Cancer Chemotherapy Protocols Commonly Used by the Authors

1. Lymphoma
   A. Induction of remission
      1. COP protocol (8-week duration)
         Cyclophosphamide: 50 mg/m^2 PO q48h for 8 weeks in dogs; 200-300 mg/m^2 PO q3 weeks in cats
         Vincristine: 0.5 mg/m^2 IV once per week for 8 weeks
         Prednisone: 40-50 mg/m^2 PO q24h for 1 week; then 20-25 mg/m^2 PO q48h for 7 weeks
      2. COAP protocol
         Cyclophosphamide: 50 mg/m^2 PO q48h or 300 mg/m^2 PO q3 weeks*
         Vincristine: 0.5 mg/m^2 IV once per week
         Cytosine arabinoside: 100 mg/m^2, IV or SC, divided q12h for 4 days
         Prednisone: 40-50 mg/m^2 PO q24h for 1 week; then 20-25 mg/m^2 PO q48h
         In cats, cytosine arabinoside is administered for only 2 days and the remaining three drugs (cyclophosphamide, vincristine, prednisone) are administered for 6 weeks rather than 8 weeks.
      3. CLOP protocol
         As in COP protocol but with the addition of L-asparaginase at a dosage of 10,000-20,000 IU/m^2 IM q4-6 weeks
      4. UW-25 protocol (This protocol uses no maintenance chemotherapy—for additional information please see text)
         Week 1: Vincristine: 0.5-0.75 mg/m^2 IV
         Prednisone: 40 mg/m^2 PO q24h
         Week 2: Cyclophosphamide: 200-250 mg/m^2, IV or PO
         Prednisone: 30 mg/m^2 PO q24h
         Week 3: Vincristine: 0.5-0.75 mg/m^2 IV
         Prednisone: 20 mg/m^2 PO q24h
         Week 4: Doxorubicin: 30 mg/m^2 (or 1 mg/kg if < 10 kg) IV
         Prednisone: 10 mg/m^2 PO q24h
         Week 5: **No treatment—discontinue prednisone if CR**
         Week 6: Vincristine: 0.5-0.75 mg/m^2 IV
         Week 7: Cyclophosphamide: 200-250 mg/m^2, IV or PO
         Week 8: Vincristine: 0.5-0.75 mg/m^2 IV
         Week 9: Doxorubicin: 30 mg/m^2 (or 1 mg/kg if < 10 kg) IV
         Week 10: **No treatment**
         Week 11: Vincristine: 0.5-0.75 mg/m^2 IV
         Week 13: Cyclophosphamide: 200-250 mg/m^2, IV or PO
         Week 15: Vincristine: 0.5-0.75 mg/m^2 IV
         Week 17: Doxorubicin: 30 mg/m^2 (or 1 mg/kg if < 10 kg) IV
         Week 18: **No treatment**
         Week 19: Vincristine: 0.5-0.75 mg/m^2 IV
         Week 21: Cyclophosphamide: 200-250 mg/m^2, IV or PO
         Week 23: Vincristine: 0.5-0.75 mg/m^2 IV
         Week 25: Doxorubicin: 30 mg/m^2 (or 1 mg/kg if < 10 kg) IV
   B. Maintenance
      1. LMP protocol
         Chlorambucil: 20 mg/m^2 PO q2 weeks
         Prednisone: 20-25 mg/m^2 PO q48h
         Methotrexate: 2.5-5 mg/m^2 PO 2 or 3 times per week

Continued

Cancer Chemotherapy Protocols Commonly Used by the Authors—cont'd

2. CCNU/Prednisone protocol
   CCNU (lomustine): 60-70 mg/m^2 PO q3 weeks
   Prednisone: 20-25 mg/m^2 PO q48h
3. LAP protocol
   Chlorambucil: 20 mg/m^2 PO q2 weeks
   Prednisone: 20-25 mg/m^2 PO q48h
   Cytosine arabinoside (Cytosar): 200-400 mg/m^2 SC q2 weeks; alternating with chlorambucil
4. COP protocol used every other week for 6 cycles; then every third week for 6 cycles; then monthly thereafter

C. "Rescue"

DOGS

1. D-MAC protocol (14-day protocol; repeat continuously for 10-16 weeks)
   Dexamethasone: 0.5 mg/lb (1 mg/kg) PO or SC on days 1 and 8
   Actinomycin D (Cosmegen): 0.75 mg/m^2 IV push on day 1
   Cytosine arabinoside (Cytosar): 200-300 mg/m^2 IV drip over 4 hours or SC on day 1
   Melphalan (Alkeran): 20 mg/m^2 PO on day 8 (after 4 doses of melphalan, substitute chlorambucil at the same dose)
2. MOPP protocol (28-day protocol; repeat continuously until relapse)
   Mechlorethamine: 3 mg/m^2 IV on days 0, 7
   Vincristine: 0.7 mg/m^2 IV on days 0, 7
   Procarbazine: 50 mg/m^2 PO q24h for days 0-13
   Prednisone: 30-40 mg/m^2 PO q24h for days 0-13
3. L-asparaginase, CCNU, and prednisone
   CCNU (lomustine): 70 mg/m^2 PO q3 weeks
   L-asparaginase: 400 u/kg SC or IM q3 weeks
   Prednisone: 2 mg/kg PO q24h, taper when remission obtained
4. Dacarbazine: 800-1000 mg/m^2 q14-21 days
5. CCNU (lomustine): 60-80 mg/m^2 q21 days
6. Rabacfosadine: 0.82-1 mg/kg IV over 30 minutes q3 weeks

CATS

1. ACD protocol (21-day cycle)
   Doxorubicin: 1 mg/kg IV on day 1
   Cyclophosphamide: 200-300 mg/m^2 PO on day 10
   Dexamethasone: 4 mg/cat PO q1-2 weeks
2. AMD protocol
   Cytosine arabinoside: 100-200 mg/m^2/day IV CRI for 1-2 days
   Mitoxantrone: 4 mg/m^2 in IV CRI, mixed in the bag with the cytosine arabinoside
   Dexamethasone: 0.5-1 mg/lb (1-2 mg/kg) PO weekly; repeat q3 weeks
3. CCNU: 10 mg/cat q3-6 weeks

II. Acute lymphoid leukemia (ALL)
   COAP, CLOP, COP, or CHOP protocols

III. Chronic lymphocytic leukemia (CLL)
1. Chlorambucil: 20 mg/m^2 PO q2 weeks (with or without prednisone, 20 mg/m^2 PO q48h)
2. Cyclophosphamide: 50 mg/m^2 PO q48h, and prednisone: 20 mg/m^2 PO q48h

IV. Acute myelogenous leukemia
1. Cytosine arabinoside: 5-10 mg/m^2 SC q12h for 2-3 weeks; then on alternate weeks
2. Cytosine arabinoside: 100-200 mg/m^2 in IV CRI over 4 hours
   Mitoxantrone: 4-6 mg/m^2 in IV CRI over 4 hours; repeat every 3 weeks

V. Chronic myelogenous leukemia
1. Hydroxyurea (Hydrea): 50 mg/kg PO q24-48h until normal white blood count

VI. Multiple myeloma
1. Melphalan (Alkeran): 2-4 mg/m^2 PO q24h for 1 week; then q48h. Can also be given at 6-8 mg/m^2 PO for 5 days, repeating every 21 days
   Prednisone: 40-50 mg/m^2 PO q24h for 1 week, then 20 mg/m^2 PO q48h
2. As in III.2

Cancer Chemotherapy Protocols Commonly Used by the Authors—cont'd

VII. Mast cell tumors (nonresectable, systemic, or metastatic)
1. Prednisone: 40-50 mg/m^2 PO q24h for 1 week; then 20-25 mg/m^2 PO q48h
2. Lomustine (CCNU): 60 mg/m^2 PO q3 weeks (with or without prednisone as in 1)
3. LVP protocol
Vinblastine: 2 mg/m^2 IV q4-6 weeks alternating with
Lomustine (CCNU): 60 mg/m^2 PO q4-6 weeks
Prednisone: 20-25 mg/m^2 PO q48h
4. Toceranib (Palladia): 2.5 mg/kg, PO q48h
5. Masitinib (Kinavet): 10-12 mg/kg PO q24h

VIII. Soft tissue sarcomas—dogs
1. VAC protocol (21-day cycle)
Vincristine: 0.75 mg/m^2 IV on days 8 and 15
Doxorubicin: 30 mg/m^2 IV (or 1 mg/kg if < 10 kg) on day 1
Cyclophosphamide: 200-300 mg/m^2 PO on day 10
Sulfa-trimethoprim: 15 mg/kg PO q12h

IX. Soft tissue sarcomas—cats
1. AC protocol (21-day cycle)
Doxorubicin: 1 mg/kg IV on day 1
Cyclophosphamide: 200-300 mg/m^2 on day 10
2. MiC protocol (21-day cycle)
Mitoxantrone: 4-6 mg/m^2 in IV drip over 4 hours on day 1
Cyclophosphamide: 200-300 mg/m^2 PO on day 10
3. Carboplatin: 10 mg/kg IV q4 weeks

X. Osteosarcoma—dogs
1. Doxorubicin: 30 mg/m^2 (or 1 mg/kg if < 10 kg) IV q2 weeks for 5 doses
2. Carboplatin: 300 mg/m^2 IV q3 weeks for 4-6 doses
3. Doxorubicin and carboplatin as before, alternating drugs q3 weeks for 2-3 doses each

XI. Carcinomas—dogs
1. FAC protocol
5-Fluorouracil: 150 mg/m^2 IV on days 8 and 15
Doxorubicin: 30 mg/m^2 (or 1 mg/kg if < 10 kg) IV on day 1
Cyclophosphamide: 200-300 mg/m^2 PO on day 10
Sulfa-trimethoprim: 15 mg/kg PO q12h
2. Carboplatin: 300 mg/m^2 IV q3 weeks
3. Gemcitabine: 675 mg/m^2 IV CRI for 30 minutes, q2 weeks

XII. Carcinomas—cats
5-Fluorouracil is toxic in cats, producing severe, and often fatal, central nervous system signs. Cisplatin is also extremely toxic, causing acute pulmonary toxicity in this species.
1. Carboplatin: 10 mg/kg IV q4 weeks
2. AC protocol (21-day cycle)
Doxorubicin: 1 mg/kg IV on day 1
Cyclophosphamide: 200-300 mg/m^2 PO on day 10
3. MiC protocol (21-day cycle)
Mitoxantrone: 4-6 mg/m^2 IV CRI over 4 hours on day 1
Cyclophosphamide: 200-300 mg/m^2 PO on day 10
4. MiCO protocol (21-day cycle)
Mitoxantrone: 4-6 mg/m^2 IV CRI over 4 hours on day 1
Cyclophosphamide: 200-300 mg/m^2 PO on day 10
Vincristine: 0.5-0.6 mg/m^2 IV on days 8 and 15

XIII. Metronomic chemotherapy protocol
- Palladia (2.5 mg/kg, PO, Mon, Wed, Fri) plus
- Cyclophosphamide (10 mg/m^2, PO, Tue, Thu, Sat) or chlorambucil (2-4 mg/m^2, PO, Tue, Thu, Sat) plus
- A nonsteroidal antiinflammatory drug at therapeutic dosages plus
- Famotidine (0.5-1 mg/kg PO q24h)

CRI, Constant rate infusion; *IM,* intramuscularly; *IV,* intravenously; *PO,* orally; *SC,* subcutaneously.
*The daily dose should be divided into two to four daily administrations. The duration of chemotherapy using this protocol varies.

PART THIRTEEN ▪ Hematology

C. Guillermo Couto

CHAPTER 82

Anemia

DEFINITION

Anemia is defined as a decrease in the red blood cell (RBC) mass. In practical terms, it can be defined as a decrease in the packed cell volume (PCV) or hematocrit (HCT), hemoglobin (Hb) concentration, or RBC count below the reference interval (RI) for the species. In the context of this chapter, PCV and HCT are used interchangeably. In special circumstances, anemia is diagnosed in a given patient with an HCT that has decreased over time, even though it may remain within reference values. For example, Greyhounds and other sighthounds (see Chapter 83) rarely have HCT values below 50%, so an anemic Greyhound may have an HCT within the RI for "generic" dogs. Because the RIs reflect the actual status in 95% of the feline and canine population, occasionally an abnormal value is actually normal for a particular animal, prompting a needless evaluation in search of other abnormalities. Remember that anemia rarely constitutes a primary diagnosis; therefore every effort should be made to identify its cause.

In a recent study of 1098 cats with anemia 633 of 1098 (57.7%) were classified as nonregenerative (NRA) and 465 of 1098 (42.3%) as regenerative (RA). The HCT was significantly lower in cats with RA compared with those with NRA ($P < 0.05$) (Furman et al., 2014).

CLINICAL AND CLINICOPATHOLOGIC EVALUATION

When interpreting the HCT, Hb concentration, or RBC count, the clinician should keep in mind that, in some situations, these values are above (e.g., sighthounds) or below (e.g., during puppyhood or pregnancy) the RI for the species. From a practical standpoint, when evaluating the erythroid series, the clinician does not need to assess all the values in the complete blood count (CBC) because several of them provide similar information. For example, the HCT, Hb concentration, and RBC count provide the same type of information—an increase in the number of RBCs usually results in an increased HCT and Hb concentration, and vice versa. Thus when evaluating the erythron in a CBC, the HCT is typically used as an indirect index of the RBC mass (or number).

The main clinical manifestations of anemia in dogs and cats include pale or icteric mucous membranes, lethargy, exercise intolerance, pica (mainly in cats), and decreased overall activity; in dogs, pica is mainly associated with pure red cell aplasia (PRCA, see later; Box 82.1). These clinical signs can be acute or chronic and vary in severity; the duration of the clinical signs may not reflect the mechanism of anemia. For example, acute clinical signs are common in cats with chronic anemia; most cats with chronic anemia compensate by shifting the oxyhemoglobin dissociation curve to the right, thus releasing oxygen to the tissues more readily. Therefore cats are clinically stable until their HCT is markedly decreased (i.e., <10% or so) and they develop acute clinical signs. Owners may also detect some of the adaptive changes to anemia, such as tachycardia or an increased precordial beat. Following are several important questions to ask the owner of an anemic cat or dog when taking a history:

- *Is the pet currently receiving any medication?* Certain drugs can cause hemolysis, gastrointestinal (GI) blood loss, or bone marrow hypoplasia.
- *Have the owners detected any blood loss or dark (tarry) stool?* GI tract bleeding from a tumor or a gastric ulcer frequently lead to iron deficiency anemia (IDA) in dogs.
- *Have the owners noticed any fleas?* Severe flea infestation can cause IDA.
- *Has the cat recently been tested for feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infections?* Retroviruses can cause bone marrow hypoplasia, myelodysplasia, or leukemias, leading to cytopenias.

BOX 82.1

Clinical Manifestations of Anemia in Cats and Dogs

History

- Breed (e.g., congenital enzymopathies, babesiosis in Pitbulls)
- Family history
- Exercise intolerance, syncopal episodes
- Pallor, jaundice
- Localized or generalized bleeding
- FeLV or FIV infection
- Vector-borne diseases (e.g., ehrlichiosis, anaplasmosis, babesiosis)
- Malnutrition, malabsorption
- Chronic inflammation, cancer
- Travel history

Physical Examination

- Pallor, jaundice, petechiae, ecchymoses
- Lymphadenopathy
- Hepatomegaly, splenomegaly
- Tachycardia, heart murmur, cardiomegaly, left ventricular hypertrophy
- Occult blood in the stool
- Hematuria, bilirubinuria

FeLV, Feline leukemia virus; *FIV,* feline immunodeficiency virus.

BOX 82.2

Drugs and Toxins That Can Cause Anemia in Cats and Dogs

Acetaminophen
Antiarrhythmics
Anticonvulsants
Antiinflammatories (nonsteroidal)
Barbiturates
Benzocaine
Chemotherapeutic agents
Chloramphenicol
Cimetidine
Gold salts
Griseofulvin
Levamisole
Methimazole
Methionine
Methylene blue
Metronidazole
Penicillins and cephalosporins
Phenothiazines
Propylthiouracil
Propylene glycol
Sulfa derivatives
Vitamin K
Zinc

- *Has the owner noticed any ticks on the dog?* Ehrlichiosis can cause bone marrow hypoplasia; babesiosis can cause hemolysis.
- *Has the dog been in a fight with a Pitbull? Babesia gibsoni* infection causes signs similar to those of immune-mediated hemolytic anemia, and it is transmitted by Pitbull bites.
- *Has the pet been vaccinated recently?* Modified live vaccines can cause bleeding as a result of platelet dysfunction or thrombocytopenia, or they may be associated with immune-mediated hemolysis.
- *Has the dog received any shots for mismating recently or has urinary incontinence?* Estrogen derivatives can cause bone marrow aplasia or hypoplasia.

In addition to these questions, a detailed travel and pharmacologic history should be obtained. Certain infectious diseases associated with anemia used to have a geographic distribution (e.g., babesiosis in the southeastern part of the United States); however, global warming and worldwide travel have extended the range of most of these infectious agents. In addition, dogs frequently travel throughout the United States; thus the geographic disease distribution is becoming less common. Some drugs and toxins that have been associated with anemia in cats and dogs are listed in Box 82.2; however, as a general rule, any drug can cause any cytopenias in a given patient (i.e., idiosyncratic reaction).

When evaluating a patient with pallor, first one must determine whether it is caused by hypoperfusion or anemia; that is, not every patient with pale mucous membranes is anemic. The simplest approach is to evaluate the HCT and capillary refill time (CRT). Dogs and cats with cardiovascular disease and hypoperfusion usually have normal HCT values and additional clinical signs, whereas symptomatic anemic dogs have low HCT; in addition, anemic dogs and cats almost always have hyperkinetic pulses. Dogs and cats with congestive heart failure can occasionally have dilutional anemia caused by intravascular fluid retention. The CRT may be difficult to evaluate in anemic patients because of the absence of contrast due to the pallor.

The clinician should also look for petechiae, ecchymoses, and evidence of deep bleeding in dogs and cats with pallor. These findings are suggestive of a platelet or clotting factor deficiency (as seen in animals with Evans syndrome, disseminated intravascular coagulation [DIC], or acute leukemias; see Chapter 87), resulting in blood loss anemia. Jaundice is common in dogs but rare in cats with hemolytic anemia; in these patients, the color of the gums is white on yellow, as opposed to white on pink, because the HCT is low. In our clinic, most dogs with jaundice have hemolysis, whereas most cats with jaundice have liver disease.

Particular attention should be paid to the lymphoreticular organs, such as the lymph nodes and spleen, because several disorders associated with anemia may also result in lymphadenopathy, hepatosplenomegaly, or both (Table 82.1). Abdominal radiographs in a dog with intravascular hemolysis may reveal metallic foreign bodies in the stomach, a potential source of zinc that frequently results in intra- and

TABLE 82.1

Disorders Commonly Associated With Anemia and Hepatomegaly, Splenomegaly, and/or Lymphadenopathy

DISORDER	FREQUENCY	SPECIES
Lymphoma	F	D, C
Mycoplasmosis	F	C > D
Acute leukemias	F	C, D
Ehrlichiosis, anaplasmosis, leishmaniasis	F*	D > C
Systemic mast cell disease	R	C > D
Bone marrow hypoplasia	R	C, D
Immune-mediated hemolytic anemia	F	D > C

C, Cat; *D*, dog; *F*, frequent; *R*, rare.
*Geographic variation.

extravascular hemolysis. Abdominal ultrasonography may reveal diffuse splenomegaly with a mottled texture in dogs with anemia caused by immune-mediated hemolysis or in those with lymphoma, leukemias, or malignant histiocytosis.

The degree of anemia may be helpful in establishing its cause. To this end, anemias are graded according to HCT level as follows:

	Dogs	Cats
Mild	30%-36%	20%-24%
Moderate	18%-29%	15%-19%
Severe	<18%	<14%

For example, if an anemic dog or cat has severe anemia, certain causes (e.g., bleeding, anemia of chronic disease [ACD], anemia of renal disease, IDA) can immediately be ruled out because none of those mechanisms is likely to result in such a severe decrease in the HCT; therefore the patient most likely has hemolysis or a bone marrow disorder (see later). The severity of the clinical signs also usually correlates with the pathogenesis of the anemia. For example, a dog or cat with severe anemia and mild to moderate clinical signs more likely has a chronic anemia (e.g., bone marrow disease); acute causes of severe anemia (e.g., hemolysis) result in clinical signs of marked severity because the adaptive compensatory changes have not yet occurred.

As part of the evaluation of a patient's PCV, the plasma should be examined for evidence of icterus (yellow), hemolysis (pink or red), or both (port wine–colored plasma), and the protein content should be determined with a refractometer. The microhematocrit tube should be carefully inspected for evidence of autoagglutination (see p. 1348), and a saline slide agglutination test should be performed (see later). A blood smear should be evaluated to detect morphologic changes that may point the clinician toward the cause of the anemia. Blood smear evaluation is a must, because it provides relevant clinicopathologic information in most patients with anemia.

A common issue that often comes up is whether a general practicing veterinarian should do CBCs in house or send them to a referral laboratory. The introduction of accurate, user-friendly, benchtop hematology analyzers has revolutionized the practice of small animal hematology. Currently, more than 75% of U.S. veterinary practices have their own analyzers. Most of these instruments are trouble-free and provide accurate results. However, when values are outside the RI or are flagged, the clinician or technician should always evaluate a blood smear from the patient in question. The blood smear constitutes the easiest, cheapest quality control for the instrument; yet, it is only evaluated by <5% of veterinarians.

New benchtop analyzers frequently provide a graphic depiction of the cell distribution (dot plot, histogram, or cytogram). Depending on the instrument, these dot plots provide clinically relevant information regarding cell size, distribution, presence of reticulocytes, left shift, nucleated RBCs, and other cell features. Representative dot plots of a normal dog and a normal cat are depicted in Fig. 82.1. The graphics provide powerful statistically relevant information. For example, with flow cytometry analyzers, the RBC graphs include approximately 80,000 erythrocytes, whereas the leukocyte graphs contain approximately 15,000 cells. For comparison, when we perform a manual leukocyte differential count, we evaluate 100 cells. Think about how long it would take us to evaluate 80,000 erythrocytes and 15,000 leukocytes in a blood smear under the microscope! As I like to say, "it's a numbers game."

Once it has been established that the patient is anemic, it should be determined whether the anemia is regenerative, nonregenerative, or due to IDA. This is accomplished by obtaining a reticulocyte count during a routine CBC (some of the in-house flow cytometry analyzers, such as the LaserCyte and ProCyteDx from IDEXX Laboratories, Westbrook, Maine, provide reticulocyte counts), obtaining a reticulocyte count from the reference laboratory, or simply evaluating a blood smear for the presence of polychromasia (Fig. 82.2). The RBC indices reported by impedance analyzers are extremely unreliable to determine regeneration; approximately 8% to 11% of dogs with regenerative anemia have the typical macrocytic hypochromic indices described in the literature; however, >70% have high red cell distribution width (RDW) and/or polychromasia (Hodges and Christopher, 2011).

Visual evaluation of the RBC dot plot allows easy classification of the anemias as regenerative, nonregenerative, or IDA (Fig. 82.3). This reflects the pathogenesis of the anemia, thereby dictating the most logical diagnostic and therapeutic approach (Box 82.3).

In brief, regenerative anemias always stem from extramedullar causes because the presence of reticulocytes or polychromatophilic RBCs (immature RBCs) in the circulation is a clear indication of a functional bone marrow; regenerative anemias can result *only* from hemolysis or blood loss.

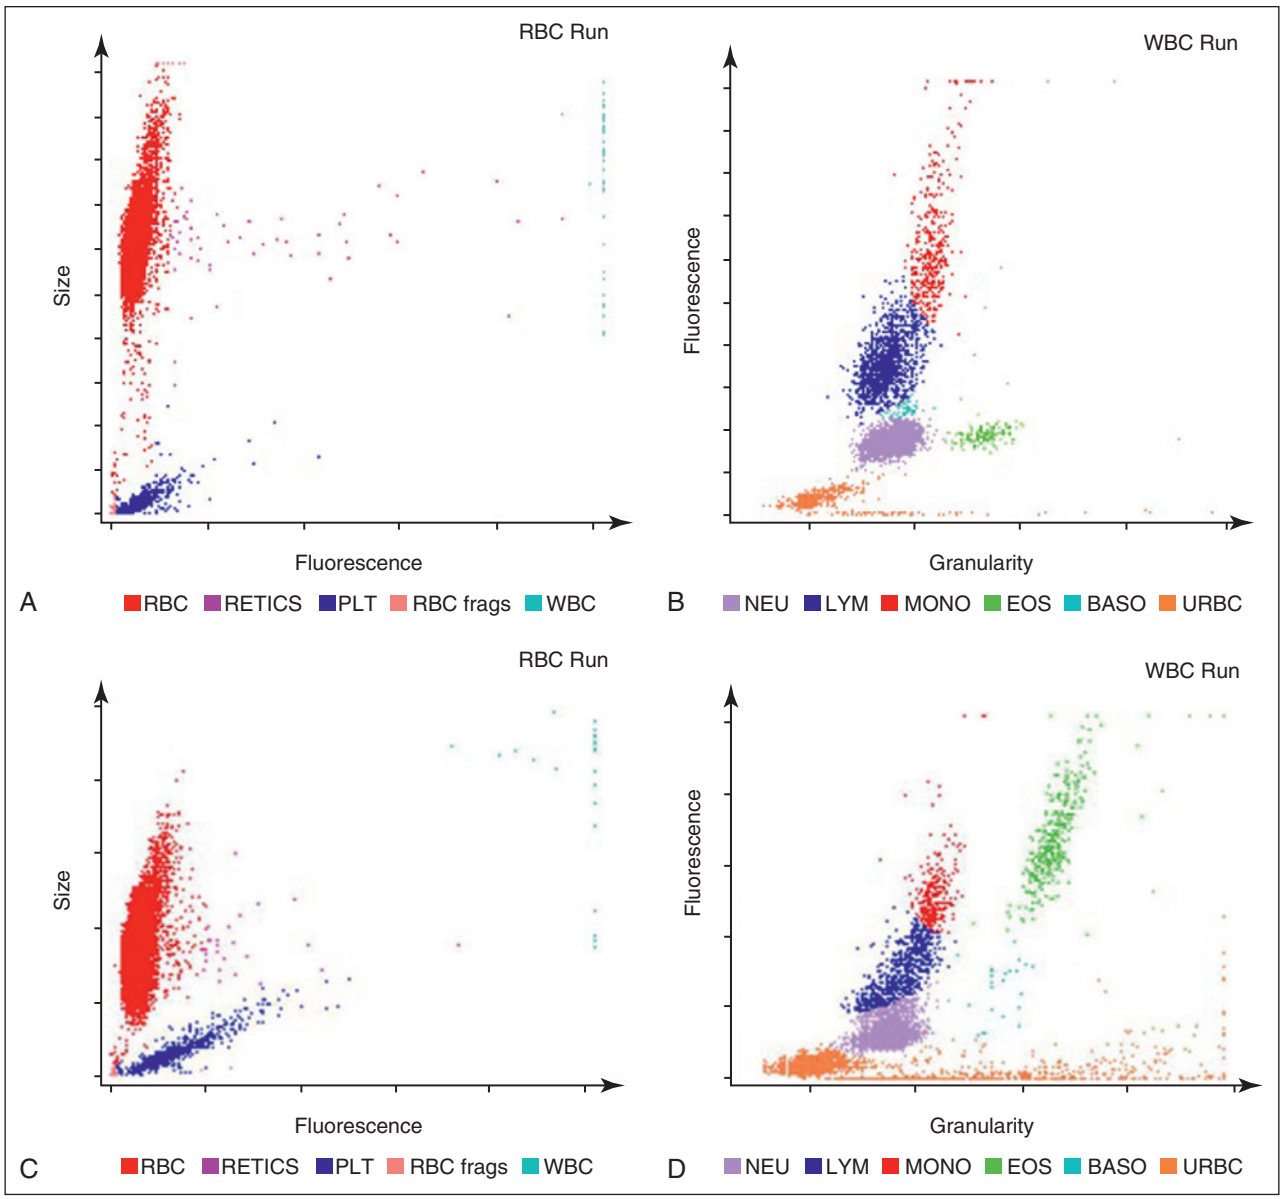

FIG 82.1
Dot plots of normal dog and cat. **(A)** and **(B)** Normal red blood cell (RBC) and white blood cell (WBC) dot plots in a normal dog. **(C)** and **(D)** Normal RBC and WBC dot plots in a normal cat. In the RBC graph, the *vertical axis* depicts size, and the *horizontal axis* shows fluorescence (RNA or DNA content). *Red dots* represent RBCs; *purple dots,* reticulocytes (RETICS); and *blue dots,* platelets (PLT). In the WBC dot plots, the vertical axis depicts fluorescence, a measure of nuclear size and complexity, whereas the horizontal axis depicts granularity (cytoplasmic complexity). *Lavender dots* represent neutrophils (NEU); *green dots,* eosinophils (EOS); *teal dots,* basophils (BASO); *blue dots,* lymphocytes (LYM); and *red dots,* monocytes (MONO). *Orange dots* are unlysed RBCs (URBC).

Nonregenerative anemias can be caused by bone marrow or extramarrow disorders, such as erythroid hypoproliferation, chronic inflammatory disease, and chronic kidney disease (CKD); obviously, anemias caused by acute hemorrhage or hemolysis are nonregenerative for the first 48 to 96 hours. Although IDA was traditionally classified as nonregenerative, most dogs with chronic blood loss leading to IDA display a mild to moderate degree of regeneration, and the RBC indices are different than in other nonregenerative anemias (i.e., they are microcytic and hypochromic; see later). Therefore I prefer to classify IDA in a separate category. Regenerative anemias are usually acute, whereas nonregenerative and IDAs are chronic.

During the initial clinical evaluation of an anemic patient, examination of the blood smear or dot plots usually suffices to determine whether the bone marrow is responding

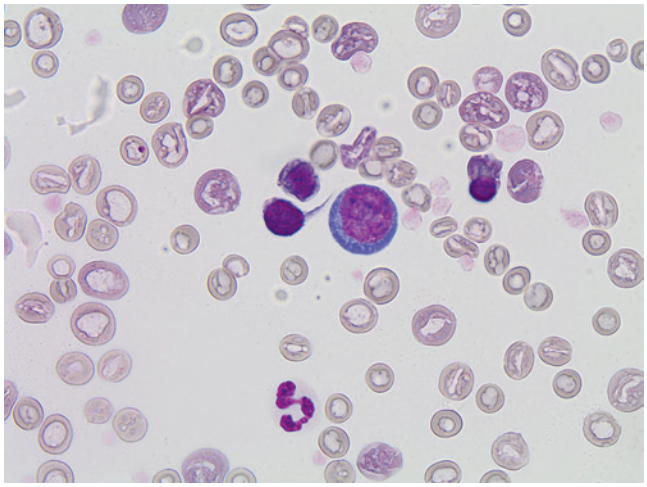

FIG 82.2

appropriately to the anemia (i.e., whether the anemia is regenerative or not; see Figs. 82.2 and 82.3). Several pieces of information can be acquired during the examination of a good-quality, properly stained blood smear, including the RBC size and morphology, approximate numbers and morphology of white blood cells and platelets, and presence of autoagglutination, nucleated RBCs, hypochromasia (IDA), polychromasia (indicative of regeneration), and RBC parasites. Ideally, the clinician or technician should *always* perform this cursory evaluation of the blood smear; a blood sample should be submitted to a diagnostic laboratory for further analysis and evaluation by a clinical pathologist if

the diagnosis is still uncertain after evaluating the blood smear. Some of the abnormalities detected during a careful examination of the blood smear and their clinical implications are summarized in Table 82.2. This evaluation should be conducted under an oil immersion lens in a monolayer field in which the erythrocytes are in a single layer and 50% of the cells are touching.

A CBC and reticulocyte count in an anemic patient provide more absolute data by which to assess the degree of regeneration. However, the information presented here must be used cautiously because the number of reticulocytes should increase proportionally to the decrease in the HCT. For example, a reticulocyte count of 120,000/µL (or ≈4%) represents an appropriate response for a dog with an HCT of 30% but not for one with an HCT of 10%.

With the advent of automated analyzers that provide reticulocyte counts, it has become apparent that up to 10% of dogs with normal HCT have a high reticulocyte count. We now know that excitement causes the release of reticulocytes from the spleen into systemic circulation; hence, an excited dog will likely have a higher reticulocyte count than a calm one. Approximately half of the dogs with a normal HCT and high reticulocyte count have catecholamine-related splenic release of reticulocytes. The other half are the most important ones: they are usually dogs with early immune-mediated hemolysis or with hemangiosarcoma (HSA); they are not yet sufficiently anemic, but they are regenerating. Therefore a blood smear should always be evaluated in a dog with reticulocytosis, regardless of the HCT.

Overall, normal dogs and cats with a normal HCT have less than 100,000 reticulocytes/µL and 50,000 reticulocytes/µL, respectively. Most dogs have between 10,000 and 60,000/µL. As noted, when evaluating dot plots from a LaserCyte or ProCyteDx (IDEXX), the presence of a large reticulocyte cloud is almost always indicative of regeneration (see Fig. 82.3); however, given that dogs with IDA frequently have reticulocytosis, the MCV and MCHC should also be evaluated.

TABLE 82.2

Interpretation of Morphologic RBC Abnormalities in Cats and Dogs

MORPHOLOGIC ABNORMALITY	COMMONLY ASSOCIATED DISORDERS
Macrocytosis	Regeneration, breed-related feature (Poodles); FeLV infection; dyserythropoiesis (bone marrow disease)
Microcytosis	Iron deficiency; breed-related characteristic (Akita, Shar Pei, Shiba Inu); portosystemic shunt or microvascular dysplasia; PRCA; polycythemia (erythrocytosis); inflammation
Hypochromasia	Iron deficiency
Polychromasia	Regeneration
Poikilocytosis	Regeneration; iron deficiency; hyposplenism
Schistocytosis (fragments)	Microangiopathy; hemangiosarcoma; DIC; hyposplenism
Spherocytosis	IHA; hemophagocytic malignant histiocytosis; babesiosis; zinc toxicity
Acanthocytosis (spur cells)	Hemangiosarcoma; lymphoma; other malignancies; liver disease; hyposplenism
Echinocytosis (burr cells)	Artifact; renal disease; pyruvate kinase deficiency anemia
Elliptocytosis	Congenital elliptocytosis (dogs)
Heinz bodies	Oxidative insult to RBCs
Howell-Jolly bodies	Regeneration; hyposplenism
Autoagglutination	IHA
Metarubricytosis	Breed-related characteristic (Schnauzer, Dachshund); extramedullary hematopoiesis; regeneration; lead toxicity; hemangiosarcoma
Leukopenia	See text.
Thrombocytopenia	See text.
Pancytopenia	Bone marrow disorder; hypersplenism

DIC, Disseminated intravascular coagulation; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *IHA,* immune hemolytic anemia; *PRCA,* pure red cell aplasia; *RBC,* red blood cell.
Modified from Couto CG et al.: Hematologic and oncologic emergencies. In Murtaugh R et al., editors: *Veterinary emergency and critical care medicine,* St Louis, 1992, Mosby.

Dogs with high reticulocyte counts and microcytosis/hypochromasia typically have IDA.

The following points generally hold true:

1. If the RBC indices are macrocytic and hypochromic, the anemia is most likely associated with the presence of high numbers of reticulocytes, which are larger and contain less Hb than mature RBCs. Therefore the anemia is likely regenerative. However, >85% of regenerative anemias are normocytic normochromic or normocytic hypochromic.
2. If the reticulocyte count is higher than 120,000/µL (or ≈4%) and the anemia is mild to moderate, the anemia is likely regenerative.
3. As part of the evaluation of a patient with regenerative anemia, it is beneficial to determine the serum or plasma protein concentration because blood loss usually results in hypoproteinemia and hemolysis does not. Other physical examination and clinicopathologic findings that help distinguish blood loss from hemolytic anemias are listed in Table 82.3.

MANAGEMENT OF THE ANEMIC PATIENT

The first basic principle of the management of anemic (or bleeding) patients is to collect all blood samples before instituting any therapy. Because the condition in most of these patients may constitute a true emergency at the time of presentation, samples often are not collected until the patient has been completely stabilized, resulting in treatment-induced changes in hematologic or serum biochemical values.

REGENERATIVE ANEMIAS

Blood Loss Anemia

Acute blood loss in otherwise normal dogs and cats results in reticulocytosis (regeneration) within 48 to 96 hours. Therefore animals evaluated shortly after a traumatic injury and severe blood loss usually have a nonregenerative anemia with a low to normal serum (plasma) protein concentration. The source of bleeding should be identified and the bleeding

TABLE 82.3

Criteria for Differentiating Blood Loss From Hemolytic Anemias

VARIABLE	BLOOD LOSS	HEMOLYSIS
Serum (plasma) protein concentration	Normal-low	Normal-high
Evidence of bleeding	Common	Rare
Icterus	No	Common
Hemoglobinemia	No	Common
Spherocytosis	No	Common
Hemosiderinuria	No	Yes
Autoagglutination	No	Occasional
Direct Coombs test	Negative	Usually positive (in IHA)
Splenomegaly	No	Common
RBC changes	No	Common (see Table 82.2)

stopped; if the patient is bleeding as a result of a systemic hemostatic defect, it should be identified and specific treatment should be initiated (see Chapter 87). Aggressive intravenous (IV) fluid therapy with crystalloids or colloids or the transfusion of blood or blood components is often required in patients with anemia caused by acute blood loss (see p. 1355).

Hemolytic Anemia

In humans, the bone marrow is capable of undergoing hyperplasia until its production rate is increased approximately sixfold to eightfold; the same is probably true for dogs and cats. As a consequence, a considerable number of RBCs must be destroyed before anemia develops. As noted, some dogs and cats with a normal HCT have high numbers of circulating reticulocytes; if the serum bilirubin concentration is marginally increased, or if there is hemoglobinuria or bilirubinuria, hemolysis should be suspected in these patients. Regardless, a blood smear should be evaluated in every dog or cat with reticulocytosis to identify morphologic RBC changes, independently of whether the HCT is normal or low. As discussed earlier, the presence of reticulocytosis in dogs with normal HCT allows for early diagnosis of common diseases such as immune-mediated hemolysis and HSA.

As is the case in cats and dogs with blood loss anemia, patients with peracute hemolysis can be in a nonregenerative state at the time of presentation because the bone marrow has not yet been able to mount a regenerative response. In addition, in some dogs with immune-mediated hemolysis, the destruction of erythroid precursors in the bone marrow results in a lack of regeneration (PRCA; see later).

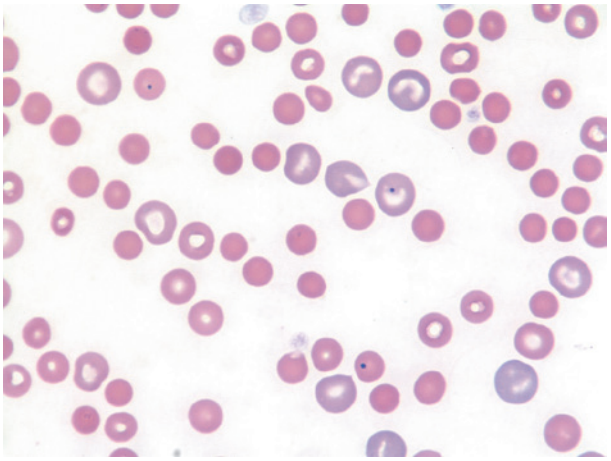

FIG 82.4
Abundant spherocytes in the blood smear of a dog with immune-mediated hemolytic anemia (IHA). Some erythrocytes and polychromatophilic erythrocytes contain Howell-Jolly bodies.

On the basis of their pathogenesis, hemolytic anemias can be classified as extravascular (i.e., the RBCs are destroyed by the mononuclear-phagocytic cells) or intravascular (i.e., the RBCs are lysed by antibody and complement, drugs, toxins, or by hitting fibrin strands). In addition, on the basis of the age of the animal at onset, anemias can be classified as congenital or acquired (Table 82.4). Most dogs and cats with hemolytic anemia seen at our clinic have acquired extravascular hemolysis.

In extravascular hemolysis, RBCs are phagocytosed by the mononuclear-phagocytic system (MPS) in the spleen, liver, and bone marrow. Stimuli that trigger RBC phagocytosis consist mainly of intracellular inclusions, such as RBC parasites or Heinz bodies and membrane coating with immunoglobulin G (IgG) or IgM (common in dogs). Congenital RBC enzymopathies can also precipitate extravascular hemolysis. Once abnormal RBCs are recognized, the MPS rapidly phagocytoses them, resulting in a decrease in the number of circulating RBCs and the generation of cells with specific morphologic changes (e.g., spherocytes). Anemia develops if the destruction of RBCs continues. Spherocytes are RBC "leftovers"; after a mononuclear-phagocytic cell takes "bites" off the cytoplasm and membrane, the membrane is resealed. The RBC then loses its redundant membrane and consequently its central pallor (Fig. 82.4). Spherocytes are characteristic of immune hemolytic anemia (IHA), although they can be seen in other disorders, such as *Babesia gibsoni* infection, zinc toxicity, or hemophagocytic malignant histiocytosis; they also appear in the recipient after transfusion of stored blood. Immune hemolysis is the most common cause of extravascular hemolytic anemia in dogs in our clinic. Drug-associated hemolysis (e.g., β-lactam antibiotics) and mycoplasmosis (formerly known as hemobartonellosis) are

C, Cat; *D,* dog; *IHA,* immune hemolytic anemia; *PFK,* phosphofructokinase.
Modified from Couto CG et al.: Hematologic and oncologic emergencies. In Murtaugh R et al., editors: *Veterinary emergency and critical care medicine,* St Louis, 1992, Mosby, p 359.

the two most common causes in cats, although IHA is now more common in this species. Other causes of extravascular hemolytic anemia in dogs and cats are listed in Table 82.4.

Intravascular hemolysis can occur as a consequence of direct RBC lysis caused by antibodies that activate complement (e.g., immune-mediated hemolysis with a high concentration of IgG or IgM), infectious agents (e.g., *Babesia canis* infection), drugs or toxins (e.g., zinc in pennies minted after 1983, in pet carrier bolts, other hardware, and zinc oxide–containing ointments), metabolic imbalances (e.g., hypophosphatemia in dogs and cats with diabetes mellitus treated with insulin), or increased shearing of RBCs (e.g., microangiopathy, DIC). Intravascular hemolysis is considerably less common in dogs and cats than extravascular hemolysis, with the notable exception of DIC in dogs with HSA, zinc toxicity, and hypophosphatemia. Certain congenital enzymopathies (e.g., phosphofructokinase [PFK] deficiency) in dogs also result primarily in intravascular hemolysis.

Dogs with congenital (frequently familial) hemolytic anemias may have relatively prolonged clinical courses at the time of presentation, with the notable exception of English Springer Spaniels with PFK deficiency–associated hemolysis, in which acute hemolytic episodes occur after they hyperventilate during excitement (e.g., going to the veterinarian or field work) due to alkaline hemolysis.

