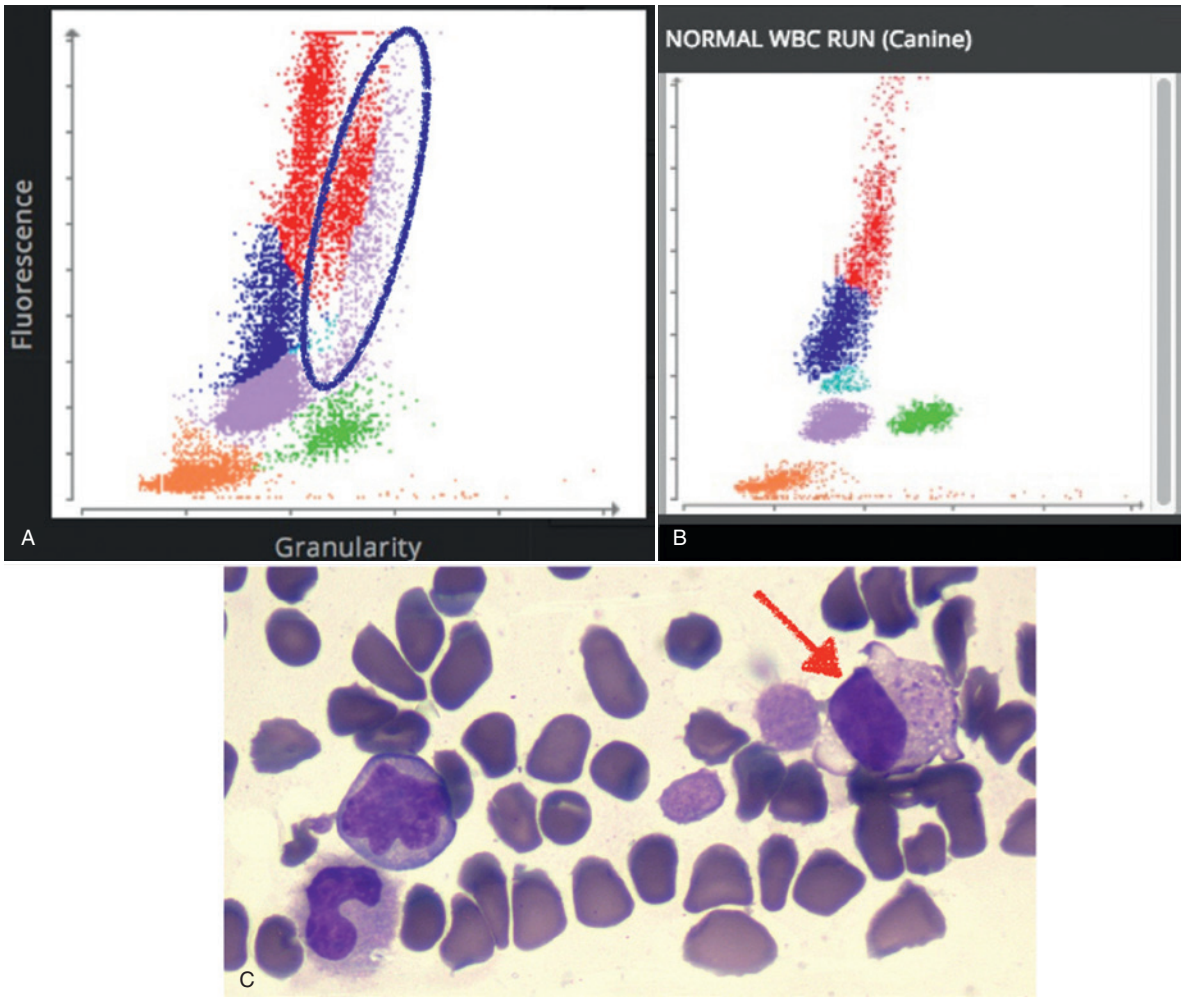

FIG 81.8
Leukocyte dotplots in a dog with systemic mast cell disease and mastocythemia **(A).** Note the second "peak" (*blue circle*) that represents the circulating mast cells, located to the right of the normal cells (the horizontal axis depicts granularity, so cells with inclusions are further to the right). **(B)** This image depicts a normal leukocyte graphic. **(C)** This image shows a circulating poorly granulated mast cell (Diff-Quick stain, ×1000). *Color code:* Purple, neutrophils; green, eosinophils; light blue, basophils; blue, lymphocytes; red, monocytes; orange, unlysed red blood cells.

treatment options are potentially curative, whereas chemotherapy or molecular-targeted therapy are generally only palliative. Treatment guidelines are provided in Table 81.2.