Dogs and cats with acquired hemolytic anemias are usually evaluated because of acute clinical signs consisting of pallor, with or without icterus (in my experience, only approximately 50% of dogs and a much lower percentage of cats with hemolytic anemia are icteric); diffuse splenomegaly may be a prominent finding. If the patient has associated thrombocytopenia (e.g., Evans syndrome, DIC), petechiae and ecchymoses may be present. Clinical signs and physical examination findings associated with the primary disease can also be present in cases of secondary hemolytic anemias; however, as opposed to humans, they are extremely rare in dogs and cats.

In the evaluation of dogs or cats with hemolytic anemia, a careful examination of the blood smear is mandatory. Morphologic abnormalities pathognomonic for or highly suggestive of a particular cause are often detected with this method (see Table 82.2). In specific circumstances, capillary blood should also be evaluated. In dogs with *B. gibsoni* infection (mainly Pitbulls), the organism is rarely visualized in peripheral blood but is often obvious in capillary blood from the pinna (Fig. 82.5). We collect blood from the tip of the pinna after constricting it for a few seconds and applying alcohol to induce vasodilation. After puncturing the pinna with a 20-gauge needle, we collect a drop of seeping blood with a microhematocrit tube and use it to make a smear. In my experience, *B. gibsoni* organisms are easier to visualize when using Diff-Quik than Giemsa or Wright-Giemsa stain.

The sample should also be tested for autoagglutination by placing a large drop of anticoagulated blood on a glass slide at room temperature and at 4° C (Fig. 82.6). Autoagglutination occurs when large amounts of Ig are bound to the RBC so that the molecules tangle with molecules in adjoining

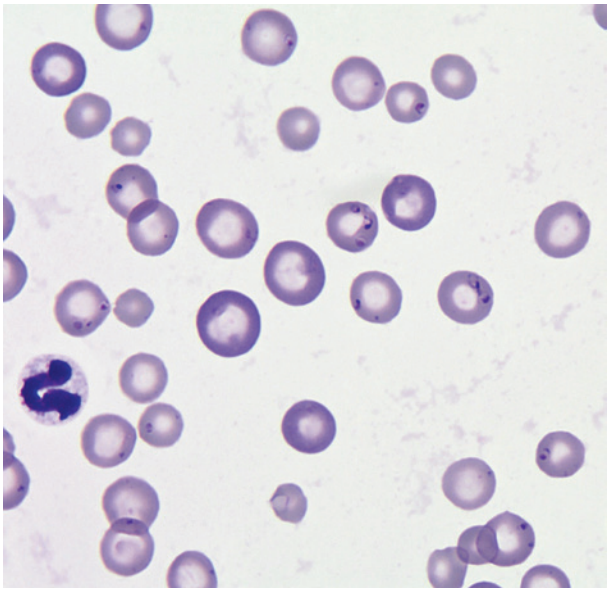

FIG 82.5
Large numbers of *B. gibsoni* in Diff-Quik stained capillary blood of a 7-year-old, female spayed Pitbull shortly after undergoing a splenectomy (×1000).

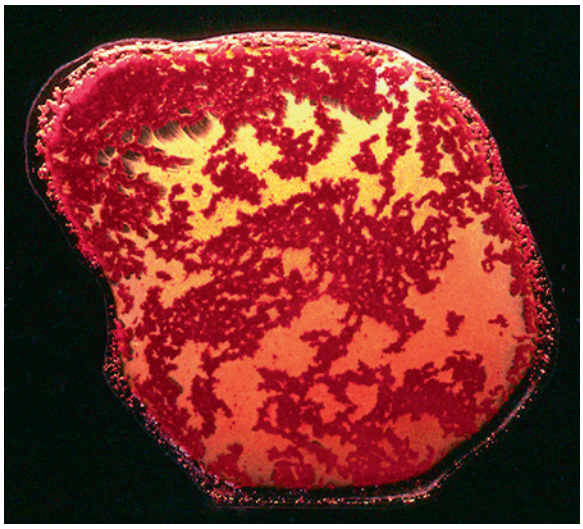

FIG 82.6
Marked saline autoagglutination in a dog with immune hemolytic anemia (IHA).

RBCs, and cause agglutination; it is sometimes referred to as Mother Nature's Coombs test (see later). It can be distinguished from rouleaux formation by adding saline solution, which disaggregates rouleaux; rouleaux formation is common in cats but rare in dogs. An easy way to do this is to place a drop of anticoagulated blood on a glass slide, adding a coverslip, and "shooting" saline solution underneath the coverslip (by capillarity) using a pipette.

A direct Coombs test to detect RBC-bound Ig should be performed in dogs and cats with suspected hemolysis and lack of autoagglutination (see later). As a general rule, the

presence of Ig coating on the RBCs indicates immune-mediated hemolysis. A positive Coombs test result should be interpreted with caution, however, because certain drugs and hemoparasites can induce the formation of antibodies that bind to the RBCs, thus causing secondary immune hemolysis (e.g., cats with mycoplasmosis or dogs with babesiosis). The administration of corticosteroids may also result in decreased binding of Ig molecules to the surface of the RBC thus resulting in false-negative results. Direct Coombs tests are usually not necessary in animals with autoagglutination because this phenomenon indicates the presence of Ig on the surface of the RBCs (i.e., biologic Coombs test). Cryoagglutination (i.e., the agglutination of RBCs if the blood sample is refrigerated for 6-8 hours) occurs in a large proportion of cats with mycoplasmosis and is usually associated with an IgM coating on the RBCs; also, more than 50% of cats with mycoplasmosis have a positive direct Coombs test.

If a causative agent cannot be identified (e.g., RBC parasite, drug, pennies in the stomach), the patient should be treated for primary or idiopathic IHA while further test results by, for example, serologic tests or polymerase chain reaction (PCR) assay for hemoparasites are pending. As noted, primary IHA is considerably more common in dogs than in cats; thus every effort should be made to identify a cause of hemolysis in cats, such as drugs or hemoparasites. For a more detailed discussion of IHA, please see the Immunology section.

Hemolytic anemias not associated with immune destruction of the RBCs are treated by removal of the cause (e.g., drug, infectious agent, gastric foreign body) and supportive therapy. Corticosteroids (see later) can be administered to suppress MPS activity while the causative agent is being eliminated, although this is not always beneficial. Doxycycline (10 mg/kg orally [PO] q24h for 21-42 days) usually results in the resolution of signs in dogs and cats with mycoplasmosis. In dogs with babesiosis, the treatment of choice depends on the specific organism (see Chapter 98).

Immune-mediated hemolytic anemia

IHA constitutes the most common form of hemolysis in dogs in most of the continental United States; this is not likely the case in areas endemic for vector borne diseases. Although two pathogenetic categories of hemolytic anemia are recognized—primary, or idiopathic, and secondary—most cases of IHA in dogs in our clinic are primary; that is, a cause cannot be found after exhaustive clinical and clinicopathologic evaluation. The immune-mediated destruction of RBCs can occur in association with drug administration (e.g., β-lactam antibiotics, barbiturates) or vaccination, but the latter has not been conclusively demonstrated. With the exception of the immune hemolysis secondary to hemoparasitism, IHA is rare in cats, although its prevalence is higher than in the past. The clinical course in dogs is typically acute, but peracute presentations are also common.

In IHA, the RBCs become coated mainly with IgG, which leads to the early removal of the coated cells by the MPS, generally in the spleen and liver. As a consequence, spherocytes are generated (see Fig. 82.4); therefore the presence of spherocytes in the blood smear of a dog with anemia is highly suggestive but not diagnostic of IHA. Spherocytes are difficult to identify in cats. Macroagglutination or microagglutination can also be detected in these patients (see Fig. 82.6).

The typical patient with IHA is a middle-aged, female, spayed Cocker Spaniel, Springer Spaniel, or small-breed dog, although there appears to be an increasing prevalence of IHA and other immune-mediated cytopenias in Golden Retrievers. Clinical signs in dogs with IHA include depression of acute (or peracute) onset, exercise intolerance, and pallor or jaundice, occasionally accompanied by vomiting or abdominal pain. Physical examination findings usually consist of pallor or jaundice, petechiae and ecchymoses if immune thrombocytopenia is also present, splenomegaly, and a heart murmur. As noted, jaundice can be absent in dogs with IHA. A subset of dogs with acute (or peracute) IHA with icterus and usually autoagglutination shows clinical deterioration within hours or days of admission because of multifocal thromboembolic disease or lack of response to conventional therapy. I treat these dogs more aggressively than the typical dog with IHA (see later).

Hematologic findings in dogs with IHA typically include strongly regenerative anemia, leukocytosis from neutrophilia with a left shift and monocytosis, increased numbers of nucleated RBCs, polychromasia, and spherocytosis. The serum (or plasma) protein concentration is usually normal to increased, and hemoglobinemia or bilirubinemia may be present (i.e., pink or yellow plasma). As noted, autoagglutination is prominent in some dogs. Thrombocytopenia is also present in dogs with Evans syndrome or DIC. Dogs with intravascular hemolysis frequently have hemoglobinuria (i.e., urine dipstick positive for blood and no RBCs in the sediment), and those with extravascular hemolysis have bilirubinuria.

The presence of polychromasia with autoagglutination and spherocytosis in a clinically ill dog with anemia of acute onset is almost pathognomonic of IHA, with the exception of Pitbulls with *B. gibsoni* infection that present with similar findings. In these cases, a direct Coombs test is usually not necessary to confirm the diagnosis. In dogs without some of these physical examination and hematologic findings, a direct Coombs test should be performed to detect Ig adsorbed to the RBC membrane. As noted, in Pitbulls, evaluation of capillary blood in a Diff-Quik–stained slide or PCR assay is mandatory to exclude *B. gibsoni* infection (see Fig. 82.5).

The direct Coombs test is negative in approximately 10% to 30% of dogs with IHA, although they still tend to respond to immunosuppressive therapy (see later). In these cases enough Ig or complement molecules may be bound to the RBC membrane to induce the MPS to stimulate phagocytosis but not enough to result in a positive Coombs test. In humans, hemolysis can occur with approximately 20 to 30 molecules of Ig bound to the RBC, whereas the direct Coombs test can only detect more than 200 to 300 molecules of Ig/cell. In some patients, prior administration of

exogenous corticosteroids may result in decreased antibody binding to the surface of the RBCs.

Immunosuppressive doses of corticosteroids (equivalent to 2-4 mg/kg of prednisone q12-24h) constitute the treatment of choice for primary IHA. Although dexamethasone can be used initially, it should not be used as maintenance therapy for prolonged periods because of its higher potential to cause GI tract ulceration or pancreatitis; in addition, if given on an alternate-day basis, it causes interference with the hypothalamic-pituitary-adrenal axis. In equivalent doses, dexamethasone does not appear to be more beneficial than prednisone in dogs. In cats with IHA, I use dexamethasone (4-5 mg/cat PO q1-2 wk) instead of prednisolone, with a high degree of success.

A high percentage of dogs treated with corticosteroids show a marked improvement within 24 to 96 hours (Fig. 82.7). Corticosteroids mainly act by three different mechanisms—they suppress MPS activity, decrease complement and antibody binding to the cells, and suppress Ig production. The first two effects are rapid in onset (hours), whereas the third effect is delayed (1-3 weeks). For additional information, see Chapters 72 and 73.

I have seen a high number of dogs with acute or peracute IHA generally associated with icterus and autoagglutination that undergo rapid deterioration and usually die of thromboembolism of the liver, lungs, or kidneys despite aggressive corticosteroid therapy (Fig. 82.8). In those patients, I use cyclophosphamide (Cytoxan), 200 to 300 mg/m^2 PO or IV in a single dose over a 5- to 10-minute period, or human IV immunoglobulin (IVIG), 0.5 g/kg as an IV infusion, in conjunction with a single IV dose of dexamethasone sodium phosphate (1-2 mg/kg). I also advocate the use of prophylactic heparin and/or aspirin therapy because dogs with hemolysis are at high risk for DIC and thrombosis. I use heparin therapy, 50 to 75 IU/kg subcutaneously (SC) q8h, and/or minidose aspirin, 0.5 mg/kg PO q24h. These dosages of heparin usually do not result in therapy-related prolongation of the activated clotting time (ACT) or activated partial

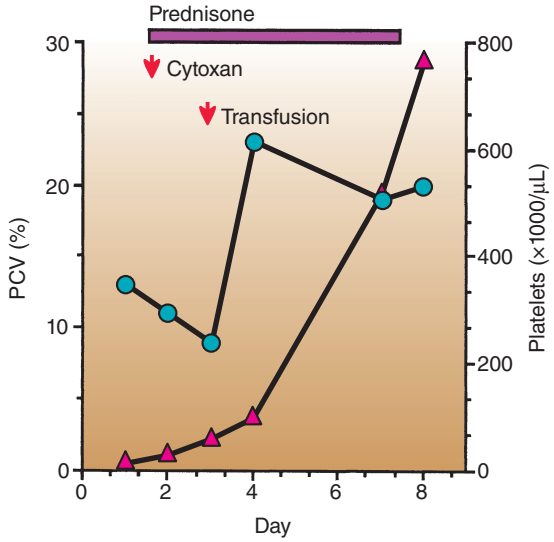

FIG 82.7

thromboplastin time (aPTT), tests used routinely to monitor heparinization. The use of low-dose or minidose aspirin has been associated with lower mortality rates in dogs with IHA. Because dogs with IHA are at high risk for thromboembolic events, I refrain from placing central venous lines; thrombosis of the anterior vena cava commonly leads to severe pleural effusion in these dogs. Aggressive fluid therapy should be administered in conjunction with these treatments in an attempt to flush the microaggregates of agglutinated RBCs from the microcirculation. (*Note:* As a general rule, circulating blood does not clot.) In patients with severe anemia, the resultant hemodilution may be detrimental. If deemed necessary, oxygen therapy should also be used, but it is rarely beneficial unless the HCT or Hb can be increased.

As noted, I use human IV IgG (HIVIGG; 0.5-1 g/kg IV infusion, single dose) with a high degree of success in dogs with refractory IHA. This treatment is aimed at blocking the Fc receptors in the MPS with a foreign Ig, thus minimizing the phagocytosis of antibody-coated RBCs. This treatment appears to have other immunomodulatory effects as well. However, the product is moderately expensive (≈$700/dose for a 10-kg dog). This approach has had such a positive impact, however, that I frequently use it as first-line therapy in dogs with severe IHA.

Drugs used for the maintenance treatment of dogs with IHA include prednisone (1-2 mg/kg PO q48h) and azathioprine (50 mg/m^2 PO q24-48h), singly or in combination. Azathioprine is associated with few adverse effects, although close hematologic and serum biochemical monitoring is necessary because of its myelosuppressive and hepatotoxic potential; if myelosuppression or hepatotoxicity occurs, a dose reduction is necessary. Occasionally azathioprine must be discontinued in dogs with hepatotoxicity.

In cats, chlorambucil is an effective immunosuppressor with very low toxicity; I have used it successfully in cats with IHA, immune-mediated thrombocytopenia, or other cytopenias, 20 mg/m^2 PO q2wk. As noted, in cats I use dexamethasone (4-5 mg/cat PO q1wk) instead of prednisone or prednisolone. In general, dogs and cats with IHA require prolonged, often lifelong, immunosuppressive treatment. Whether an animal requires continuous treatment is determined by trial and error; decremental doses of the immunosuppressive drug(s) are administered for a given period (usually 2-3 weeks), at which time the patient is reevaluated clinically and hematologically. If the PCV has not decreased or has increased, and the patient is clinically stable or has shown improvement, the dose is reduced by 25% to 50%. This procedure is repeated until the drug is discontinued or the patient relapses. In the latter case, the dosage used previously that had beneficial effects is used again. In my experience, most dogs with IHA require lifelong treatment. Alternative treatments for dogs with refractory IHA include cyclosporine, mycophenolate, mofetil, and possibly splenectomy. For details, see Chapters 72 and 73.

Chlorambucil (20 mg/m^2 PO q2wk) appears to be the best induction and maintenance agent in cats with IHA refractory to corticosteroids or in those who develop corticosteroid-induced diabetes mellitus. In my experience, azathioprine causes pronounced myelosuppression in cats and should not be used.

One of the biggest dilemmas the clinician faces in the treatment of a dog with IHA is whether to administer a transfusion of blood or blood components. As a general rule, a transfusion should not be withheld if it represents a lifesaving procedure. However, because patients with IHA are already destroying their own antibody-coated RBCs, they may also be prone to destroying transfused RBCs, although this has not been scientifically proven. My recommendation is to administer a transfusion to any animal with IHA that is in dire need of RBCs (i.e., withholding a transfusion would result in the animal's death). I usually pretreat these patients with dexamethasone sodium phosphate (0.5-1 mg/kg IV), administer fluids through an additional IV catheter, and continue the heparin or aspirin therapy. Although cross-matching is indicated, time is usually of the essence; therefore non–cross-matched "universal" donor blood or packed RBCs are frequently administered.

Another issue pertaining to transfusion in dogs with IHA autoagglutination has to do with blood typing; if blood typing cards are used, the results will be false-positive for dog erythrocyte antigen (DEA) 1.1 (see later, "Transfusion Therapy"). Finally, no rule of thumb exists (e.g., PCV value, lack of response to oxygen therapy) regarding when to administer a transfusion. The clinician should use his or her best clinical judgment to determine when a transfusion of blood or blood components is necessary (e.g., does the patient exhibit tachypnea, dyspnea, or orthopnea?). If available, "universal donor" packed RBCs should be used instead of whole blood because they deliver a high oxygen-carrying capacity in a smaller volume; IHA is an isovolemic anemia.

NONREGENERATIVE ANEMIAS

With the exception of ACD, nonregenerative anemias do not appear to be clinically as common as regenerative forms in dogs, whereas the opposite is true in cats. Five forms of nonregenerative anemia are typically recognized in cats and dogs (see Box 82.3). Because IDA can be mildly to moderately regenerative, and the RBC indices are so different from those in other forms of nonregenerative anemia (microcytic, hypochromic versus normocytic, normochromic; see Boxes 82.3 and 82.4 and Tables 82.2 to 82.4) that it is easily identified as such, I prefer to classify it in a separate category. Anemia of endocrine disease is typically mild and usually is an incidental finding in dogs with hypothyroidism or hypoadrenocorticism (see Chapters 48 and 50). In general, most nonregenerative anemias and IDA in cats and dogs are chronic, thus allowing for physiologic adaptation to the decrease in the RBC mass. As a consequence, these types of anemias may be detected incidentally during the routine evaluation of a cat or dog, which to the owner is asymptomatic. In many cases (e.g., ACD), the anemia is mild, and clinical signs are absent. Although most nonregenerative anemias are chronic, two situations are commonly

BOX 82.4

Classification and Causes of Nonregenerative Anemia in Cats and Dogs

Anemia of chronic disease
Bone marrow disorders
- Bone marrow (or erythroid) aplasia-hypoplasia
- Myelophthisis
- Myelodysplastic syndromes
- Myelofibrosis
- Osteosclerosis, osteopetrosis

Anemia of renal disease
Acute blood loss or hemolysis (first 48-96 hours)
Anemia of endocrine disorders
- Hypoadrenocorticism
- Hypothyroidism

TABLE 82.5

Distinguishing Features of Anemia of Chronic Disease (ACD) and Iron Deficiency Anemia (IDA) in Dogs

PARAMETER	ACD	IDA
Serum iron concentration	↓	↓↓
Total iron-binding capacity	N	N↑
Percentage saturation	↓	↓↓
Bone marrow iron stores	↑	↓
Platelet count	N, ↓, ↑	↑, ↑↑
Fecal occult blood	N	±
Ferritin	N	↓

↓, Low; ↓↓, markedly low; ↑, high; ↑↑, markedly high; *N*, normal; ±, positive or negative.

encountered in which this form of anemia is acute—acute blood loss (first 48-96 hours) and peracute hemolysis. In these two cases, the bone marrow has not yet had time to mount a regenerative reticulocyte response, and the patients have severe clinical signs.

When evaluating dogs and cats with symptomatic nonregenerative anemias of acute onset, the clinician should try to answer the following questions:

- Has this patient had an acute blood loss or does it have hemolytic anemia and has not yet been able to mount a regenerative response (i.e., <48-96 hours have elapsed since the event)?
- Does this patient have chronic anemia but is now symptomatic because of intercurrent disease (e.g., heart failure, sepsis)?

Most clinical and clinicopathologic abnormalities in cats and dogs with nonregenerative anemia have been discussed. In general RBCs in dogs and cats with nonregenerative anemias are normocytic and normochromic; however, in cats with FeLV-related hypoproliferative anemias, RBCs are usually macrocytic and normochromic. As noted, in dogs and cats with IDA, the RBC indices are microcytic and hypochromic.

The clinical evaluation of a cat or dog with nonregenerative anemia differs radically from that of a patient with a regenerative form because the absence of regeneration reflects primary or secondary bone marrow abnormalities (e.g., bone marrow disorder, ACD). Therefore, after extramarrow causes have been ruled out by performing a physical examination and serum biochemical profile and urinalysis, a bone marrow aspiration or biopsy is typically indicated in these patients.

Anemia of Chronic Disease

ACD is the most common form of nonregenerative anemia in cats and dogs, but because it is mild it almost never results in clinical signs of anemia and the patients are usually evaluated as a consequence of their primary disorder (e.g., cancer, infection). ACD develops secondary to a variety of chronic inflammatory, degenerative, or neoplastic conditions. Although the term *anemia of chronic disease* implies a chronic onset, it has been established that cats can develop ACD in as little as 2 weeks. However, some of those cats were receiving fluid therapy that might have resulted in hemodilution (Ottenjan et al., 2006). In most cats with ACD, the PCV values range from approximately 18% to 25%, whereas in dogs they range from approximately 25% to 35%. Therefore ACD can usually be excluded in dogs with a PCV less than 20% and in cats with a PCV less than 17% to 18%. The RBC indices are normocytic and normochromic, and the CBC may also reflect the nature of the primary problem (e.g., leukocytosis, neutrophilia, monocytosis, hyperproteinemia resulting from a polyclonal gammopathy). Some cats with ACD have microcytic hypochromic RBC indices, a condition that mimics IDA.

Sustained inflammatory or neoplastic processes cause iron to be sequestered within the bone marrow MPS, and it is therefore not available to the erythroid precursors for normal erythropoiesis. This unavailability of iron is mainly mediated by hepcidin, lactoferrin, and other acute-phase reactants released from leukocytes during inflammation. In cats and dogs with ACD, the serum iron concentration and total iron-binding capacity (TIBC, or transferrin concentration) are usually decreased and the Hb saturation is low, but iron stores in the bone marrow are increased (Table 82.5). Although serum ferritin concentrations are the main feature that distinguishes ACD from IDA (i.e., high in ACD and low in IDA) in humans, the results of ferritin assays in dogs and cats with IDA and ACD are not as clear-cut. Therefore, to differentiate ACD from IDA conclusively, evaluation of bone marrow iron stores by Prussian blue staining is important. After a diagnosis of ACD has been confirmed, every effort should be made to identify the cause of the problem if it is not already evident.

Dogs and cats with ACD usually do not require specific or supportive therapy because treatment of the primary disorder causes the anemia to resolve. Although some have advocated the use of anabolic steroids in dogs and cats with ACD, these agents appear to be of little or no benefit. For a recent review of ACD I dogs and cats, please see Chikazawa and Dunning.

Bone Marrow Disorders

Neoplastic, hypoplastic, or dysplastic bone marrow disorders can result in anemia and other cytopenias. In these conditions, a so-called crowding out of the normal erythroid precursors by neoplastic or inflammatory cells (myelophthisis), paucity or absence of erythroid precursors (hypoplasia or aplasia, respectively), or maturation arrest of the erythroid precursors (dysplasia) occur. All these disorders, with the exception of PRCA (see the following section), typically affect more than one cell line, and the patients are bicytopenic or pancytopenic (see Chapter 86). In general, these disorders are chronic and the clinical signs are those of anemia (see p. 1340), with or without signs of the underlying disorder. Although some information regarding the pathogenesis of this type of anemia can be obtained by evaluating the clinical and hematologic data, a definitive diagnosis is usually made on the basis of the cytologic or histopathologic appearance of a bone marrow specimen and possibly by the results of serologic tests or PCR assay for the infectious agent (e.g., FeLV, FIV, *Ehrlichia canis*). Numerous "anemia panels" that combine serology and PCR for common infectious agents in both dogs and cats are offered by reference laboratories.

Bone marrow (or erythroid) aplasia-hypoplasia

Bone marrow aplasia-hypoplasia is characterized by aplasia or hypoplasia of all the bone marrow cell lines (bone marrow aplasia-hypoplasia or aplastic pancytopenia) or of selected cell lines, for example, erythroid precursors (RBC aplasia-hypoplasia or PRCA). This form of anemia (or combined cytopenias) can be caused by a variety of agents or disorders (see Chapter 86). The following discussion pertains to PRCA; some authors have referred to PRCA as the nonregenerative form of immune-mediated anemia. Pathologists prefer to use PRCA for patients in which there is aplasia-hypoplasia of all the RBC precursors. However, because the clinical and clinicopathologic findings are identical independently of where in the RBC series the maturation arrest occurs, I prefer to use PRCA.

Clinically, dogs and cats with PRCA are evaluated because of the clinical signs already discussed. Pica is common in dogs with PRCA. In contrast to ACD, in which the degree of anemia and thus the severity of the clinical signs is mild, cats and dogs with PRCA usually have a PCV of less than 15% and are usually symptomatic. Hematologically, severe (normocytic normochromic) nonregenerative anemia is usually the only abnormality; macrocytosis in the absence of reticulocytes is a consistent finding in cats with FeLV- or FIV-related aplastic anemia, and mild microcytosis can occasionally be present in dogs with PRCA. The large RBC volume in cats with retroviral infections is attributed to the erythroid dysplasia or dyserythropoiesis induced by the virus. Dogs with PRCA occasionally have circulating spherocytes, indicating an immune basis for the anemia. The direct Coombs test is also positive in more than 50% of these dogs, and their anemia responds to immunosuppressive therapy. Cats and dogs with bone marrow aplasia-hypoplasia are pancytopenic (see Chapter 86).

FeLV and FIV testing should be done in all cats with severe nonregenerative anemia, independently of their MCV. A bone marrow aspiration or biopsy specimen should also be obtained to rule out other bone marrow disorders.

The FeLV envelope protein p15E suppresses erythropoiesis in vitro and causes aplastic anemia in FeLV-infected cats. The anemia in these cats is usually chronic and severe—a PCV of 5% to 6% is relatively common—and despite supportive therapy, the condition of the patient deteriorates, leading the owners to request euthanasia. The supportive treatment of these cats includes whole blood or packed RBC transfusions, as needed; the interval between transfusions usually shortens with each transfusion until the cat needs transfusions weekly. Interferon administered orally may improve clinical signs, without resolution of the anemia, in some of these cats (see Chapter 96).

FeLV-negative cats with PRCA may have a positive direct Coombs test and frequently benefit from immunosuppressive doses of corticosteroids. I typically use 4 to 5 mg of dexamethasone/cat PO q1 to 2 weeks instead of the conventional prednisone or prednisolone daily or every other day. This steroid formulation is safe and effective, and I have not seen the development of secondary diabetes mellitus in the cats treated. The use of human recombinant erythropoietin (EPO; see later) does not appear to be indicated in these cats because their endogenous EPO activity is higher than that of normal cats. In addition, the long-term use of human recombinant EPO may lead to the development of anti-EPO antibodies and resultant refractory anemia.

Bone marrow aspirates in dogs and cats with PRCA reveal erythroid hypoplasia or hyperplasia of the early erythroid precursors and a maturation arrest at the rubricyte or metarubricyte stage. As noted, this poses an interesting situation because most clinical pathologists use PRCA only for the dogs and cats that have erythroid hypoplasia and IHA with delayed erythroid regeneration or nonregenerative form of immune-mediated anemia for those with erythroid hyperplasia and a maturation arrest. However, from a clinical standpoint, both situations behave the same way and respond to the same treatment, so I prefer to use PRCA for dogs and cats with either of these bone marrow cytologic findings.

The same treatment as that used during the maintenance phase of IHA is recommended for affected dogs (prednisone, 2-4 mg/kg PO q24-48h, and/or azathioprine, 50 mg/m^2 PO q24-48h). In cats, I have successfully used dexamethasone alone (as noted earlier) or in combination with chlorambucil, 20 mg/m^2 PO q2 weeks. Responses occur in approximately 70% to 80% of patients, but clinical and hematologic recovery may take 2 to 3 months; long-term (often lifelong) treatment is usually required. Supportive treatment and

transfusions of blood or packed RBCs are sometimes necessary. Because these patients are normovolemic, the latter is preferable. In addition, because transfusions may need to be administered on an ongoing basis, cross-matching is recommended before the administration of each transfusion. Of note, in dogs one of the mechanisms of adaptation to chronic hypoxia (e.g., anemia) is an increase in the intraerythrocytic 2,3-diphosphoglycerate (2,3-DPG) concentration, resulting in a lower oxygen affinity; that is, the delivery of oxygen to the tissues is facilitated. Because stored RBCs have lower concentrations of 2,3-DPG, the transfused cells have a higher affinity for oxygen. As a result, the transfusion of stored blood to a patient with chronic anemia may result in transient decompensation because approximately 24 hours is usually required for the transfused, stored RBCs to regain 50% of the normal 2,3-DPG concentration and become recharged.

Myelophthisis, myelodysplastic syndromes, myelofibrosis, and osteosclerosis-osteopetrosis

These disorders are discussed in Chapter 86.

Anemia of Renal Disease

The kidney is the main site of production of EPO, the principal stimulus of erythropoiesis. In addition, in dogs and cats with CKD, the life span of RBCs is considerably shorter and subclinical to clinical GI tract bleeding is present; high concentrations of parathyroid hormone may also suppress erythropoiesis. Consequently, anemia is common in these patients. The anemia is usually normocytic and normochromic, with few or no reticulocytes. HCT levels in dogs and cats with ARD are usually in the 20% to low 30% range, although HCT levels from 13% to 19% are common. Of note, the HCT in these patients is usually that low only after they have undergone intensive fluid therapy; on presentation, the anemia is not that severe because the patients are markedly dehydrated.

Improvement in renal function may result in marginal increases in the RBC mass. Anabolic steroids are rarely beneficial in improving the anemia in these patients. Human recombinant EPO has been used successfully to treat anemia in cats and dogs with chronic renal failure. A dose of 100 to 150 IU/kg SC, twice weekly, is administered until the HCT returns to a target value (usually 20%-25%); the interval between injections is then lengthened for maintenance therapy. The HCT usually returns to normal within 3 to 4 weeks of the initiation of treatment. Given the fact that this EPO is foreign to dogs and cats, an appropriate antibody response usually nullifies the beneficial effects of long-term therapy (6-8 weeks) in more than 50% of patients. Recently, darbepoetin was successfully used to treat anemia of renal disease in dogs (Fiocchi et al., 2017). In a study of 33 dogs with CKD and anemia, the median starting dosage and highest dosage of darbepoetin administered were 0.5 and 0.8 μg/kg SC once weekly, respectively. Response to treatment was defined as achieving a PCV ≥30% or an increase in PCV ≥10%. Twenty-eight of 33 dogs (85%) achieved a PCV ≥30%, and 22 of 33 (67%) dogs achieved an increase in PCV ≥10%; the median time to hematologic response was 29 days. No dog sustained a response at a dosing interval >q21 days. Potential adverse events included increased blood pressure requiring treatment ($n = 12$), seizures ($n = 5$), vomiting ($n = 3$), diarrhea ($n = 3$), and possible PRCA ($n = 2$) (Fiocchi et al., 2017).

Acute and Peracute Blood Loss or Hemolysis

After an acute episode of blood loss or hemolysis, the bone marrow takes approximately 48 to 96 hours to release enough reticulocytes to result in regeneration. Therefore blood loss and hemolytic anemias are nonregenerative during the initial phases of recovery.

In most dogs and cats with acute blood loss, profound bleeding is historically or clinically evident. If no obvious cause of bleeding is found, or if the patient is bleeding from multiple sites, the hemostatic system should be evaluated in search of a coagulopathy (see Chapter 87). Sites of internal bleeding should be evident after a complete physical examination is performed.

Once the bleeding has been stopped, the anemia typically resolves within days to weeks. The initial management of a bleeding episode should include supportive therapy and IV crystalloids or plasma expanders. If necessary, blood or packed RBCs or Hb solutions, if available, should be administered.

The management of dogs with peracute hemolysis was discussed earlier in the chapter.

Iron Deficiency Anemia

IDA is traditionally classified as nonregenerative, even though mild to moderate regeneration usually occurs. Moreover, as noted, the RBC indices in dogs and cats with IDA are microcytic and hypochromic, distinguishing it from other forms of anemia. When evaluating the CBC of a dog with microcytic hypochromic anemia, the clinician must remember that microcytosis occurs in some breeds (e.g., Akita, Shiba Inu, Shar Pei) and in dogs with other disorders, such as portosystemic shunts (see Table 82.2).

This form of anemia is well characterized in dogs with chronic blood loss. In cats, IDA has been well documented only in weanling kittens in whom iron supplementation results in rapid resolution of the clinical and hematologic abnormalities. IDA is extremely uncommon in adult cats; I have seen it primarily in association with chronic blood loss in cats with GI lymphoma. Given its rarity in cats, the following discussion of IDA pertains primarily to dogs.

Chronic blood loss leading to iron depletion is common in dogs with GI tract bleeding caused by neoplasia, gastric ulcers, or endoparasites (e.g., hookworms), and in those with a heavy flea infestation. Other causes of chronic blood loss, such as urogenital bleeding and iatrogenic bloodletting, are extremely rare. Recently, in a multicenter study of 688 dogs and 163 cats, the prevalence of anemia upon admission was 32%; the overall prevalence during the hospitalization period was 56% (Lynch et al., 2015). The RBC indices were not

reported in this study, so the prevalence of true IDA is unknown. The last recorded PCV was significantly lower than the admission PCV for both dogs (admission PCV, 42%; last recorded PCV, 34%, $P < 0.0001$) and cats (admission PCV, 31%; last recorded PCV, 26%, $P < 0.0001$). Patients that developed anemia had significantly more blood samples collected (nonanemic, 5 blood samples; anemic, 7 blood samples, $P < 0.0001$). Hospitalized cats were significantly more likely to develop anemia than dogs ($P < 0.0001$), but anemic dogs were significantly less likely to survive to discharge ($P = 0.0001$). Surgical patients were at higher risk of developing hospital-acquired anemia compared with medical patients (odds ratio [OR], 0.63; 95% confidence interval [CI], 0.4-0.9; $P = 0.01$). Blood products were administered to 198 patients (158 dogs and 40 cats); packed RBCs were the most commonly administered product in 129 cases (100 dogs and 29 cats).

In my experience, the most common cause of symptomatic IDA in adult dogs that present for evaluation of signs associated with anemia is GI neoplasia.

Dogs with IDA are typically evaluated because of the signs of the anemia or because of GI tract signs such as diarrhea, melena, or hematochezia. Mild IDA is occasionally recognized during the routine evaluation of heavily parasitized dogs (mostly pups). Hematologically, most dogs with IDA have microcytic hypochromic indices, mild reticulocytosis, high RBC distribution width (RDW) with an occasional bimodal population of RBCs, thrombocytosis, low serum iron and TIBC (transferrin) concentrations, extremely low percentage of saturation (usually <10%), low serum ferritin concentration, and low iron stores in the bone marrow (see Box 82.5; Fig. 82.9). The typical tetrad of hematologic abnormalities in dogs with IDA is microcytosis, hypochromasia, mild regeneration, and thrombocytosis. "Anemia of the elderly," a progressive, age-related microcytic hypochromic anemia documented in people, was recently described in senior and geriatric dogs (Radakovich et al., 2017).

Because the most common cause of IDA in adult dogs is chronic GI tract bleeding, the stools should always be evaluated for occult blood with commercially available kits (see Chapter 27); if the results are negative, they should be evaluated again two or three times during a period when the animal is not eating canned dog food; myoglobin in canned dog food can rarely result in false-positive reactions. If occult blood is present in the stool, a GI tract neoplasm should be ruled out. Tumors commonly associated with IDA in dogs include GI stromal tumors (GISTs), leiomyomas and leiomyosarcomas, lymphomas, and carcinomas. In dogs with weight loss, IDA, positive fecal blood test results, and lack of clinical signs associated with the GI tract, the most likely diagnosis is a jejunal tumor (usually a GIST or leiomyosarcoma); I refer to these tumors as the silent GI neoplasms.

Another condition that can lead to IDA is chronic upper GI tract bleeding secondary to gastroduodenal ulceration, although most of these dogs have overt clinical signs associated with the GI tract (e.g., vomiting, hematemesis, weight loss). In pups or kittens with IDA, fecal flotation or a direct smear for hookworms and thorough physical examination to search for fleas are mandatory because these are the two most common causes of IDA in young dogs and cats.

IDA usually resolves within 6 to 8 weeks after the primary cause has been eliminated. Oral or intramuscular iron supplementation is usually not necessary to hasten the resolution of the hematologic abnormalities; a sound commercial diet usually achieves the same effect. As a general rule, if the cause can be eliminated, I do not use iron supplementation. The dietary iron requirement for adult dogs and cats is approximately 1.3 mg/kg/day.

BOX 82.5

Bone Marrow Disorders in Cats and Dogs

Marrow (or Erythroid) Aplasia-Hypoplasia

- FeLV (C)
- Immune-mediated disorders (D, C)
- Estrogen (D)
- Phenylbutazone (D)
- Other drugs (D, C)
- Idiopathic (D, C)

Myelophthisis

- Acute leukemias (D > C)
- Chronic leukemias (D > C)
- Multiple myeloma (D, C)

TRANSFUSION THERAPY

Veterinary transfusion medicine has made great strides in the past decade. Several commercial blood banks for pets are now available; most of them store blood components derived from processing units of whole blood or collected by apheresis. In a typical situation, a unit of whole blood is spun

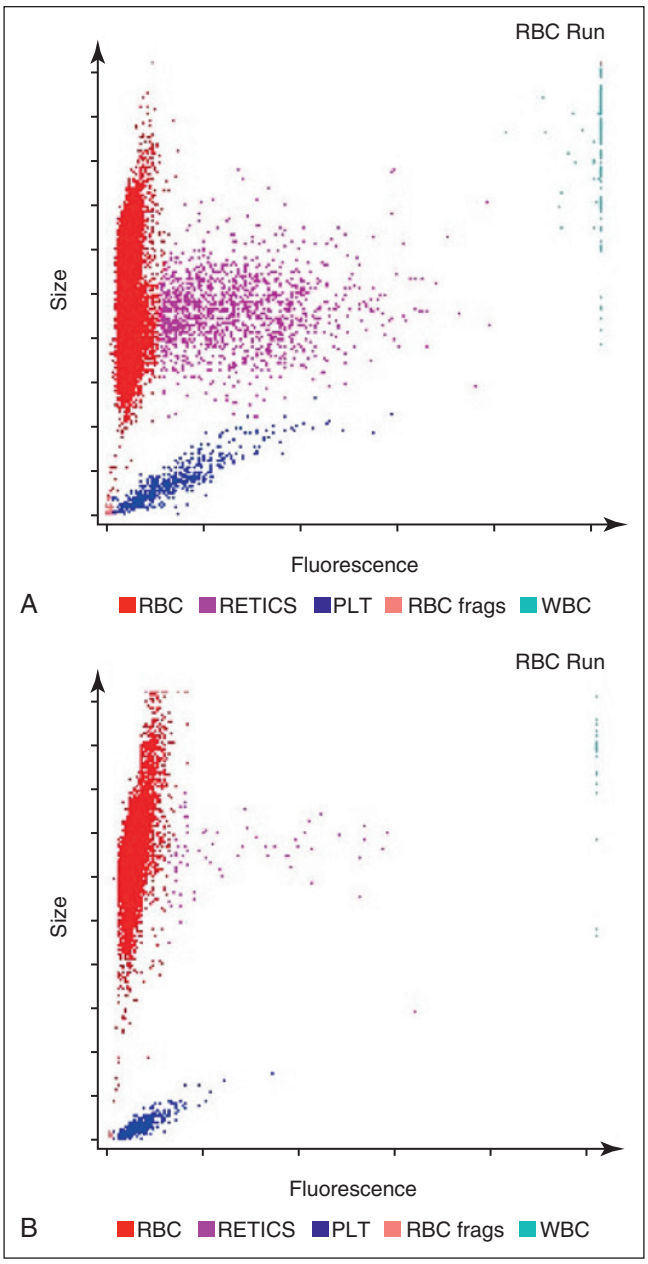

FIG 82.9
(A) Dot plots of a Greyhound with severe flea infestation and iron deficiency anemia (IDA) compared with a dot plot in a normal Greyhound. Note the RBC cloud lower in the vertical axis in **(A)** than in **(B)** indicating a low mean corpuscular volume, and the large reticulocyte cloud (RETICS) in *purple* **(A).** *PLT,* Platelets.

immediately after collection, and packed RBCs (pRBCs) and fresh-frozen plasma (FFP) stored at −20° C to −30° C are prepared. The pRBCs are preserved by adding a nutrient solution and can be stored for up to 5 weeks. After 1 year of storage at −20° C to −30° C, FFP is supposed to lose the labile clotting factors (V and VIII) and is referred to as stored plasma (SP) or frozen plasma (FP); however, we demonstrated that 5-year-old FP is still hemostatically active and can be used for transfusion (Urban et al., 2013). Some blood banks prepare platelet-rich plasma (PRP) or platelet concentrates by apheresis; a new platelet concentrate is now commercially available in the United states (Bodevet; http://www.bodevet.com). If FFP is allowed to warm up in a refrigerator, a sludge forms in the bottom of the bag when it reaches approximately 4° C to 6° C. That sludge can be separated by a short centrifugation, yielding cryoprecipitate (CRYO), a small volume rich in factor VIII, fibrinogen, and von Willebrand factor (vWF); the supernatant is termed *cryopoor plasma.*

The transfusion of whole blood or blood components (e.g., pRBCs, PRP, FFP, CRYO, or SP) is indicated in several clinical situations. Whole blood or pRBC transfusion is usually required to restore the oxygen-carrying capacity in patients with anemia. Whole blood may be used if the anemic patient is hypovolemic or if he or she needs clotting factors in addition to RBCs, whereas pRBCs are recommended for normovolemic dogs and cats with anemia (i.e., PRCA, ARD, hemolysis). Transfusion therapy should be used with caution in animals with IHA (see p. 1351) because a massive transfusion reaction may occur.

Clotting factor deficiencies (see Chapter 87) resulting in hemorrhage can be corrected through the administration of whole fresh blood if considerable blood loss has occurred or, ideally, FFP, FP, or SP. Cryoprecipitate contains a high concentration of factor VIII and vWF, so it is typically used in dogs with hemophilia A or von Willebrand disease. Cryopoor plasma is a good source of clotting factors (except for fibrinogen, factor VIII, and vWF) and albumin; therefore it is indicated in patients with common coagulopathies, such as rodenticide toxicity. PRP or platelet transfusions, if available, can be used in dogs and cats with severe thrombocytopenia resulting in spontaneous bleeding (Table 82.6). However, the platelet count of the recipient is rarely increased enough to halt bleeding. PRP and platelet transfusions are of little or no benefit in patients with peripheral platelet destruction (e.g., immune-mediated thrombocytopenia) because the platelets are removed from the circulation immediately after the transfusion. Transfusion with whole fresh blood, PRP, or FFP is also indicated for the management of patients with DIC (see Chapter 87).