A solitary MCT in an area in which complete surgical excision is feasible, and in which the regional lymph node is free of metastasis, should be removed by aggressive *en bloc* resection (i.e., ideally with 2- to 3-cm margins around and one plane underneath the tumor). If a complete excision is obtained (according to the pathologist evaluating the specimen), and the tumor is a low-grade, grade 1 or 2 MCT, there is usually no need for further treatment (i.e., the dog is most likely cured). If the excision appears incomplete, the clinician can take one of three courses of action: (1) perform a second surgery in an attempt to excise the remaining tumor (the excised area should be submitted for histopathologic evaluation to assess the completeness of excision); (2) irradiate the surgical site (numerous protocols are available); or (3) administer a short course (3-6 months) of chemotherapy (discussed later). The three options appear to be equally effective, resulting in approximately an 80% probability of long-term survival.

A solitary MCT in an area in which surgical excision is difficult or impossible, or at a site where the cosmetic or functional results are unacceptable (e.g., prepuce, eyelid), can be successfully treated with radiotherapy. Approximately two thirds of dogs with a grade 1 or 2 localized MCT treated with radiotherapy alone are cured. Irradiation is also recommended for the management of tumors in high-risk areas. Intralesional injections of corticosteroids (triamcinolone, 1 mg intralesionally per centimeter of tumor diameter q2-3 weeks) can also successfully shrink the tumor (although it is usually only palliative). An alternative approach is to use neoadjuvant chemotherapy (i.e., chemotherapy before surgery). In these dogs a combination of vinblastine and prednisone (with or without lomustine) can be used to decrease the tumor size; then surgery is performed, followed by additional chemotherapy (discussed later).

Once metastatic or disseminated MCTs (or SMCD) develop, a cure is rarely obtained. The main exceptions are grade II, low-mitotic index MCT with confirmed metastasis to the regional lymph node, excised during surgery for the primary lesion, and treated with an aggressive course of postoperative chemotherapy. Treatment in other dogs consists of chemotherapy and supportive care, with a goal of palliating the neoplasm and its complications. There are multiple chemotherapy protocols that are widely used for dogs with MCTs, although four are used with relative frequency by the authors and are discussed here. We typically recommend

TABLE 81.1

Clinical Staging Scheme for Dogs With Mast Cell Tumors

STAGE	DESCRIPTION
I	One tumor confined to the dermis without regional lymph node involvement a. Without systemic signs b. With systemic signs
II	One tumor confined to the dermis with regional lymph node involvement a. Without systemic signs b. With systemic signs
III	Multiple dermal tumors or a large infiltrating tumor with or without regional lymph node involvement a. Without systemic signs b. With systemic signs
IV	Any tumor with distant metastases or recurrence with metastases a. Without systemic signs b. With systemic signs

TABLE 81.2

Treatment Guidelines for Dogs With Mast Cell Tumors

STAGE	GRADE	RECOMMENDED TREATMENT	FOLLOW-UP
I	1, 2	Surgical excision	Complete → observe Incomplete → second surgery or radiotherapy
I	3	Chemotherapy*	Continue chemotherapy
II	1, 2, 3	Surgical excision or radiotherapy	CCNU and prednisone (see below)*
III, IV	1, 2, 3	Chemotherapy*	Continue chemotherapy

Chemotherapy protocols for dogs with mast cell tumors:

1. Prednisone, 50 mg/m^2 by mouth (PO) q24h for 1 week; then 20-25 mg/m^2 PO q48h indefinitely plus lomustine (CCNU), 60 mg/m^2 PO q3 weeks
2. Prednisone, 50 mg/m^2 PO q24h for 1 week; then 20-25 mg/m^2 PO q48h indefinitely plus lomustine (CCNU), 60 mg/m^2 PO q6 weeks, alternating doses with vinblastine, 2 mg/m^2 IV q6 weeks (the dog receives lomustine, 3 weeks later vinblastine, 3 weeks later lomustine again, and so on)

*For more information, see table at the end of this chapter.

an alternating chemotherapy protocol including vinblastine, lomustine, and prednisone (see chemotherapy table on page 1337) in dogs with nonsurgical or disseminated MCTs. This has been associated with a 50% to 70% response rate and can afford improvement in quality of life for these patients. Lomustine or vinblastine can also be used as a single-agent therapy (in combination with prednisone); however, these are generally associated with a less favorable response rate (<40%). As described in a previous chapter, hepatotoxicity is a relatively frequent complication associated with lomustine administration, and when lomustine is combined with vinblastine, it allows administration of lomustine every 4 to 6 weeks instead of every 3 weeks, which may decrease the prevalence of clinically relevant hepatoxicity.

As stated earlier, dogs with grade 2, low-mitotic index MCTs with confirmed metastasis to the regional lymph node (and no distant metastases) that are treated with adequate local control (complete surgical excision or incomplete excision followed by radiotherapy) and an alternating protocol of vinblastine, lomustine, and prednisone can have prolonged survival times. In a study of 21 dogs receiving this treatment combination (the lymph node was removed at the time of surgery), the MST was 45 months (Lejeune et al., 2015). For that reason, aggressive therapy should still be discussed for dogs with MCTs that have confirmed regional lymph node metastasis, because if a low-mitotic index tumor is found, long-term survival is likely in most dogs.

Because a variable proportion of canine MCTs have c-kit mutations, small molecule tyrosine kinase inhibitors (TKIs) such as toceranib (Palladia [Zoetis, Madison, NJ], 2.5 mg/kg orally [PO], every other day) are effective in approximately 40% of canine MCTs and in up to 90% of MCTs with c-kit mutations (London et al., 2009; reviewed in London CA, 2013). Masitinib (Kinavet, AB Science, Short Hills, NJ) has also been shown to prolong the disease-free intervals in dogs with MCTs independently of the presence of c-kit mutations; however, it is no longer available in the United States. Adverse effects in dogs receiving small molecule TKI are mainly anorexia, vomiting, or diarrhea, and are dose dependent. These can be seen in up to 50% of dogs receiving TKI therapy.

MAST CELL TUMORS IN CATS

Etiology and Epidemiology

Although MCTs are relatively common in cats, they rarely result in the considerable clinical problems seen in dogs with this neoplasm. Most cats with MCTs are middle-aged or older (median, 10 years old), with apparently no gender-related predilection, although some purebred cats may be at higher risk of development (Siamese, Burmese, Russian Blue, Ragdoll) (Melville et al., 2015). Feline leukemia virus and feline immunodeficiency virus do not play a role in the development of this tumor.

As opposed to the dog in which most MCTs are cutaneous or subcutaneous, cats exhibit two main forms of feline MCTs: cutaneous MCT, splenic or visceral mast cell disease, and intestinal MCT. Although they may coexist in the same cat, most often these disease entities occur singularly.

Clinical and Pathologic Features

Visceral MCTs are most commonly seen in the spleen of cats, and involvement of the liver, abdominal lymph nodes, bone marrow, and peripheral blood are often found. Most affected cats initially have nonspecific signs such as anorexia and vomiting; abdominal distention caused by massive splenomegaly is a consistent feature. As in dogs, the hematologic abnormalities in cats with SMCD are extremely variable and include cytopenias, mastocythemia, basophilia, eosinophilia, or a combination of these; however, a high percentage of cats may have normal CBCs.