Less frequently, plasma is prescribed to correct hypoalbuminemia. However, only rarely can relevant increases in the recipient's serum albumin concentration be achieved. Colloids or human albumin solutions are more effective for restoring plasma oncotic pressure.

BLOOD GROUPS

Several blood groups have been recognized in dogs; these include DEA 1.1 and 1.2 (formerly known as blood group A), DEA 3 through 8, and *Dal*; two new blood groups (*Kai1* and *Kai2*) were recently reported (Euler et al., 2016). We have stated repeatedly that dogs do not have naturally occurring antibodies against blood group antigens; therefore theoretically they can only acquire them after receiving a transfusion or after pregnancy. However, in a recent

report, 17% of dogs that had never received a transfusion were found to be incompatible by cross-matching (Odunayo et al., 2017). In addition, studies have reported a lack of association between pregnancy and the development of antibodies in dogs (Blais et al., 2009). Transfusion reactions can occur if blood positive for DEA 1.1, 1.2, or 7 is transfused, so donors should be negative for those antigens. However, clinically relevant acute hemolytic transfusion reactions are extremely rare in dogs. Transfusion of blood from a donor who has not been typed and has never been transfused to a recipient, independently of their blood type, is generally safe.

Blood groups in cats include A, B, AB, and *Mik*. Cats tested in the United States have almost exclusively been type A; the prevalence of type B cats varies greatly from geographic region to region and among breeds. Breeds in which 15% to 30% of the cats are type B include Abyssinian, Birman, Himalayan, Persian, Scottish Fold, and Somali; breeds in which more than 30% of cats are type B include the British Shorthair and Devon Rex. Because fatal transfusion reactions commonly occur in type B cats receiving type A blood, cats should always be cross-matched or typed before receiving a transfusion. In those cases, a type B cat should be used as a donor. Most type B cats seen in our clinic in the past 10 years have been domestic short-haired cats. Blood typing is also vital in cattery situations to prevent neonatal isoerythrolysis in type A or AB kittens born to type B queens.

CROSS-MATCHING AND BLOOD TYPING

Cross-matching is an alternative to blood typing in in-house donors or animals that have had prior transfusions, in cats, or in animals that will require multiple transfusions. Cross-matching detects many incompatibilities but does not guarantee complete compatibility. Major and minor cross-match kits are now commercially available for both dogs and cats (http://www.rapidvet.com/xmatch_info.html); this kit has recently been validated (ADD REFS PENDING). Blood compatible on cross-matching results in significantly higher post-transfusion HCTs in the recipient (Weltman et al., 2014).

Rapid, cage-side blood-typing cards for DEA 1.1 in dogs and for groups A and B in cats (RapidVet-H, DMS Laboratories, Flemington, NJ) and a gel-based system (DME VET Quick-Test DEA 1.1 and A+B, Alvedia, Limonest, France) have been validated and are now commercially available.

Interestingly, in some countries transfusing blood from dogs into cats appears to be a common emergency practice. However, the presence of strong antibodies against cat erythrocytes was recently demonstrated in dogs (Priolo et al., 2017); this procedure is strongly discouraged.

BLOOD ADMINISTRATION

Refrigerated blood may be warmed before or during administration, particularly in small dogs or cats; excessive heat should be avoided, however, because fibrinogen precipitation or autoagglutination may occur. However, warming up the blood before transfusion appears to have no effect on the recipient's core temperature, so it may not be necessary. The administration set should have a blood transfusion filter in place to remove clots and other particulate matter, such as platelet aggregates. The blood is usually administered via the cephalic, saphenous, or jugular veins. However, intraosseous infusion may be performed in small animals, neonates, or animals with poor peripheral circulation. To administer fluids or blood intraosseously, the skin over the femur is surgically prepared, and the skin and periosteum of the femoral

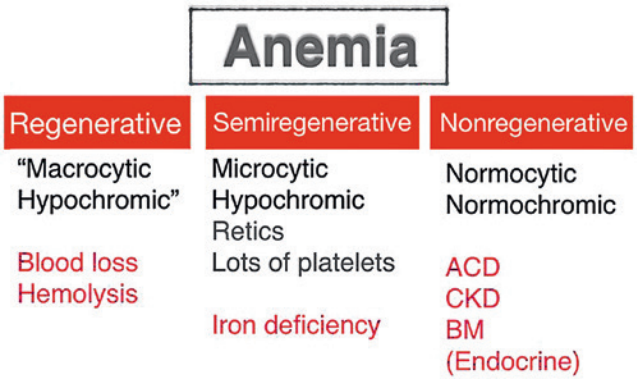

FIG 82.10
Pathogenetic classification of anemias.

trochanteric fossa are anesthetized with 1% lidocaine. A bone marrow needle (18 gauge) or intraosseus catheter is placed into the marrow cavity parallel to the shaft of the femur. Suction with a 10-mL syringe should yield marrow elements (fat, spicules, and blood), confirming correct placement of the needle. The blood is administered through a standard blood administration set.

The recommended rate of administration is variable but should not exceed 22 mL/kg/day (up to 20 mL/kg/h can be used in hypovolemic animals). Dogs and cats in heart failure may not tolerate a rate of more than 5 mL/kg/day. To prevent bacterial contamination, blood should not be exposed to room temperature during administration for longer than 4 to 6 hours; blood is considered to be contaminated if it has been at room temperature for more than 6 hours. If necessary, two smaller volumes of blood can be administered in succession. Blood should never be administered with lactated Ringer's solution because of the calcium chelation with citrate and consequent clot formation that may occur. Normal saline solution (0.9% NaCl) should be used instead. A simple rule of thumb to predict the increase in the recipient's HCT is to remember that 2.2 mL/kg (or 1 mL/lb) of transfused whole blood will raise the HCT by 1% if the donor has an HCT of approximately 40%. In cats, a unit of whole blood or pRBCs increases the recipients HCT by approximately 5% (i.e., from 10% to 15%).

COMPLICATIONS OF TRANSFUSION THERAPY

Transfusion-related complications can be divided into those that are immunologically mediated and those that are of nonimmunologic origin. Immune-mediated reactions include urticaria, hemolysis, and fever. Non–immune-mediated complications include fever or hemolysis resulting from the transfusion of improperly stored blood, circulatory overload, citrate intoxication, disease transmission, and the metabolic burden associated with the transfusion of aged blood. Signs of immediate immune-mediated hemolysis appear within minutes of the start of transfusion and include tremors, emesis, and fever; these are extremely rare in dogs but common in cats receiving incompatible blood products. Delayed hemolytic reactions are more common and are manifested primarily by an unexpected decline in the HCT after transfusion over days in association with hemoglobinemia, hemoglobinuria, and hyperbilirubinemia. Circulatory overload may be manifested by vomiting, dyspnea, or coughing. The syndrome of transfusion-associated lung injury (TRALI, a syndrome of peracute pulmonary disease associated with transfusion of blood components) was recently documented in dogs, although the prevalence is low (3.7%) (Thomovsky et al., 2014). Citrate intoxication occurs when the infusion rate is too fast or the liver cannot metabolize the citrate. Signs of citrate intoxication are related to hypocalcemia and include tremors and cardiac arrhythmias. If signs of a transfusion reaction are recognized, the transfusion must be slowed or halted.

CHAPTER 83

Clinical Pathology in Greyhounds and Other Sighthounds

Since the early 1990s, more than 250,000 retired racing Greyhounds (RRGs) have been placed in adoptive homes, and this number continues to increase each year. Practicing veterinarians are facing an increasing number of Greyhounds for routine wellness examinations and medical and surgical ailments. Consequently, they must be aware of the unique hematologic and biochemical idiosyncrasies characteristic of the breed (Zaldívar-López et al., 2011a).

The Greyhounds' history as racing sighthounds has resulted in a unique physiology that distinguishes them from other breeds. Greyhounds have larger muscle mass than most breeds; high hematocrit (HCT); lengthened carpal, tarsal, metacarpal, and metatarsal bones; and a keen sense of sight. These adaptations, among others, have likely contributed to the unique hematologic and biochemical characteristics in Greyhounds compared with non-Greyhound breeds, which have been well documented over the last 50 years. Results of routine clinical pathology tests in RRGs frequently lie outside the reference ranges for dogs. Some of the hematologic peculiarities in Greyhounds have also been described in other sighthounds. This chapter reviews clinicopathologic features specific to Greyhound dogs; these may also apply to other sighthound breeds. We recently reported hematology and chemistry reference intervals (RIs) for Deerhounds (please see Sheerer et al., 2013).

HEMATOLOGY

Although many clinicopathologic differences between Greyhounds and other breeds have been investigated, most of the research has focused on differences in hematologic values in the breed. Hematologic RIs for the breed have been published (Campora et al., 2011).

ERYTHROCYTES

Previous studies have reported that Greyhounds have a higher HCT value and hemoglobin (Hb) concentration when compared with non-Greyhound dogs. Traditionally, high HCT, Hb, and red blood cell (RBC) values have been considered an adaptation to exercise, under selective breeding for superior track performance, resulting in dogs with higher total oxygen-carrying capacity; however, numerous studies are being done to further investigate the underlying factors influencing these hematologic features in Greyhounds. The macrocytosis historically reported in Greyhounds does not appear to be reproducible with current instruments.

Pretraining Greyhounds between 9 and 10 months of age were found to already have higher HCT, Hb, and RBC values, and a tendency toward higher MCV when compared with non–breed-specific reference ranges (Shiel et al., 2007a). The selective breeding for speed in this breed is likely the cause of altered Hb function and properties because of the imperative need for an adequate oxygen supply at the tissue level under extreme conditions—that is, during the race (Zaldívar-López et al., 2011b). Greyhounds have lower Hb P_{50} values (the partial pressure of oxygen at which 50% of the Hb is saturated) than non-Greyhounds. The oxyhemoglobin dissociation curve is left-shifted; thus the Greyhound's Hb has a higher affinity for oxygen than non-Greyhounds, despite similar concentrations of RBC 2,3-diphosphoglycerate (2,3-DPG; Sullivan et al., 1994). Therefore the high Hb and HCT in Greyhounds may be a compensatory change secondary to decreased oxygen delivery to the tissues (low P_{50}), as seen in humans with high-affinity hemoglobinopathies. We recently documented that Greyhound Hb has a few unique amino acid mutations relevant to the oxygen affinity properties, changing the position of the globin chains and "hoarding" oxygen (Bhatt et al., 2011). Unpublished molecular genetics studies of Greyhound Hb have confirmed this fact.

Excited or apprehensive Greyhounds frequently have a high HCT and reticulocyte count. We demonstrated that, immediately after a race, the HCT and reticulocyte count increase proportionally for a brief period of time (60-90 minutes) (Horvath et al., 2014). This likely represents splenic release of reticulocytes in response to catecholamines.

Interestingly, the dog erythrocyte antigen (DEA) distribution is different in Greyhounds than in other breeds. In a recent study, only 13.3% of RRGs had DEA 1.1 antigen in

contrast with 60.6% in all other breeds combined; 2.9% had DEA 1.2 antigen (versus 0 in other breeds). Almost two thirds (63.4%) of the Greyhounds were considered universal donors in contrast with 18.2% in the other breeds (Iazbik et al., 2010). In contrast, approximately 50% of Galgos Españoles (Spanish Greyhounds) are positive for DEA 1.1 antigen.

LEUKOCYTES

Previous studies reported lower mean white blood cell (WBC) counts in Greyhounds compared with other breeds. As noted, adult Greyhound RIs have been established for total WBC, neutrophil, and lymphocyte counts (Campora et al., 2011). In most Greyhounds, eosinophils lack the typical orange/pink granules when using Wright-Giemsa or rapid hematology stains. These atypical eosinophils may be mistaken for toxic neutrophils on a routine blood smear stained with Diff-Quik, leading to an unnecessary search for a source of infection (Iazbik et al., 2005). These gray eosinophils also occur in some other sighthound breeds, such as Whippets, Scottish Deerhounds, and Italian Greyhounds but are uncommon in Galgos Españoles.

PLATELETS

Greyhounds have lower platelet concentrations (PLT) than dogs of other breeds (Zaldívar-López et al., 2011a). The stem cell competition model of hematopoiesis has been proposed as a possible mechanism for the low platelet count observed in Greyhounds, suggesting that bipotential stem cells within the bone marrow are programmed to become megakaryocytes or erythrocyte precursors.

Other proposed mechanisms for low platelet counts in Greyhounds include splenic or pulmonary sequestration or a chronic, low-grade, immune-mediated process leading to decreased platelet life span. Anecdotally, platelets tend to clump more in Greyhounds than in other breeds, behaving more like feline platelets. Therefore in-depth investigation of a potential underlying cause of thrombocytopenia is not necessary in healthy Greyhounds with moderate decreases in platelet count (<100,000/μL).

HEMOSTASIS

The main function of the hemostatic system is to keep the blood flowing within the cardiovascular system. The term *Greyhound bleeder* was proposed to describe dogs that tend to bleed spontaneously following minor trauma or after a simple surgical procedure (Lara-Garcia et al., 2008). Severe postoperative bleeding 1 to 4 days after limb amputation for osteosarcoma or trauma has also been reported in Greyhounds, often resulting in the need for blood component therapy during the postoperative period. Historically, Greyhounds with spontaneous bleeding have had normal platelet counts for the breed, von Willebrand factor (vWF) concentration, one-stage prothrombin time (OSPT), and activated partial thromboplastin time (aPTT) at the time of postoperative hemorrhage, making common bleeding disorders such as thrombocytopenia and clotting factor or vWF deficiencies unlikely causes of the bleeding.

When using the PFA-100 (platelet function analyzer; Dade Behring, West Sacramento, CA) to investigate primary hemostasis, healthy Greyhounds had shorter mean closure times (CTs)—the time required for a platelet plug to form in the capillary aperture and halt blood flow—than the non-Greyhound group; however, CT ranges were similar to reported values for other dog breeds (Couto et al., 2006). Surprisingly, the lower platelet counts observed in the breed were not associated with prolongation of the CT; the shorter CTs in Greyhounds are likely explained by the higher PCV, and thus viscosity, in the breed. A higher PCV and whole blood viscosity lead to peripheral platelet distribution and consequent increased interaction with the blood vessel surface. Shorter CTs in the breed may be an adaptive platelet response to accommodate higher shear in Greyhounds because Greyhounds also have significantly higher arterial blood pressure and aortic velocity than non-Greyhounds.

Thromboelastography (TEG) allows for the evaluation of blood coagulation via assessment of the speed and strength of clot formation. TEG is dependent on the function of the primary and secondary hemostatic systems and fibrinolysis, all of which can be affected by certain illnesses, environmental conditions, and pharmacologic agents. It was found that Greyhounds have slower clot kinetics and weaker clot strength when compared with non-Greyhounds (Vilar et al., 2008).

Mechanisms of postoperative bleeding have been investigated in retired racers; it was found that approximately one in four Greyhounds has moderate to severe bleeding 36 to 48 hours after routine gonadectomy (Lara-Garcia et al., 2008). Numerous parameters were used to evaluate primary and secondary hemostasis preoperatively—platelet count (PLT), OSPT, aPTT, platelet function using the PFA-100, fibrinogen (FIB), D-dimer, plasminogen, antiplasmin (AP), antithrombin (AT) levels, vWF concentration (vWF Ag), vWF collagen binding assay (vWF CBA), and factor XIII assay. Hemostasis assays were repeated in RRGs that developed bleeding complications at the time of the event, and in an age- and sex-matched control group of RRGs that underwent the same surgical procedures at the same time and did not bleed. Results from this study suggest that excessive postoperative bleeding in RRGs is not attributable to a primary or secondary hemostatic defect but may be related to altered fibrinolysis; the bleeders had lower AP levels than nonbleeders preoperatively, suggesting activated fibrinolysis and a hypocoagulable state.

CLINICAL CHEMISTRY

Several studies reported differences in specific serum biochemical values in Greyhounds when compared with those of the general canine population. Veterinarians working with Greyhounds must consider these breed-specific differences when interpreting serum chemistry profiles because

interpretation based on standard canine reference ranges may lead to misdiagnoses. These differences have been confirmed in a recent study with a large number of healthy animals, in which even narrower and therefore more breed-specific RIs were established for Greyhound biochemistry parameters (Dunlop et al., 2011).

CREATININE/SDMA

Creatinine concentrations are significantly higher in Greyhounds than in non-Greyhounds (1.6 and 1.03 mg/dL, respectively; Feeman et al., 2003). Greyhounds have considerable muscle mass and predictably have higher body stores of phosphocreatine, which may result in higher serum creatinine concentrations. Greyhounds have a higher glomerular filtration rate (GFR) than non-Greyhounds (Drost et al., 2006). Therefore the most likely cause of high serum creatinine concentrations in Greyhounds is the large muscle mass. These differences in serum urea and creatinine concentrations were recently confirmed using a large number of Greyhounds, and the study indicated even narrower RIs (11.34-26.18 and 1.12-1.98 mg/dL, respectively; Dunlop et al., 2011). Actively racing Greyhounds usually have blood urea nitrogen values above the RI for dogs, primarily because of a raw meat–based diet.

Simmetric dimethylarginine (SDMA) is an amino acid metabolite excreted exclusively by glomerular filtration (Braf et al., 2014). Shortly after this test became available recently, we noticed that results were frequently above the RI (0-14 µg/dL) in a high proportion of Greyhounds. After several studies, it is clear that the RIs for SDMA should be higher in Greyhounds; a recent study proposes using 19.9 µg/dL as the upper limit of the RI for Greyhounds) (Liffman et al., in press); this should prevent overdiagnosing renal disease in this breed.

LIVER ENZYMES

Dunlop et al. (2011) reported narrower RIs for liver enzyme levels in Greyhounds, finding higher alanine aminotransferase (ALT) activity compared with the generic canine RI. The mechanism of this change is yet to be determined.

SERUM ELECTROLYTES AND ACID-BASE BALANCE

Serum concentrations of sodium, chloride, and bicarbonate are higher in Greyhounds than in non-Greyhounds, and serum calcium (and ionized calcium), magnesium, and potassium concentrations are lower (Zaldívar-López et al., 2011a). The same study also found that Greyhounds have higher serum glucose concentrations when using a Nova analyzer (Nova Analytical Systems, Niagara Falls, NY) but lower glucose concentrations than the non-Greyhounds when using a Roche Hitachi 911 analyzer (GMI, Ramsey, MN).

Venous and arterial blood gas results in Greyhounds are presented in Table 83.1. Greyhounds have significantly higher pH, partial pressure of oxygen (P_{O_2}), oxygen saturation (S_{O_2}), oxyhemoglobin (O_2Hb), total Hb (tHb), oxygen content (O_2Ct), and oxygen capacity (O_2Cap), and significantly lower deoxyhemoglobin (HHb) and P_{50} values when compared with non-Greyhounds (Zaldívar-López et al., 2011b). These findings support the fact that this breed is able to carry a higher concentration of total oxygen in the blood. As noted, this breed also has a lower P_{50} and therefore high oxygen affinity. Current studies on hemoglobin-based oxygen carriers have revealed that in certain tissues, a high-affinity oxygen carrier is beneficial, delivering oxygen to the tissues that need it most, which would be of benefit during strenuous exercise. Although counterintuitive to traditional wisdom, these mechanisms could explain the benefits of having a high-affinity Hb.

TABLE 83.1

Venous Cooximetry and Blood Gas Reference Intervals*

PARAMETER	REFERENCE INTERVAL	
	GREYHOUNDS	NON-GREYHOUNDS
P_{O_2} (mm Hg)	36.3-84.3	34.6-69.6
P_{CO_2} (mm Hg)	25.6-39.9	24.7-44.4
S_{O_2} (%)	78.6-99.8	54.4-99.8
tHb (g/dL)	18.1-25.0	15.0-21.3
O_2Hb (%)	75.6-97.4	54.7-96.1
COHb (%)	0.9-3.9	0.4-4.5
MetHb (%)	0.0-2.2	0.1-2.8
HHb (%)	0.4-21.2	2.7-40.0
P_{50} (mm Hg)	26.0-28.4	21.4-38.4
O_2Ct (mL/dL)	19.7-32.0	13.3-24.6
O_2Cap (mL/dL)	23.8-34.1	20.2-28.5

COHb, Carboxyhemoglobin; *HHb,* deoxyhemoglobin; *MetHb,* methemoglobin; *O_2Cap,* oxygen capacity; *O_2Ct,* oxygen content; *O_2Hb,* oxyhemoglobin; *P_{CO_2},* partial pressure of carbon dioxide; *P_{O_2},* partial pressure of oxygen; *S_{O_2},* oxygen saturation; *tHb,* total hemoglobin.

*$n = 57$. These were established by our group (Zaldívar-López et al., 2011b) using the STP CCX Analyzer (Nova Biomedical, Waltham, MA).

PROTEIN

Recently published Greyhound-specific reference ranges for total protein, albumin, and globulin are 5.2 to 6.7, 2.7 to 3.7, and 2.2 to 3.3 g/dL, respectively (Dunlop et al., 2011). Thus Greyhounds have lower plasma, serum protein, and globulin concentrations.

The hypoglobulinemia in Greyhounds using serum protein electrophoresis has been investigated further (SPE; Fayos et al., 2005). The concentrations of total protein, total globulin, and α_1-, α_2-, β_1-, and β_2-globulins were significantly lower and the albumin-to-globulin ratio (A/G) was significantly higher in Greyhounds than in non-Greyhounds. No significant difference was found in albumin or γ-globulin concentrations. Possible mechanisms include chronic plasma

volume expansion associated with chronic conditioning and training; however, this mechanism does not explain why only some protein fractions are affected or why they persist after Greyhounds retired from racing. It has been recently reported that mean serum immunoglobulin A (IgA) and IgM concentrations in Greyhounds are lower than in non-Greyhounds, which may contribute to the low β-globulin concentrations in Greyhounds (Clemente et al., 2010).

The concentration of acute-phase proteins in Greyhounds has been evaluated (Couto et al., 2009). Serum concentrations of C-reactive protein (CRP), haptoglobin (Hp), acid-soluble glycoprotein (ASG), ceruloplasmin (CP), and serum amyloid A (SAA) were measured and compared between a group of healthy RRGs and age- and gender-matched healthy non-Greyhound controls. The concentrations of Hp, determined by colorimetric and immunoturbidimetric methods, and ASG were significantly lower in Greyhounds than in non-Greyhounds. CRP and CP concentrations were not significantly different between groups, and SAA concentrations were below the detection limit in all dogs. Because Hp and ASG migrate in the α-globulin fraction, results from this study may explain the low α-globulin concentrations in Greyhounds.

THYROID HORMONES

Greyhounds, Whippets, Salukis, Scottish Deerhounds, Sloughis, and other sighthound breeds have basal total T_4 (tT_4) concentrations below non–breed-specific reference ranges. Free T_4 (fT_4) concentrations can also be low, although not to the same extent as tT_4. However, thyroid-stimulating hormone (TSH) concentrations are normal; in Greyhounds, they are in the lower quartile of the RI (Shiel et al., 2007b, 2010). Highly variable triiodothyronine (T_3) concentrations have been reported; however, fT_3 concentrations in Greyhounds are usually below non–breed-specific reference ranges. No increase in the tT_4 concentration after the administration of exogenous TSH has also been described in Greyhounds (Gaughan and Bruyette, 2001). Shiel et al. (2007b) investigated thyroid hormone concentration in pretraining Greyhounds. Young pretraining Greyhounds had lower tT_4 and fT_4 concentrations and a tendency toward higher total T_3 concentrations when compared with non–breed-specific reference ranges.

A recent study by Shiel et al. (2010) retrospectively assessed the use of serum thyroid hormone concentrations by veterinarians to diagnose hypothyroidism in 398 sighthounds, including Greyhounds (n = 347) and other sighthounds such as Borzois (n = 22), Salukis (n = 11), Irish Wolfhounds (n = 14), and Scottish Deerhounds (n = 4). A cross-sectional study was also performed to assess serum thyroid hormone concentrations in healthy Salukis. Practitioners who had submitted blood samples for thyroid hormone testing had diagnosed hypothyroidism in 286 of 398 (71.9%) sighthounds on the basis of low serum concentrations of tT_4 or tT_3 alone. Seventeen sighthounds (4.3%) also had low fT_4 or fT_3 concentrations, and 30 sighthounds (7.5%) were diagnosed with hypothyroidism despite the fact that all measured thyroid hormone concentrations were within their respective reference limits. Only 65 sighthounds (16.3%) had additional abnormalities suggestive of hypothyroidism (high serum TSH concentration or positive thyroglobulin autoantibody [TGAA]). In addition, when compared with standard (non–breed-specific) reference limits, 154 of 282 Salukis (54.6%) had tT_4 values, and 67 of 216 Salukis (31%) had fT_4 values below reference limits. These findings support the fact that other sighthound breeds also have low serum tT_4 concentrations.

CARDIAC TROPONINS AND PRO-B NATRIURETIC PEPTIDE

Previously documented cardiovascular findings in healthy Greyhounds included a higher heart weight–to–body weight ratio, higher left ventricular free wall thickness, functional murmurs with no detectable structural or physiologic abnormalities, and higher vertebral heart scores (VHSs) than non-Greyhounds. Cardiac troponin I (cTnI) is a polypeptide found specifically in cardiac muscle. Serum concentrations of cTnI have been used as diagnostic and prognostic indicators of heart disease, including cardiac infarction in humans and cardiomyopathy in dogs. Greyhounds have significantly higher serum cTnI concentrations compared with non-Greyhounds; however, no significant differences in serum cTnI were noted between Greyhounds and Boxers with and without arrhythmogenic right ventricular cardiomyopathy (ARVC; LaVecchio et al., 2009). Interestingly, several Greyhounds in our study had cTnI concentrations within or above the range of Boxers with ARVC. Greyhounds with a heart murmur, high VHS, and high cTnI level could be incorrectly diagnosed with myocardial disease; thus until a more precise reference range is established, caution should be used when interpreting serum cTnI concentrations in Greyhounds with suspected cardiac disease.

N-terminal pro-B-type natriuretic peptide (NT-proBNP) is a cardiac biomarker whose plasma concentration is high in some dogs with cardiopulmonary disease. NT-proBNP is a diagnostic tool that can be used to help determine if a patient has congestive heart failure. Greyhounds have functional heart murmurs, relative cardiomegaly, and high serum cTnI concentration.

We prospectively evaluated healthy client-owned dogs including RRGs and non-Greyhounds and found that plasmaNT-proBNPconcentration in Greyhounds was significantly higher than in non-Greyhound control dogs (946 versus 632 pmol/L; $P < 0.005$); 46% of Greyhounds had NT-proBNP > 1000 pmol/L.

Again, using generic RIs for dogs will result in classifying numerous Greyhounds as having heart disease when running these assays.

Renin, Angiotensin, Aldosterone

Given that Greyhounds have unique cardiovascular features, including the fact that they have well-documented white coat hypertension, we evaluated the RAAS in 20 Greyhounds and 20 age- and weight-matched non-Greyhound dogs (Martinez

et al., 2017). The serum angiotensin-converting enzyme (ACE) activity was determined by fluorometric assay. All other RAAS hormones were determined by radioimmunoassay. Symmetric dimethylarginine (SDMA) was measured by immunoassay. Measurements were compared with blood pressure and urine albumin concentration.

Serum creatinine (1.5±0.2 versus 1.0±0.1 mg/dL, $P < 0.001$), sodium (149, range 147-152 versus 148, range 146-150 mEq/L, $P = 0.017$), and SDMA (16.1±2.9 versus 12.2±1.8 µg/dL, $P < 0.001$) concentrations were significantly higher in Greyhounds than in non-Greyhounds. Plasma renin activity (0.69, range 0.10-1.93 versus 0.65, range 0.27-2.93 ng/mL/h, $P = 0.60$) and ACE activity (4.5, range 2.1-8.5 versus 4.6, range 2.1-11.4 activity/mL; $P = 0.77$) were similar between groups and did not correlate with higher systolic pressures and albuminuria in Greyhounds. Plasma aldosterone concentration was significantly lower in Greyhounds versus non-Greyhounds (11, range 11-52 versus 15, range 11-56 pg/mL, respectively; $P = 0.002$). The lower aldosterone concentration in Greyhounds is likely an appropriate physiologic response to higher serum sodium concentration and blood pressure, suggesting that angiotensin II effects in the renal tubule predominate over those of aldosterone.

Cobalamine, Folate, and Homocysteine

Two decades ago, we made the observation that most normal RRGs had lower serum cobalamine concentreations than non-Greyhound dogs (Fig. 83.1). Recently, Grützner et al. (2012) documented that Greyhounds are the breed with the highest probability of having hypocobalaminemia. In subsequent studies, we evaluated the serum concentration of homocysteine, because in humans hypocobalaminemia and hypofolatemia have been associated with hyperhomocysteinemia. High serum homocysteine concentrations frequently result in cardiovascular disease and in thrombosis (Heilman et al., 2016). Hyperhomocysteinemia was identified in 41% of the 423 serum samples; however, it was significantly more common in Greyhounds with hypocobalaminemia and hypofolatemia (92%) than in those with normal concentrations of cobalamine and folate (61%, $P = 0.0806$). Serum homocysteine concentrations were significantly higher in healthy Greyhounds than in those with diarrhea or thrombosis; however, there were no differences in folate or cobalamine concentrations among these three groups.

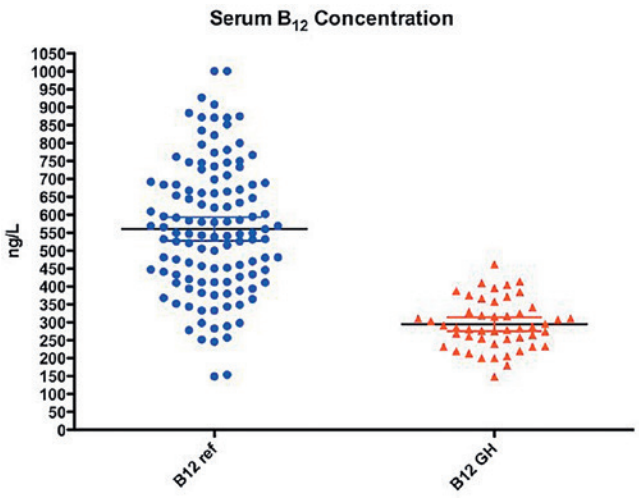

FIG 83.1
Serum cobalamin concentrations in Greyhounds and non-Greyhound dogs.

The low cobalamin and folate concentrations commonly seen in the breed should be taken into consideration when interpreting "diarrhea panels," because hypocobalaminemia and hypofolatemia are typically associated with several enteropathies, leading to unnecessary additional diagnostics in Greyhounds with diarrhea.

CLINICAL PATHOLOGY IN GREYHOUNDS: THE AUTHOR'S EXPERIENCE

Because of the well-known clinicopathologic peculiarities of this breed, the establishment of Greyhound-specific RIs has been of great interest to me for a long time. Several studies have been done involving different physiologic parameters (hematology, chemistry, coagulation, and blood gases) to help characterize these differences and establish RIs valid and specific for the breed.

The dogs used for the generation of these RIs are from two different populations. The first group is from the Greyhound Spay-Neuter-Dental Clinic at The Ohio State University for third- or fourth-year veterinary students in which Greyhounds from an adoption group (Greyhound Adoption of Ohio, Chagrin Falls, OH; www.greyhoundadoptionofoh.org) are spayed or neutered before being placed in adoptive homes. This program has a current animal use protocol (IACUC). Samples were collected over a 5-year span. The second group is the Greyhound blood donor population, which is a homogeneous population of healthy RRGs. Animals from both groups were considered healthy based on a normal physical examination and negative serology for *Ehrlichia canis, Anaplasma phagocytophilum, Borrelia burgdorferi,* and *Dirofilaria immitis* (Canine SNAP 4Dx Test, IDEXX Laboratories, Westbrook, ME).

Jugular or cephalic venous samples were collected in tubes containing sodium EDTA (for complete blood count [CBC]) and sodium citrate (for hemostasis assays), and without anticoagulant (for biochemical profiles). All CBC and hemostasis samples were analyzed within 4 hours of collection; the nonanticoagulated blood was immediately centrifuged and the serum was analyzed within 4 hours of sample collection. Samples for CBC were evaluated with LaserCyte or ProCyte Dx (IDEXX Laboratories) using the appropriate software settings. Samples with flags were not reevaluated because of a lack of additional blood samples. In a subset of dogs, CBCs were evaluated using a Cell-Dyn 3500 (Abbott Diagnostics, Santa Clara, CA). Differential WBC counts were performed manually by the staff at the Clinical

Pathology Laboratory at OSU, and plasma protein concentrations were obtained using a refractometer. The results obtained from the three hematology analyzers (CD-3500, LaserCyte, and ProCyte) are shown in Table 83.2.

The serum biochemistry profiles were determined using a COBAS c501 analyzer (Roche Diagnostics, Indianapolis; Table 83.3). For the conventional hemostasis assays (OSPT, aPTT, and FIB concentration), we used two different analyzers, the ACL 200 Coagulation Analyzer (Instrumentation Laboratory, Lexington, MA) and Stago Compact Analyzer (Diagnostica Stago, Parsippany, NJ). RIs are shown in Table 83.4.

Proposed RIs are summarized in Tables 83.1 through 83.4.

CONCLUSIONS

Greyhounds have hematologic and serum biochemical values that frequently lie outside the reference ranges established for non-Greyhounds, suggesting differences in many aspects of their physiology. For these reasons, the establishment of breed- or group-specific (e.g., sighthounds) reference ranges is essential for the correct diagnosis and subsequent treatment of medical disorders based on clinicopathologic abnormalities. As the number of RRG adoptions increases in the United States, veterinarians will be faced with the challenge of interpreting laboratory parameters in light of the hematologic idiosyncrasies of the breed. Although the sample size in these studies is not as large as recommended for the creation of RIs, approximate intervals have been provided that will benefit clinicians by providing a better understanding of the hematologic and biochemical differences between Greyhounds and non-Greyhounds, thus helping avoid misdiagnoses based on wrong RIs for these sighthound breeds.

CHAPTER 84

Erythrocytosis

DEFINITION AND CLASSIFICATION

Erythrocytosis is defined as an increase in the circulating red blood cell (RBC) mass and is manifested hematologically as an increase in the packed cell volume (PCV) or hematocrit (HCT) above the reference interval (RI). Because determination of the RBC mass in a clinical setting is cumbersome and impractical, a diagnosis of erythrocytosis is typically made on the basis of the high HCT, not an increased RBC mass. Certain dog breeds, such as most sighthounds, have HCT values above the RI for the species; this also occurs in dogs that live at high altitudes. For example, normal actively racing or retired racing Greyhounds can have an HCT as high as 70%. An increase in the RBC numbers may lead to severe hemorheologic alterations, resulting in clinical signs secondary to hyperviscosity. Although the term *polycythemia* is commonly used to refer to this hematologic abnormality, it is incorrect because the term actually means an increase in the numbers of all circulating cells ("poly" means multiple).

On the basis of its pathogenesis, erythrocytosis can be classified as relative or absolute (Box 84.1). The term *relative erythrocytosis* refers to hemoconcentration (i.e., dehydration) and is characterized by an increased PCV, usually in association with an increased serum or plasma protein concentration; in dogs and cats with relative erythrocytosis, the RBC mass is normal. Dogs with hemorrhagic gastroenteritis (HGE) frequently have relative erythrocytosis associated with normal serum or plasma protein concentration; the reason for the lack of increase in the protein concentration is unknown, but the erythrocytosis resolves with appropriate fluid therapy. In absolute or true erythrocytosis, the RBC mass is increased; it can be classified as primary or secondary depending on the pathogenesis and serum erythropoietin (Epo) concentration or activity.

Primary erythrocytosis (polycythemia rubra vera [PRV]) results from an autonomous, Epo-independent proliferation of RBC precursors in the bone marrow and is considered a myeloproliferative disease. As a consequence, most dogs and cats with PRV have low to nondetectable serum Epo concentrations. Recently, JAK2 mutations were identified in a dog with PRV (Beurlet et al., 2011); this mutation is common in humans with PRV. In a recent study, the clinical and hematologic features of 18 cats with primary erythrocytosis were reviewed (Darcy et al., 2018).

Secondary erythrocytosis results from increased orthotopic (produced by the kidneys) or heterotopic (produced in sites other than the kidneys) Epo production. Orthotopic (physiologically appropriate) Epo production occurs in response to tissue hypoxia, such as that occurring at a high altitude and in the settings of chronic cardiopulmonary disease, right-to-left cardiovascular shunts, and carboxyhemoglobinemia. Tumor-associated erythrocytosis (heterotopic or orthotopic Epo production) has been observed in humans with a wide variety of neoplasms, in dogs with renal masses, and in dogs with spindle cell sarcomas (e.g., nasal fibrosarcoma, schwannoma, cecal gastrointestinal stromal tumor). In a recent retrospective study we conducted, 15/29 (51%) of dogs with renal lymphoma had erythrocytosis. Hormonal stimuli may also trigger erythrocytosis in animals with normal tissue oxygenation, such as in dogs with hyperadrenocorticism and cats with hyperthyroidism. At the author's clinic, secondary erythrocytosis is more common in dogs, and PRV is more common in cats. However, erythrocytosis is rare in both species. Interestingly, although infiltrative renal diseases (e.g., lymphoma, feline infectious peritonitis) are common in cats, they rarely result in secondary erythrocytosis. Recently a cat with a renal adenocarcinoma and secondary erythrocytosis was reported.

Clinical and Clinicopathologic Findings

The clinical signs may occur acutely and consist primarily of functional abnormalities of the central nervous system (e.g., behavioral, motor, or sensory changes; seizures). In cats, signs of a transverse myelopathy are common; in the retrospective study of 18 cats with erythrocytosis, the most common clinical signs were seizures and mentation changes (Darcy et al., ePub ahead of print). A common manifestation of erythrocytosis in dogs is paroxysmal sneezing, likely caused by increased blood viscosity in the nasal mucosa.

BOX 84.1

Classification and Causes of Erythrocytosis in Cats and Dogs

Relative Erythrocytosis (Pseudoerythrocytosis)

Hemoconcentration

Absolute Erythrocytosis

Primary

PRV

Secondary

Appropriate (i.e., secondary to decreased tissue oxygenation)
- Pulmonary disease
- Right-to-left cardiovascular shunts
- High altitude
- Hemoglobinopathies?

Inappropriate (normal tissue oxygenation)
- Hyperadrenocorticism
- Hyperthyroidism
- Renal masses
- Neoplasms in other areas

PRV, Polycythemia rubra vera; *?,* not well documented in cats or dogs.

Cardiopulmonary signs may occasionally be present. Although the erythrocytosis usually develops gradually, most affected animals do not exhibit clinical signs until the RBCs have reached a critical mass or the PCV has reached a certain percentage. A PCV of 70% to 80% is relatively common in cats and dogs with absolute erythrocytosis. Physical examination and historical findings in dogs and cats with erythrocytosis may also include bright red mucous membranes (plethora), erythema, differential cyanosis, polyuria, polydipsia, splenomegaly, renal masses, and a neoplasm elsewhere.

Hematologic abnormalities are usually limited to the erythrocytosis and reticulocytosis (in light of a high HCT), although thrombocytosis may be present in cats and dogs with PRV. Microcytosis caused by relative iron deficiency (i.e., the erythron is extremely active and is relatively iron deficient) is common in dogs with erythrocytosis.

Diagnosis and Treatment

Relative erythrocytosis (i.e., dehydration) should be ruled out first. This is done primarily on the basis of the serum (or plasma) protein concentration, which is typically high in dogs and cats with this form of erythrocytosis. However, in certain circumstances, such as HGE, dogs may have a high HCT but a relatively normal serum protein concentration. Radioisotopic RBC mass determinations are commonly performed in humans with erythrocytosis, but this test is usually not done in small animals.

The initial approach used in small animals with absolute erythrocytosis is to decrease the blood viscosity by reducing the number of circulating RBCs. This can be accomplished by performing therapeutic phlebotomies, in which a certain volume of blood (≈20 mL/kg) is collected from a central vein through a blood collection set. In cats, a 19-gauge butterfly catheter coupled to a 60-mL syringe containing 500 to 600 U of heparin diluted in 3 to 5 mL of saline solution is typically used to collect blood from the jugular vein under chemical restraint; we use sevoflurane inhalant anesthesia. Interestingly, leeches have been used in a cat with PRV (Nett et al., 2001). Gradual phlebotomy (5 mL/kg, repeated as needed) is recommended for dogs and cats with right-to-left shunts and erythrocytosis because an increased RBC mass appears to be the body's way of enhancing oxygen delivery to the tissues, thereby compensating for the chronic hypoxemia in these animals. Because sudden decreases in blood volume can result in marked hypotension, a peripheral vein catheter can be used to administer an equivalent volume of saline solution at the same time that blood is being collected. However, collapsing episodes during or immediately after phlebotomy are extremely rare. As a result of its high viscosity in patients with erythrocytosis, it may be extremely difficult to obtain blood through a relatively small (e.g., 19-gauge) catheter.

Once the patient's condition has been stabilized, the cause of the erythrocytosis should be sought (Fig. 84.1). The following approach is recommended. The patient's cardiopulmonary status should first be evaluated by auscultation, precordial palpation, thoracic radiography, or echocardiography (see Chapters 1 and 2). An arterial blood sample should be obtained for blood gas analysis to rule out hypoxemia and pulse oximetry used to evaluate oxygenation. In some animals with erythrocytosis, the blood viscosity is so high that the blood gas analyzer, which is usually flow-dependent, cannot generate results; in this case, a therapeutic phlebotomy should be performed before a sample is resubmitted for testing (i.e., the partial pressure of oxygen, P_{O_2}, does not change after therapeutic phlebotomy). If the P_{O_2} is normal, excretory abdominal ultrasonography or computed tomography should be performed to determine whether masses or infiltrative lesions are present in the kidneys. If no such lesions are found, the patient most likely does not have renal secondary erythrocytosis, so a search for an extrarenal neoplasm should be conducted. Determination of serum Epo activity is not currently available for dogs and cats. In my experience, bone marrow evaluation of cats and dogs with erythrocytosis is unrewarding; in most cases the only abnormality is a decreased myeloid-to-erythroid ratio as a result of erythroid hyperplasia.

If PRV is diagnosed, hydroxyurea (30 mg/kg PO q24h) is administered for 7 to 10 days, after which the dosage can be gradually decreased or the dosing interval gradually lengthened to fulfill the patient's needs. Phlebotomy should be repeated as dictated by the patient's clinical signs. If the final diagnosis is secondary erythrocytosis, the primary disorder should be treated (e.g., surgery for a renal mass). The hydroxyurea protocol can also be used successfully in dogs with right-to-left shunts and secondary erythrocytosis (Moore and Stepien, 2001).

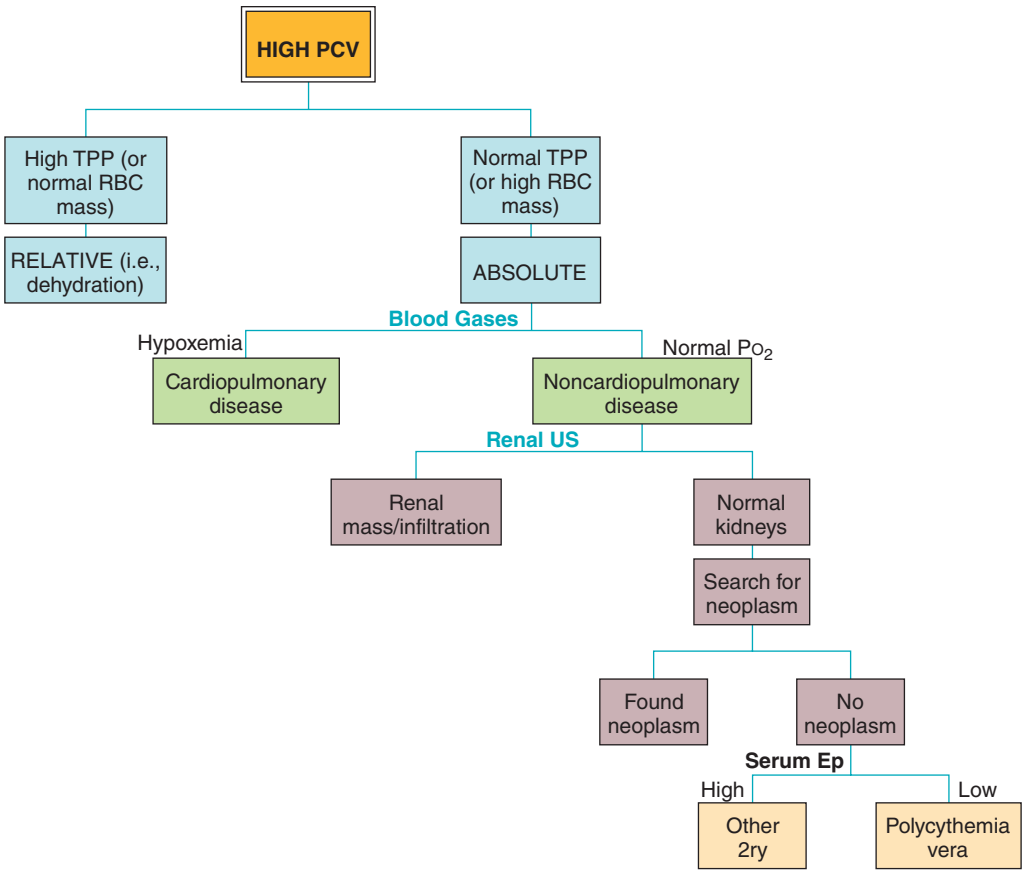

FIG 84.1
Diagnostic approach to the dog or cat with erythrocytosis. *Ep,* Erythropoietin; *PCV,* packed cell volume; *RBC,* red blood cell; *TPP,* total plasma protein; *US,* ultrasonography; *2ry,* secondary.

Most dogs and cats with PRV have extremely long survival times (>2 years) if treated with hydroxyurea, with or without a phlebotomy. Because this drug is potentially myelosuppressive, complete blood counts should be performed every 4 to 8 weeks and the dose adjusted according to the neutrophil count (see Chapter 75). The prognosis in dogs and cats with secondary erythrocytosis depends on the nature of the primary disease.

CHAPTER 85

Leukopenia and Leukocytosis

GENERAL CONSIDERATIONS

The leukogram, evaluated as part of the complete blood count (CBC), includes a quantification of the total number of white blood cells (WBCs) and the differential WBC count; ideally, it should also include morphologic leukocyte evaluation. Although a specific disorder is rarely diagnosed on the basis of the leukogram, the information obtained may be useful in limiting the number of differential diagnoses or in predicting the severity of the disease and its prognosis. In addition, sequential leukograms are helpful in monitoring a patient's response to therapy.

According to standard laboratory techniques, all nucleated cells are counted during a WBC count, including nucleated red blood cells (nRBCs). Differential leukograms determined by particle counters used at human referral laboratories are typically not valid for cats and dogs. New veterinary benchtop analyzers provide reliable WBC total and differential counts. The ProCyte Dx provides a five-part differential WBC count (neutrophils, lymphocytes, monocytes, eosinophils, and basophils) and includes flags for nRBCs and left shift or toxic neutrophils, whereas the impedance-based analyzers provide a three- or five-part differential count. As a general rule, when a benchtop hematology analyzer yields values outside the reference interval (RI) or the values are flagged, the clinician or a technician should carefully examine the graphics (see Figs. 79.6, 80.4, 80.6, 82.1, 82.3, and 82.9) and a blood smear.

Leukocytosis occurs if the WBC count exceeds the upper limit of the RI for the species; leukopenia occurs if the WBC count is below the RI. In some breeds of dogs (e.g., Belgian Tervuren, Greyhound), the WBC and neutrophil counts are frequently below the RI for the species, thus resulting in an erroneous diagnosis of leukopenia and neutropenia in an otherwise healthy dog. This should be kept in mind in dogs undergoing chemotherapy (see Chapters 75 and 76) because treatment delays based on a low WBC or neutrophil count (normal for the breed) have a detrimental effect on the patient's well being.

A differential WBC count may be reported in relative (percentages) or absolute numbers (number of cells per microliter). However, the absolute leukocyte numbers, not the percentages, should always be evaluated because the latter may be misleading, particularly if the WBC count is very high or very low. For example, a total WBC count of 3000 cells/μL (or 3×10^9/L) and a differential WBC count of 90% lymphocytes and 10% neutrophils can lead to one of the following two conclusions:

1. Based on the percentages alone, the dog has lymphocytosis and neutropenia; in this situation, the clinician may erroneously focus on the lymphocytosis rather than the neutropenia.
2. Based on the absolute numbers, the dog has severe neutropenia (300 cells/μL) with a normal lymphocyte count (i.e., 2700 cells/μL).

The latter obviously reflects the actual clinical situation. The clinician should then concentrate on determining the cause of the neutropenia and ignore the normal lymphocyte count.

NORMAL LEUKOCYTE MORPHOLOGY AND PHYSIOLOGY

From a morphologic standpoint, leukocytes can be classified as polymorphonuclear or mononuclear. Polymorphonuclear cells include the neutrophils, eosinophils, and basophils; the mononuclear cells include the monocytes and lymphocytes. Their basic morphologic and physiologic characteristics are outside the scope of this chapter.

The following morphologic changes have important clinical implications and should thus be recognized:

1. Neutrophils may become toxic in response to injury (Fig. 85.1); toxic neutrophils display characteristic cytoplasmic changes, including basophilia or granulation, vacuolation,

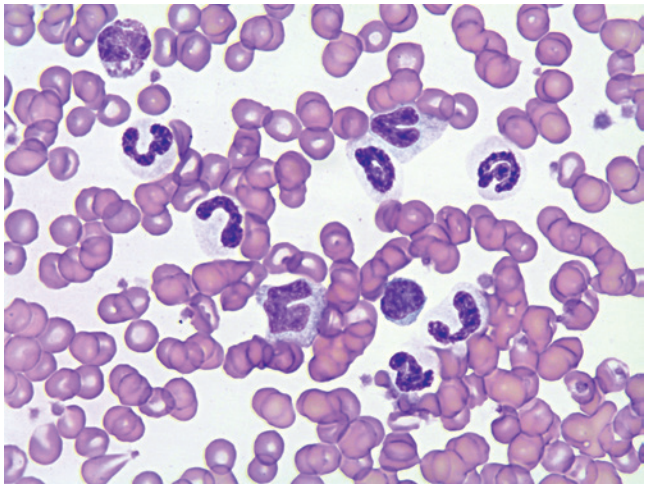

FIG 85.1
Left shift and toxic changes in a dog with an intraabdominal abscess (Diff-Quik stain; ×1000).

and Döhle bodies (small, bluish cytoplasmic inclusions that consist of aggregates of endoplasmic reticulum). This change occurs in the bone marrow and indicates that the neutrophils are "losing the battle" against the offending agent.

2. Giant neutrophils, bands, and metamyelocytes are large polyploidal cells that may result from skipped cell division; they represent yet another manifestation of systemic inflammation and are more common in cats than dogs.

Other neutrophil morphologic abnormalities recognized during a careful examination of blood smears include the Pelger-Huët anomaly (cats and dogs) and Chédiak-Higashi syndrome (cats). The Pelger-Huët anomaly occurs when the nucleus of polymorphonuclear leukocytes fails to divide, but the nuclear chromatin and cytoplasm maturation is complete (i.e., the nucleus has a band-like appearance, with mature clumped chromatin). Cats and dogs with this anomaly typically have profound "left shifts" in the absence of clinical signs. On careful examination of the smear, however, the cells in the left shift are mature cells with nuclear hyposegmentation and not immature neutrophils. This anomaly may be acquired or inherited (autosomal dominant) and is usually considered of minimal clinical relevance. We have seen it primarily in Australian Cattle dogs and in dogs undergoing chemotherapy.

Chédiak-Higashi syndrome, a lethal autosomal recessive condition of Persian cats with smoke-colored haircoats and yellow eyes, is characterized by enlarged neutrophilic and eosinophilic granules in association with partial albinism, photophobia, increased susceptibility to infections, bleeding tendencies, and abnormal melanocytes.

Nuclear hypersegmentation (i.e., four or more distinct nuclear lobes) may result from a prolonged neutrophil transit time (old neutrophils). It occurs in dogs with hyperadrenocorticism, cats and dogs receiving corticosteroid therapy, and cats and dogs with chronic inflammatory disorders.

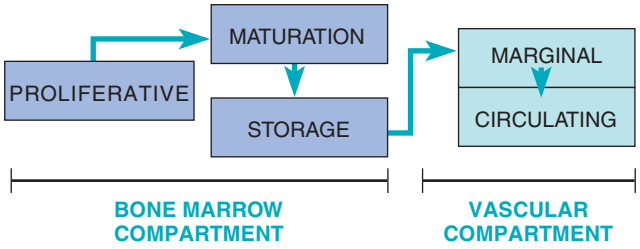

FIG 85.2
Theoretical neutrophil compartments in bone marrow and blood.

A basic review of neutrophil physiology follows. Three theoretical physiologic neutrophil compartments exist in the bone marrow (Fig. 85.2). The proliferative compartment is composed of dividing cells (myeloblasts, progranulocytes, and myelocytes); myeloblasts take approximately 48 to 60 hours to mature into metamyelocytes. The maturation compartment consists of metamyelocytes and band neutrophils; the transit time through this compartment is 46 to 70 hours. The storage compartment is composed of mature neutrophils; the transit time in this compartment is approximately 50 hours, and it contains an estimated 5-day supply of neutrophils. Mature neutrophils leave the bone marrow by a random process that involves changes in cell deformability and adhesiveness.

Two neutrophil pools are present in the vascular compartment (see Fig. 85.2). The marginal neutrophil pool (MNP) consists of neutrophils that are adhered to the vascular endothelium (and are thus not counted during a CBC). The circulating neutrophil pool (CNP) consists of the neutrophils circulating in the blood (i.e., the cells counted during a differential WBC count). The total blood neutrophil pool is composed of the MNP plus the CNP. In dogs the CNP is approximately equal in size to that of the MNP. However, in cats the MNP is approximately two to three times the size of the CNP. The neutrophil has an average blood transit time of approximately 6 to 8 hours in dogs and 10 to 12 hours in cats, with all blood neutrophils replaced every 2 to 2.5 days. Once the neutrophils leave the blood vessel (by diapedesis), they normally do not return to the circulation and are lost in the lungs, gut, other tissues, urine, or saliva.

LEUKOCYTE CHANGES IN DISEASE

Because the lower limit for the reference range for basophil and monocyte counts is 0, basopenia and monocytopenia are not discussed.

NEUTROPENIA

Neutropenia is defined as an absolute decrease in the number of circulating neutrophils. It can result from decreased (or impaired) cell production within the bone marrow or from

BOX 85.1

Causes of Neutropenia in Cats and Dogs

Decreased or Ineffective Production of Cells in the Proliferating Pool

Myelophthisis (neoplastic infiltration of the bone marrow)

Myeloproliferative disorders (D, C)
Lymphoproliferative disorders (D, C)
Systemic mast cell disease (D, C)
Malignant histiocytosis (D, C?)
Myelofibrosis (D, C)

Drug-induced neutropenia

Anticancer and immunosuppressive agents (C, D)
Chloramphenicol (C)
Griseofulvin (C)
Sulfa-trimethoprim (D, C)
Estrogen (D)
Phenylbutazone (D)
Phenobarbital (D)
Other

Toxins

Industrial chemical compounds (inorganic solvents, benzene) (D, C)
Fusarium sporotrichiella toxin (C)

Infectious diseases

Parvovirus infection (D, C)
Retrovirus infection (feline leukemia virus, feline immunodeficiency virus) (C)
Myelodysplastic or preleukemic syndromes (C)
Cyclic neutropenia (C)
Histoplasmosis (D, C)
Ehrlichiosis (D, C)
Anaplasmosis (D, C)
Toxoplasmosis (D, C)
Early canine distemper virus infection (D)
Early canine hepatitis virus infection (D)

Other

Idiopathic bone marrow hypoplasia-aplasia (D, C)
Cyclic neutropenia of gray Collies (D)
Trapped neutrophil syndrome of Border Collies (D)
Acquired cyclic neutropenia (D, C)
Steroid-responsive neutropenia (D, C)

Sequestration of Neutrophils in the Marginating Pool

Endotoxic shock (D, C)
Anaphylactic shock (D, C)
Anesthesia (D?, C?)

Sudden, Excessive Tissue Demand, Destruction, or Consumption

Infectious diseases

Peracute, overwhelming bacterial infection (e.g., peritonitis, aspiration pneumonia, salmonellosis, metritis, pyothorax) (D, C)
Viral infection (e.g., canine distemper or hepatitis, preclinical stage) (D)

- **Drug-induced disorders (D, C) (see above)**
- **Immune-mediated disorders (D, C)**
- **Paraneoplastic (D)**
- **"Hypersplenism" (D?)**

Note: Entries in **boldface** are common causes; entries in *italics* are relatively common causes; entries in regular typeface are uncommon causes.
C, Cat; *D,* dog; *?,* poorly documented.

the increased margination or destruction of circulating neutrophils (Box 85.1). Neutropenia is relatively common in cats and dogs. The clinician should keep in mind, however, that normal cats may have neutrophil counts of 1800 to 2300/μL; this reference range is also true for Greyhounds and some of the other sighthounds.

In dogs and cats evaluated in a teaching hospital (Brown and Rogers, 2001), infectious diseases (feline leukemia virus, feline immunodeficiency virus, parvovirus) were the most common comorbid conditions, accounting for almost 52% of the cases of neutropenia. Sepsis or endotoxemia accounted for 11% of the cases, as did drug-associated neutropenia (e.g., chemotherapy, phenobarbital, antibacterials); primary bone marrow disease was found in 4% of the patients. The cause of the neutropenia was unclear in 21% of the patients. Border Collies commonly have neutropenia; this syndrome has been described as the trapped neutrophil syndrome, an autosomal recessive trait caused by a mutation in the *VPS13B* gene (Mizukami et al., 2012). Steroid-responsive (immune-mediated) neutropenia is relatively common in dogs and cats. Recently, Devine et al. reviewed the records of 35 dogs with this condition (Devine et al., 2017). The most common clinical signs were lethargy/anorexia (63%), pyrexia (46%), vomiting/diarrhea (43%), pain/lameness (34%), and lymphadenopathy (17%); 11% of the dogs were asymptomatic (Devine et al., 2017). Bone marrow cytologic evaluation revealed myeloid hyperplasia in 66% and myeloid hypoplasia in 29% of the dogs; 20% of the samples had a maturation arrest. Most dogs (97%) had a rapid and sustained response to corticosteroid therapy at immunosuppressive doses; some dogs also received additional immunosuppressive drugs. The neutropenia relapsed in 34% of the dogs on discontinuation of the immunosuppressive treatment.

Clinical signs in neutropenic cats and dogs are usually vague and nonspecific; they include anorexia, lethargy, pyrexia, and mild gastrointestinal tract signs, as described

earlier. Oral ulceration, a common feature of neutropenia in humans, does not seem to occur in small animals. Neutropenia is frequently an incidental finding in an otherwise healthy dog or cat (i.e., the patient is asymptomatic). If the neutropenia is caused by peripheral neutrophil consumption (a septic process), most animals exhibit clinical signs. Dogs and cats with parvoviral enteritis have neutropenia in association with severe vomiting, diarrhea, or both. Cats and dogs with neutropenia can occasionally present in septic shock (pale, hypoperfused, hypothermic) and should be treated aggressively.

The evaluation of neutropenic cats and dogs should include the following:

- Detailed drug history (e.g., estrogen or phenylbutazone in dogs, griseofulvin in cats; see Box 85.1)
- Vaccination history (e.g., was the cat vaccinated against panleukopenia or the dog against parvoviral enteritis?)
- Complete physical examination and imaging in search of a septic focus
- Serologic, virologic, or molecular tests for infectious diseases (e.g., feline leukemia virus, feline immunodeficiency virus, canine ehrlichiosis and anaplasmosis, parvoviral enteritis, etc.)
- If necessary, bone marrow cytologic or histopathologic studies

Evaluation of changes in a blood smear or analyzer graphics is important for establishing the pathogenesis of the neutropenia. As a general rule, benchtop hematology analyzers provide total neutrophil counts and do not distinguish mature neutrophils from bands, reemphasizing the value of evaluating the blood smear. As discussed earlier, the ProCyte Dx provides a left shift flag; in addition, toxic neutrophils or bands can easily be recognized by evaluating the graphics (Fig. 85.3). If a dog or cat has anemia and/or thrombocytopenia in association with neutropenia, and if the anemia is nonregenerative, a primary bone marrow disorder should be strongly suspected. If a dog or cat has regenerative anemia and spherocytosis in association with neutropenia, an immune-mediated disease or hemophagocytic malignant histiocytosis should be considered in the differential diagnoses.

The presence of toxic changes in the neutrophils or a left shift (see later) tend to suggest infection; that is, toxic changes and left shifts are typically absent in dogs and cats with steroid-responsive neutropenia or primary bone marrow disorders. In a study of 248 dogs with toxic neutrophil changes conducted in Israel (Aroch et al., 2005), dogs with pyometra, parvoviral infection, peritonitis, pancreatitis, and septicemia were significantly, and not surprisingly, more likely to have toxic changes than those in the control group. The mortality rate was significantly higher in the dogs

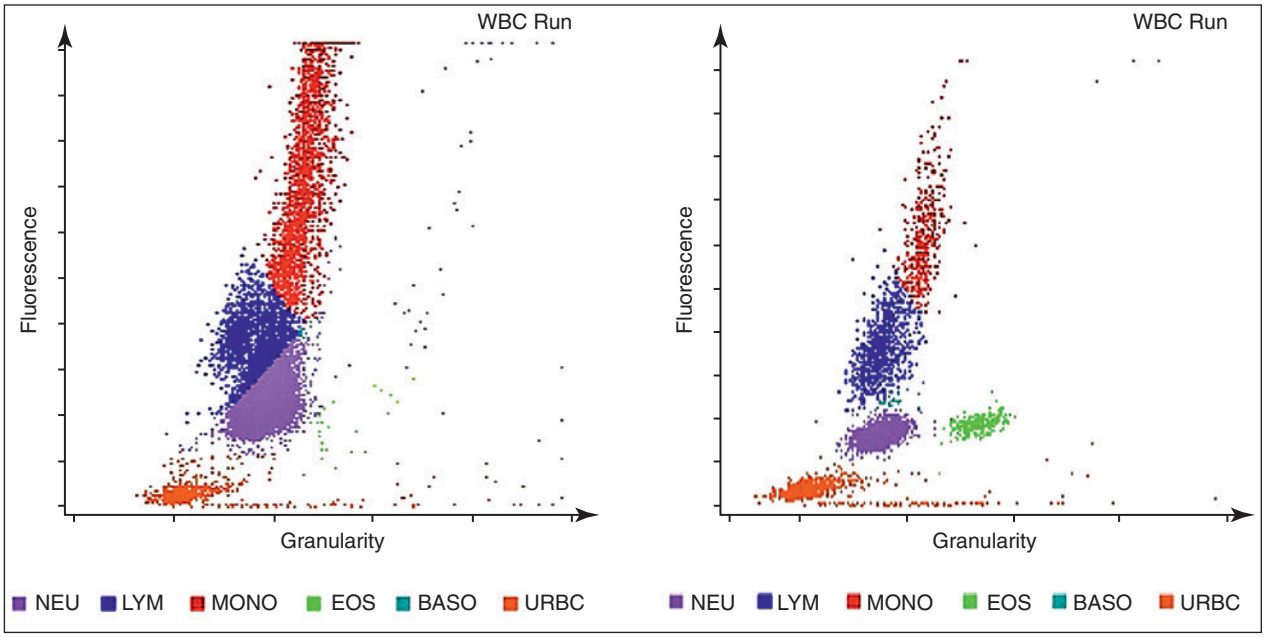

FIG 85.3
Leukocyte graphics (dot plots) from a ProCyteDx depicting left shift/neutrophil toxicity in a dog with sepsis *(left)* and in a normal dog *(right)*. Notice the absence of individual clouds and the straight line between the neutrophil *(purple)* and lymphocyte *(blue)* populations and between the lymphocyte *(blue)* and monocyte *(red)* populations. You can see the remaining normal lymphocyte population bulging on the left of the lymphocyte cloud. The wide monocyte cloud also reflects left shift/toxicity and/or activated or reactive monocytes.

with toxic neutrophils (24.2 versus 11.7%, $P < 0.001$); the cost of hospitalization was also significantly higher. Interestingly, toxic neutrophil changes were also significantly associated with acute renal failure, immune-mediated hemolytic anemia, and disseminated intravascular coagulation. Similar results were found in a study of 150 cats (Segev et al., 2006); cats with toxic neutrophils had a similar mortality rate than control cats (20% versus 15%), but the duration of hospitalization was significantly longer (3.0 versus 1.1 days).

In a recent study of 31 cats (Klainbart et al., 2017), sepsis was associated with pyothorax (32%), septic peritonitis (23%), feline panleukopenia virus infection (16%), bite wounds (16%), cellulitis/abscesses (10%), and pyometra (3%). Most cats had tachycardia and were febrile. Most cats (88%) had toxic neutrophils and/or a left shift (73%). The 30-day survival rate was 63%.

Evaluation of sequential leukograms in neutropenic dogs and cats is helpful in excluding transient or cyclic neutropenia (or cyclic hematopoiesis).

If the pathogenesis of neutropenia cannot be ascertained, sophisticated diagnostic techniques such as testing for antineutrophil antibodies, leukocyte nuclear scanning, or leukocyte kinetic studies can be performed. As noted, normal cats and Greyhounds can have low neutrophil counts. Therefore, if a cat or a Greyhound with a neutrophil count of 1800 to 2300/µL is brought in for evaluation (or, more likely, if the "neutropenia" is detected during a routine hematologic evaluation), a conservative approach (e.g., repeat the CBC in 2-3 weeks) is indicated as long as no other clinical or hematologic abnormalities are found (e.g., left shift, toxic changes).

Because corticosteroid-responsive (or immune-mediated) neutropenia has been well characterized in cats and dogs, if most infectious and neoplastic causes of neutropenia have been ruled out in an asymptomatic neutropenic animal, an in-hospital therapeutic trial of immunosuppressive doses of corticosteroids (prednisone, 2-4 mg/kg/day orally [PO] for dogs, or dexamethasone, 4 mg/cat PO once a week) can be instituted. Responses are usually observed within 24 to 96 hours of the start of treatment in these patients. Treatment is continued as for dogs with immune hemolytic anemia and other immune-mediated disorders (see Chapters 72 and 73; Fig. 85.4).

Asymptomatic, afebrile neutropenic dogs and cats should be treated with broad-spectrum bactericidal antibiotics because they are at high risk for sepsis. My drug of choice for dogs is trimethoprim-sulfamethoxazole, 15 mg/kg PO q12h; another drug that can be used in dogs and is preferred in cats is enrofloxacin (or another fluoroquinolone), 5 to 10 mg/kg PO q24h. Antibiotics with an anaerobic spectrum should not be used because they deplete intestinal anaerobes, a protective bacterial population; recent research has clearly illustrated the role of the microbiome in modulating the immune response in mammals.

Neutropenic febrile (or symptomatic) cats and dogs constitute a medical emergency and should be treated with aggressive intravenous (IV) antibiotic therapy. My treatment of choice consists of a combination of ampicillin (20 mg/kg IV q8h) and enrofloxacin (5-10 mg/kg IV q24h).

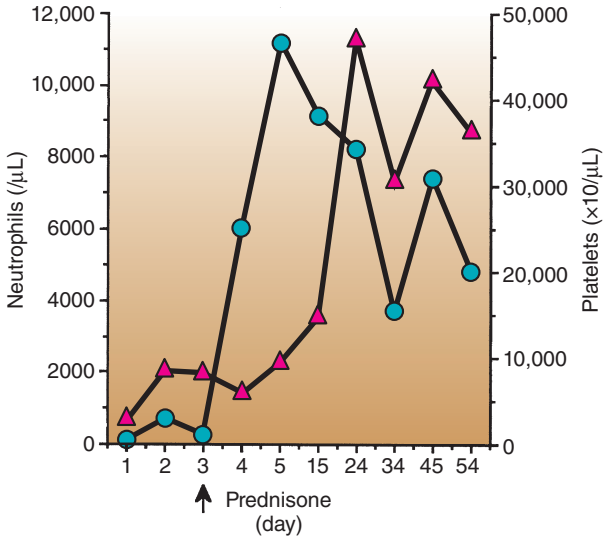

FIG 85.4
Response to therapy in a 6-year-old, female, spayed Airedale Terrier with steroid-responsive neutropenia and thrombocytopenia. Note the rapid response to immunosuppressive doses of prednisone. –•–, Polymorphonuclear neutrophils (in microliters); –Δ–, platelets ($\times 10^3/\mu L$).

Neutrophil production can be stimulated by the administration of human recombinant granulocyte colony-stimulating factor (G-CSF; 5 µg/kg subcutaneously q24h). Although results are spectacular, the responses are usually short-lived because of the counteractive effects of anti-CSF antibodies produced by the affected dog or cat. Lithium carbonate (10 mg/kg PO q12h) can increase the neutrophil counts in dogs; the therapeutic trough serum concentration of lithium is 0.8 to 1.5 mmol/L. This drug should be used with caution in dogs with a decreased glomerular filtration rate because it is primarily excreted by the kidneys. Lithium carbonate does not appear to be effective in cats and may be toxic.

NEUTROPHILIA

Neutrophilia is defined as an absolute increase in the number of neutrophils; it is the most common cause of leukocytosis in dogs and cats. Several terms used to characterize neutrophilia are defined in the following text.

The term *mature neutrophilia* refers to an increase in the number of segmented (mature) neutrophils, without an increase in the number of immature forms (e.g., bands). The term *neutrophilia with a left shift* refers to an increase in the number of mature and immature neutrophils (>300/µL, or 0.3×10^9/L bands). A regenerative left shift is associated with increased numbers of immature neutrophils in

which the number of immature forms does not exceed the number of mature neutrophils; most dogs and cats with a regenerative left shift have leukocytosis. A degenerative left shift occurs when the number of immature forms exceeds that of mature neutrophils; the number of the latter may be normal, low, or high. Degenerative left shifts are usually suggestive of an aggressive disease; toxic neutrophil changes (see earlier) are common in dogs and cats with degenerative left shifts. Disorders commonly associated with degenerative left shifts include pyothorax, septic peritonitis, bacterial pneumonia, pyometra, prostatitis, and acute pyelonephritis. The term *extreme neutrophilia* refers to situations in which the neutrophil count is above 50,000/μL (50×10^9/L); it can be associated with a left shift or mature neutrophilia. Diseases typically associated with extreme leukocytosis include septic foci (e.g., pyometra), immune-mediated diseases, hepatozoonosis, mycobacteriosis, and chronic myelogenous leukemia. A leukemoid reaction refers to a marked neutrophilia with a severe left shift, which includes metamyelocytes and myelocytes. It indicates severe inflammatory disease and may be difficult to distinguish from chronic granulocytic (myelogenous) leukemia (see Chapter 80).

Although a high percentage of cats and dogs with neutrophilia have underlying infectious disorders, neutrophilia is not synonymous with infection. Rather, neutrophilia in cats and dogs is commonly the result of inflammatory or neoplastic processes. Several disorders resulting in neutrophilia are listed in Box 85.2.

Of note, neutrophilia commonly results from endogenous epinephrine release (physiologic neutrophilia). This neutrophilia, which is associated with the release of neutrophils from the MNP, is transient (lasting 20-30 minutes after endogenous release of catecholamines) and is commonly associated with erythrocytosis and lymphocytosis, the latter primarily in cats.

The endogenous release or exogenous administration of corticosteroids results in stress- or corticosteroid-induced neutrophilia, which are associated with decreased neutrophil egress from the vasculature and increased bone marrow release of neutrophils from the storage pool. Other hematologic changes typical of a stress leukogram include lymphopenia, eosinopenia, and monocytosis; the latter is uncommon in cats. These abnormalities are commonly seen in sick dogs and cats. Dogs with hypoadrenocorticism and inflammatory/infectious diseases typically lack the neutrophilic response of normal dogs; that is, they are sick but do not have a stress leukogram.

Clinical signs in cats and dogs with neutrophilia are usually secondary to the underlying disorder. Pyrexia may or may not be present. If the patient has persistent neutrophilia, the neutrophils display toxic changes (see p. 1371), or a degenerative left shift is present, every effort should be made to identify a septic focus or an infectious agent promptly. The workup in these animals should include a thorough physical examination (e.g., abscess), thoracic and abdominal radiography (e.g., pneumonia, pleural or abdominal effusion), abdominal ultrasonography (e.g., peritonitis, pancreatic or hepatic abscess), and the collection of blood, urine, fluid, or tissue samples for cytology and bacterial and fungal cultures. As noted, autologous or allogeneic neutrophils labeled with radionuclides (e.g., technetium-99m or indium-111) can be injected intravenously and the septic focus or foci identified by gamma camera imaging, but this is rarely done; an inflammatory focus can also be detected by radiolabeled ciprofloxacin.

The treatment of dogs and cats with neutrophilia is aimed at the primary cause. Empiric antibiotic therapy with a broad-spectrum bactericidal antibiotic (e.g., trimethoprim-sulfamethoxazole, enrofloxacin, cephalosporin, amoxicillin) is an acceptable approach if a cause for the neutrophilia cannot be identified after exhaustive clinical and clinicopathologic evaluation or as the first line of treatment in a fairly asymptomatic dog or cat.

BOX 85.2

Causes of Neutrophilia in Cats and Dogs

Physiologic or Epinephrine-Induced Neutrophilia

- Fear (C)
- Excitement (?)
- Exercise (?)

Note: Entries in **boldface** are common causes; entries in *italics* are relatively common causes; entries in regular typeface are uncommon causes.
C, Cat; *D,* dog; *?,* poorly documented.

EOSINOPENIA

Eosinopenia is defined as an absolute decrease in the number of circulating eosinophils. It is commonly seen as part of the stress leukogram or with exogenous corticosteroid administration and is usually of little clinical relevance.

EOSINOPHILIA

Eosinophilia is defined as an absolute increase in the circulating eosinophil numbers. It is relatively common in small animals and can have a variety of causes (Box 85.3). Because eosinophilia is common in dogs and cats with endoparasites or ectoparasites, no animal should undergo a thorough evaluation for eosinophilia before parasitic causes have been ruled out. In cats, flea infestation usually results in marked increases in the eosinophil count (>15,000/μL, or 15×10^9/L). In dogs, eosinophilia is frequently seen in roundworm and hookworm infestations or with dirofilariasis or dipetalonemiasis. Three other relatively common causes of eosinophilia in cats include eosinophilic granuloma complex, bronchial asthma, and eosinophilic gastroenteritis. A clinical entity resembling feline hypereosinophilic syndrome has been reported in Rottweilers (Sykes et al., 2001); in addition, lesions compatible with oral eosinophilic granulomas have been reported in Siberian Huskies. Eosinophilia can also occur in dogs and cats with mast cell tumors, but it is rare. In cats, eosinophilia may occur in association with lymphoma (i.e., tumor-associated eosinophilia).

Clinical signs in dogs and cats with eosinophilia are related to the primary disorder rather than to the hematologic abnormality. Because eosinophilia is so commonly found in animals with parasitic diseases, clinical evaluation of these animals should mainly be aimed at excluding these disorders. Once this has been done, other causes of eosinophilia should be pursued (see Box 85.3) by using the appropriate diagnostic procedure (e.g., tracheal wash or pulmonary fine-needle aspiration for pulmonary infiltrates with eosinophils, endoscopic biopsy for eosinophilic gastroenteritis). Treatment is usually aimed at the primary disorder.

A syndrome with high eosinophil counts in peripheral blood and tissue infiltration with eosinophils has been well documented in cats, Rottweilers, and occasionally other dog breeds. This syndrome is termed *hypereosinophilic syndrome* and is usually indistinguishable from eosinophilic leukemia. These patients have primarily gastrointestinal tract signs, although multisystemic signs are also common. In cats, treatment with immunosuppressive doses of corticosteroids, 6-thioguanine, cytosine arabinoside, cyclophosphamide, and other anticancer agents (see Chapter 76) has been unrewarding, and most affected patients die within weeks of diagnosis. Clinical response to some of these drugs has been documented in Rottweilers.

BOX 85.3

Causes of Eosinophilia in Cats and Dogs

Parasitic Disorders

- *Ancylostomiasis (D)*
- **Dirofilariasis (D, C)**
- **Dipetalonemiasis (D)**
- **Ctenocephalides (D, C)**
- Filaroidiasis (C)
- Aelurostrongylosis (C)

- Feline urologic syndrome (C?)
- Cardiomyopathy (D?, C?)
- Renal failure (D?, C?)
- Hyperthyroidism (C?)
- Estrus (D?)

Note: Entries in **boldface** are common causes; entries in *italics* are relatively common causes; entries in regular typeface are uncommon causes.
C, Cat; *D,* dog; *?,* poorly documented.

BASOPHILIA

Basophilia is defined as an absolute increase in the basophil numbers and is commonly associated with eosinophilia. Because basophils are similar to tissue mast cells, their numbers increase in disorders characterized by excessive immunoglobulin E production and binding and in a variety of nonspecific inflammatory disorders. Causes of basophilia are listed in Box 85.4.

MONOCYTOSIS

Monocytosis refers to an absolute increase in monocyte numbers. It can occur in response to inflammatory, neoplastic, or degenerative stimuli. In some patients with acute leukemia, the WBC dot plots reveal a large monocyte cloud of abnormal configuration, even though the total monocyte numbers may be normal (see Fig. 80.4). Although monocytosis has traditionally been observed primarily in chronic inflammatory processes, it is also common in acute disorders. Causes of monocytosis in cats and dogs are listed in

BOX 85.4

Causes of Basophilia in Cats and Dogs

Disorders Associated With Immunoglobulin E Production and Binding

- Heartworm disease (**D,** C)

Box 85.5. The monocytosis in dogs is typically more pronounced than that in cats; monocytosis is extremely rare in Greyhounds.

Monocytosis is part of a stress leukogram in dogs. It can result from a variety of bacterial, fungal, and protozoal diseases. In the Midwest, systemic fungal disorders (e.g., histoplasmosis and blastomycosis) are relatively common causes. Because monocytes are precursors of tissue macrophages, granulomatous and pyogranulomatous reactions commonly result in monocytosis (see Box 85.5). In addition, immune-mediated injury resulting in cell destruction (e.g., immune hemolysis, polyarthritis) and certain neoplasms (e.g., lymphomas) may cause monocytosis. Some neoplasms secrete CSFs for monocytes and can result in marked monocytosis (>5000/μL or 5×10^9/L). Although rare, monocytic leukemia can occur.

The nature of the clinical evaluation in patients with monocytosis is similar to that used with neutrophilia: it should concentrate on identifying infectious foci. If an immune-mediated disorder is suspected, arthrocentesis to obtain fluid for analysis or other immune tests (see Chapters 69 and 71) should be performed. Treatment should be aimed at the primary disorder.

LYMPHOPENIA

Lymphopenia is defined as an absolute decrease in the lymphocyte count. It constitutes one of the most common hematologic abnormalities in hospitalized or sick dogs and cats, in which it is attributed to the effects of endogenous corticosteroids (stress leukogram). The typical lymphocyte count in a sick dog or cat is 1000 to 1500/μL. Lymphopenia is also commonly identified in dogs and cats with chronic loss of lymph, such as those with chylothorax or intestinal lymphangiectasia (Box 85.6).

In general, cats and dogs with lymphopenia have obvious clinical abnormalities. As a general rule, it should be ignored (i.e., a diagnosis should not be pursued) in sick cats and dogs and in those receiving corticosteroids or chemotherapy. The lymphocyte count should be reevaluated after the clinical abnormalities have resolved or steroid therapy has been

discontinued. Contrary to popular belief, lymphopenia does not appear to predispose to infection.

In addition, I pay particular attention to the absence of lymphopenia in a sick dog (or cat), because it suggests that there is a lymphocyte response (i.e., vector borne diseases, immune mediated diseases), that the stress leukogram is absent due to lack of corticosteroids (Addison), or that the analyzer is counting other cells as lymphocytes.

LYMPHOCYTOSIS

Lymphocytosis is defined as an absolute increase in lymphocyte numbers. It is common in several clinical situations, including fear (cats; see earlier, "Neutrophilia"), vaccination (dogs and possibly cats), chronic ehrlichiosis (dogs), anaplasmosis (dogs and cats), Addison disease (hypoadrenocorticism, dogs), and chronic lymphocytic leukemia (CLL). The lymphocytes are morphologically normal in all these disorders, with the exception of vaccination reactions, in which reactive lymphocytes (larger cells with a dark blue cytoplasm) are commonly seen. High numbers of morphologically abnormal (blast) lymphoid cells are found in dogs and cats with acute lymphoblastic leukemia (see Chapter 80).

In cats with marked lymphocytosis and neutrophilia, endogenous release of catecholamines should be ruled out as the cause of these hematologic abnormalities. If the cat is fractious and blood cannot be collected without a considerable struggle, a blood sample should be collected under chemical restraint.

Recent vaccination should be ruled out in dogs with lymphocytosis and reactive lymphocytes in the blood smear. Most dogs with lymphocyte counts of more than 10,000 cells/μL (10×10^9/L) have chronic ehrlichiosis, CLL, or leishmaniasis; dogs with monocytic ehrlichiosis or anaplasmosis frequently have increased numbers of large granular lymphocytes (LGLs), larger lymphocytes with abundant cytoplasm, and large azurophilic cytoplasmic granules. LGL lymphocytosis can also occur in dogs with CLL. Lymphocyte counts of more than 20,000 cells/μL (20×10^9/L) are extremely rare in dogs with ehrlichiosis; that is, dogs with more than 20,000 lymphocytes/μL more likely have CLL. A high proportion of these dogs also has hyperproteinemia caused by a monoclonal or polyclonal gammopathy (see Chapter 89). The clinical and hematologic features of monocytic ehrlichiosis and CLL are similar (e.g., cytopenia, hyperproteinemia, hepatosplenomegaly, lymphadenopathy). Serologic tests or polymerase chain reaction (PCR) testing for *Ehrlichia canis,* immunophenotyping of peripheral blood lymphocytes, PCR assay for clonality, and bone marrow aspiration findings may be helpful in differentiating these two disorders. Bone marrow cytologic findings in dogs with chronic ehrlichiosis usually consist of generalized hematopoietic hypoplasia and plasmacytosis, whereas hypoplasia with increased numbers of lymphocytes is more common in dogs with CLL; some dogs with CLL have normal bone marrow cytologic findings. Causes of lymphocytosis in cats and dogs are listed in Box 85.7.

CHAPTER 86

Combined Cytopenias and Leukoerythroblastosis

DEFINITIONS AND CLASSIFICATION

Combined cytopenias commonly result from decreased bone marrow (BM) production or, less frequently, from increased destruction or sequestration of circulating cells. The following terms are used throughout this chapter. *Bicytopenia* is a decrease in the numbers of two circulating blood cell lines (anemia and neutropenia, anemia and thrombocytopenia, or neutropenia and thrombocytopenia). If all three cell lines are affected (anemia, neutropenia, thrombocytopenia), this is termed *pancytopenia* (from the Greek word *pan,* meaning "all"). When evaluating a complete blood count (CBC) for leukopenia, it is best to evaluate only the neutrophils (i.e., neutropenia) because in some patients with neoplastic or reactive lymphocytosis, the total white blood cell (WBC) count may be normal or even high, but the neutrophil count is low. In most cases, if anemia is present, it is nonregenerative. If regenerative anemia occurs in association with other cytopenias, the cause usually is peripheral destruction of cells. A *leukoerythroblastic reaction* (LER, or leukoerythroblastosis) refers to the presence of immature WBCs (left shift) and nucleated red blood cells (nRBCs) in the circulation. In these cases, the WBC count is usually high, but it can be normal or low.

As noted, cytopenias can develop as a result of decreased production or increased peripheral destruction of the affected cell line(s). In general, bicytopenias and pancytopenias result from primary BM disorders (i.e., there is a problem in the "cell factory"; Box 86.1), although they may also result from peripheral blood cell destruction, such as what occurs in sepsis, disseminated intravascular coagulation (DIC), and some infectious and immune-mediated diseases.

LERs result from a variety of mechanisms (Box 86.2), but in general the presence of immature blood cells in the circulation is secondary to their premature release from the BM or from other hematopoietic organs (spleen, liver). This premature release can result from the following: (1) an increased demand for blood cells (e.g., hemolytic anemia, blood loss, peritonitis), resulting in a shorter transit time through the BM compartments or extramedullary hematopoietic sites; or (2) the crowding out of normal BM precursors (e.g., leukemia, BM lymphoma). They may also be prematurely released from a site of extramedullary hematopoiesis (EMH) (i.e., spleen, liver) as a result of the absence of normal feedback mechanisms. Because the nuclei of the nRBCs are pitted primarily in the spleen, splenectomized patients may have LERs. Recently, the presence of circulating nRBCs (normoblastemia) in dogs undergoing anticancer chemotherapy was well characterized (Moretti et al., 2015). In addition, normoblastemia is commonly seen in healthy Miniature Schnauzers and in Dachshunds.

CLINICOPATHOLOGIC FEATURES

The clinical signs and physical examination findings in dogs and cats with combined cytopenias or LERs are usually related to the underlying disorder rather than the hematologic abnormalities per se, with the exception of pallor and spontaneous bleeding (petechiae, ecchymoses) secondary to anemia and thrombocytopenia, respectively. Pyrexia may be present if the patient is markedly neutropenic and is septic or bacteremic.

An important aspect of the clinical evaluation of these patients is the history. A detailed history should be obtained, inquiring specifically about the therapeutic use of drugs (e.g., estrogen or phenylbutazone in dogs, griseofulvin or chloramphenicol in cats), exposure to benzene derivatives (rare), travel history, vaccination status, and exposure to other animals, among others. Most drugs that cause anemia or neutropenia can also cause combined cytopenias (see Boxes 82.2 and 85.1).