Intestinal MCTs are the third most common type of intestinal tumor in cats. Cats with intestinal MCTs are usually evaluated because of gastrointestinal signs such as anorexia, vomiting, or diarrhea. Abdominal masses are palpated in approximately one half of these cats. Most tumors involve the small intestine, where they can be solitary or multiple. Metastatic disease affecting the mesenteric lymph nodes, liver, spleen, and lungs is commonly found at the time of presentation. Multiple intestinal masses in cats are most commonly associated with lymphoma and with MCT, although both neoplasms can coexist. Gastrointestinal tract ulceration has also been documented in affected cats.

Cats with cutaneous MCTs usually initially have solitary or multiple, small (2-15 mm), white to pink dermoepidermal masses, primarily in the head and neck regions, although solitary dermoepidermal or subcutaneous masses also occur in other locations. It has been reported that, on the basis of the clinical, epidemiologic, and histologic features, MCTs in cats can be classified as either mast cell–type MCTs (common) or histiocytic-type MCTs (rare). Cats with mast cell–type MCTs are usually older than 4 years of age and have solitary dermal masses; Siamese cats may have a predilection. Cats with histiocytic-type MCTs are primarily younger Siamese cats, generally under the age of 4 years. Typically, such cats have multiple (miliary) subcutaneous masses that exhibit a benign biologic behavior. Some of these neoplasms appear to regress spontaneously. The subcutaneous MCTs commonly seen in dogs are extremely rare in cats. Unlike the situation in dogs, the histopathologic grade does not appear to correlate well with the biologic behavior of MCTs in cats. There also appears to be a specific syndrome where cats with multiple cutaneous MCTs can also have splenic mast cell disease, so careful abdominal palpation and/or abdominal imaging may be warranted in these cats. In these cats, cutaneous lesions can resolve with splenectomy alone.

Diagnosis and Treatment

The diagnostic approach to cats with MCT is similar to that in dogs. As in dogs, some mast cells in cats are poorly granulated and the granules may not be easily identified during a routine cytologic or histopathologic evaluation.

As a general rule, surgery is indicated for cats with a solitary cutaneous mass, for cats with two to five skin masses, and for cats with intestinal or splenic involvement. As discussed previously, cutaneous MCTs in cats are less aggressive than in dogs, and in most affected cats, removal of a solitary dermoepidermal MCT using a biopsy punch is curative; the same applies to cats with fewer than five dermoepidermal MCTs. Cats with splenic MCT can have prolonged survival times when undergoing splenectomy, even if metastatic disease is present at the time of treatment, with survival times over 1 to 2 years recently reported (Kraus et al., 2015). In the more recent study, there was no definitive benefit seen in cats that received chemotherapy following splenectomy; however, cats that did not undergo splenectomy had a significantly shorter survival than cats those who were splenectomized. If chemotherapy is pursued, the most common agents tend to be corticosteroids (prednisone, dexamethasone), alkylating agents (chlorambucil, lomustine), vinblastine, or TKIs. Cats with intestinal MCTs are generally treated with surgery and/or chemotherapy, and initial survival times were shown to be quite poor due to the presence of metastatic disease in many cats. However, recently, a larger study reported an overall MST of 1.5 years in cats treated with a variety of chemotherapy, surgery, or steroids alone, so more prolonged survivals may be possible even without surgery (Barrett et al., 2018).

We recommend using chlorambucil (20 mg/m^2, PO, q2 weeks) with or without dexamethasone (4-5 mg total dose, q1-2 weeks, PO or subcutaneously) after splenectomy or intestinal MCT removal in cats with systemic disease. In most cases, survival times of 1 to 2 years are common.

INJECTION SITE SARCOMAS IN CATS

An association between injections/vaccination and the development of sarcomas has been recognized in cats since the early 1990s, and epidemiologic studies have confirmed the association. In this syndrome, fibrosarcomas (FSAs) or other types of sarcomas develop in the subcutis or muscle in the interscapular region or the thigh, common sites of injection/vaccination. It is estimated that a sarcoma develops in 1 to 2 of 10,000 cats that receive an injection. Although the exact pathogenesis is still unclear, both the adjuvants and the local immune response against the antigens (i.e., inflammation) have been implicated as causative agents. A recent epidemiologic study reported that cats with injection site sarcoma (ISS) had a higher probability of having received long-acting corticosteroid injections in the interscapular region, whereas cats with rear limb ISS were significantly less likely to have received recombinant vaccines than inactivated vaccines (Shrivastav et al., 2012).