The physical examination of dogs and cats with combined cytopenias may reveal the presence of spontaneous hemorrhages compatible with a primary hemostatic disorder (e.g., thrombocytopenia) or pallor secondary to the anemia. Several physical examination findings may help the clinician establish a more presumptive or definitive diagnosis in patients with cytopenias or LER. Of particular interest is the finding of male-feminizing signs in a male dog (usually

a cryptorchid) with pancytopenia, which may indicate the presence of a Sertoli cell tumor or, less frequently, an interstitial cell tumor or a seminoma with secondary hyperestrogenism. The finding of generalized lymphadenopathy, hepatomegaly or splenomegaly, or intraabdominal or intrathoracic masses may direct the clinician toward a specific group of presumptive diagnoses. For example, the finding of a cranial or midabdominal mass in a dog with regenerative anemia, thrombocytopenia, and LER is highly suggestive of splenic hemangiosarcoma.

The presence of diffuse splenomegaly suggests that the spleen may be sequestering or destroying circulating blood cells or that EMH is occurring in response to a primary BM disorder. Cytologic evaluation of spleen specimens obtained by percutaneous fine-needle aspiration is always indicated in dogs and cats with cytopenias and diffuse splenomegaly to determine whether the enlarged spleen is the cause or consequence of the cytopenia (see Chapter 88).

Serologic studies and/or polymerase chain reaction (PCR) assays for infectious diseases is usually indicated in dogs and cats with bicytopenias or pancytopenias. Infectious diseases associated with bicytopenias and pancytopenias commonly diagnosed on serologic or PCR results include monocytic ehrlichiosis in dogs, anaplasmosis in dogs and cats, *Babesia gibsoni* infection in dogs (usually in Pitbulls, where there is combined regenerative anemia and thrombocytopenia), leishmaniasis in dogs (and occasionally in cats), systemic mycoses (i.e., histoplasmosis) in cats (and rarely in dogs), and feline leukemia virus (FeLV) and feline immunodeficiency virus infections in cats. If the clinical and hematologic features of the case point toward an immune-mediated disease (e.g., presence of polyarthritis or proteinuria, spherocytosis), a direct Coombs test and antinuclear antibody test should be done (see Chapter 71). It is also helpful to submit fluid obtained from one or more joints for cytologic evaluation because the presence of suppurative nonseptic arthritis suggests an immune pathogenesis or a vector-borne disease.

Because establishing whether the cytopenia is the result of peripheral cell destruction or a BM disorder is important,

*Hematopoiesis may play a role in the pathogenesis of the LER in several of the disorders mentioned in the text.

evaluation of the cell factory is logical if no evidence of RBC regeneration in the blood smear or CBC exists (see Chapter 82). Therefore BM aspiration and, ideally, BM core biopsy to obtain specimens for histopathologic studies should be performed in all dogs and cats with combined cytopenias, except for dogs with highly likely or confirmed Evans syndrome and dogs and cats with DIC; that is, the anemia is regenerative, so it is assumed that the factory is working properly. Algorithms for the evaluation of BM findings in dogs and cats with bicytopenia and pancytopenia are shown in Figs. 86.1 and 86.2. In private practice, obtaining a BM aspirate is usually easier; BM core biopsies are usually performed at specialty practices.

A BM evaluation should also be part of the clinical workup in animals with LERs to determine whether the immature WBCs and RBCs in the circulation are secondary to a primary BM disorder or a disorder such as EMH. Because abdominal neoplasms, particularly hemangiosarcoma, are commonly associated with LERs in dogs, abdominal ultrasonography should be done. If diffuse splenomegaly is detected, percutaneous fine-needle aspiration of the spleen should be performed. If splenic or hepatic masses or both are present, the patient should be evaluated as described in Chapter 78.

Abrams-Ogg et al. (2012) evaluated the use of a 15-gauge needle and power driver in comparison to a standard

13-gauge Jamshidi needle to obtain BM biopsies in experimental Beagles. Use of a 15-gauge needle to obtain a humeral BM biopsy was significantly easier than obtaining a humeral BM biopsy using a 13-gauge needle or an iliac BM biopsy using a 15-gauge needle. The quality of the biopsies obtained with a 13-gauge needle was better than for biopsies of the humerus or ilium using a 15-gauge needle. Only sites sampled with a 13-gauge needle were identifiable grossly after the procedure. In most biopsies, cell density and cellularity were lower when a 15-gauge needle was used.

Weiss (2006) reviewed BM aspirates, core biopsies, and medical records of 717 dogs evaluated for presumptive BM disorders. Approximately 2% of the specimens evaluated were nondiagnostic, 22% were normal, 26% had changes secondary to another primary disease, 24% had nondysplastic and nonneoplastic conditions, 9% had dysplasia, and 18% had neoplasia. Less than 5% of the specimens evaluated had BM hypoplasia and approximately 20% were hyperplastic; acute leukemias were more common than chronic leukemias.

Turinelli et al. recently reviewed the cytomorphologic findings in BM aspirates in both dogs (Turinelli et al., 2015) and cats (Turinelli and Gavazza, 2018). Seventy percent of 295 canine BM samples were diagnostic; 25% were classified as BM (myeloid and or erythroid) hyperplasia, 19.3% were normal, 12.9% had hematopoietic malignancy, 7.8% had aplasia/hypoplasia, and 1.3% had dysplasia. In cats, 46.7% of 152 BM samples were classified as hyperplastic, 15.1% were dysplastic, 13.8% were normal, 11.2% were hematopoietic malignancies, and 9.9% were aplastic/hypoplastic (Turinelli and Gavazza, 2018).

BONE MARROW APLASIA-HYPOPLASIA

BM aplasia-hypoplasia is a disorder characterized by peripheral blood cytopenias and a paucity or absence of hematopoietic precursors in the BM. As noted, BM aplasia-hypoplasia is commonly associated with the administration of certain drugs, such as griseofulvin or chloramphenicol in cats and phenylbutazone or estrogen in dogs. It is also commonly associated with infectious diseases, such as canine monocytic ehrlichiosis, leishmaniasis, and FeLV infection. A corticosteroid-responsive syndrome of combined cytopenias or pancytopenia has been recognized in dogs and cats in our clinic. Some of these patients with pancytopenia have hypercellular BM (see later), suggesting that the cells are destroyed peripherally or at the late stages of BM production.

BM aspirates from dogs and cats with BM aplasia or hypoplasia typically show hypocellularity or acellularity, and a BM biopsy is frequently necessary to obtain specimens for histopathologic analysis so that a definitive diagnosis can be made. Once infectious diseases (e.g., *Ehrlichia canis* titer or rapid assay, FeLV p27 determination) and drug exposure

have been ruled out, a therapeutic trial of immunosuppressive doses of corticosteroids (with or without other immunosuppressive drugs; see Chapter 72) may be warranted. Anabolic steroids and erythropoietin do not appear to be beneficial in these patients.

Myelophthisis

Infiltration of the BM with neoplastic or inflammatory cells can lead to the crowding out of normal hematopoietic precursors and therefore the development of peripheral blood cytopenias. Disorders resulting in myelophthisis are listed in Box 86.1. Often these animals are evaluated because of anemia, although fever and bleeding caused by neutropenia and thrombocytopenia, respectively, can also be presenting complaints. The presence of hepatomegaly, splenomegaly, or lymphadenopathy in a dog or cat with anemia or combined cytopenias is highly suggestive of some of the neoplastic or infectious disorders listed in Box 86.1.

A definitive diagnosis in dogs and cats with myelophthisis is obtained by evaluating the cytologic or histopathologic characteristics of a BM specimen. Given the fact that certain neoplastic or granulomatous disorders can show a patchy or multifocal distribution, the findings yielded by a BM core biopsy specimen are usually more reliable than those yielded by an aspirate. Once a cytologic or histopathologic diagnosis is obtained, treatment is aimed at the primary neoplasm (i.e., with chemotherapy) or infectious agent (see specific sections for detailed discussion).

MYELODYSPLASTIC SYNDROMES

Myelodysplastic syndromes (MDSs) include a host of hematologic and cytomorphologic changes that may precede the development of acute leukemias by months or years; in humans, they are associated with specific molecular genetic changes. In addition to the morphologic abnormalities in blood and BM, functional abnormalities of granulocytes and platelets have been documented in humans with MDS. Therefore recurrent infections, spontaneous bleeding tendencies, or both are common in these patients, even when the neutrophil and platelet counts are within normal limits. These abnormalities have also been observed in cats with MDS.

MDS has been recognized in dogs and cats but appears to be more common in retrovirus-infected cats. In dogs, clinical signs are nonspecific and include lethargy, depression, and anorexia. Physical examination findings include hepatosplenomegaly, pallor, and pyrexia; hematologic changes include pancytopenia or bicytopenia, macrocytosis, normoblastemia, and reticulocytopenia. Acute myelogenous leukemia (AML) subsequently developed 3 months after the initial diagnosis of MDS in one patient (Couto et al., 1984). The cytologic BM abnormalities were similar to those described in cats (see later). Some authors have proposed classifying dogs with primary MDSs into those with refractory anemia and those with true myelodysplasia, following similar classification schemes used in humans. However, because almost no clinical information was provided for the dogs that were evaluated, that classification scheme is of questionable clinical relevance.

Several reports of MDS in cats have appeared in the literature. More than 80% of cats in whom the FeLV status was investigated were found to be viremic. Most cats were evaluated because of nonspecific clinical signs such as lethargy, weight loss, and anorexia. Other signs, such as dyspnea, recurrent infections, and spontaneous bleeding, were observed in a few cats. Physical examination revealed hepatosplenomegaly in more than half of the cats; generalized lymphadenopathy and pyrexia were detected in approximately one third. In my experience, secondary myelodysplasia associated with infectious, inflammatory, or immune-mediated diseases is quite common in cats, so a cytologic diagnosis of MDS should be interpreted with caution (i.e., it is not always a "death sentence"), and a search for comorbidities should be conducted.

Hematologic abnormalities in cats with MDS are similar to those seen in dogs; they include isolated or combined cytopenias, macrocytosis, reticulocytopenia, metarubricytosis, and macrothrombocytosis. Morphologic changes in the BM include a normal to increased cellularity, less than 30% blasts, an increased myeloid-to-erythroid ratio, dyserythropoiesis, dysmyelopoiesis, and dysthrombopoiesis. Megaloblastic RBC precursors are common, with occasional binucleated, trinucleated, or tetranucleated rubricytes or metarubricytes. The morphologic abnormalities in the myeloid cell line include giant metamyelocytes and asynchronous nuclear-cytoplasmic maturation.

Acute leukemia subsequently developed within weeks to months of the diagnosis in approximately one third of cats with MDS described in the literature. MDS commonly progresses to AML in humans, with only isolated reports of progression to acute lymphocytic leukemia (ALL). However, according to Maggio et al. (1978), in one series of 12 cats with MDS, ALL subsequently developed in 9. This may reflect the fact that cytochemical staining was not done to classify the leukemic cells, and cells were thus morphologically classified as lymphoid when they were myeloid. However, because all the cats that showed progression to ALL were also viremic with FeLV, the hematologic changes preceding the development of leukemia did not reflect a "spontaneous" hematologic disorder (as seen in human beings and dogs) but were rather a manifestation of the morphologic and functional changes induced by FeLV.

The management of dogs and cats with MDS is still controversial. A variety of treatments have been used in humans with MDS, but none has proved effective. Chemotherapy, supportive therapy, anabolic steroids, inductors of differentiation, hematopoietic growth factors, and androgenic steroids, among others, have been reported to be of benefit in some humans with MDS. Currently, the preferred approach in humans is treatment with supportive therapy and inductors of differentiation or hematopoietic growth factors. Because most patients are older, chemotherapy does not constitute the first treatment option, given its toxicity. I recommend supportive therapy (e.g., fluids, blood components, antibiotics) and low-dose cytosine arabinoside as an

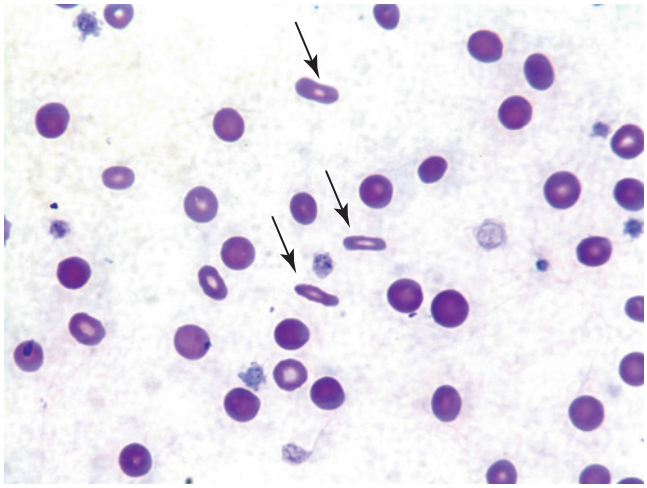

FIG 86.3
Elliptocytosis in an Airedale Terrier with myelofibrosis. Elliptocytes *(arrows)* are intermixed with normal RBCs and spherocytes. The patient had complete resolution of the hematologic and morphologic RBC changes after treatment with corticosteroids and azathioprine (Wright-Giemsa stain; ×1000).

inductor of differentiation (see Box 80.3). Novel therapeutic approaches in humans with MDS include primarily targeting the MDS clone or using nonspecific azanucleosides such as azacytidine, targeted molecular therapy, immunotherapy, and hypomethylating agents.

MYELOFIBROSIS AND OSTEOSCLEROSIS

Fibroblasts or osteoblasts within the BM can proliferate in response to retroviral infections, chronic noxious stimuli, or unknown causes, leading to fibrous or osseous replacement of the BM cavity, thereby displacing the hematopoietic precursors. These syndromes are termed *myelofibrosis* and *osteosclerosis,* respectively. Although both syndromes are rare, they have been observed in FeLV-infected cats and in dogs with chronic hemolytic disorders, such as the pyruvate kinase deficiency anemia. Peripheral blood elliptocytosis and dacryocytosis appear to be a common feature in dogs with myelofibrosis (Fig. 86.3). A limited number of dogs and cats with idiopathic myelofibrosis have been reported; in some of these cases, previous exposure to drugs (e.g., phenobarbital, phenytoin, phenylbutazone, colchicine) was documented. In my experience, the clinical and hematologic features associated with myelofibrosis in dogs frequently resolve after immunosuppressive treatment with a combination of corticosteroids and azathioprine (see Chapter 72).

A presumptive diagnosis of osteosclerosis or osteopetrosis is made on the basis of the presence of combined cytopenias together with increased osseous radiographic density and can be confirmed by a core biopsy of the BM. Unfortunately, no effective treatment is currently available.

CHAPTER 87

Disorders of Hemostasis

GENERAL CONSIDERATIONS

Spontaneous or excessive bleeding is relatively common in dogs and rare in cats. As a general rule, a systemic hemostatic abnormality is the underlying cause of excessive bleeding in dogs and cats that have sustained trauma or are undergoing a surgical procedure, and in dogs evaluated because of spontaneous bleeding tendencies. Spontaneous bleeding disorders are extremely common in dogs evaluated at our clinic but are rare in cats. Approaching these patients' bleeding in a logical and systematic fashion allows the clinician to confirm the presumptive diagnosis in most cases.

In addition to bleeding, abnormal hemostatic mechanisms can also cause thrombosis and thromboembolism (TE), potentially leading to organ failure. Thromboembolic disorders are rare in dogs and cats without underlying cardiovascular disorders (e.g., cats with hypertrophic cardiomyopathy and aortic TE; see Chapter 12), but they are now increasingly being recognized and documented in dogs with liver disease, protein losing nephropathy, endocrinopathies, and other diseases.

The most common disorder leading to spontaneous bleeding in dogs seen at our clinic is thrombocytopenia, mainly due to immune-mediated mechansims. Other common hemostatic disorders leading to spontaneous bleeding in dogs evaluated at our hospital include disseminated intravascular coagulation (DIC) and rodenticide poisoning. Congenital clotting factor deficiencies resulting in spontaneous bleeding are rare. Although von Willebrand disease (vWD) is common in certain breeds (see p. 1398), it is not a common cause of spontaneous bleeding in our patients. Abnormalities in hemostasis screens are frequently noted in cats with liver disease, feline infectious peritonitis (FIP), or neoplasia; however, spontaneous or intra- or postoperative bleeding tendencies are extremely rare in these patients. Decreased production of platelets (thrombocytopenia) or virus-induced thrombocytopathia resulting in spontaneous bleeding is occasionally seen in cats with retrovirus-induced bone marrow disorders.

PHYSIOLOGY OF HEMOSTASIS

Under normal conditions, injury to a blood vessel leads to immediate vascular changes (e.g., vasoconstriction) and rapid activation of the hemostatic system. Changes in axial blood flow lead to exposure of circulating blood to subendothelial collagen, resulting in the rapid adhesion of platelets to the affected area. The adhesion of platelets to the subendothelium is mediated by adhesive proteins, such as von Willebrand factor (vWF) and fibrinogen, among others. After adhering to the area of endothelial damage, platelets aggregate and form the primary hemostatic plug, which is short-lived (seconds) and unstable. The primary hemostatic plug serves as a framework in which secondary hemostasis occurs because most of the clotting factors assemble the thrombus or clot on the platelet plug.

Although the intrinsic, extrinsic, and common coagulation pathways have been well characterized and are still used to teach physiology of hemostasis, coagulation in vivo does not necessarily follow these distinct pathways. Also, the cellular and biochemical phases of coagulation occur almost simultaneously. For example, factors XII and XI do not appear to be necessary for the initiation of coagulation; for example, dogs and cats with factor XII deficiency do not have spontaneous bleeding tendencies. It is now generally accepted that the physiologic mechanism responsible for clotting in vivo is primarily tissue factor (TF) activation of factor VII. In the past 2 decades, the traditional coagulation cascade has been thought of as a common pathway from early in the process; the traditional intrinsic, extrinsic, and common pathways are now known to be interrelated (Furie and Furie, 2008).

In the traditional scheme, activation of the contact phase of the coagulation cascade occurs almost simultaneously with platelet adhesion and aggregation (Fig. 87.2) and leads to the formation of fibrin through the intrinsic coagulation cascade. A good mnemonic is to refer to the intrinsic system as the "dime store" coagulation cascade: "It is not $12, but $11.98" (for factors XII, XI, IX, and VIII). Factor XII is activated by contact with the subendothelial collagen and

by the platelet plug; once it has been activated, fibrin, or the secondary hemostatic plug, forms. Prekallikrein (Fletcher factor) and high-molecular-weight kininogen (HMWK) are important co-factors for factor XII activation. The role of the contact phase of coagulation in vivo is questionable. The secondary hemostatic plug is stable and long-lasting. In addition, whenever tissue trauma occurs, the release of tissue procoagulants (collectively referred to as TF) results in activation of the extrinsic coagulation cascade, also leading to the formation of fibrin (see Fig. 87.2). As discussed earlier, all these steps occur almost simultaneously, and fibrin formation starts within seconds of the endothelial damage. TF is ubiquitous and present on the membrane of most cells, with the exception of normal endothelium. As noted, this pathway is now thought to be responsible for initiating clotting in mammals.

The stimuli that activate coagulation also activate the fibrinolytic and kinin pathways. Fibrinolysis is extremely important as a safeguard mechanism because it prevents excessive clot or thrombus formation. When plasmin lyses fibrinogen and fibrin, it generates fibrin degradation products (FDPs), which impair additional platelet adhesion and aggregation in the site of injury. Once fibrin has been stabilized by complexing factor XIII, plasmin biodegradation generates D-dimers instead. The activation of plasminogen into plasmin results in the destruction (lysis) of an existing clot (or thrombus) and interferes with the normal clotting mechanisms—inhibition of platelet aggregation and clotting factor activation in the affected area. Therefore excessive fibrinolysis usually leads to spontaneous bleeding. Two molecules stimulate plasminogen activation into plasmin, tissue plasminogen activator (tPA) and urokinase-type plasminogen activator. Three plasminogen activator inhibitors (PAIs), PAI-1, PAI-2, and PAI-3, inhibit fibrinolysis, thus leading to thrombosis.

Other systems that oppose blood coagulation also become operational once intravascular clotting has occurred. The best characterized include antithrombin (AT), a protein synthesized by hepatocytes that acts as a co-factor for heparin and inhibits the activation of factors IX, X, and thrombin. AT also inhibits tPA. Proteins C and S are two vitamin K–dependent anticoagulants also produced by hepatocytes. These three factors are some of the natural anticoagulants that prevent excessive clot formation.

CLINICAL MANIFESTATIONS OF SPONTANEOUS BLEEDING DISORDERS

In the evaluation of a cat or dog with spontaneous or excessive bleeding, the clinician should ask the owners the following questions, which may provide additional clues to the pathogenesis of the coagulopathy:

- Is this the first bleeding episode? If it is occurring in a mature animal, an acquired coagulopathy is suspected. (*Note:* We have seen dogs with hemophilia A present with their first bleeding episode at 8 years of age.)
- Has the patient had any surgeries before this and, if so, did it bleed excessively? If the pet has had previous bleeding episodes during elective surgeries as a young animal, a congenital coagulopathy is suspected.
- Do any littermates have similar clinical signs? Did the litter have an increased perinatal mortality rate? These findings also support a congenital coagulopathy.
- Has the animal recently been vaccinated with modified-live vaccines? Modified-live vaccines can cause thrombocytopenia, platelet dysfunction, or both.
- Is the patient currently receiving any medication that may cause thrombocytopenia or platelet dysfunction (e.g., nonsteroidal antiinflammatory drugs [NSAIDs], sulfas, antibiotics, phenobarbital)?
- Does the patient have access to rodenticides or does it roam freely? This may indicate rodenticide toxicity.

The clinical manifestations of primary hemostatic abnormalities are different from those of secondary hemostatic abnormalities (Box 87.1). The clinician should be able to classify the type of coagulopathy on the basis of the physical examination findings before submitting any samples for clinicopathologic evaluation. This is easy to conceptualize by thinking about the normal coagulation mechanisms. For example, a functional primary hemostatic plug cannot form in a cat or dog with severe thrombocytopenia or platelet dysfunction. Because this plug is short-lived and eventually covered with fibrin (generated through the secondary hemostatic mechanisms), the patient experiences multiple, short-lived bleeds that are arrested as soon as fibrin is formed, resulting in multiple small and superficial hemorrhages around blood vessels. This is analogous to turning on and off a faucet connected to a garden hose with multiple perforations (an irrigator); multiple spurts of water (blood) form adjacent to the hose (the vessel; Fig. 87.3, *A*). On the other hand, a short-lived primary hemostatic plug can form in a cat or dog with severe clotting factor deficiencies (e.g., hemophilia, rodenticide poisoning); enough functional platelets are present, but fibrin cannot be generated. The result of this

BOX 87.1

Clinical Manifestations of Primary and Secondary Hemostatic Defects

Primary Hemostatic Defect

Petechiae common
Hematomas rare
Bleeding in skin and mucous membranes
Bleeding immediately after venipuncture

Secondary Hemostatic Defect

Petechiae rare
Hematomas common
Bleeding into muscles, joints, and body cavities
Delayed bleeding after venipuncture

is a delayed, continuous, long-lasting bleed, leading to hematoma formation or bleeding into a body cavity. This is analogous to turning on a faucet connected to a regular garden hose with a single large opening; in this situation, water (blood) continues to flow and collect in large amounts next to the opening in the hose (vessel; see Fig. 87.3, *B*).

Spontaneous bleeding infrequently occurs in cats and dogs with excessive fibrinolysis. I have evaluated a limited number of dogs with protein-losing nephropathy and nephrotic syndrome in which spontaneous bleeding (i.e., petechiae and ecchymoses) appeared to result from enhanced fibrinolysis. However, fibrinolysis is relatively difficult to evaluate using laboratory methods other than thromboelastography (TEG), so additional data are being currently generated on this area.

Dogs (and cats) with primary hemostatic defects (i.e., platelet disorders) therefore have typical manifestations of superficial bleeding, consisting of petechiae, ecchymoses, bleeding from mucosal surfaces (e.g., melena, hematochezia, epistaxis, hematuria), and prolonged bleeding immediately after venipuncture. In clinical practice, most primary hemostatic disorders are caused by decreased numbers of circulating platelets (thrombocytopenia). Recently, a bleeding score for thrombocytopenic dogs was proposed for dogs (Makielski et al., 2018). Primary hemostatic defects occasionally result from primary or secondary platelet dysfunction (e.g., uremia, vWD, monoclonal gammopathies, vector-borne diseases). Primary hemostatic defects caused by vascular disorders are extremely rare in cats and dogs and will not be discussed.

Clinical signs in dogs and cats with secondary hemostatic defects (i.e., clotting factor deficiencies) consist of deep bleeding, including bleeding into body cavities and joints, and deep hematomas, most of which are discovered as a lump or mass. Certain congenital coagulopathies, including factor XII, prekallikrein, and HMWK deficiencies, result in a marked prolongation of the activated coagulation time (ACT) or activated partial thromboplastin time (aPTT) without spontaneous or prolonged bleeding (see later).

Most secondary bleeding disorders seen in clinical practice are caused by rodenticide poisoning or liver disease; selective congenital clotting factor deficiencies occasionally can lead to spontaneous secondary bleeding disorders. A combination of primary and secondary bleeding disorders (mixed disorders) is seen almost exclusively in dogs and cats with DIC.

We recently described a syndrome of delayed postoperative bleeding in former racing Greyhounds that occurs in approximately 25% to 30% of dogs who undergo surgery. It consists of superficial bleeding around the surgical site starting 36 to 48 hours after the surgery, which becomes systemic and is often life-threatening (Lara García et al., 2008; Marin et al., 2012a and b). We have also observed a similar syndrome in other sighthound breeds, including Deerhounds and Italian Greyhounds. For additional discussion, see Chapter 83.

CLINICOPATHOLOGIC EVALUATION OF THE BLEEDING PATIENT

Clinicopathologic evaluation of the hemostatic system is indicated primarily in two subsets of patients: in those with spontaneous or prolonged bleeding, and before surgery in patients with disorders commonly associated with bleeding tendencies (e.g., splenic hemangiosarcoma [HSA] and DIC in dogs; liver disease and clotting factor deficiency in dogs and cats) or a suspected congenital coagulopathy (e.g., before ovariohysterectomy in a Doberman Pinscher suspected of having subclinical vWD).

When evaluating a cat or dog with a spontaneous bleeding disorder, the clinician should keep in mind that the preliminary clinical diagnosis can usually be confirmed by performing some simple point-of-care (real-time) tests. If these tests do not yield a definitive answer, or if a more specific diagnosis is needed (e.g., the identification of specific clotting factor deficiencies), a plasma sample can be submitted to a referral veterinary diagnostic laboratory or specialized coagulation laboratory (e.g., New York State Diagnostic Laboratory, Cornell University, Ithaca, NY). As discussed later, TEG is now widely used to evaluate patients with coagulopathies.

Some simple point-of-care tests include the evaluation of a blood smear or the graphics from the hematology analyzer; determination of the ACT, one-stage prothrombin time (OSPT), and APTT; quantification of FDP or D-dimer concentrations; and buccal mucosa bleeding time (BMBT; Table 87.1). Examination of a good-quality, well-stained blood smear (e.g., Diff-Quik) provides important clues regarding platelet numbers and morphology, as does evaluation of graphics generated by flow cytometry hematology analyzers.

The first part of this examination should involve scanning the smear at low power to identify platelet clumps;

TABLE 87.1

Simple Point-of-Care Tests for Rapid Classification of Hemostatic Disorders

TEST	RESULTS	MOST LIKELY DISORDER(S)*
Platelet estimation in blood smear	Low	Thrombocytopenia
ACT	Prolonged	Intrinsic, common system defect
FDP–D-dimer	Positive	Enhanced fibrinolysis, thrombosis, thromboembolism, DIC
BMBT	Prolonged	Thrombocytopenia, thrombocytopathia

ACT, Activated clotting time; *BMBT,* buccal mucosa bleeding time; *DIC,* disseminated intravascular coagulation; *FDP,* fibrin degradation product.
*If prolonged (or positive).

platelet clumping commonly results in pseudothrombocytopenia. Next the oil immersion lens should be used to examine several representative monolayer fields (i.e., where approximately 50% of the red blood cells [RBCs] touch each other), and the number of platelets in five fields should be averaged. In dogs, 12 to 15 platelets should be present in each oil immersion field; in normal cats, 10 to 12 platelets per field should be seen. As a general rule, each platelet in an oil immersion field represents 12,000 to 15,000 platelets/μL (the number of platelets/oil immersion field × 15,000 = platelets/μL). Cats and dogs with platelet counts of >30,000/μL and normal platelet function do not bleed spontaneously. Therefore the cause of bleeding is usually not thrombocytopenia if more than two or three platelets are visualized in each oil immersion field. The evaluation of platelet numbers should also include evaluation of the morphology of individual platelets because abnormal platelet morphology may reflect impaired platelet function.

As mentioned earlier, evaluation of the RBC dot plots in a LaserCyte or ProCyte Dx Hematology Analyzer (IDEXX Laboratories, Westbrook, ME) also provides valuable information on platelet numbers and clumping. For a discussion of dot plot evaluation, see Fig. 87.1.

The second set of point-of-care tests of hemostatic function are the ACT, OSPT, and aPTT. For the aPTT, 2 mL of whole fresh blood (WFB) is added to a tube containing diatomaceous earth; this activates the contact phase of coagulation, thus assessing the integrity of the intrinsic and common pathways (factors I, II, V, VIII, and IX to XII; see Fig. 87.2). If the activity of individual clotting factors involved in these pathways has decreased by more than 70% to 75%, the ACT is prolonged (normal, 60-90 seconds). Common coagulopathies associated with prolongation of the ACT are listed in Table 87.2. This test is rarely done today because of the availability of simple point-of-care instruments.

We routinely use a point-of-care instrument in dogs and cats (Coag Dx Analyzer, IDEXX Laboratories). This

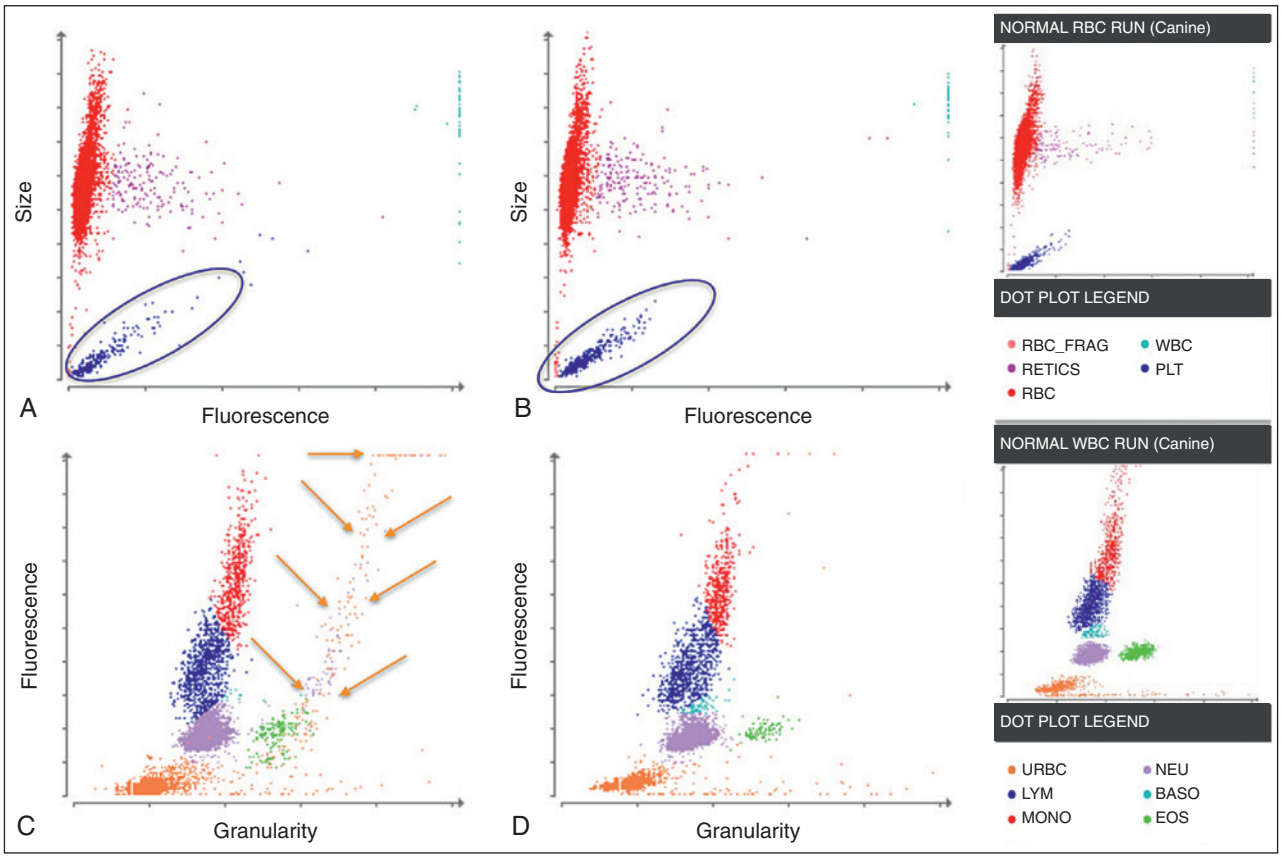

FIG 87.1
Dotplots from a dog with pseudothrombocytopenia **(A and C)**, and the same dog after obtaining a new blood sample **(B and D)** obtained with a ProCyteDx hematology analyzer. In the red blood cell graphics, note the lower density of platelet *(blue circle)* in panel A, compared with B (new blood sample). In the leukocyte graphics please note the curvilinear "cloud" *(orange arrows)* in panel C that represents platelet clumping and is no longer present in panel D (new sample). Normal RBC and WBC graphics are provided in the right. *BASO*, Basophils; *EOS*; eosinophils; *LYM*, lymphocytes; *MONO*, monocytes; *NEU*, neutrophils; *PLT*, platelets; *RBC*, red blood cells; *RBC_FRAG*, red blood cell fragments; *RETICS*, reticulocytes; *URBC*, unlysed red blood cells; *WBC*, white blood cells.

instrument performs determinations of the aPTT or OSPT with only a small volume of blood for each test; nonanticoagulated or citrated samples can be used. The reference ranges for the aPTT with this instrument are different from those for the aPTT determined in referral diagnostic laboratories.

The third real-time test that can be easily performed in practice is determination of the FDP or D-dimer concentration with the commercially available latex agglutination tests; circulating FDPs or D-dimers are generated during the cleavage of fibrin and fibrinogen (i.e., fibrinolysis) before or after binding to factor XIII, respectively. This test is commonly positive in dogs, some cats with DIC, and some patients with thrombosis or TE. The FDP test is also positive in more than half of dogs with bleeding caused by rodenticide poisoning, likely because vitamin K antagonists are believed to release fibrinolysis by inhibiting the production of PAI-1.

A fourth point-of-care test that can be performed primarily in dogs is the BMBT (Box 87.2), in which a template (SimPlate, various manufacturers) is used to make an incision in the buccal mucosa and the time until bleeding completely ceases is determined. The BMBT is abnormal in cats and dogs with thrombocytopenia or with platelet dysfunction. In an animal with clinical signs of a primary bleeding disorder (e.g., petechiae, ecchymoses, mucosal bleeding) and a normal platelet count, a prolonged bleeding time indicates an underlying platelet dysfunction (e.g., resulting from NSAID therapy or vWD) or, less likely, a vasculopathy.

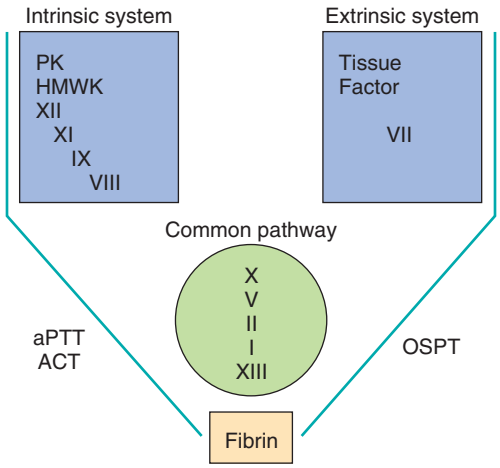

FIG 87.2
Traditional intrinsic, extrinsic, and common coagulation pathways. *ACT,* Activated coagulation time; *aPTT,* activated partial thromboplastin time; *HMWK,* high-molecular-weight kininogen; *OSPT,* one-stage prothrombin time; *PK,* prekallikrein.

BOX 87.2

Procedure for Determining Buccal Mucosa Bleeding Time in Dogs

1. Position the animal in lateral recumbency with manual restraint.
2. Place a 5-cm wide strip of gauze around the maxilla to fold up the upper lip, causing moderate engorgement of the mucosal surface.
3. Position the SimPlate against the upper lip mucosa and push the trigger.
4. Start a stopwatch when the incisions are made.
5. Blot the blood with a gauze or blotting paper placed 1 to 3 mm ventral to the incision without dislodging the clot.
6. Stop the stopwatch when the incision ceases to bleed.
7. Normal times are 2 to 3 minutes.

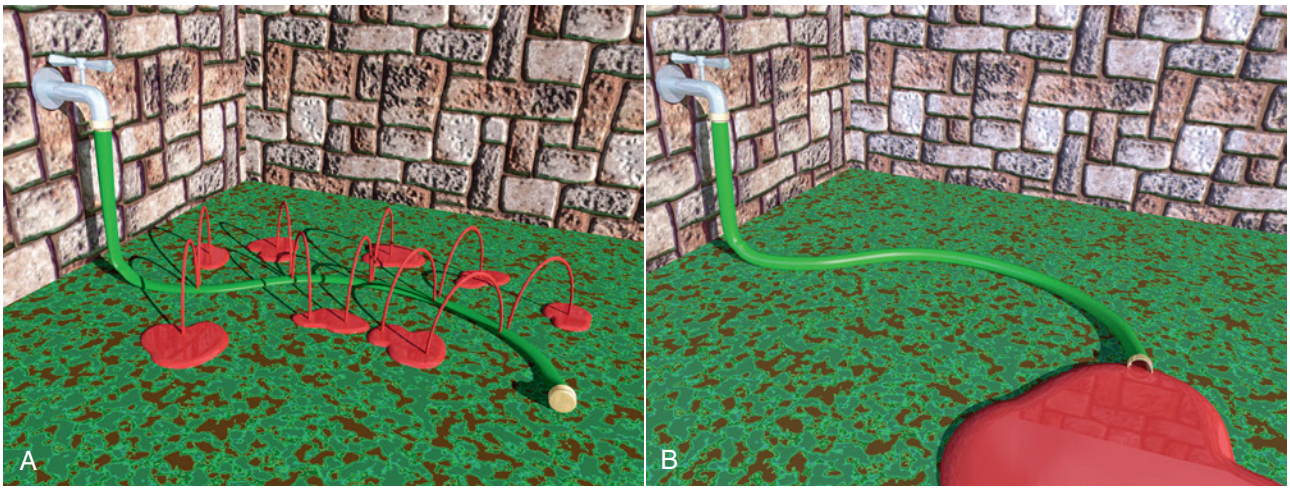

FIG 87.3

TABLE 87.2

Interpretation of Hemostasis Screens

DISORDER	BT	ACT	OSPT*	aPTT	PLATELETS	FIBRINOGEN	FDP/D-DIMER
Thrombocytopenia	↑	N	N	N	↓	N	N
Thrombocytopathia	↑	N	N	N	N	N	N
vWD	↑	N/↑?	N	N/↑?	N	N	N
Hemophilias	N	↑	N	↑	N	N	N
Rodenticide toxicity	N/↑	↑	↑↑	↑	N/↓	N/↓	N/↑
DIC	↑	↑	↑	↑	↓	N/↓	↑
Liver disease	N/↑	↑	N/↑	↑	N/↓	N/↓	N

ACT, Activated coagulation test; *aPTT,* activated partial thromboplastin time; *BT,* bleeding time; *DIC,* disseminated intravascular coagulation; *FDP,* fibrin degradation product; *N,* normal or negative; *OSPT,* one-stage prothrombin time; *vWD,* von Willebrand disease; ↑, high or prolonged; ↓, decreased or shortened; *?,* questionable.
*OSPT and aPTT are considered prolonged if they are 25% or more than the concurrent controls.

Unfortunately, the BMBT has high interoperator and intraoperator variability (as high as 80%), and the results are not reproducible, even by the same operator. The PFA-100 (see later) has largely replaced the BMBT in most veterinary teaching hospitals.

By performing these simple tests after evaluating the clinical features of the bleeding disorder, the clinician should be able to narrow down the number of differential diagnoses. For example, the blood smear evaluation reveals whether the patient is thrombocytopenic or not. If the patient is not thrombocytopenic but petechiae and ecchymoses are present, a prolonged bleeding time or PFA-100 closure time support the existence of a platelet function defect (although this situation is uncommon). A prolonged ACT or aPTT indicates an abnormality in the intrinsic or common pathways, a prolonged OSPT documents a defect in the extrinsic pathway (i.e., factor VII), and a positive test result for FDPs or D-dimer supports the presence of primary or secondary fibrinolysis.

If further confirmation of a presumptive diagnosis is required, plasma can be submitted to a referral laboratory or a specialized coagulation laboratory (see p. 1393). Most commercial veterinary diagnostic laboratories routinely evaluate hemostatic profiles. Samples should be submitted in a purple-topped tube (sodium EDTA) for platelet count, a blue-topped tube (sodium citrate) for coagulation studies (OSPT, aPTT, fibrinogen concentration, D-dimer), and a special blue-topped tube (Thrombo-Wellcotest, Thermo Fisher Scientific, Lenexa, KS) for FDP determination (the last tube is usually supplied by the diagnostic laboratory). The blue-topped tubes are now primarily available in 3.2% sodium citrate concentrations. The results of routine hemostasis assays are not affected by the concentration of citrate used (Morales et al., 2007). It is important to submit the right samples in the appropriate anticoagulant. The guidelines for sample submission to commercial laboratories are summarized in Table 87.3.

TABLE 87.3

Specimens Required for Laboratory Evaluation of Hemostasis

SAMPLE	TUBE TOP COLOR	TEST(S)
EDTA blood	Purple	Platelet count
Citrated blood	Blue	OSPT, aPTT, fibrinogen, AT, vWF, clotting factor assays, D-dimer, TEG, PFA-100
Thrombin	Blue	FDP

aPTT, Activated partial thromboplastin time; *AT,* antithrombin; *EDTA,* ethylenediamine tetraacetic acid; *FDP,* fibrin degradation product; *OSPT,* one-stage prothrombin time; *PFA-100,* platelet function analyzer; *TEG,* thromboelastograph; *vWF,* von Willebrand factor assay.

A routine coagulation screen (or hemostatic profile) usually contains the OSPT, aPTT, platelet count, fibrinogen concentration, and FDP and D-dimer concentration. In some laboratories, AT activity may also be included. The OSPT primarily evaluates the extrinsic pathway, whereas the aPTT primarily evaluates the intrinsic pathway. Because the end product in these assays is always fibrin formation, both tests also evaluate the common pathway (see Fig. 87.2). The D-dimer assay evaluates for systemic fibrinolysis, as does the FDP test; however, as noted, the D-dimer is formed after fibrin has been stabilized by factor XIII. Thus it is more indicative of intravascular thrombus formation. The interpretation of routine hemostasis profiles is summarized in Table 87.2.

New instruments now allow evaluation of other aspects of hemostasis. For example, the platelet function analyzer PFA-100 (Siemens Healthcare Diagnostics, Deerfield, IL) is

a simple, cage-side instrument for evaluating platelet adhesion and aggregation. This instrument is available in several specialized clinical hemostasis laboratories and has been extensively evaluated in dogs. The PFA-100 is sensitive for the screening of vWD. The Thromboelastograph Hemostasis Analyzer system (TEG; Haemonetics, Braintree, MA), also available in several specialized hemostasis laboratories, uses native or anticoagulated blood activated with a variety of agonists. This instrument evaluates global hemostasis, including platelet adhesion and aggregation, fibrin formation, fibrinolysis, and clot retraction. The TEG is ideal to monitor response to blood component therapy in patients with coagulopathies. I have found that it provides a wealth of information in patients with hypercoagulability and those with spontaneous bleeding and normal results of hemostasis profiles. Platelet mapping is a new TEG-based method that allows the titration of antiplatelet agents in humans; we have found it to be very reliable in dogs. However, this analyzer requires a fresh (<2 hours) blood sample, so the patient likely needs to be referred to the center where the tests will be conducted.

As noted, if an unusual coagulopathy or specific clotting factor deficiency is suspected, blood should be submitted to a specialized veterinary coagulation laboratory. Congenital and acquired clotting factor deficiencies that occur in cats and dogs are listed in Box 87.3.

Thrombocytopenia can be caused by decreased production or increased destruction, consumption, or sequestration of platelets; therefore a bone marrow aspiration for cytologic evaluation is indicated in cats and dogs with thrombocytopenia of unknown cause. Other tests can also be performed in thrombocytopenic cats and dogs, including determinations of titers or a polymerase chain reaction (PCR) assay for vector-borne diseases, or evaluation for retrovirus infection (see Chapters 91 and 96).

Finally, clinicians occasionally encounter a patient with abnormal results of hemostasis profiles but without spontaneous bleeding. The most common abnormality in the hemostasis profile of a dog or cat without a tendency to bleed is a prolongation of the aPTT. Often the prolongation is marked (>50% above the control or upper limit of the reference range for the laboratory). If this abnormality is found during a presurgical evaluation, the surgery may be delayed needlessly if the clinician is not familiar with some of the following clinical conditions. As noted, dogs and cats with factor XII deficiency do not bleed but have a prolonged aPTT; determination of factor XII activity will provide a diagnosis. Prekallikrein and HMWK are co-factors for the contact activation of factor XII. Dogs with prekallikrein or HMWK deficiencies have prolonged aPTT but do not bleed; incubation of the plasma samples for a few hours overrides the factor deficiency and corrects the aPTT. Finally, the presence of circulating anticoagulants, also referred to as lupus anticoagulants or antiphospholipid antibodies, results in prolongation of the aPTT without bleeding. A simple test to determine whether the patient with a prolonged aPTT has a clotting factor deficiency (e.g., factor XII) or circulating anticoagulants is to perform an aPTT after diluting the patient's sample 50:50 with normal or pooled dog plasma (dilution assay). As noted, the aPTT becomes prolonged when the patient has less than 30% activity of an individual factor. If the patient has factor XII deficiency, for example, and 0% factor XII activity, mixing the sample 50:50 with normal dog plasma (with a factor XII activity of 100%) will result in a final factor XII activity of 50% and thus the aPTT will be normal. Circulating anticoagulants also inhibit the clotting factors in normal dog plasma, so when the samples are mixed 50:50, the aPTT remains prolonged. Recently, the presence of prolonged aPTT and antiphospholipid antibodies was documented in healthy Bernese Mountain dogs (Nielsen et al., 2011a and b).

BOX 87.3

Congenital and Acquired Clotting Factor Defects

Congenital Clotting Factor Defects

Factor I, or hypofibrinogenemia and dysfibrinogenemia (Bichon Frise, Borzoi, Collie; DSH)
Factor II, or hypoprothrombinemia (Boxer, Otterhound, English Cocker Spaniel)
Factor VII, or hypoproconvertinemia (Alaskan Klee Kai, Beagle, Malamute, Scottish Deerhound, Schnauzer; DSH)
Factor VIII, or hemophilia A (many breeds but mainly German Shepherd Dogs and Golden Retrievers; DSH)
Factor IX, or hemophilia B (many breeds of dogs; DSH and many cat breeds)
Factor X, or Stuart-Prower trait (Cocker Spaniel, Jack Russell Terrier; DSH)
Factor XI, or hemophilia C (English Springer Spaniels, Great Pyrenees, Kerry Blue Terriers; DSH)
Factor XII, or Hageman factor (Miniature Poodles, Shar Pei; DSH, DLH, Siamese, Himalayan cats)
Prekallikrein (Fletcher factor) deficiency (various dog breeds)

Acquired Clotting Factor Defects

Liver disease

Decreased production of factors
Qualitative disorders?
Cholestasis

Vitamin K antagonists (rodenticides)

DIC

DIC, Disseminated intravascular coagulation; *DLH,* domestic long-haired cat; *DSH,* domestic short-haired cat.
Modified from Brooks MB: Hereditary coagulopathies. In Weiss DJ, Wardrop KJ, editors: *Schalm's veterinary hematology,* ed 6, Ames, Iowa, 2010, Wiley-Blackwell, p 661.

MANAGEMENT OF THE BLEEDING PATIENT

Several basic principles apply to the management of cats and dogs with spontaneous bleeding disorders. Specific

principles are discussed in the following paragraphs. In general, a patient with a spontaneous bleeding disorder should be managed aggressively because these disorders are potentially life-threatening; at the same time, iatrogenic bleeding should be minimized. As a general rule, trauma should be minimized, and the patient must be kept quiet, preferably confined to a cage and leash-walked, if necessary. Exercise should be avoided or markedly restricted.

Venipunctures should be done with the smallest gauge needle possible, and pressure should be applied to the puncture site for a minimum of 5 minutes. A compressive bandage should also be applied to the area once pressure has been released. If repeated samples for packed cell volumes (PCVs) and plasma protein determinations are necessary, they should be obtained from a peripheral vein with a 25-gauge needle to fill one or two microhematocrit tubes by capillarity. A bandage should be applied after each venipuncture.

Invasive procedures should be minimized. For example, urine samples should never be collected by cystocentesis because of the risk of intraabdominal, intravesical, or intramural bladder bleeding. Certain invasive procedures, however, can be performed safely. These include bone marrow aspiration, fine-needle aspiration (FNA) of lymph nodes or superficial masses, FNA of the spleen (the thick fibromuscular capsule of the carnivore spleen seals the needle hole as soon as the needle is removed), and intravenous catheter placement, although seepage from the catheter is common in thrombocytopenic patients.

Certain types of surgeries can also be safely performed in some cats and dogs with coagulopathies. For example, pedicle surgery (e.g., splenectomy) can be performed with minimal bleeding (i.e., seepage from the abdominal wound) in dogs with marked thrombocytopenia (i.e., <25,000 platelets/μL).

A transfusion of blood or blood components is indicated in some dogs and cats with spontaneous bleeding disorders. WFB or a combination of packed RBCs and fresh-frozen plasma (FFP) should be used if the animal is anemic and lacking one or more clotting factors; plasma transfusions are of no benefit in thrombocytopenic animals. FFP can be used to replenish clotting factors in a cat or dog with a normal or mildly decreased PCV (i.e., the animal is not symptomatic). Although it was traditionally thought that stored blood and frozen plasma were deficient in factors V and VIII and were not hemostatically active, it was recently demonstrated that frozen, 5-year-old plasma is hemostatically active (Urban et al., 2013). In general, WFB, platelet-rich plasma, and platelet transfusions rarely provide sufficient platelets to halt spontaneous bleeding in a cat or dog with thrombocytopenia, particularly if the bleeding is the result of platelet consumption. Some guidelines for transfusion therapy are discussed in Chapter 82.

Nonspecific procoagulants such as epsilon-aminocaproic acid (EACA) or tranexamic acid have been used successfully to manage spontaneous bleeding in a variety of clinical situations (Marin et al., 2012a and b). In Greyhounds with delayed postoperative bleeding, 500 to 1000 mg (≈15-50 mg/kg) of EACA, orally (PO) q8h for 5 days, successfully prevents or resolves spontaneous bleeding. We have also used this protocol successfully in thrombocytopenic dogs, dogs with bleeding hemangiosarcomas, trauma patients, and those with hemophilia.

A recent study of tranexamic acid, used as a 10 mg/kg IV injection followed by q3h infusion (10 mg/kg) did not result in toxicity or consistent changes in TEG results (Kelmer et al., 2015); rapid IV injection of tranexamic acid typically induces vomiting.

Recent studies evaluated the efficacy of both aminocaproic acid or *Yunnan baiyao*, a traditional Chinese herbal drug, in both normal dogs and dogs with bleeding right atrial masses and pericardial effusion.

One study found *Yunnan baiyao* to be safe but it did not induce changes in the TEG tracing or parameters in 10 normal Beagles (Frederick et al., 2017); however, Tansey et al. (2018) reported that using it at a dosage of 1 capsule q12h in client-owned dogs of over 15 kg, this herb increases clot strength and is well tolerated. Reported dosages for this compound range from 1 capsule once a day to 3 capsules 3 times a day.

In a retrospective case-controlled study of 67 dogs with right atrial masses and pericardial effusion, both *Yunnan baiao* and aminocaproic acid, either singly or in combination, were found to be safe (Murphy et al., 2017) but they did not significantly affect outcome, when compared with control dogs.

PRIMARY HEMOSTATIC DEFECTS

Primary hemostatic defects are characterized by the presence of superficial and mucosal bleeding (e.g., petechiae, ecchymoses, hematuria, epistaxis) and are usually associated with thrombocytopenia. Platelet dysfunction is a rare cause of spontaneous bleeding in dogs and cats. Primary hemostatic defects caused by vascular problems are extremely rare and thus are not discussed here. These defects are the most common cause of spontaneous bleeding in dogs seen at our hospital.

THROMBOCYTOPENIA

Thrombocytopenia represents the most common cause of spontaneous bleeding in dogs seen at our clinic. Decreased numbers of circulating platelets can be the result of one or more of the following abnormalities (Box 87.4):

- Decreased platelet production
- Increased platelet destruction
- Increased platelet consumption
- Increased platelet sequestration

Increased platelet destruction represents the most common cause of thrombocytopenia in dogs in our clinic but is rare in cats. Usually, the peripheral destruction of platelets results from immune-mediated, drug-related, and

BOX 87.4

Causes of Thrombocytopenia in Dogs and Cats

Decreased Platelet Production

Immune-mediated megakaryocytic hypoplasia
Idiopathic bone marrow aplasia
Drug-induced megakaryocytic hypoplasia (estrogens, phenylbutazone, melphalan, lomustine β-lactams)
Myelophthisis
Cyclic thrombocytopenia
Retroviral infection
Canine monocytic ehrlichiosis
Feline monocytic ehrlichiosis?

Increased Platelet Destruction, Sequestration, or Utilization

Immune-mediated thrombocytopenia
Infectious (e.g., *Anaplasma* spp., *Bartonella* spp., sepsis)
Live viral vaccine–induced thrombocytopenia
Drug-induced thrombocytopenia
Microangiopathy
Disseminated intravascular coagulation
Hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura
Vasculitis
Splenomegaly
Splenic torsion
Endotoxemia
Acute hepatic necrosis
Neoplasia (immune mediated, microangiopathy)

Note: Entries in **boldface** are common causes; entries in *italics* are relatively common causes; entries in regular typeface are uncommon causes.

infectious mechanisms; increased platelet consumption occurs most commonly in dogs and cats with DIC (see later), and sequestration is usually caused by splenomegaly or, rarely, hepatomegaly (see Box 87.4).

Approach to the Patient With Thrombocytopenia

Before assessing a patient with primary hemostatic bleeding, the clinician must remember that in some breeds, platelet counts below the reference range for dogs are common. Platelet counts in Greyhounds typically range from 80,000 to 120,000/μL, whereas in Cavalier King Charles Spaniels with macrothrombocytopenia, platelet counts < 50,000/μL are common. In the latter the global platelet function is normal. Because of the tendency of feline platelets to clump in the EDTA tube, we see a few cats per year referred for evaluation of asymptomatic thrombocytopenia. Evaluation of the blood smear or hematology analyzer graphics in those cats reveals platelet clumping, and hence, pseudothrombocytopenia. Iloprost, a prostaglandin I_2 analogue added to the blood collection tube, can effectively decrease platelet aggregation in cats and eliminate or minimize thrombocytopenia (Riond et al., 2015).

Once thrombocytopenia has been confirmed by a platelet count, evaluation of a blood smear or analyzer graphics, its pathogenesis should be identified. The absolute platelet count may offer clues to its cause; for example, platelet counts of <25,000/μL are common in dogs with immune-mediated thrombocytopenia (IMT), whereas platelet counts of 50,000 to 75,000/μL are more common in dogs with ehrlichiosis, anaplasmosis, lymphoma with splenic involvement, or rodenticide toxicity.

The patient's drug history should be obtained from the owner. If the pet is receiving any medication, the thrombocytopenia should be considered drug-related until proven otherwise. The drug should be discontinued, if possible, and the platelet count reevaluated within 2 to 6 days. If the count returns to normal, a retrospective diagnosis of drug-associated thrombocytopenia is made. Drugs that have been associated with thrombocytopenia in cats and dogs can also cause anemia and neutropenia (see Boxes 82.2 and 85.1).

Because retroviral disorders commonly affect the bone marrow and may result in thrombocytopenia in cats, feline leukemia virus (FeLV) and feline immunodeficiency virus tests should be performed first. A bone marrow aspiration is indicated in a thrombocytopenic cat with no history of previous medication and a negative retrovirus status. The risk of bleeding during or after bone marrow aspiration in a thrombocytopenic animal is minimal. If determined by the laboratory, a mean platelet volume is high in most cats with FeLV infection (i.e., macrothrombocytosis); however, macrothrombocytes are also seen in cats and dogs with peripheral platelet destruction, consumption, or sequestration, in which they may be analogous to reticulocytes (young, immature, large platelets) and in normal Cavalier King Charles Spaniels.

Bone marrow evaluation may also be indicated for dogs with thrombocytopenia. Given the high prevalence of IMT, at our clinic we usually elect to treat a dog with a presumed diagnosis of IMT. If the patient does not respond to immunosuppressive drugs within 2 to 3 days, a bone marrow aspiration may be performed.

Hyperplasia of megakaryocytes occurs in response to peripheral destruction, consumption, or sequestration of platelets. Occasionally dogs and cats with IMT have decreased numbers of megakaryocytes and abundant free megakaryocyte nuclei in the bone marrow. This is thought to be mediated by antibodies directed against platelets that also destroy the megakaryocytes. Infiltrative or dysplastic bone marrow disorders causing thrombocytopenia are easy to identify on a bone marrow smear.

Because IMT is a diagnosis of exclusion, vector-borne diseases (e.g., canine ehrlichiosis or anaplasmosis, Rocky Mountain spotted fever, leishmaniasis, babesiosis, bartonellosis) should theoretically be ruled out by evaluating the appropriate serology or PCR and a blood smear. In thrombocytopenic dogs, we perform a SNAP-4DX Plus test (IDEXX Laboratories) as the first line of diagnostics to rule out *Ehrlichia*, *Anaplasma*, and *Borrelia* as causative agents; however, acutely infected dogs may be thrombocytopenic

and have a negative test result because they have not yet mounted an appropriate immune response.

As discussed in Chapter 95, some of these diseases have breed distribution (i.e., leishmaniasis in Foxhounds in the United States) or geographic distribution (e.g., leishmaniasis in Mediterranean countries). As a general rule, if the patient is asymptomatic other than the bleeding, the thrombocytopenia is not likely caused by sepsis or vector-borne diseases, although occasionally asymptomatic thrombocytopenic dogs have subclinical vector-borne diseases, such as anaplasmosis or rickettsiosis. If sepsis is suspected on the basis of clinical signs and clinicopathologic findings (e.g., fever, tachycardia, poor perfusion, toxic leukocyte changes, degenerative left shift in the leukogram, hypoglycemia, hyperbilirubinemia), urine and blood should be obtained for bacterial cultures; as discussed earlier, cystocentesis should be avoided in bleeding patients.

The presence of spherocytic hemolytic anemia or autoagglutination in a dog with thrombocytopenia is highly suggestive of Evans syndrome (combination of IMT and immune hemolytic anemia [IHA]). A direct Coombs test is usually positive in these cases. On rare occasions, a direct Coombs test is positive in a dog with IMT and borderline anemia, further supporting a diagnosis of Evans syndrome (see Chapters 73 and 82).

A hemostasis screen should always be performed to rule out DIC in a thrombocytopenic animal found to have RBC fragments in a blood smear or evidence of secondary bleeding (e.g., hematomas, bleeding into body cavities). The rest of the hemostasis screen is usually normal in dogs and cats with selective thrombocytopenia.

Several tests are available to evaluate antiplatelet antibodies (see Chapter 71). However, most of these are not clinically reliable, and a diagnosis of IMT can be made only after other causes of thrombocytopenia have been excluded, regardless of the results of the antiplatelet antibody tests.

Abdominal radiographs and ultrasonograms may reveal an enlarged spleen not evident during physical examination. Diffuse splenomegaly (splenic sequestration of platelets) may be the cause of the thrombocytopenia, or it may reflect work hypertrophy (mononuclear phagocytic system hyperplasia) and extramedullary hematopoiesis in a dog with IMT. Splenic nodules are usually an incidental finding in dogs with thrombocytopenia and may represent extramedullary hematopoiesis or hyperplasia; FNA of the nodules should establish a cytologic diagnosis. Despite the low platelet counts, clinically relevant bleeding is extremely rare.

Often a specific diagnosis of IMT is obtained only after a therapeutic trial with corticosteroids (see later and Chapters 72 and 73) results in resolution of the thrombocytopenia. If the clinician is in doubt regarding whether the thrombocytopenia is caused by a vector-borne diseases or IMT (in dogs), immunosuppressive doses of corticosteroids can be administered in conjunction with doxycycline (5-10 mg/kg PO q12-24h) until serologic or PCR test results become available. This combination of agents has no deleterious effects on dogs with vector-borne diseases, but not all of them are doxycycline responsive.

Blood or blood components should be transfused as needed (see Chapter 82). However, the transfusion of WFB, platelet-rich plasma, or platelets rarely, if ever, results in normalization of the platelet count or even in increases in the platelet count to safe levels. In addition, in most dogs, platelet transfusions are cost-prohibitive. Symptomatic prohemostatic treatment with aminocaproic or tranexamic acid, or *Yunnan baiyao* can be used in patients with life-threatening bleeding.

Immune-Mediated Thrombocytopenia

IMT is the most common cause of spontaneous bleeding in dogs but is rare in cats. It affects primarily middle-aged female dogs; Cocker Spaniels and Old English Sheepdogs are overrepresented. The clinical signs are those of a primary hemostatic defect and include petechiae, ecchymoses, and mucosal bleeding. As discussed earlier, a bleeding score for thrombocytopenic dogs was proposed for dogs (Makielski et al., 2018). Acute collapse may occur if bleeding is pronounced; if the anemia is mild, most dogs are fairly asymptomatic. IMT is acute or peracute in onset in most dogs. During physical examination, signs of primary hemostatic bleeding (e.g., petechiae, ecchymoses, mucosal bleeding), with or without splenomegaly, may be found.

The complete blood count (CBC) in dogs with IMT is characterized by thrombocytopenia with or without anemia, depending on the degree of spontaneous bleeding and presence or absence of concurrent IHA; the anemia can be regenerative or nonregenerative, depending on the time of onset of the bleeding. Mature leukocytosis may also be present. However, as a general rule, in dogs with IMT hematologic changes are limited to the thrombocytopenia. If IHA is associated with IMT (i.e., Evans syndrome), a Coombs-positive regenerative anemia with spherocytosis or autoagglutination is present. Bone marrow cytologic studies typically reveal megakaryocytic hyperplasia, although megakaryocytic hypoplasia with free megakaryocyte nuclei is occasionally present. In addition to the thrombocytopenia, the bleeding time is the only other abnormal test result (ACT, aPTT, OSPT, FDP–D-dimer, and fibrinogen concentration are normal). An inverse linear correlation is usually present between the platelet count and BMBT (i.e., a longer BMBT with lower platelet counts). Ideally, vector-borne diseases and drug-induced thrombocytopenia should be ruled out before establishing a definitive diagnosis of IMT.

My approach is as follows: If the index of suspicion for IMT is high—that is, a fairly asymptomatic dog with spontaneous primary hemostatic bleeding and thrombocytopenia as the sole hematologic abnormality—I institute a therapeutic trial with immunosuppressive doses of corticosteroids (equivalent to 2-8 mg/kg/day of prednisone). Responses are usually seen within 24 to 96 hours. No clinical evidence exists that dexamethasone is more effective than prednisone in controlling IMT. In my experience, acute gastrointestinal (GI) tract ulceration is considerably more prevalent in dogs

receiving dexamethasone than in those receiving prednisone. Because an acute upper GI tract bleed is usually catastrophic in a dog with thrombocytopenia, prednisone is my drug of choice. H_2 antihistamines such as famotidine (0.5-1 mg/kg PO q12-24h) or proton pump inhibitors (omeprazole 0.5-1 mg/kg, PO, q24h) should be used in combination with the corticosteroids.

FWB, stored blood, or packed RBCs should be administered as needed to maintain adequate oxygen-carrying capacity (see Chapter 82, "Transfusion Therapy"). In my experience, in addition to immunosuppressive doses of corticosteroids, cyclophosphamide given intravenously (IV) or PO in a single dose of 200 to 300 mg/m^2 is effective for inducing remission. However, it should not be used as a maintenance agent because it may result in sterile hemorrhagic cystitis when used on a long-term basis. Vincristine at a dose of 0.5 mg/m^2 given IV traditionally has been recommended for dogs with IMT. This drug stimulates megakaryocyte endomitosis, resulting in early platelet release from the bone marrow. However, because vinca alkaloids bind to tubulin, the platelets released prematurely are not fully functional (tubulin is responsible for platelet aggregation), and the patients may have further bleeding before the platelet count increases. As discussed in Chapters 72 and 82, human intravenous immunoglobulin (0.5-1 g/kg IV, single dose) has been used successfully in dogs with refractory or life-threatening IMT. Transfusion of platelet concentrates may be indicated, but platelet numbers rarely increase significantly given that the thrombocytopenia is due to peripheral consumption. In a retrospective study (Ng et al., 2016), the transfusion of cryopreserved platelets to 43 thrombocytopenic dogs had no influence on survival.

Failure to induce remission, which normalizes the platelet count, is usually the result of insufficient drug (low doses or the need for a second agent), insufficient duration of therapy (the drugs have not yet had time to become effective), or an incorrect diagnosis. In the event of one of these, the treatment protocol can easily be amended, with the thrombocytopenia usually resolving as a result. Azathioprine (50 mg/m^2 PO q24-48h) is effective in maintaining remission but is not a good agent for inducing remission. In some dogs azathioprine is better tolerated than long-term corticosteroid therapy, although close hematologic monitoring is recommended given its myelosuppressive properties and low potential for hepatotoxicity. See Chapters 72 and 73 for additional information and drug dosages.

The prognosis is good in most dogs with IMT, although they may require lifelong treatment. Dogs with refractory IMT can be successfully treated with pulse-dose cyclophosphamide, human immunoglobulin, mycophenolate mofetil, or splenectomy.

IMT has become more prevalent in cats over the past few years. The typical clinical presentation is different from dogs in that most cats have chronic thrombocytopenia that does not lead to spontaneous bleeding. A platelet count of 10,000 to 30,000/µL is relatively common in an otherwise healthy cat without spontaneous bleeding. As discussed earlier, in thrombocytopenic dogs and cats, it is imperative to determine whether the patient has platelet aggregates by evaluating a blood smear or the graphics from the analyzer (see Fig. 87.1). I have followed up several of these cats for months to years, and their platelet counts do not increase markedly with treatment, questioning the diagnosis of IMT. Interestingly, a high proportion of these cats also have regenerative or nonregenerative anemia, neutropenia, lymphocytosis, or combinations thereof, so an infectious process such as anaplasmosis or ehrlichiosis cannot be excluded. The cytopenias may resolve for no apparent reason, only to have a decrease in another cell line months later. Because most of these cats do not bleed, the clinician should be aware that increasing drug dosages or adding drugs may cause more problems than monitoring the platelet count. My treatment of choice for cats with IMT or immune-mediated cytopenias is a combination of dexamethasone (4 mg total dose, q1-2 wk) and chlorambucil (20-30 mg/m^2 PO q2wk). I have also successfully used human intravenous immunoglobulin G in a limited number of cats with immune-mediated cytopenias. See Chapter 73 for more discussion of IMT.

PLATELET DYSFUNCTION

The presence of primary hemostatic bleeding in a patient with a normal platelet count is highly suggestive of a platelet dysfunction syndrome, although vasculopathies and enhanced fibrinolysis should also be considered. Platelet dysfunction syndromes can be congenital or acquired (Box 87.5); however, they rarely result in spontaneous bleeding. More often a prolonged BMBT is noted preoperatively in

an otherwise healthy animal, or the animal has a family history of bleeding or pronounced bleeding during a previous surgery. Congenital platelet dysfunction syndromes are rare, with the notable exception of vWD. Some authors classify vWD among the congenital clotting factor deficiencies; however, because its clinical manifestations are those of a primary hemostatic defect, I include it in this section. Acquired platelet function disorders are more common; clinically they are mainly secondary to monoclonal gammopathies, ehrlichiosis, uremia, retroviral infections, or drug therapy.

von Willebrand Disease

vWD is the most common inherited bleeding disorder in humans and dogs but is rare in cats. The term *von Willebrand syndrome* (vWS) is reserved for an acquired vWF deficiency. vWD can be classified into three types (Table 87.4). Dogs with the disease typically have a decreased concentration or activity (type 1 vWD), absence of circulating vWF (type 3 vWD), or low to normal concentrations of an abnormal vWF (type 2 vWD), which result in mild (if any) spontaneous bleeding or, more likely, prolonged surgical bleeding. In dogs vWD can be inherited as an autosomal dominant trait with incomplete penetrance or, more rarely, an autosomal recessive trait (see later). This disorder has been reported to occur in more than 50 breeds of dogs but is more common in Doberman Pinschers, German Shepherd Dogs, Poodles, Golden Retrievers, and Shetland Sheepdogs. In these breeds the defect is inherited as an autosomal dominant trait with incomplete penetrance. In Scottish Terriers and Shetland Sheepdogs, it can be inherited as an autosomal recessive trait; homozygous dogs have no detectable vWF concentrations and are usually severely affected. Type 1 vWD has been purportedly reported to occur in association with clinical hypothyroidism in dogs; however, most scientifically controlled studies have failed to prove an association between

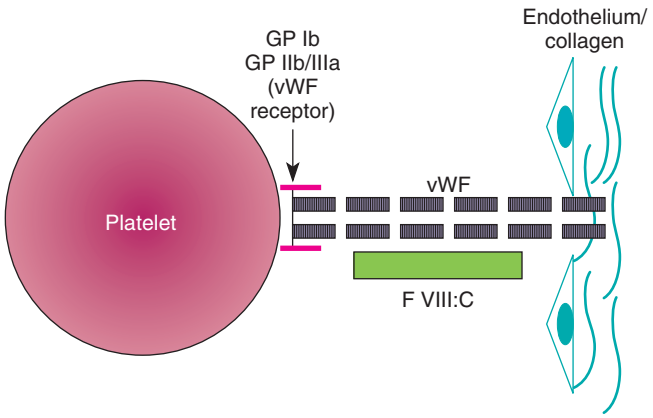

FIG 87.4
Interaction between vWF, platelet, and subendothelial surfaces. *F VIII:C,* Factor VIII coagulant; *GP,* glycoprotein; *vWF,* von Willebrand factor.

vWD and hypothyroidism in dogs. Type 2 vWS has been reported in dogs with aortic valvular disease; in those dogs, the high shear associated with turbulent flow across the valve resulted in selective depletion of high-molecular-weight vWF multimers (Tarnow et al., 2005).

In humans vWF is produced by megakaryocytes and endothelial cells, circulates in plasma complexed to factor VIII coagulant (factor VIII C), and is one of the major adhesive proteins in the body. In the dog, platelets do not contribute as much vWF to plasma as in humans. vWF is mainly responsible for causing platelets to adhere to the subendothelial structures (e.g., collagen) in areas of high shear once endothelial cell damage has occurred, thus initiating the formation of the primary hemostatic plug (Fig. 87.4). The vWF molecule circulates coiled; it uncoils at the site of endothelial damage, binds to the subendothelium and then to the platelet receptors, and the platelets are reeled in to the site of

injury. As a consequence, vWD is usually characterized by primary hemostatic defects (e.g., petechiae, ecchymoses, mucosal bleeding). However, most dogs with vWD do not bleed spontaneously but bleed excessively during or after surgery; excessive bleeding during teething or estrus can also occur, but petechiae and ecchymoses are rare. Most dogs with vWD and spontaneous bleeding seen at our clinic are brought in for the evaluation of diffuse oropharyngeal or vaginal bleeding. People with vWD can also have low circulating concentrations of factor VIII, leading to spontaneous secondary hemostatic bleeding (i.e., the clinical findings of hemophilia A); however, this is extremely rare in dogs. Perinatal death, abortions, or stillbirths are common in litters with vWD.

The hemostasis screen results and platelet counts are normal in most dogs with vWD. However, the results of a PFA-100 test or BMBT usually assist in establishing a diagnosis. As a general rule, the PFA-100 closure time or BMBT is prolonged if the vWF concentration or activity is low. The BMBT may be the most cost-effective method for screening dogs for vWD, although its results are not foolproof. It can be done before surgery in breeds at risk or if the owner or breeder is interested in determining whether the dog is likely to have this disorder. However, a normal bleeding time does not necessarily rule out vWD. At our clinic we routinely use the PFA-100 before surgery in dogs at high risk for vWD so that appropriate therapy can be instituted before or during surgery. A diagnosis of vWD can be confirmed by quantifying vWF in specialized veterinary coagulation laboratories. Genetic testing for vWD in specific breeds is available through commercial diagnostic laboratories (VetGen; https://www.vetgen.com/canine-vWD1.html).

Most dogs with type 1 vWD can be successfully treated before surgery or during a bleeding episode with desmopressin acetate (DDAVP), which causes a massive release of vWF from the endothelial cells and results in shortening of the BMBT and the PFA-100 closure times within 30 minutes of administration. A single 1-µg/kg dose of DDAVP (intranasal preparation) given subcutaneously consistently lessens bleeding in dogs with type 1 vWD despite modest increases in vWF concentration. DDAVP is not effective in dogs with types 2 or 3 vWD because these dogs have an abnormal (i.e., nonfunctional) vWF or lack vWF. Cryoprecipitate is the blood component of choice for dogs with vWD; a unit of cryoprecipitate is defined as the volume obtained from a unit of FFP (see Chapter 82). We use a dosage of 1 U cryoprecipitate/10 kg of body weight; therefore a Doberman Pinscher typically receives 3 U. If cryoprecipitate is not available, FFP or WFB can be used. DDAVP can also be administered to the blood donor dog 1 hour before blood is collected to maximize the yield of vWF. Systemic prohemostatic agents such as aminocaproic or tranexamic acids, and *Yunnan baiyao* can also be used in these patients. The use of topical hemostatic agents such as fibrin, collagen, or methacrylate is also indicated to control the local bleeding. As is the case in dogs with other inheritable disorders, dogs with congenital vWD should not be bred.

Other Congenital Platelet Function Defects

Platelet function defects leading to spontaneous primary hemostatic bleeding have been reported in at least three breeds of dogs (Otterhounds, Foxhounds, and Basset Hounds). The clinical signs and clinicopathologic abnormalities are similar to those seen in dogs with vWD, but the vWF concentrations are normal or high. A syndrome of spontaneous and postoperative bleeding resembling Scott syndrome in humans from a lack of platelet procoagulant activity has been well characterized in German Shepherd Dogs (Jandrey et al., 2012).

SECONDARY HEMOSTATIC DEFECTS

Dogs with secondary hemostatic defects are usually evaluated because of collapse, exercise intolerance, dyspnea, abdominal distention, lameness, subcutaneous bruising, or masses. The collapse and exercise intolerance are usually caused by anemia resulting from intracavitary bleeding, as are the dyspnea and abdominal distention. The lameness is usually caused by hemarthrosis, and the masses or lumps usually represent hematomas. Cats and dogs with secondary hemostatic disorders do not have petechiae or ecchymoses, or mucosal bleeding (e.g., melena, epistaxis) is rarely seen. In general, the severity of the bleeding is directly related to the severity of the deficiency of the clotting factor(s). Liver disease and rodenticide poisoning leading to vitamin K deficiency are the two most common causes of secondary hemostatic defects seen at our clinic; however, the former is rarely associated with spontaneous bleeding. As noted, these disorders are more common in dogs than in cats and are far less common than primary hemostatic defects.

CONGENITAL CLOTTING FACTOR DEFICIENCIES

Congenital clotting factor deficiencies, as well as the breeds affected, are listed in Box 87.3. They are relatively common in dogs but are rare in cats. Most genetic mutations leading to these defects have been well characterized, and some laboratories now offer genetic testing for congenital coagulopathies. Hemophilia A and B are sex-linked traits; the modes of inheritance of other coagulopathies vary. In affected animals, the severity of the bleeding is usually inversely proportional to the concentration of the individual clotting factor affected (e.g., bleeding is more severe in association with a very low factor activity). Clinical signs usually include spontaneous hematoma formation, which the owners may describe as lumps, and bleeding into body cavities, as well as signs compatible with so-called fading puppy syndrome and protracted umbilical cord bleeding after birth. Abortions or stillbirths in the litter are common. Petechiae and ecchymoses are not present in dogs with congenital clotting factor deficiencies. Cats with congenital clotting factor deficiency usually do not bleed spontaneously but have intraoperative or delayed postoperative bleeding.

Carriers of the defect may be asymptomatic but usually have prolonged clotting times in vitro. Certain factor deficiencies (so-called contact factors), including factors XII and XI, Fletcher factor (prekallikrein), and HMWK, are also found in otherwise asymptomatic animals (i.e., no excessive bleeding) with a markedly prolonged aPTT. However, massive and often life-threatening postoperative bleeding starting 24 to 36 hours after surgery is common in dogs with factor XI deficiency.

Most dogs and cats with congenital coagulopathies are treated with supportive and transfusion therapies; no other treatments appear to be beneficial, but anecdotally, aminocaproic acid may help control bleeding. There is ongoing research on gene therapy in canine models of hemophilia and other inherited coagulopathies. As with animals with other congenital defects, dogs and cats with coagulopathies should not be bred.

VITAMIN K DEFICIENCY

Vitamin K deficiency in small animals usually results from the ingestion of vitamin K antagonists (e.g., warfarin, diphacinone, brodifacoum, bromadiolone), although it can also occur as a consequence of malabsorption in dogs and cats with obstructive cholestasis, infiltrative bowel disease, or liver disease. Four clotting factors are vitamin K–dependent: factors II, VII, IX, and X. Proteins C and S, two natural anticoagulants, are also vitamin K–dependent. Because of its clinical relevance, the following discussion focuses only on rodenticide poisoning, which is relatively common in dogs and extremely rare in cats.

Most dogs with toxicity are evaluated because of acute collapse and a possible history of rodenticide ingestion. Coughing, thoracic pain, and dyspnea are also common. These dogs usually have clinical signs compatible with secondary bleeding, such as hematomas and bleeding into body cavities. The most common site of bleeding in dogs evaluated at our clinic is the thorax; some dogs have superficial skin bruising in areas of friction, such as the axilla or groin. Other abnormalities include pale mucous membranes, anemia (usually regenerative if sufficient time has elapsed since the acute bleeding episode), and hypoproteinemia. Sudden death may occur as a result of central nervous system or pericardial hemorrhage.

If the rodenticide has been ingested minutes to hours before presentation, induced vomiting and the administration of activated charcoal may eliminate or neutralize most of it. If the ingestion is questionable and no clinical signs of coagulopathy are present (e.g., hemothorax, hemoabdomen, bruising), determination of the OSPT is recommended. Because factor VII is the shortest lived vitamin K–dependent protein (circulating half-life, 4-6 hours), the OSPT is usually prolonged before spontaneous bleeding becomes evident.

The typical hemostasis screen in a dog with symptomatic vitamin K deficiency reveals marked prolongation of the OSPT and aPTT; this is one of the few clinical situations in which the OSPT is typically longer than the aPTT. The FDP test is positive in more than half of affected dogs and mild thrombocytopenia is present (70,000-125,000/μL), which is likely caused by an excessive consumption of platelets from protracted bleeding.

These animals usually require immediate transfusions of WFB or FFP (or cryopoor plasma) to replenish the coagulation factors (and packed RBCs if the animal is anemic). It may take 8 to 12 hours before vitamin K therapy appreciably shortens the OSPT and subsequently decreases bleeding.

Vitamin K is available in several forms, but vitamin K_1 is the most effective. It is available for oral or parenteral use. Intravenous administration of vitamin K is not recommended because of the risk of anaphylactic reactions or Heinz body formation; intramuscular injections in a dog with a coagulopathy usually result in hematoma formation. Subcutaneous administration of vitamin K_1 with a 25-gauge needle (loading dose 5 mg/kg, followed in 8 hours by 2.5 mg/kg subcutaneously [SC] q8h) is preferred if the patient is properly hydrated. Administration of oral loading doses of vitamin K_1 has been advocated for the treatment of dogs with rodenticide poisoning (5 mg/kg with a fatty meal, then 2.5 mg/kg q8-12h); this is my preferred treatment. Because vitamin K is lipid-soluble, its absorption is enhanced if given with fatty meals. Animals with cholestatic or malabsorptive syndromes may require continued subcutaneous injections of vitamin K. In critical cases the OSPT should be monitored every 8 hours until it normalizes.

If the anticoagulant is known to be warfarin or another first-generation hydroxycoumarin, 1 week of oral vitamin K_1 is usually sufficient to reverse the coagulopathy. However, if it is indanedione or any of the second- or third-generation anticoagulants, oral vitamin K_1 therapy must be maintained for at least 3 weeks and possibly as long as 6 weeks. Most currently available rodenticides contain second- and third-generation anticoagulants. If the rodenticide ingested is unknown, the animal should be treated for 1 week, at which time vitamin K treatment is discontinued. An OSPT is then determined within 24 to 48 hours of the last dose. If the OSPT is prolonged, therapy should be reinstituted and maintained for 2 more weeks and the OSPT reevaluated at the end of this period.

MIXED (COMBINED) HEMOSTATIC DEFECTS

DISSEMINATED INTRAVASCULAR COAGULATION

DIC, previously called consumptive coagulopathy or defibrination syndrome, is a complex syndrome in which excessive intravascular coagulation leads to multiple-organ microthrombosis (multiple organ failure [MOF]) and paradoxic bleeding caused by the inactivation or excessive consumption of platelets and clotting factors as a result of enhanced fibrinolysis. DIC is not a specific disorder but rather a common pathway in a variety of disorders. Moreover, DIC constitutes a dynamic phenomenon in which the patient's status and the results of coagulation tests change markedly,

rapidly, and repeatedly during treatment. This syndrome is relatively common in dogs and cats.

Pathogenesis

Several general mechanisms can lead to the activation of intravascular coagulation and therefore to the development of DIC, including the following:

- Endothelial damage
- Platelet activation
- Release of tissue procoagulants

Endothelial damage commonly results from electrocution or heat stroke, although it may also play a role in sepsis-associated DIC. Platelets can be activated by a variety of stimuli, but mainly they are activated by viral infections (e.g., FIP in cats) or sepsis. Tissue procoagulants (likely TF) are released in several common clinical conditions, including trauma, hemolysis, pancreatitis, bacterial infections, acute hepatitis, and possibly some neoplasms (e.g., HSA). TF is ubiquitous and is expressed in almost every cell membrane, except for inactive or resting endothelial cells; therefore exposure of any cell membrane to circulating blood activates the extrinsic system.

The best way to understand the pathophysiologic process of DIC is to consider the entire vascular system as a single, giant blood vessel and the pathogenesis of the disorder as an exaggeration of the normal hemostatic mechanisms. Once the coagulation cascade has been activated in this giant vessel (i.e., it is widespread within the microvasculature in the body), several events take place. Although they are described sequentially, most of them actually occur simultaneously, and the intensity of each varies with time, thus making for an extremely dynamic process.

First, the primary and secondary hemostatic plugs are formed (see p. 1387). Because this is happening in thousands or tens of thousands of small vessels simultaneously, multiple thrombi form in the microcirculation. If this process is left unchecked, ischemia (resulting in MOF) eventually develops. During this excessive intravascular coagulation, platelets are consumed and destroyed in large quantities, leading to thrombocytopenia. Second, the fibrinolytic system is activated systemically, resulting in clot lysis and the inactivation (or lysis) of clotting factors and impaired platelet function. Third, AT, proteins C and S, and other natural anticoagulant systems are consumed in an attempt to halt intravascular coagulation, leading to exhaustion of these systems. Fourth, the formation of fibrin strands within the microcirculation leads to the development of hemolytic anemia and further compounds the thrombocytopenia as the RBCs are sheared by these fibrin strands (i.e., fragmented RBCs or schistocytes).

When all these events are considered, it is easy to understand the following: (1) why an animal with multiple organ thrombosis caused by excessive intravascular coagulation and the depletion of natural anticoagulants is bleeding spontaneously (as a result of thrombocytopenia, impaired platelet function, and inactivation of clotting factors); and (2) why one of the therapeutic approaches that appears to be beneficial in halting the bleeding in dogs and cats with DIC is to administer heparin or other anticoagulants paradoxically (i.e., if sufficient AT is available, heparin halts intravascular coagulation, which in turn decreases activation of the fibrinolytic system, thus releasing its inhibitory effect on the clotting factors and platelet function).

In addition to the events just described, impaired tissue perfusion results in the development of secondary enhancers of DIC, including hypoxia; lactic acidosis; hepatic, renal, and pulmonary dysfunction; and the release of myocardial depressant factor. The function of the mononuclear-phagocytic system also is impaired so that FDPs and other by-products, as well as bacteria absorbed from the intestine, cannot be cleared from the circulation. These factors also must be dealt with therapeutically (see p. 1403).

The prevalence of primary disorders associated with DIC in 50 dogs and 21 cats evaluated by the author is depicted in Table 87.5. Neoplasia (primarily HSA), liver disease, and immune-mediated blood diseases were the most common disorders associated with DIC in dogs, whereas liver disease (primarily hepatic lipidosis), neoplasia (mainly lymphoma), and FIP were the disorders most frequently associated with DIC in cats.

In my experience, symptomatic DIC in dogs (i.e., that associated with bleeding) is most commonly associated with HSA, followed by sepsis, pancreatitis, hemolytic anemia, gastric dilation-volvulus, and liver disease. Symptomatic DIC is extremely rare in cats but hemostatic evidence of DIC is common, accounting for approximately two thirds of the abnormal hemostatic profiles in this species. As noted, DIC is common in cats with liver disease, hypertrophic cardiomyopathy, sepsis, malignant neoplasms, or FIP. We have also observed symptomatic DIC in two cats receiving methimazole. The pathogenesis of DIC in dogs with HSA appears to be complex and multifactorial; the major mechanism triggering intravascular coagulation in dogs with this neoplasm was thought to be the abnormal irregular endothelium in the neoplasm (i.e., exposure to subendothelial collagen and the activation of coagulation). However, some canine HSAs appear to synthesize a cancer procoagulant because dogs with small HSAs can have severe DIC, whereas some dogs with widely disseminated HSA have normal hemostasis.