Despite changes in vaccination recommendations in 2001 to administer rabies vaccine in the right rear leg as distally as possible, the feline leukemia virus (FeLV) vaccine in the left rear leg as distally as possible, and the FVRCP±C vaccine in the right shoulder, a high proportion of tumors still develops in the interscapular region (Shaw et al., 2009). Current vaccination protocols for cats should be evaluated by general practitioners, so that safe vaccination practices are routinely used (see Recommended Reading for the most recent American Association of Feline Practitioners (AAFP) guidelines).

A rapidly growing soft tissue mass develops in the region weeks to months after vaccination or injection in cats with ISSs. A vaccine- or injection-associated inflammatory reaction may precede the development of this neoplasm. Therefore an ISS should be suspected in any cat with a superficial or deep mass in the interscapular or thigh regions, and every effort should be made to establish a diagnosis immediately. The current recommendation is to use the "3, 2, 1 Rule": worry if the mass persists for more than 3 months after vaccination, is larger than 2 cm in diameter, or grows 1 month after the injection.

Although FNA findings may provide a definitive answer, more often an incisional or needle biopsy is necessary because sarcomas do not consistently exfoliate cells (see Chapter 71). However, excisional biopsies are not recommended, as shorter survival times may be seen in cats that have undergone an excisional biopsy prior to definitive treatment.

Although most FSAs in dogs and cats have a low metastatic potential, ISSs are quite aggressive and should be treated accordingly. Although multiple studies are currently in progress, on the basis of the results of studies reported in the literature and on the findings in cats seen at the author's clinic, the rate of metastases of ISSs can be high (probably as high as 50%-70% in cats with recurrent tumors). Pulmonary metastatic lesions can be detected at presentation in up to 20% of cats with ISSs.

The treatment of choice for cats with ISS is *aggressive surgical excision* (see Chapter 75). In keeping with the maxim "cut it once, but cut it all," an *en bloc* resection (to include any biopsy tracts) should be performed immediately after the diagnosis is established, provided there is no metastatic disease (Phelps et al., 2011). Cats treated with aggressive surgery have significantly longer disease-free survival times than cats treated with conservative surgery (274 versus 66 days); also, cats with tumors in the limbs have significantly longer disease-free survival times than cats with tumors in the trunk (325 versus 66 days; Hershey et al., 2000). Cats that experience local recurrence after the first aggressive surgery have significantly shorter MSTs than those without recurrence (365 versus 1100 days [Romanelli et al., 2008] and 499 versus 1461 days [Phelps et al., 2011]); as expected, cats with metastases at presentation also have shorter MSTs than those without distant metastases (165 versus 930 days [Romanelli et al., 2008] and 388 versus 1528 days [Phelps et al., 2011]). Complete surgical excision of a relatively small ISS (i.e., <2 cm in diameter) is usually associated with long-term remissions and even cure. Although the role of postoperative adjuvant chemotherapy has not been thoroughly evaluated, cats with large or incompletely excised tumors may benefit from treatment with mitoxantrone and

cyclophosphamide, doxorubicin and cyclophosphamide, or carboplatin. One of the author's clinics has seen objective complete or partial responses in cats with nonresectable or metastatic ISS treated with doxorubicin/cyclophosphamide combinations (Fig. 81.9) or with carboplatin alone; some of these cats have been in remission for longer than 1 year. If metastatic disease is already present, chemotherapy is not usually effective.

In cats with nonresectable, high-grade ISS, the authors have seen objective responses to doxorubicin/cyclophosphamide or doxorubicin/lomustine chemotherapy, and neoadjuvant chemotherapy (i.e., chemotherapy to decrease the size of the mass, then surgery, then additional chemotherapy) has been used successfully in cats with high-grade ISS in the clinic. Small molecule TKIs are currently being investigated in cats with ISSs; however, initial studies have not shown overwhelming response rates.