Clinical Features

Dogs with DIC can have several clinical presentations; the two common forms are chronic silent (subclinical) and acute (fulminant) DIC. In the chronic silent form, the patient does not have evidence of spontaneous bleeding, but clinicopathologic evaluation of the hemostatic system reveals abnormalities compatible with this syndrome (see later). This form of DIC appears to be common in dogs with malignancy and other chronic disorders. The acute form may represent a true acute phenomenon (e.g., after heat stroke, electrocution, or acute pancreatitis) or, more commonly, it represents acute decompensation of a chronic silent process (e.g., HSA).

Acute DIC is extremely rare in cats. Regardless of the pathogenesis, dogs with acute DIC often are brought in because of profuse spontaneous bleeding and constitutional signs attributable to anemia or parenchymal organ thrombosis (MOF). The clinical signs of bleeding indicate both primary bleeding (e.g., petechiae, ecchymoses, mucosal bleeding) and secondary bleeding (blood in body cavities); diffuse intraoperative bleeding is frequently the first sign detected by the clinician. Clinical and clinicopathologic evidence of organ dysfunction is also present. Most cats with DIC seen at our clinic do not have evidence of spontaneous bleeding; clinical signs in these cats are those associated with the primary disease.

In a recent retrospective study of 50 dogs with DIC conducted in our clinic, only 26% had evidence of spontaneous bleeding, whereas only one of 21 cats with DIC had evidence of spontaneous bleeding. Most patients were presented for evaluation of their primary problem and were not bleeding spontaneously; DIC was diagnosed as part of the routine clinical evaluation.

Diagnosis

Several hematologic findings help support a presumptive clinical diagnosis of DIC. These include a regenerative hemolytic anemia (although occasionally, because the patient has a chronic disorder such as cancer, the anemia is nonregenerative), hemoglobinemia (caused by intravascular hemolysis), RBC fragments or schistocytes, thrombocytopenia, neutrophilia with a left shift and toxic changes, and rarely neutropenia. Most of these features are evident with the evaluation of a spun hematocrit and blood smear.

Serum biochemical abnormalities in patients with DIC include hyperbilirubinemia from hemolysis or hepatic thrombosis, azotemia and hyperphosphatemia if severe renal microembolization has occurred, increase in liver enzyme activities caused by hypoxia or hepatic microembolization, decreased total carbon dioxide content caused by metabolic acidosis, and panhypoproteinemia if the bleeding is severe enough. Another manifestation of MOF is the development of multifocal ventricular premature contractions resulting in a tachyarrhythmia and easily visualized in an electrocardiogram.

Urinalysis usually reveals hemoglobinuria and bilirubinuria and occasionally proteinuria and cylindruria. Urine samples in dogs with acute DIC should not be obtained by cystocentesis because severe intravesical or intramural bleeding may result.

Hemostatic abnormalities in dogs with DIC include thrombocytopenia, prolongation of the OSPT or aPTT (>25% of the concurrent control), normal or low fibrinogen concentration, positive FDP or D-dimer test, and decreased AT concentration. Using a TEG, fibrinolysis can be enhanced in these animals. At our clinic, DIC is diagnosed if the patient has four or more of the hemostatic abnormalities just described, particularly if schistocytes are present.

The hemostatic abnormalities in 50 dogs and 21 cats with DIC evaluated in our clinic are listed in Table 87.6. In dogs thrombocytopenia, prolongation of the aPTT, anemia, and schistocytosis were common; in contrast with previous descriptions of the syndrome in dogs, regenerative anemia, prolongation of the OSPT, and hypofibrinogenemia were not. In cats prolongation of the aPTT and/or OSPT, schistocytosis, and thrombocytopenia were common,

whereas the presence of FDPs and hypofibrinogenemia were rare.

Estrin et al. (2006) have described clinical and clinicopathologic findings in 46 cats with DIC. Spontaneous bleeding was present in 15% of the cats; 43 of 46 cats died or were euthanized. The most common underlying disorders were lymphoma, other forms of neoplasia, pancreatitis, and sepsis. The median PT of nonsurvivors was more prolonged than in survivors ($P = 0.005$). DIC in cats can result from a variety of neoplastic, infectious, and inflammatory disorders and is associated with a high case fatality rate.

Treatment

Once a diagnosis of DIC has been established, or even if the degree of suspicion is high that DIC is present, treatment should be instituted without delay. Unfortunately, no controlled clinical trials have been performed in veterinary medicine evaluating the effects of different treatments in dogs or cats with DIC, so this discussion reflects my personal recommendations for the treatment of dogs with this disorder (Box 87.6).

Unquestionably, removing or eliminating the precipitating cause constitutes the main therapeutic goal in patients with DIC, but this is not always possible. Conditions in which the precipitating causes can be eliminated or ameliorated include a primary HSA (surgical excision), disseminated or metastatic HSA (chemotherapy), sepsis (appropriate antimicrobial treatment), and IHA (immunosuppressive treatment). In most other situations (e.g., electrocution, heat stroke, pancreatitis), the cause can rarely be eliminated within a short time. Therefore the treatment of dogs with DIC is aimed at the following:

- Halting intravascular coagulation
- Maintaining good parenchymal organ perfusion
- Preventing secondary complications

BOX 87.6

Treatment of Dogs and Cats With Disseminated Intravascular Coagulation

1. Eliminate the precipitating cause.
2. Halt intravascular coagulation:
   Heparin
   - Minidose: 5-10 IU/kg SC q8h
   - Low dose: 50-100 IU/kg SC q8h
   - Intermediate dose: 300-500 IU/kg, SC or IV, q8h
   - High dose: 750-1000 IU/kg, SC or IV, q8h

   Blood or blood products (provide AT, other anticoagulants, and clotting factors)
3. Maintain parenchymal organ perfusion:
   Aggressive fluid therapy
4. Prevent secondary complications:
   Oxygen
   Correction of acid-base imbalance
   Antiarrhythmics
   Antibiotics

AT, Antithrombin.

Of note, if blood and blood products were available in an unlimited supply, as is the case in most human hospitals, small animal patients with DIC would not die of hypovolemic shock. Most dogs with DIC die of pulmonary or renal dysfunction. At our clinic, so-called DIC lungs (i.e., intrapulmonary hemorrhages with alveolar septal microthrombi) appear to be a common cause of death in these patients.

Halting Intravascular Coagulation

I use a dual approach to halt intravascular coagulation—the administration of heparin and blood or blood products. As noted, heparin is a co-factor for AT and therefore is not effective in preventing the activation of coagulation unless AT activity in the plasma is sufficient. Because AT activity in animals with DIC is usually low as a result of consumption and possibly inactivation, the patient should be provided with sufficient quantities of this anticoagulant. The most cost-efficient way of achieving this is to administer FFP. The old adage that administering blood or blood products to a dog with DIC is analogous to "adding logs to a fire" has not been true, in my experience. Therefore blood or blood products should never be withheld based solely on this.

Heparin has been used historically to treat DIC in humans and dogs. However, controversy still exists regarding whether it is beneficial. In my experience, the survival rate in dogs with DIC seems to have increased since I started using heparin and blood products. Although this can also be attributed to improvement in patient care, I believe that heparin is beneficial in such patients and indeed may be responsible for the increased survival rate.

Sodium heparin is given in a wide range of doses. Following are the four traditional dose ranges:

- Minidose: 5 to 10 IU/kg SC q8h
- Low dose: 50 to 100 IU/kg SC q8h
- Intermediate dose: 300 to 500 IU/kg, SC or IV, q8h
- High dose: 750 to 1000 IU/kg, SC or IV, q8h

I use low-dose heparin in combination with the transfusion of blood or blood components. The rationale is that this dose of heparin does not prolong the ACT or aPTT in normal dogs (a minimum of 150-250 IU/kg q8h is required to prolong the aPTT in normal dogs), and it appears to be biologically active in these animals, given that some of the clinical signs and hemostatic abnormalities are reversed in animals receiving this dosage. The fact that it does not prolong the aPTT or ACT is extremely helpful in dogs with DIC. For example, if a dog with DIC is receiving intermediate-dose heparin, it is impossible to predict, on the basis of hemostatic parameters, whether a prolongation of the aPTT is caused by excessive heparin administration or progression of this syndrome. As laboratory tests for the determination of heparin levels become widely available, this may become a moot point. Until then, my clinical impression is that if an animal with DIC receiving minidose or low-dose heparin shows a prolonged ACT or aPTT, the intravascular coagulation is deteriorating and a treatment change is necessary. The use of low-molecular-weight heparin in dogs with DIC has been investigated. In an experimental model of DIC in Beagles, high doses of low-molecular-weight heparin resulted in resolution of the clinicopathologic abnormalities associated with DIC (Mischke et al., 2005).

I recently used cryoprecipitate infusions to treat five dogs with DIC successfully; three had hemangiosarcoma and two had gastric dilation-volvulus (GDV). Lepirudin, a novel leech recombinant AT, has proved beneficial in preventing MOF in an experimental model of sepsis with enteric organisms in Greyhounds. However, this treatment is currently cost-prohibitive.

If evidence of severe microthrombosis is present (e.g., marked azotemia, lactic acidosis, increase in liver enzyme levels, multifocal ventricular premature contractions), dyspnea, or hypoxemia, intermediate- or high-dose heparin can be used, with the goal of prolonging the ACT to 2 to 2.5 times the baseline value, or normal if the baseline time was already prolonged. TEG can also be used to monitor heparinization. If overheparinization occurs, protamine sulfate can be administered by slow intravenous infusion (1 mg for each 100 IU of the last dose of heparin; 50% of the calculated dose is given 1 hour after the heparin and 25% 2 hours after the heparin). The remainder of the dose can be administered if clinically indicated. Protamine sulfate should be administered with caution because it can be associated with acute anaphylaxis in dogs. Once improvement in the clinical and clinicopathologic parameters has been achieved, the heparin dose should be tapered gradually, over 1 to 3 days, to prevent rebound hypercoagulability, a phenomenon commonly observed in humans.

Aspirin and other antiplatelet agents can also be given to prevent platelet activation and thus halt intravascular coagulation. Doses of 0.5 to 10 mg/kg of aspirin given orally every 12 hours in dogs and every third day in cats have been recommended, although in my experience aspirin is rarely of clinical benefit. If it is used, the patient should be closely watched for severe GI tract bleeding, because this NSAID can cause gastroduodenal ulceration, which could be catastrophic in a dog with a severe coagulopathy such as DIC.

Maintaining Good Parenchymal Organ Perfusion

Good parenchymal organ perfusion is best achieved with aggressive fluid therapy consisting of crystalloids or plasma expanders such as dextran (see Table 87.6). The purpose of this therapy is to dilute out the clotting and fibrinolytic factors in the circulation, flush out microthrombi from the microcirculation, and maintain the precapillary arterioles patent so that blood is shunted to areas in which oxygen exchange is efficient. However, care should be taken not to overhydrate an animal with compromised renal or pulmonary function.

Preventing Secondary Complications

As noted, numerous complications occur in dogs with DIC. Attention should be directed toward maintaining oxygenation by oxygen mask, cage, or nasopharyngeal catheter, correcting acidosis, eliminating cardiac arrhythmias, and preventing secondary bacterial infections. The ischemic GI mucosa no longer functions as an effective barrier to microorganisms, bacteria are absorbed and cannot be cleared by the hepatic mononuclear-phagocytic system, and sepsis occurs.

Prognosis

The prognosis for dogs and cats with DIC is still grave. Despite the numerous acronyms for DIC coined over the past few decades (e.g., "death is coming," "dead in cage," "dog in cooler"), most patients recover with appropriate treatment if the inciting cause can be controlled. In the retrospective study of DIC in dogs conducted at OSU-VTH, the mortality rate was 54%; however, the mortality rate in dogs with minor changes in the hemostasis screen (fewer than three abnormalities) was 37%, whereas in dogs with severe hemostatic abnormalities (more than three hemostatic abnormalities) it was 74%. In addition, marked prolongation of the aPTT and marked thrombocytopenia were negative prognostic factors. The median aPTT in dogs that survived was 46% over the controls, whereas it was 93% over the controls in dogs that did not survive. Similarly, the median platelet count in dogs that survived was 110,000/μL, and in dogs that did not survive it was 52,000/μL.

THROMBOSIS

Thrombotic and thromboembolic disorders appear to be considerably less common in cats and dogs than in humans. Several situations can result in thrombosis or TE, including stasis of blood, activation of intravascular coagulation in an area of abnormal or damaged endothelium, decreased activity of natural anticoagulants, and decreased or impaired fibrinolysis. Thrombosis has been recognized clinically as associated with cardiomyopathy, hyperadrenocorticism, protein-losing enteropathy and nephropathy, and IHA. A syndrome of aortoiliac thrombosis has been recognized primarily in Cavalier King Charles Spaniels, Greyhounds, and other sighthound breeds (Goncalves et al., 2008; Lake-Bakaar et al., 2012).

Diagnosing TE is not an easy task. Clinical signs are variable and include signs associated with parenchymal organ ischemia (e.g., dyspnea from pulmonary TE, high liver enzyme activities in patients with hepatic TE, intermittent rear limb claudication in dogs with aortic thrombosis). A positive D-dimer test has been reported to be associated with TE disease in dogs, but that is not my experience. TEG is a rapid and sensitive test to diagnose TE disease in some dogs (Fig. 87.5); however, in a large proportion of dogs with overt thrombosis, the TEG tracings are normal.

Stasis of blood and possibly an irregular endothelial surface appear to be the major causes in cats with aortic (iliac) TE secondary to hypertrophic cardiomyopathy. Arterial pathology and high blood viscosity associated with a high hematocrit are suspected in Greyhounds and other sighthounds. Decreased activity of the natural anticoagulant AT plays a major role in the thrombosis seen in dogs with protein-losing nephropathy or protein-losing enteropathy; in addition, humans with hypertension frequently have a high concentration of PAI-1, which in turn inhibits fibrinolysis, thus resulting in a net procoagulant effect. This mechanism may also be important in dogs with protein-losing nephropathy and hypertension. The decreased AT activity stems from the fact that this is a relatively small molecule (≈60 kDa) that is easily lost in the urine or gut contents in dogs with either of these two disorders. The thrombosis commonly seen in dogs with hyperadrenocorticism is likely related to the induction of PAI-1 synthesis by corticosteroids (corticosteroids inhibit fibrinolysis). An increased risk for TE has been recognized in dogs with IHA. Although the pathogenesis of these disorders is obscure, the release of procoagulants from the lysed RBCs has been postulated as a cause; sludging of autoagglutinated RBCs in the microcirculation is also likely to contribute to this procoagulant state.

Dogs and cats at high risk for thrombosis or TE should receive anticoagulants. The two drugs commonly used in cats and dogs at risk for this condition are aspirin and heparin. Coumarin derivatives are commonly used in humans, but in dogs and cats they can result in excessive bleeding. In recent reports of human AT deficiency, anabolic steroids such as stanozolol have also been suggested to decrease the risk of thrombotic disorders because of their stimulatory effect on the fibrinolytic system. The recognition and management of pulmonary TE are discussed in Chapter 22.

CHAPTER 88

Lymphadenopathy and Splenomegaly

APPLIED ANATOMY AND HISTOLOGY

The lymph nodes and spleen constitute the main source of immunologic and mononuclear-phagocytic (MP) cells in the body. Because these lymphoid structures are in a constant dynamic state, they continuously reshape and change in size in response to antigenic stimuli. In general, the response of the cells within a lymph node to different stimuli is similar to that occurring in the spleen. However, the spleen responds primarily to bloodborne antigens (mainly nonopsonized organisms), whereas the lymph nodes respond to antigens arriving through the afferent lymphatics (i.e., local tissue response). The response of the lymph nodes and spleen to different stimuli is briefly reviewed in this chapter.

Lymph nodes are reniform, encapsulated, well-developed structures responsible for filtering lymph and participating in immunologic reactions. Fig. 88.1 depicts the basic microscopic anatomy of a lymph node in a carnivore. It is composed of a capsule, subcapsular spaces, cortex, paracortex, and medulla. Each of these areas has specific functions. The capsule surrounds and supports all other structures within the node (stroma). The subcapsular spaces (or sinuses) contain mainly MP cells responsible for "filtering" particles arriving through the afferent lymphatics and presenting the antigens to the lymphoid cells. The cortex contains mainly B-cell areas in the germinal centers; when properly stimulated, the primary follicles turn into secondary follicles, containing primarily early lymphoid cells in the center. The paracortex is composed primarily of T cells and is therefore involved in cell-mediated immunity. The medulla contains the medullary cords, in which the committed B cells persist and may expand to solid areas of plasma cells in response to antigenic stimulation. Between the medullary cords, the medullary sinuses form an endothelial sieve containing varying numbers of MP cells, which screen the efferent lymph. The lymph flows from the medulla to the efferent lymphatics in the hilus.

An understanding of the different histologic and functional characteristics of these anatomic areas aids in understanding the pathogenesis of lymphadenopathy. For example, a lymph node reacting to a bacterial infection has primarily B-cell hyperplasia characterized by increased numbers of secondary follicles. This histologic-functional compartmentalization should be kept in mind when interpreting cytologic or histopathologic lymph node specimens.

Recently, Suami et al. described lymphatic territories (lymphosomes), areas that drain specific lymph nodes and are useful when identifying sentinel lymph nodes during oncologic surgery (Suami et al., 2013).

FUNCTION

The two main functions of the lymph nodes are to filter particulate material and participate in immunologic processes. Particulate material is filtered as lymph flows through the areas rich in MP cells while it moves from the afferent to the efferent lymphatics. During this transit, particulate material is taken up and processed by the MP or antigen-processing (AP) cells and presented to the lymphoid cells to elicit a humoral or cellular immune response.

The spleen has multiple functions, including extramedullary hematopoiesis, filtration and phagocytosis, remodeling of red blood cells (RBCs), removal of intraerythrocytic inclusions, storage of RBCs and platelets, metabolizing of iron, and immunologic functions. The canine spleen also stores reticulocytes and releases them into circulation in response to catecholamine release (Horvath et al., 2014). Because of its nonsinusal nature, the feline spleen is less efficient at removing intracellular inclusions than its canine counterpart.

LYMPHADENOPATHY

Etiology and Pathogenesis

In this chapter, lymphadenopathy is defined as lymph node enlargement. According to the distribution, the following terms are used to characterize lymphadenopathy. *Solitary lymphadenopathy* refers to the enlargement of a single lymph

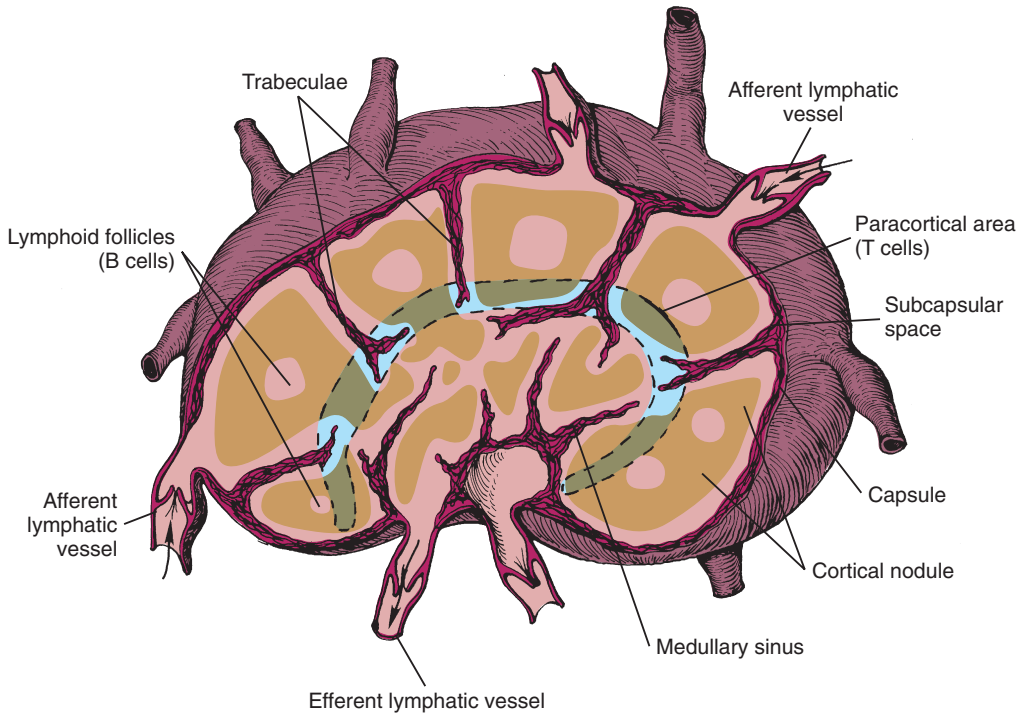

FIG 88.1
Microscopic anatomy of a typical lymph node in a carnivore. (From Couto CG: Diseases of the lymph nodes and spleen. In Ettinger SJ, editor: *Textbook of veterinary internal medicine—diseases of the dog and cat,* ed 3, Philadelphia, 1989, WB Saunders.)

node. *Regional lymphadenopathy* is the enlargement of a chain of lymph nodes draining a specific anatomic area. *Generalized lymphadenopathy* is a multicentric lymph node enlargement affecting more than one anatomic area. Lymphadenopathies can also be classified as superficial or deep (or visceral) according to their anatomic location.

Lymph nodes enlarge as a consequence of the proliferation of normal cells that normally reside in the node, or infiltration with normal or abnormal cells. Rarely lymph nodes enlarge as a result of vascular changes (e.g., hyperemia, congestion, neovascularization, edema).

When normal cells proliferate within a lymph node in response to antigenic stimuli (e.g., vaccination, infection), the term *reactive lymphadenopathy* (or lymph node hyperplasia) is used. Lymphoid and MP-AP cells proliferate in response to immunologic and infectious stimuli, although occasionally a clinician evaluates a dog or cat in which a cause for the reactive lymphadenopathy cannot be identified. Because these lymphoid structures are usually presented with many antigens simultaneously, the cell proliferation that occurs in reactive lymphadenopathies is polyclonal; that is, a wide variety of morphologic types of lymphoid and MP-AP cell types are present in a cytologic or histopathologic specimen.

When polymorphonuclear leukocytes or macrophages predominate in the cellular infiltrate, the term *lymphadenitis* is used. This is usually, but not always, a result of infectious processes. Depending on the predominant cell type in the infiltrate, lymphadenitides are classified as suppurative (neutrophils predominate), granulomatous (macrophages predominate), pyogranulomatous (macrophages and neutrophils predominate), or eosinophilic (eosinophils predominate). A focal area of suppurative inflammation with marked liquefaction (i.e., pus) is referred to as a lymph node abscess. The agents that commonly cause the different types of lymphadenitis are listed in Table 88.1.

Infiltrative lymphadenopathies usually result from the displacement of normal lymph node structures by neoplastic cells and, infrequently, from extramedullary hematopoiesis. Neoplasms affecting the lymph nodes can be primary hematopoietic tumors or secondary (metastatic) neoplasms. Lymph node infiltration by hematopoietic malignancies (i.e., lymphoma) constitutes one of the most common causes of generalized lymphadenopathy in dogs (see Table 88.1).

Clinical Features

From a clinical standpoint, familiarization with the location and palpation characteristics of normal lymph nodes, which should always be evaluated during a routine physical examination, is important. The following lymph nodes are palpable in normal dogs and cats: mandibular, prescapular (or superficial cervical), axillary (in approximately half of animals), superficial inguinal, and popliteal (Fig. 88.2). Lymph nodes that are palpable only when markedly enlarged include the facial, retropharyngeal, mesenteric, and iliac (sublumbar) lymph nodes.

TABLE 88.1

Classification of Lymphadenopathies in Dogs and Cats

TYPE	SPECIES
Proliferative and Inflammatory Lymphadenopathies	
Infectious	
Bacterial	
Actinomyces spp.	D, C
Borrelia burgdorferi	D
Brucella canis	D
Corynebacterium spp.	C
Mycobacterium spp.	D, C
Nocardia spp.	D, C
Streptococci	D, C
Contagious streptococcal lymphadenopathy	C
Yersinia pestis	C
Bartonella spp.	D, C
Localized bacterial infection	D, C
Septicemia	D, C
Rickettsial	
Ehrlichiosis	D, C
Anaplasmosis	D, C
RMSF	D
Salmon poisoning	D
Fungal	
Aspergillosis	D, C
Blastomycosis	D, C
Coccidioidomycosis	D
Cryptococcosis	D, C
Histoplasmosis	D, C
Phaeohyphomycosis	D, C
Phycomycosis	D, C
Sporotrichosis	D, C
Pneumocystis spp.	D
Other mycoses	D, C
Algal	
Protothecosis	D, C
Parasitic	
Babesiosis	D
Cytauxzoonosis	C
Demodicosis	D, C
Hepatozoonosis	D
Leishmaniasis	D
Neospora caninum	D
Toxoplasmosis	D, C
Trypanosomiasis	D
Viral	
Canine viral enteritides	D
Feline immunodeficiency virus	C
Feline infectious peritonitis	C
Feline leukemia virus	C
Infectious canine hepatitis	D
Noninfectious	
Dermatopathic lymphadenopathy	D, C
Drug reactions	D, C
Idiopathic	D, C
Distinctive peripheral lymph node hyperplasia	C
Plexiform vascularization of lymph nodes	C
Immune-mediated disorders	
Systemic lupus erythematosus	D, C
Rheumatoid arthritis	D
Immune-mediated polyarthritides	D, C
"Puppy strangles" (juvenile cellulitis)	D
Other immune-mediated disorders	D, C
Localized inflammation	D, C
Postvaccinal	D, C
Infiltrative Lymphadenopathies	
Neoplastic	
Primary hemolymphatic neoplasms	
Leukemias	D, C
Lymphomas	D, C

C, Cats; *D,* dogs; *RMSF,* Rocky Mountain spotted fever.
Modified from Hammer AS, et al.: Lymphadenopathy. In Fenner NR, editor: *Quick reference to veterinary medicine,* ed 2, Philadelphia, 1991, JB Lippincott.

When evaluating dogs and cats with lymphadenopathy or diffuse splenomegaly, the clinician can glean important information from the history. Certain diseases are prevalent in certain breeds, such as mycobacterial infections in Basset Hounds and Schnauzers; histiocytic neoplasms in Bernese Mountain dogs, Rottweilers, Labradors, Golden Retrievers, and Flat Coated retrievers; others have a defined geographic or seasonal prevalence, including leishmaniasis in the Mediterranean region of Europe, salmon poisoning in the Pacific Northwest, and some systemic mycoses, such as histoplasmosis in the Ohio River Valley. Systemic (constitutional) clinical signs are usually present in dogs with systemic

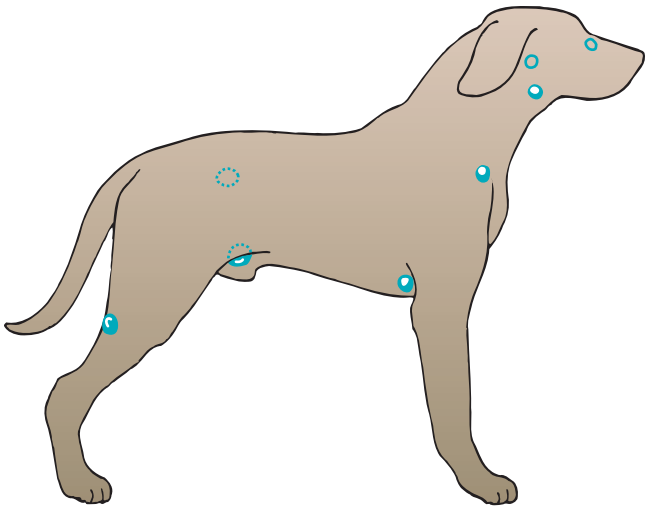

FIG 88.2
Anatomic distribution of clinically relevant lymph nodes in a dog. The nodes are in the same general location in cats. The lymph nodes depicted by the *darkened circles* include, from cranial to caudal, the mandibular, prescapular, axillary, superficial inguinal, and popliteal lymph nodes. The lymph nodes depicted by the *open circles* include, from cranial to caudal, the facial, retropharyngeal, and iliac or sublumbar lymph nodes. (From Couto CG: Diseases of the lymph nodes and spleen. In Ettinger SJ, editor: *Textbook of veterinary internal medicine—diseases of the dog and cat,* ed 3, Philadelphia, 1989, WB Saunders.)

mycoses, salmon poisoning, Rocky Mountain spotted fever (RMSF), anaplasmosis, ehrlichiosis, bartonellosis, leishmaniasis, or acute leukemia, and in some dogs and cats with immune-mediated diseases. Clinical signs are rare or can be absent in dogs and cats with chronic lymphocytic leukemia, anaplasmosis, most lymphomas, and reactive lymphadenopathies occurring after vaccination; cats with idiopathic reactive lymphadenopathy (see later) are usually asymptomatic.

Clinical signs in dogs and cats with lymphadenopathy or splenomegaly are vague and nonspecific and are usually related to the primary disease rather than the organ enlargement. They include anorexia, weight loss, weakness, abdominal distention, vomiting, diarrhea, polyuria-polydipsia (PU-PD; in dogs with lymphoma-associated hypercalcemia), or a combination of these. Enlarged lymph nodes can occasionally result in obstructive or compressive signs (e.g., dysphagia resulting from enlarged retropharyngeal nodes, coughing resulting from enlarged tracheobronchial nodes; see Fig. 79.7).

The distribution of the lymphadenopathy is also of diagnostic relevance. In patients with solitary or regional lymphadenopathy, the area drained by the lymph node(s) should be examined meticulously because the primary lesion is generally found there. As discussed earlier, Suami et al. recently published an excellent review of lymphatic territories. Most cases of superficial solitary or regional lymphadenopathy in dogs and cats result from localized inflammatory or infectious processes or from metastatic neoplasia (less commonly), whereas most cases of deep (e.g., intraabdominal, intrathoracic) solitary or regional lymphadenopathy result from metastatic neoplasia or systemic infectious diseases (e.g., systemic mycoses). Recently, cyst-like lesions of intraabdominal lymph nodes in patients with both nonneoplastic (70%) or neoplastic (30%) lesions were described (Liotta et al., 2017). Idiopathic mesenteric purulent lymphadenopathy was also recently described in dogs (Salavati Schmitz, 2016). Most cases of generalized lymphadenopathy are caused by systemic fungal or bacterial infections (dogs), nonspecific hyperplasia (mainly cats), or lymphoma (dogs; Table 88.2).

The characteristics of the lymph nodes on palpation are also important. In most dogs and cats with lymphadenopathy, regardless of the distribution, the lymph nodes are firm, irregular, and painless; their temperature is normal to the touch (cold lymphadenopathies); and they do not adhere to the surrounding structures. However, in patients with lymphadenitis, the lymph nodes may be softer than usual and more tender and warmer than normal; they may also adhere to surrounding structures (fixed lymphadenopathy). Fixed lymphadenopathies may also be the presenting feature in dogs and cats with metastatic lesions, lymphomas with extracapsular invasion, or certain infectious diseases (e.g., mycobacteriosis).

The size of the affected lymph nodes is also important. Massive lymphadenopathy—lymph node size 5 to 10 times normal—occurs almost exclusively in dogs with lymphoma, malignant histiocytosis (Fig. 88.3), or infectious lymphadenitis (lymph node abscess formation; hilar lymphadenopathy in dogs with histoplasmosis). In cats, the

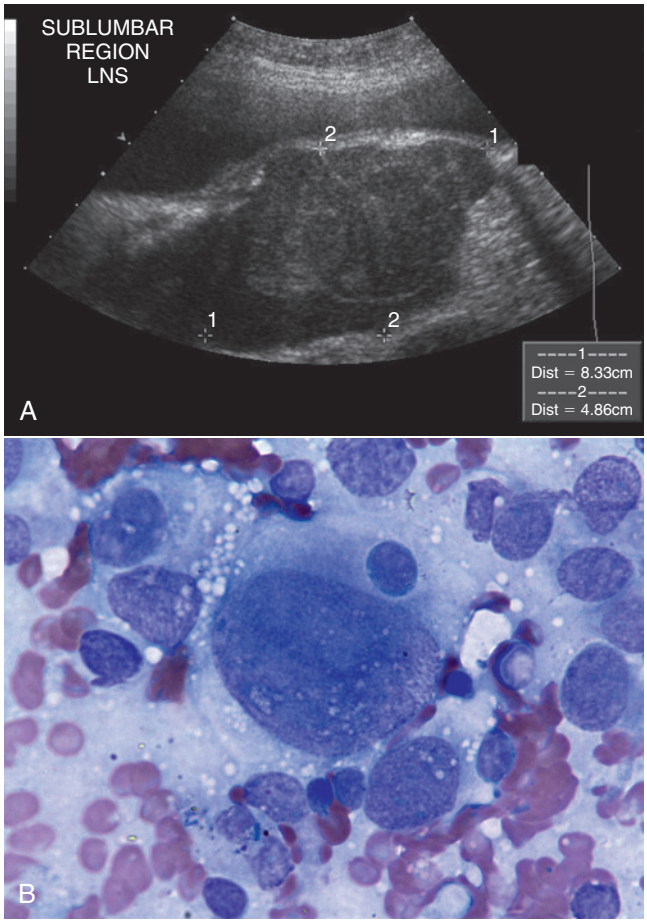

FIG 88.3
(A) Ultrasonographic image of massive sublumbar (iliac) lymphadenopathy in a Great Pyrenees with malignant histiocytosis. **(B)** Cytologic evaluation revealed a pleomorphic population of round cells exhibiting cytophagia (Diff-Quik stain; ×1000).

syndrome of distinctive lymph node hyperplasia usually results in massive lymphadenopathy (Fig. 88.4). Rarely metastatic lymph nodes exhibit this degree of enlargement; the main example of massive metastatic lymphadenopathy is the apocrine gland adenocarcinoma metastases to the sublumbar lymph nodes. Recognizing that lymph nodes of normal size may contain metastatic neoplasia is important; this is relatively common in dogs with mast cell tumors, where a node that is normal on palpation may contain large numbers of metastatic mast cells. Dogs with salmon poisoning may also have marked generalized lymphadenopathy as the presenting feature, preceded by or in conjunction with bloody diarrhea. Mild to moderate lymph node enlargement (two to four times the normal size) occurs mostly in a variety of reactive and inflammatory lymphadenopathies (e.g., ehrlichiosis, bartonellosis, anaplasmosis, RMSF, systemic mycoses, leishmaniasis, immune-mediated diseases, skin diseases) and in leukemias.

As noted, the area draining the enlarged lymph node(s) should always be thoroughly examined (Suami et al., 2013),

FIG 88.4
Massive mandibular lymphadenopathy in a young feline leukemia virus–positive cat with idiopathic reactive lymphadenopathy. The lymphadenopathy resolved with supportive care.

paying particular attention to the skin, subcutis, and bone. In dogs and cats with generalized lymphadenopathy, evaluation of other hemolymphatic organs, such as the spleen, liver, and bone marrow is important.

SPLENOMEGALY

Etiology and Pathogenesis

Splenomegaly is defined as a localized or diffuse splenic enlargement. The term *localized splenomegaly* (or splenic mass) refers to a localized palpable enlargement of the spleen. Diffuse splenic enlargement occurs as a consequence of the proliferation of normal cells or infiltration with normal or abnormal cells. Rarely diffuse splenic enlargement can occur as a result of vascular changes (e.g., hyperemia, congestion). Focal splenomegaly is more common in dogs, and diffuse splenomegaly is more common in cats.

Diffuse splenomegaly is classified into four major categories in terms of its pathogenesis—lymphoreticular hyperplasia, inflammatory (e.g., splenitis), infiltration with abnormal cells (e.g., lymphoma) or substances (e.g., amyloidosis), and congestion (Table 88.3).

The spleen commonly reacts to bloodborne antigens and RBC destruction with hyperplasia of the MP-AP and lymphoid components. This hyperplasia has been referred to as work hypertrophy because it usually results in varying degrees of splenic enlargement. Hyperplastic splenomegaly is relatively common in dogs with ehrlichiosis, leishmaniasis, bacterial endocarditis, systemic lupus erythematosus, or chronic bacteremic disorders such as diskospondylitis and brucellosis, and in cats with mycoplasmosis or immune-mediated cytopenias.

RBC phagocytosis by the splenic MP system in humans can lead to hyperplasia of this cell population, resulting in

TABLE 88.3

Pathogenetic Classification of Splenomegaly in Dogs and Cats

TYPE	SPECIES
Inflammatory and Infectious Splenomegaly	
Suppurative splenitis	
Penetrating abdominal wounds	D, C

C, Cats; *D,* dogs; *EMH,* extramedullary hematopoiesis.
Modified from Couto CG: Diseases of the lymph nodes and the spleen. In Ettinger S, editor: *Textbook of veterinary internal medicine,* ed 3, Philadelphia, 1989, WB Saunders.

splenomegaly. The same seems to occur in dogs and cats with certain hemolytic disorders, including immune-mediated hemolytic anemia, drug-induced hemolysis, pyruvate kinase deficiency anemia, phosphofructokinase deficiency anemia, familial nonspherocytic hemolysis in Poodles and Beagles, Heinz body hemolysis, and mycoplasmosis. Rarely an area of focal splenomegaly is diagnosed histopathologically as hyperplasia (i.e., nodular hyperplasia) after performing a splenectomy.

As in the lymph nodes, if polymorphonuclear leukocytes or macrophages predominate in the cellular infiltrate, the term *splenitis* is used. The infiltrates are also classified according to the cell type as suppurative, granulomatous, pyogranulomatous, or eosinophilic. Splenic abscesses can also form, often in association with a perforation by a foreign body. Necrotizing splenitis caused by gas-forming anaerobes can occur in dogs in association with splenic torsion or neoplasia. Lymphoplasmacytic splenitis cannot be distinguished cytologically from splenic hyperplasia. The causative agents for different types of splenitis are listed in Table 88.3. In a recent study of 33 dogs with splenitis in Italy (Ferri et al., 2016), most dogs had purulent (suppurative; 27%) or pyogranulomatous (24%) splenitis. In most dogs with purulent splenitis, bacteria could be identified when

using Gram stain. Most dogs with pyogranulomatous splenitis had leishmaniasis.

Infiltrative splenomegalies are also common in small animals. Marked splenomegaly is a common finding in dogs and cats with acute and chronic leukemias, although it is more common in dogs; in dogs and cats with systemic mastocytosis; and in dogs with malignant histiocytosis. In addition, diffuse neoplastic infiltration of the spleen commonly occurs in dogs and cats with lymphoma or multiple myeloma. Diffuse splenomegaly may be the only physical examination and imaging finding in cats with monoclonal gammopathies; fine-needle aspiration (FNA) of the spleen reveals diffuse infiltration with plasma cells and is a common presentation for myeloma in this species. Metastatic splenic neoplasms usually result in focal splenomegaly but are rare.

Nonneoplastic causes of infiltrative splenomegaly are uncommon, with the exception of extramedullary hematopoiesis (EMH), which is more common in dogs than in cats. Because the spleen retains its fetal hematopoietic potential during adult life, a variety of stimuli—such as anemia, severe splenic or extrasplenic inflammation, neoplastic infiltration of the spleen, bone marrow hypoplasia, and splenic congestion—may cause the spleen to resume its fetal hematopoietic function and produce RBCs, white blood cells, and platelets. Finding EMH by percutaneous FNA of the spleen is the norm in dogs and cats with diffuse or focal splenomegaly; the presence of hematopoietic blasts may lead to an erroneous diagnosis of lymphoma in some of these patients. I have also observed splenic EMH in dogs with pyometra, immune-mediated hemolysis, immune-mediated thrombocytopenia, several infectious diseases, and a variety of malignant neoplasms as well as in seemingly healthy dogs. Another disorder that commonly results in prominent infiltrative splenomegaly is the hypereosinophilic syndrome of cats (and some dogs, such as Rottweilers), a disease characterized by peripheral blood eosinophilia, bone marrow hyperplasia of the eosinophil precursors, and multiple-organ infiltration by mature eosinophils (see Chapter 85).

The canine and feline spleens have a great capacity to store blood, and under normal circumstances they store between 10% and 20% of the total blood volume. However, tranquilizers and barbiturates can cause splenic blood pooling because of relaxation of the smooth muscle of the splenic capsule, leading to congestive splenomegaly. The blood that has pooled in an enlarged spleen can account for up to 30% of the total blood volume. Anesthetics rarely used these days, such as halothane, also may result in marked decreases of 10% to 20% in the packed cell volume and plasma protein concentration in dogs as a result of the same mechanism.

Portal hypertension can lead to congestive splenomegaly; however, such splenic congestion does not appear to be as common in dogs and cats as it is in humans. Causes of portal hypertension that may lead to splenomegaly in small animals include right-sided congestive heart failure, obstruction of the caudal vena cava as a result of congenital malformations, neoplasia, heartworm disease, and intrahepatic obstruction of the vena cava. Splenic vein thrombosis is a common incidental finding in dogs; it is usually associated with the administration of corticosteroids and is typically of no clinical relevance. Ultrasonographic evaluation in these patients usually reveals markedly distended splenic, portal, or hepatic veins or thrombi.

A relatively common cause of congestive splenomegaly in dogs is splenic torsion (DeGroot et al., 2016). Torsion of the spleen, by itself or in association with gastric dilation-volvulus syndrome, commonly results in marked splenomegaly caused by congestion. Splenic torsion can occur independently of gastric dilation-volvulus syndrome. Most affected dogs are large, deep-chested breeds, primarily Great Danes, Chows, and German Shepherd Dogs. Clinical signs can be acute or chronic. Dogs with acute splenic torsion are usually evaluated because of acute abdominal pain and distention, vomiting, depression, and anorexia. Dogs with chronic splenic torsion display a wide variety of clinical signs, including anorexia, weight loss, intermittent vomiting, abdominal distention, PU-PD, hemoglobinuria, and abdominal pain. Physical examination usually reveals marked splenomegaly, and radiographs typically reveal a C-shaped spleen. Ultrasonography of the abdomen in these patients may show greatly distended splenic veins. Hematologic abnormalities usually include regenerative anemia, leukocytosis with a regenerative left shift, and leukoerythroblastosis. Disseminated intravascular coagulation appears to be a common complication in dogs with torsion of the spleen. A high percentage of dogs with splenic torsion have hemoglobinuria, possibly as a consequence of intravascular or intrasplenic hemolysis. Dogs with splenic torsion and hemoglobinuria seen at our clinic occasionally have a positive direct Coombs test result. The treatment of choice for dogs with splenic torsion is splenectomy.

Splenic masses are more common than diffuse splenomegaly in dogs, whereas the opposite is true for cats. Most splenectomies in dogs are done to remove splenic masses. Because splenic masses in cats are extremely uncommon, the following discussion pertains primarily to localized splenomegaly in dogs.

Most oncologists use the rule of two thirds—two thirds of the splenic masses are tumors, two thirds of the tumors are malignant, and two thirds of the malignant tumors are hemangiosarcomas (HSAs). However, the prevalence of different histologic types of splenic masses may vary geographically.

Splenic masses can be classified according to their histopathologic features and biologic behavior as neoplastic or nonneoplastic. Neoplastic splenic masses can be benign or malignant and mainly include hemangiomas (HAs) and HSAs, although the former are less common than the latter. Other neoplastic splenic masses found occasionally are leiomyosarcomas, fibrosarcomas, leiomyomas, myelolipomas, metastatic carcinomas or sarcomas, malignant histiocytic tumors, and occasionally lymphomas. As a general rule, the larger the splenic mass, the less likely it is to be a malignant tumor (Mallinckrodt and Gottfried, 2011). Nonneoplastic splenic masses include primarily hematomas,

lymphoreticular hyperplasia, and abscesses, although splenic infarcts are occasionally described as splenic masses in dogs. As noted, a splenic mass is occasionally diagnosed as a hyperplastic nodule (or nodular hyperplasia) on histopathology after splenectomy. Almost 2 decades ago, Spangler and Kass (1998) proposed using the term *splenic fibrohistiocytic nodule* (FHN) to describe a continuum of focal lesions composed of macrophages, spindle cells, and lymphoid cells. They graded them into well, moderately, and poorly differentiated, and proposed that the grading had prognostic value.

However, recent studies have challenged this concept, and it is now believed that the splenic FHN is a catchall term for a variety of disorders in dogs. In a review of 31 splenic FHNs using histology and immunohistochemistry (Moore et al., 2012), 13 (42%) were reclassified as nodular hyperplasia, 4 (13%) as lymphoma, 8 (26%) as stromal sarcomas, and 6 (19%) as histiocytic sarcomas. Reclassifying these lesions has allowed for a more accurate prognosis.

However, other authors disagree with this approach. Recently, Sabatini et al. conducted a histopathologic, immunophenotyping, and molecular study of splenic nodular lesion in dogs and found that 29% were diagnosed as lymphoid nodular hyperplasia (LNH), 34% as complex nodular hyperplasia (CNH), 31% as marginal zone lymphoma, and 6% as mantle cell lymphoma (Sabatini et al., 2018). LNH and CNH are lesions traditionally classified as FHN. Regardless of the histologic subtype, the median survival time after splenectomy in this study was 1087 days.

HSAs are malignant vascular tumors of the spleen; they are extremely common in dogs, constituting the most common primary neoplasm in surgically collected splenic tissues (i.e., splenectomy). These neoplasms are extremely rare in cats. For a more detailed discussion, see Chapter 81.

Clinical Features

History taking and physical examination in dogs with splenomegaly are similar to those in dogs with lymphadenopathy. The clinical signs in dogs with splenomegaly are vague and nonspecific; they include anorexia, weight loss, weakness, abdominal distention, vomiting, diarrhea, PU-PD, or a combination of these. PU-PD is relatively common in dogs with marked splenomegaly, particularly in those with splenic torsion. Although the pathogenesis of the PU-PD is unclear, psychogenic polydipsia provoked by abdominal pain and distention of the splenic stretch receptors may be a contributory mechanism. Splenectomy in these dogs usually results in prompt resolution of the signs. Other signs associated with splenomegaly result from the hematologic consequences of the splenic enlargement and include spontaneous bleeding caused by thrombocytopenia, pallor caused by anemia, and fever caused by neutropenia or the primary disorder.

During a routine physical examination in pups and cats, the normal spleen is easily palpated as a flat structure oriented dorsoventrally in the left anterior abdominal quadrant. In some deep-chested dogs (e.g., Irish Setters, German Shepherd Dogs), the normal spleen is also easily palpated during routine examination in the ventral midabdomen or left anterior quadrant. This is also the case in Miniature Schnauzers and in some Cocker Spaniels. The fullness of the stomach determines to what extent a normal spleen is palpable in other breeds of dogs. It is easily palpated postprandially because its contour conforms to the greater curvature of the stomach so that it lies parallel to the last rib. However, not all enlarged spleens are palpable, and not every palpable spleen is abnormal. The characteristics of the spleen on palpation vary. In dogs an enlarged spleen can be smooth or irregular ("lumpy-bumpy"). In most cats with marked splenomegaly, the surface of the organ is smooth; a diffusely enlarged, lumpy spleen in a cat suggests systemic mast cell disease. As noted, animals with hematologic abnormalities secondary to splenomegaly may also have pallor, petechiae, or ecchymoses.

APPROACH TO PATIENTS WITH LYMPHADENOPATHY OR SPLENOMEGALY

Clinicopathologic Features

A complete blood count (CBC), serum biochemistry profile, and urinalysis should be obtained, particularly in dogs and cats with generalized or regional lymphadenopathies and those with diffuse splenomegaly. Changes in the CBC may indicate a systemic inflammatory process (e.g., leukocytosis with neutrophilia, left shift, monocytosis) or hemolymphatic neoplasia (e.g., circulating blasts in acute leukemia or lymphoma, marked lymphocytosis suggestive of chronic lymphocytic leukemia or ehrlichiosis). Occasionally the causative agent may be identified during examination of a blood smear (e.g., histoplasmosis, mycoplasmosis, trypanosomiasis, babesiosis). The polymerase chain reaction (PCR) assay for clonality and immunophenotyping with flow cytometry is commonly used in our clinic in patients with lymphadenopathy or splenomegaly and circulating abnormal cells or lymphocytosis. PCR for infectious agents should always be done in patients with splenitis or lymphoreticular hyperplasia.

The spleen exerts a marked influence on the CBC, resulting in two patterns of hematologic changes in dogs and cats with splenomegaly: hypersplenism and hyposplenism, or asplenia. Hypersplenism results from increased MP activity, but it is rare and characterized by cytopenias in the presence of a hypercellular bone marrow; these changes resolve after splenectomy. Hyposplenism is more common and results in hematologic changes similar to those seen in splenectomized animals, such as thrombocytosis, schistocytosis, acanthocytosis, Howell-Jolly bodies, and increased numbers of reticulocytes and nucleated RBCs. We documented the release of reticulocytes stored in the spleen in response to catecholamines in racing Greyhounds.

Anemia in dogs and cats with lymphadenopathy or splenomegaly can occur as a result of the several mechanisms already discussed. In brief, anemia of chronic disease can be

seen in inflammatory, infectious, or neoplastic disorders; hemolytic anemia is usually present in patients with hemoparasitic lymphadenopathies or splenomegaly and in some dogs with malignant histiocytosis or hemophagocytic syndrome. Severe nonregenerative anemia may be seen in dogs with chronic ehrlichiosis, in cats with feline leukemia virus–related disorders or feline immunodeficiency virus–related disorders, and in dogs and cats with primary bone marrow neoplasms (e.g., leukemias, multiple myeloma).

Thrombocytopenia is a common finding in patients with ehrlichiosis, RMSF, anaplasmosis, sepsis, lymphomas, leukemias, multiple myeloma, systemic mastocytosis, and some immune-mediated disorders. Pancytopenia is common in dogs with chronic ehrlichiosis or systemic immune-mediated disorders, in dogs and cats with lymphoma or leukemia, and in cats with disorders associated with retroviral infections.

Two major serum biochemical abnormalities are of diagnostic value in dogs and cats with lymphadenopathy or diffuse splenomegaly: hypercalcemia and hyperglobulinemia. Hypercalcemia is a paraneoplastic syndrome that occurs in approximately 10% to 20% of dogs with lymphoma and multiple myeloma, although it may also occur in dogs with blastomycosis or other chronic inflammatory disorders. It is extremely rare in cats with these diseases. Monoclonal hyperglobulinemia commonly occurs in dogs and cats with multiple myeloma and occasionally in dogs with lymphoma, ehrlichiosis, or leishmaniasis (see Chapter 89). Polyclonal hyperglobulinemia commonly occurs in dogs and cats with systemic mycoses, in cats with feline infectious peritonitis, and in dogs with ehrlichiosis, anaplasmosis, or leishmaniasis (see Chapter 89).

Serologic and microbiologic studies should always be conducted in dogs and cats with suspected infectious lymphadenopathy-splenomegaly. Serologic tests or PCR assay for canine ehrlichiosis, RMSF, brucellosis, and systemic mycoses may help diagnose regional or systemic lymphadenopathies. Lymph node specimens for bacterial and fungal cultures should also be obtained if necessary.

Imaging

Radiographic abnormalities in dogs with lymphadenopathy can be related to the primary disorder or can reflect the location and degree of lymphadenopathy. In general, plain radiographs or computed tomography (CT) scans are helpful in dogs and cats with solitary lymphadenopathy to search for primary bone inflammation or neoplasia, in those with generalized peripheral (superficial) lymphadenopathy to detect intrathoracic or intraabdominal lymph node enlargement (see Fig. 79.7), and in those with deep regional lymphadenopathy involving the thoracic cavity to determine the distribution and size of the affected nodes and changes in the pulmonary parenchyma and pleural space.

The spleen is normally well visualized on plain abdominal radiographs, but its appearance can vary widely. On dorsoventral or ventrodorsal views, the spleen is seen between the gastric fundus and left kidney. The size and location of the spleen are more variable on lateral radiographs than on ventrodorsal or dorsoventral projections. In some breeds, such as Greyhounds, the spleen appears to be large on plain radiographs and ultrasonograms. On plain radiographs, large splenic masses usually appear in the caudal abdomen or the midabdomen. Tranquilization or anesthesia usually results in a diffuse congestive splenomegaly, making radiographic interpretation of splenic size extremely difficult. CT is a useful diagnostic tool for dogs with focal or diffuse splenomegaly.

Ultrasonography is the noninvasive procedure of choice to evaluate intraabdominal lymphadenopathy and splenomegaly because it can accurately depict the size of enlarged lymph nodes and the spleen (Figs. 88.5 and 88.6) so that the patient's response to therapy can be monitored. In addition, ultrasound-guided FNA or biopsies can be performed with minimal complications. Abdominal ultrasonography can reveal diffuse splenomegaly, splenic masses, splenic congestion, hepatic nodules, or other changes; in addition, color flow Doppler allows for the evaluation of splenic blood flow (Huynh and Berry, 2017). A major issue a clinician frequently must deal with is the incidental splenic nodule in an older dog; these lesions are common and usually clinically irrelevant but tend to cloud the clinical picture in a patient with intraabdominal neoplasia. If possible, splenic nodules should be aspirated and evaluated cytologically; occasionally, immunophenotyping or PARR are needed to distinguish between lymphoma and regenerative nodules. Of note, however, is that the presence of hepatic nodules in a dog with a splenic mass does not constitute a valid reason for an owner to decline treatment or request euthanasia because regenerative liver nodules are indistinguishable from metastatic lesions. Moreover, hypoechoic splenic nodules are frequently found in normal dogs. Computerized tomography cannot readily distinguish between benign and malignant masses in dogs (Jones et al., 2016).

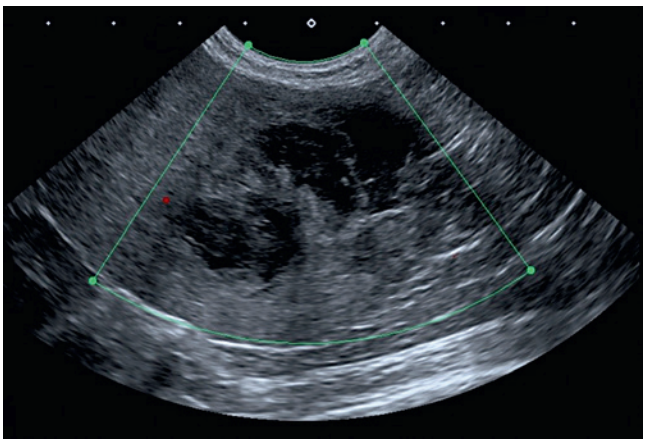

FIG 88.5
Ultrasonographic appearance of a complex rapidly growing splenic mass in a 12-year-old female spayed Greyhound. Note the lack of blood flow on color flow Doppler. Splenectomy revealed a hyperplastic lymphoid nodule with hematoma formation.

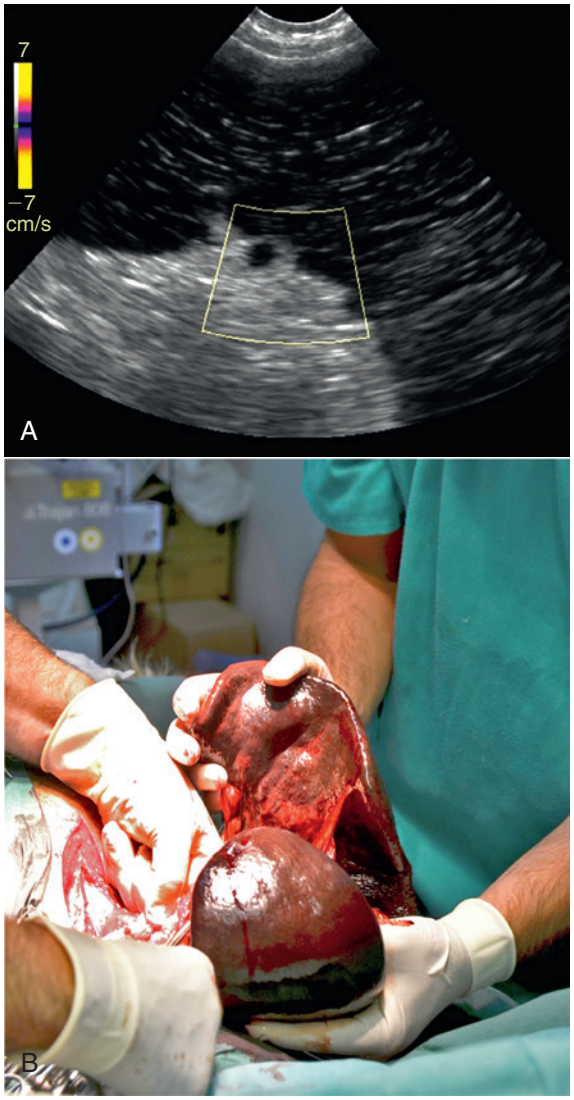

FIG 88.6
(A) Ultrasonographic appearance of a splenic torsion in a Chow Chow. Note the hypoechoic echotexture and lack of blood flow on color Doppler. **(B)** Surgical procedure in the same dog. Notice the markedly enlarged, deep purple torsed spleen. (**A** courtesy Dr. Pablo Gómez Ochoa, Vetoclok, Zaragoza, Spain.)

Radionuclide imaging of the spleen (and, less commonly, of lymph nodes) using technetium-99m–labeled sulfur colloid has become an accepted method of splenic imaging in humans and small animals. However, this technique only evaluates the spleen's ability to clear particulate matter and rarely provides a morphologic diagnosis.

Additional Diagnostic Tests

Evaluation of bone marrow aspirates or core biopsy specimens may be beneficial in dogs and cats with generalized lymphadenopathy or splenomegaly caused by hemolymphatic neoplasia or systemic infectious diseases. For example, acute or chronic leukemia in dogs may be difficult to diagnose on the basis of lymph node cytologic findings alone because the diagnosis is usually that of lymphoma, with the presence of well-differentiated or poorly differentiated lymphoid cells. In those cases, the combination of hematologic and bone marrow findings is usually diagnostic. Bone marrow evaluation should always be done before splenectomy in patients with cytopenias because the spleen may assume the primary hematopoietic function in dogs and cats with primary bone marrow disorders, such as hypoplasia or aplasia. Splenectomy in these animals could remove the sole source of circulating blood cells, leading to death.

Cytologic evaluation of lymph node and splenic aspirates provides the clinician with a wealth of information and often constitutes the definitive diagnostic procedure in animals with lymphadenopathy or diffuse splenomegaly. In my experience, cytologic evaluation of appropriately collected specimens yields diagnostic findings in approximately 80% to 90% of dogs and 70% to 75% of cats with lymphadenopathy and in approximately 80% of dogs and cats with diffuse splenomegaly.

Although superficial lymph nodes can be aspirated with minimal difficulty, the successful aspiration of intrathoracic or intraabdominal lymph nodes or spleen requires some expertise and occasionally must be done under the guidance of imaging techniques (e.g., ultrasonography, CT; see Chapter 74). To perform FNA of a superficial node, the area does not have to be surgically prepared. However, the aspiration of intrathoracic and intraabdominal structures (e.g., spleen) requires surgical preparation of the area and adequate restraint of the animal. Certain intraabdominal lymph nodes (e.g., markedly enlarged mesenteric or iliac nodes) are easily aspirated transabdominally by using manual isolation of the mass. Splenic aspirates are obtained with the animal in right lateral or dorsal recumbency, with manual restraint or mild sedation. Transabdominal splenic FNA in dogs or cats chemically restrained with phenothiazine tranquilizers or barbiturates usually yields blood-diluted specimens as a result of splenic congestion; the same occurs when a syringe is attached to the needle and suction is applied (LeBlanc et al., 2009).

Splenic biopsies for histopathology can also be obtained percutaneously using ultrasonographic guidance and a Tru-Cut–style needle. In a recent study, percutaneous FNA samples were compared with needle core biopsies (NCBs). Forty-one dogs with splenic lesions were studied prospectively (Watson et al., 2010). Safety was assessed in 38 dogs, and no complications were encountered. Clinical and anatomic pathologists reviewed each FNA and NCB sample, respectively, without knowledge of the other's results. Diagnoses were categorized as neoplastic, benign, inflammatory, normal, or nondiagnostic. The level of agreement between sampling methods was categorized as complete, partial, disagreement, or not available. Test correlation was performed in 40 dogs. Nondiagnostic results occurred in 5 of 40 NCB (12.5%) and no FNA samples. Neoplasia was diagnosed in 17 of 40 dogs (42.5%), benign changes in 20 of 40 dogs (50%), inflammatory disorders in 0 of 40 dogs, and normal in 2 of 40 dogs (5%). One of the 40 dogs (2.5%) had a

diagnosis that was equivocal for neoplasia on both tests and therefore was not categorized. Of the 35 dogs that had diagnostic samples, cytopathologic and histopathologic diagnoses agreed completely in 18 of 35 dogs (51.4%) and partially in 3 of 35 dogs (8.6%) and were in disagreement in 14 of 35 dogs (40.0%). Pathologists collaboratively reviewed diagnoses that were in disagreement or partial agreement and altered their individual diagnoses in 6 of 17 dogs (35.3%) to be within partial or complete agreement, respectively. Percutaneous FNA and NCB can be performed safely in dogs with sonographic splenic changes. Results suggest that adding NCB to FNA provides complementary information in dogs with suspected splenic neoplasia. This combined protocol may improve detection of splenic neoplasia and provide neoplastic subclassification.

In a patient with generalized lymphadenopathy, the clinician must decide which lymph node to aspirate. Obviously aspiration of a node in which the tissue changes are representative of the ongoing disease is important. Therefore a specimen should not be obtained from the largest lymph node because the necrosis may preclude a definitive diagnosis. Because clinical and subclinical gingivitis is common in older dogs and cats, mandibular lymph nodes should not be routinely aspirated because they are usually reactive, and findings may obscure the primary diagnosis. The techniques of FNA are described in Chapter 74.

Several reviews of the cytologic evaluation of lymphoid tissues have appeared in the veterinary literature (see later, "Suggested Readings"). In brief, normal lymph nodes are composed primarily of small lymphocytes (80%-90% of all cells); a small number of macrophages, medium or large lymphocytes, plasma cells, and mast cells can also be found. Normal spleens are similar except that RBCs are in high concentration given this organ's vascularity. Reactive lymph nodes (Fig. 88.7) and hyperplastic spleens are characterized by variable numbers of lymphoid cells in different stages of development (small, medium, and large lymphocytes; plasma cells); hematopoietic precursors are common in dogs and cats with splenic hyperplasia. The cytologic features of lymphadenitis-splenitis vary with the causative agent and the type of reaction elicited. Causative agents can frequently be identified in cytologic specimens (see Fig. 74.2). Metastatic neoplasms have different cytologic features, depending on the degree of involvement and cell type. Carcinomas, adenocarcinomas, melanomas, and mast cell tumors are easily diagnosed on the basis of cytologic findings. However, the cytologic diagnosis of sarcomas may be difficult because the neoplastic cells that comprise this tumor do not exfoliate easily. Primary lymphoid neoplasms (lymphomas) are characterized by a monomorphic population of lymphoid cells, which are usually immature and show a fine chromatin pattern, one or more nucleoli, basophilic cytoplasm, and vacuolation (Fig. 88.8). For a more detailed description of cytologic changes, see Chapter 74.

When the cytologic examination of an enlarged lymph node or spleen does not yield a definitive diagnosis, excision of the affected node or incisional or even excisional splenic biopsy to obtain a specimen for histopathologic examination is indicated. Excision of the whole node is preferable; core biopsy specimens are difficult to interpret because the lymph node architecture is often poorly preserved. A percutaneous needle biopsy of the spleen can be done under ultrasonography; alternatively, a wedge of tissue can be obtained during a splenic biopsy or, if the surgeon deems it necessary, a splenectomy can be performed; recently, single-port laparoscopy-assisted splenectomy techniques have been described in dogs (Wright et al., 2016). Care should be taken in handling the tissues during surgical

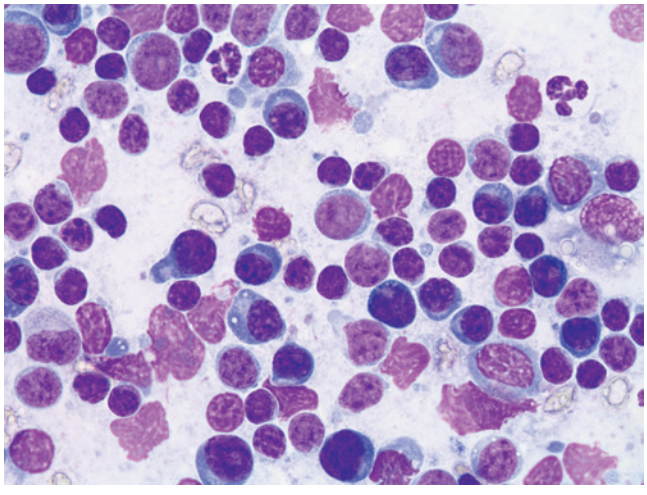

FIG 88.7
Cytologic features of a reactive lymph node in a dog. Note the heterogeneous cell population containing small, intermediate, and large lymphocytes and abundant plasma cells (Diff-Quik stain; ×1000).

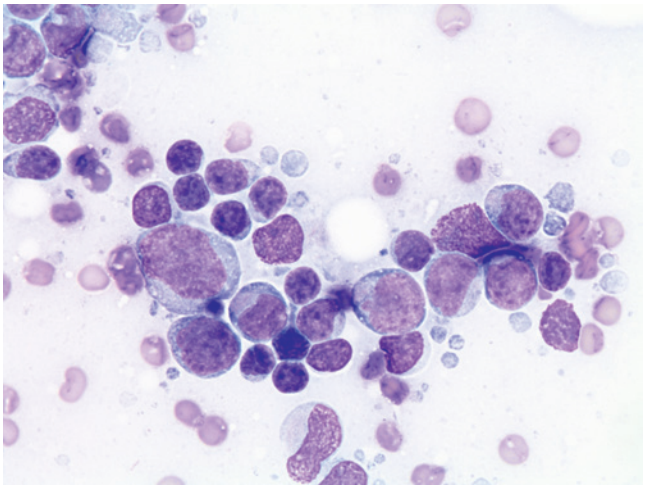

FIG 88.8
Cytologic features of a lymph node aspirate from a dog with massive generalized lymphadenopathy (lymphoma). Note a monomorphic population of large round cells with a lacy chromatin pattern (neoplastic cells) intermixed with small, darker, normal lymphocytes; lymphoglandular bodies are present (Diff-Quik stain; ×1000).

manipulation because trauma may induce considerable artifactual changes, which would preclude interpretation of the specimen. The popliteal lymph nodes are easily accessible and are the ones usually excised in dogs and cats with generalized lymphadenopathy.

Once a node is excised, it should be sectioned in half lengthwise, impression smears made for cytologic analysis, and the node fixed in 10% buffered formalin (one part of tissue to nine parts of fixative). The specimen is then ready to be sent to a laboratory for evaluation. Samples can also be saved for cytochemical or immunohistochemical evaluation, ultrastructural studies, microbiologic studies, and/or molecular evaluation, including a PCR assay for organisms or clonality. The same guidelines apply to the preparation of splenic specimens.

MANAGEMENT OF LYMPHADENOPATHY OR SPLENOMEGALY

As noted, no specific treatment exists for dogs or cats with local, regional, or generalized lymphadenopathy or diffuse splenomegaly. Treatment should be directed at the cause(s) of the lymphadenopathy or splenomegaly rather than at the enlarged lymph nodes or spleen. Exploratory celiotomies or laparoscopy provide considerable information regarding the gross morphologic characteristics of an enlarged spleen and adjacent organs and tissues. However, direct visualization of these structures may be misleading because differentiation of some benign splenic masses (e.g., hematoma, HA) from their malignant counterpart (e.g., HSA) on the basis of gross morphology alone may be impossible. As discussed earlier (see "Imaging"), in rare cases the surgeon may recommend to the owners that the animal be euthanized on the operating table because it has a splenic mass and nodules in the liver, only to find out that the hepatic nodules represent nodular hyperplasia or EMH and the primary mass was actually benign (e.g., HA or hematoma).

Splenectomy is indicated in the event of splenic torsion (see Fig. 88.6, *B*), splenic rupture, symptomatic splenomegaly, or most splenic masses. The value of splenectomy is questionable in dogs with immune-mediated blood disorders, dogs and cats with splenomegaly caused by lymphoma in which chemotherapy has not induced splenic remission, and dogs and cats with leukemias. Splenectomy is contraindicated in patients with bone marrow hypoplasia in which the spleen is the main site of hematopoiesis.

Although rare, a syndrome of postsplenectomy sepsis has been documented in approximately 3% of dogs that undergo this surgical procedure in our clinic. The syndrome is similar to its human counterpart. Most dogs with postsplenectomy sepsis evaluated at our clinic were undergoing immunosuppressive therapy at the time of surgery or had undergone splenectomy for a neoplasm. This sepsis is usually rapid in onset (hours to days), so prophylactic bactericidal antibiotic therapy is recommended postoperatively. All dogs with clinically recognized postsplenectomy sepsis at our clinic died within 12 hours of onset, despite aggressive treatment.

The clinician occasionally encounters a patient in which the enlarged lymph node mechanically compresses or occludes a viscus, airway, or vessel. This may result in marked clinical abnormalities, such as intractable coughing caused by tracheobronchial lymphadenopathy (see Fig. 79.7), colonic obstruction caused by iliac lymphadenopathy, or anterior vena cava syndrome caused by cranial vena cava and thoracic duct obstruction. Several treatment options are available for these situations. If the lymph node is surgically resectable, excision or drainage should be attempted. If the node is not surgically resectable or if surgery or anesthesia poses a high risk for the animal, one or more of the following can be used:

1. Irradiation can shrink a neoplastic lymph node and ameliorate the signs in animals with primary or metastatic neoplastic lesions. Antiinflammatory doses of corticosteroids can be used (0.5 mg/kg orally q24h) in animals with fungal lesions such as *Histoplasma*-induced tracheobronchial lymphadenopathy.
2. Intralesional injections of corticosteroids (prednisolone, 50-60 mg/m^2) can be successful in dogs and cats with solitary lymphomas or metastatic mast cell tumors if irradiation is not feasible.
3. Systemic antibiotic therapy may be beneficial in animals with solitary suppurative lymphadenitis.

CHAPTER 89

Hyperproteinemia

The plasma protein fraction is composed mainly of albumin, globulins, and fibrinogen; fibrinogen is absent in serum as a result of clotting and conversion into fibrin. In some breeds, such as the Greyhound, serum protein concentrations are below the reference ranges for most laboratories (Fayos et al., 2005). The term *hyperproteinemia* is given to an absolute or relative increase in the serum or plasma protein concentration. Before further evaluation of a cat or dog with hyperproteinemia, the clinician should make sure that the condition is not attributable to a preanalytic issue (e.g., interference of other substances in protein determination), which constitutes one of the most common causes of hyperproteinemia. Lipemia and, to a lesser degree, hemolysis typically result in artifactual increases in the plasma or serum protein concentration.

Once true hyperproteinemia has been established, the clinician should determine whether it is relative or absolute. Relative hyperproteinemia is usually accompanied by erythrocytosis and is caused by hemoconcentration (i.e., dehydration). However, in an anemic cat or dog, relative hyperproteinemia may be present in association with a normal packed cell volume (PCV); that is, the PCV is low, but hemoconcentration results in an artifactual increase. The relative proportions (ratio) of albumin and globulin provide considerable information regarding the pathogenesis of hyperproteinemia. This information is usually contained in reports of serum biochemistry profiles from most referral diagnostic laboratories and in-house analyzers. Occasionally only the total serum protein and serum albumin concentrations are reported. In this case, the total globulin concentration is determined simply by subtracting the albumin concentration from the total protein concentration.

In dogs and cats with relative hyperproteinemia (i.e., hemoconcentration), both the albumin and globulin concentrations are increased above the reference values, whereas in those with absolute hyperproteinemia, only the globulin concentration is increased, usually in association with a mild or marked hypoalbuminemia. Hyperalbuminemia does not occur because the liver is already at its maximal synthetic capacity. The finding of hyperalbuminemia and hyperglobulinemia indicates the presence of dehydration or a preanalytic issue. Rehydration results in resolution of relative hyperproteinemia.

When exposed to an electrical field (i.e., protein electrophoresis), the protein molecules migrate according to their shape, charge, and molecular weight. Staining of the electrophoresis gel after migration usually reveals six distinct protein bands—albumin (closer to the anode or negative electrode), α_1-globulin, α_2-globulin, β_1-globulin, β_2-globulin, and γ-globulin (closer to the cathode or positive electrode; Fig. 89.1, *A*). The albumin fraction is responsible for conferring oncotic properties on body fluids. Acute-phase reactants (APRs), also termed *acute-phase proteins,* migrate in the α_2 and α_1 regions, whereas immunoglobulins (Igs) and complement usually migrate in the β and γ regions. APRs in dogs and cats include C-reactive protein (CRP), serum amyloid A (SAA), haptoglobin (Hp), α_1-acid glycoprotein (AGP), and ceruloplasmin (Cp). Most of these APRs can be measured in serum, plasma, or fluids in commercial diagnostic laboratories; in-house diagnostic kits for CRP are commercially available worldwide. Igs migrate in the following order (from anode to cathode and beginning in the α_2 region): IgA, IgM, and IgG. By evaluating a protein electrophoretogram, the clinician can gain insight into the pathogenesis of the hyperglobulinemia.

Increased production of globulins occurs in a variety of clinical situations but mainly in two groups of disorders: inflammatory-infectious and neoplastic. In inflammation and infection, the hepatocytes elaborate a variety of globulins, collectively termed *APRs,* which result in increases in the α_2- and α_1-globulin fractions. Because the hepatocytes are reprogrammed to produce APRs, the albumin production is switched off, resulting in hypoalbuminemia; albumin is considered a negative APR. In conjunction with these changes, the immune system produces a variety of immune proteins (mainly Igs), which results in increases in the α_2, β, or γ regions or a combination of these.

Because the immune system reacts against an organism (e.g., a bacterium) by producing antibodies against each somatic antigen, several clones of lymphocyte–plasma cells

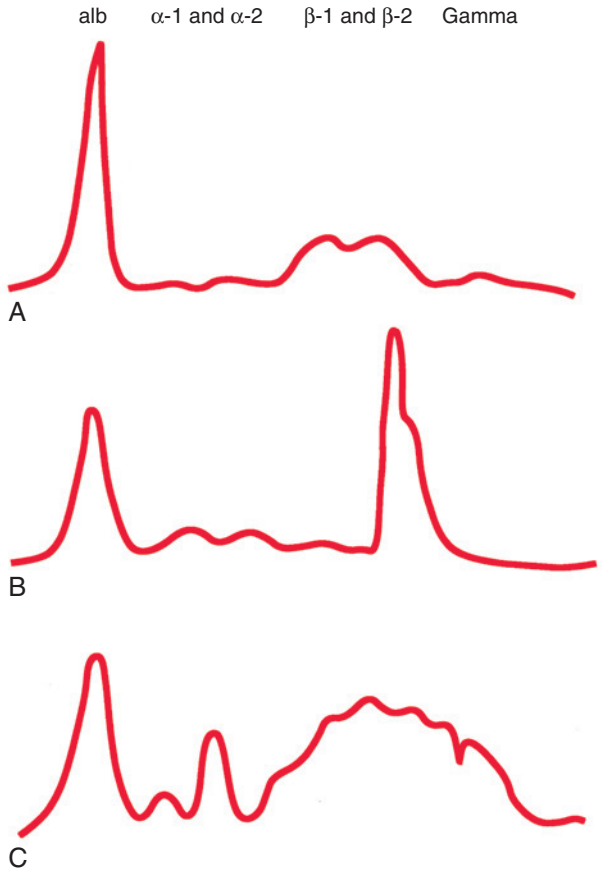

FIG 89.1
(A) Normal canine or feline serum protein electrophoretogram. **(B)** Electrophoretogram from a dog with multiple myeloma and a monoclonal gammopathy in the β_2-γ region. Note the narrow spike approximately the same width as the albumin band. **(C)** Electrophoretogram from a cat with feline infectious peritonitis and a typical polyclonal gammopathy. Note the α-2 spike (APRs) and the broad-based β-γ spikes.

are instructed to produce specific antibody molecules simultaneously; that is, each clone is programmed to produce one specific antibody type against a specific antigen. As a consequence, immune stimulation leads to the appearance of a polyclonal band in the β or γ region, or both. This polyclonal band is broad-based and irregular and contains most of the Igs and complement generated by the immune cells. A typical inflammatory-infectious electrophoretogram therefore consists of a normal to mildly decreased albumin concentration and hyperglobulinemia resulting from increased concentrations of α_2-globulins (i.e., APR) and β-γ globulins (polyclonal gammopathy; see Fig. 89.1, *C*).

Typical inflammatory-infectious electrophoretograms are seen in several common disorders, including chronic pyoderma, pyometra, and other chronic suppurative processes; feline infectious peritonitis (FIP); feline and canine mycoplasmosis and other hemoparasite infections; canine ehrlichiosis, anaplasmosis, and leishmaniasis; chronic immune-mediated disorders (e.g., systemic lupus erythematosus, immune polyarthritis); and some neoplastic diseases, although these are rare (Box 89.1). Polyclonal gammopathies are also common in otherwise healthy old cats.

Monoclonal gammopathies occur when one clone of immune cells produces the same type and subtype of Ig molecule. Because these molecules are identical, they migrate in a narrow band (monoclonal spike, or M component), located typically in the β or γ region (see Fig. 89.1, *B*). Monoclonal gammopathies occur in dogs with multiple myeloma, chronic lymphocytic leukemia, or lymphoma (the latter infrequently). They are also occasionally present in dogs with ehrlichiosis or leishmaniasis; recently, a monoclonal gammopathy associated with *Bartonella henselae* infection was reported in a dog (Tabar et al., 2011) (Box 89.2). In cats

BOX 89.2

Diseases Associated With Monoclonal Gammopathies in Dogs and Cats

Multiple myeloma
Chronic lymphocytic leukemia
Lymphoma
"Idiopathic" monoclonal gammopathy
Ehrlichiosis
Leishmaniasis
Bartonellosis
Feline infectious peritonitis
Chronic inflammation

monoclonal gammopathies are uncommon and occur in association with plasma cell tumors or lymphoma, but they can rarely occur in cats with FIP (Taylor et al., 2010; Qurollo et al., 2014).

Occasionally an M component is detected in an otherwise asymptomatic cat or dog, but additional evaluation fails to reveal a source for the monoclonal gammopathy. Although this likely represents the counterpart of human idiopathic monoclonal gammopathy, the patient should be reevaluated frequently for a clinically emerging malignancy. In cats the source of the M component is usually the spleen, in which a neoplastic population of well-differentiated plasma cells is frequently identified in asymptomatic cats with a monoclonal gammopathy. Therefore these cats likely have atypical myeloma.

The treatment of dogs and cats with monoclonal or polyclonal gammopathies is aimed at the primary disease. Refer to specific sections throughout this text for discussion of these treatments.

CHAPTER 90

Fever of Undetermined Origin

FEVER AND FEVER OF UNDETERMINED ORIGIN

The term *fever* refers to a syndrome of malaise or nonspecific systemic clinical signs accompanied by pyrexia or hyperthermia. In this chapter, however, the terms *fever* and *pyrexia* are used interchangeably. Fever constitutes a protective physiologic response to infectious and noninfectious causes of inflammation that enhances the host's ability to eliminate a noxious agent.

A variety of stimuli, including bacteria, endotoxins, viruses, immune complexes, activated complement, and necrotic tissue, trigger the release of endogenous pyrogens by the phagocytic system, mainly the mononuclear cells, or macrophages. These endogenous pyrogens include interleukin-1, tumor necrosis factor, and interleukin-6, among others. They activate the preoptic nucleus of the hypothalamus, raising the set point of the thermostat by generating heat through muscle contraction and shivering, and conserving heat through vasoconstriction.

In humans several patterns of fever have been associated with specific disorders; however, this does not appear to be the case in dogs and cats. In people with continuous fever, the pyrexia is maintained for several days or weeks. This type of fever is associated with bacterial endocarditis, central nervous system lesions, tuberculosis, and some malignancies. In people with intermittent fever, the body temperature decreases to normal but rises again for periods of 1 to 2 days; this is seen in brucellosis and some malignancies. In remittent fever the temperature varies markedly each day but is always above normal (39.2° C [103° F]); this type of fever is associated with bacterial infections. The term *relapsing fever* is used to refer to febrile periods that alternate with variable periods of normal body temperature, as seen in humans with malaria.

The term *fever of undetermined* (or unknown) *origin* (FUO) is used liberally in veterinary medicine to refer to a febrile syndrome for which a diagnosis is not evident. In human medicine, FUO refers to a febrile syndrome of more than 3 weeks' duration that remains undiagnosed after 1 week of thorough in-hospital evaluation. If the term FUO were to be used in the same way in animals as is recommended for humans, few dogs and cats would actually have it. Therefore, in this chapter, the discussion focuses on the approach to a dog or cat with fever that does not respond to antibacterial antibiotic treatment and for which a diagnosis is not obvious after a minimal workup has been performed (e.g., complete blood count [CBC], serum biochemistry profile, urinalysis).

As a general rule, the clinician typically presumes that a dog or cat with fever has an infection until proved otherwise. This appears to be true in reality, as shown by the fact that a large proportion of dogs and cats with fever respond to nonspecific antibacterial treatment. No clinicopathologic evaluation is performed in most of these animals because the fever responds promptly to treatment.

DISORDERS ASSOCIATED WITH FEVER OF UNDETERMINED ORIGIN

In humans, certain infectious, neoplastic, and immune-mediated disorders are commonly associated with FUO. Approximately one third of patients have infectious diseases, one third have cancer (mainly hematologic malignancies, such as lymphoma and leukemia), and the remaining third have immune-mediated, granulomatous, or miscellaneous disorders. In 10% to 15% of patients with FUO, the underlying disorder remains undiagnosed, despite intensive efforts. In a study of 66 dogs with fever, infectious diseases were diagnosed in 26% of the patients, immune-mediated disease in 35%, neoplasia in 8%, and a diagnosis could not be obtained in 23% (Battersby et al., 2006). In a more recent study of 50 dogs with fever evaluated in a teaching hospital in France, 48% of dogs were diagnosed with inflammatory noninfectious diseases, 18% with infectious disease, and 6% with neoplasia; a final diagnosis could not be obtained in 28% of cases (Chervier et al., 2012). In this study, of the initial diagnostic procedures, hematology (23%), biochemistry (25%), and imaging (27%) were the most helpful in obtaining a diagnosis, whereas immunology and bacteriology were the

least useful (≈4% each); cytology and histopathology were the advanced diagnostic methods that provided the most answers (56%).

Thus, in contrast to what was previously thought, infectious diseases do not appear to be the most common cause of FUO in dogs (and likely cats). Instead, inflammatory noninfectious disorders, including immune-mediated diseases, represent most cases with FUO that are eventually diagnosed (Table 90.1). Interestingly, despite aggressive evaluation, the cause of the fever cannot be determined in 10% to 25% of small animals.

DIAGNOSTIC APPROACH TO THE PATIENT WITH FEVER OF UNDETERMINED ORIGIN

A dog or cat with FUO should be evaluated in a systematic fashion. In general, a three-stage approach is used at our

TABLE 90.1

Causes of Fever of Undetermined Origin in Dogs and Cats

CAUSE	SPECIES AFFECTED
Infectious	
Bacterial	
Bacterial endocarditis	D
Brucellosis	D
Tuberculosis	D, C
Mycoplasmosis	D, C

BOX 90.1

Diagnostic Evaluation of Dog or Cat With Fever of Undetermined Origin

First Stage

- CBC
- Serum biochemistry profile and thyroxine concentration
- Urinalysis
- Urine bacterial culture and susceptibility
- FNA of enlarged organs, masses, or swellings

Second Stage

- Thoracic radiographs
- Abdominal ultrasonography
- Echocardiography
- Serial bacterial blood cultures
- Immune tests (antinuclear antibody, rheumatoid factor)
- Acute-phase reactant measurements (e.g., CRP)
- Serum protein electrophoresis
- Serologic tests or PCR assay (see Table 90.1)
- Arthrocentesis (cytologic studies and culture)
- Biopsy of any lesion or enlarged organ
- Bone marrow aspiration (for cytologic studies and bacterial and fungal culture)
- Cerebrospinal fluid analysis
- Leukocyte or ciprofloxacin scanning
- Exploratory celiotomy

Third Stage

- Therapeutic trial (antipyretics, antibiotics, corticosteroids)

CBC, Complete blood count; *CRP,* C-reactive protein; *FNA,* fine-needle aspiration; *PCR,* polymerase chain reaction.

clinic (Box 90.1). The first stage consists of a thorough history taking and physical examination, as well as a minimal database (CBC, serum biochemistry, urinalysis). The second stage consists of additional noninvasive and invasive diagnostic tests. The third stage consists of a therapeutic trial, which is instituted if no diagnosis can be determined after completion of the second stage.

History and Physical Examination

When a febrile patient does not respond to antibacterial treatment, a course of action must be formulated. A thorough history should be obtained and a complete physical examination performed. The history rarely provides clues to the cause of the fever. However, a history of ticks may indicate a vector-borne disease, administration of tetracycline (mainly to cats) may indicate a drug-induced fever, and travel to areas in which systemic mycoses are endemic should prompt further investigation, consisting of cytologic or serologic studies or fungal cultures/polymerase chain reaction (PCR).

During a physical examination, the lymphoreticular organs should be evaluated because numerous infectious diseases affecting these organs (e.g., ehrlichiosis, anaplasmosis, Rocky Mountain spotted fever, bartonellosis, leishmaniasis, leukemia, systemic mycoses) may cause fever. Enlarged lymph nodes or spleen should be evaluated cytologically by performing fine-needle aspiration (FNA). An FNA sample can also be obtained for bacterial and fungal culture and susceptibility or for PCR assay if the cytologic studies reveal evidence of infection or inflammation. Any palpable mass or swelling should also be evaluated by using specimens obtained by FNA to rule out granulomatous, pyogranulomatous, suppurative inflammation, and neoplasia (see Chapter 74).

The clinician should thoroughly inspect and palpate the oropharynx, searching for signs of pharyngitis, stomatitis, or tooth root abscesses. The bones should also be thoroughly palpated, particularly in young dogs, because metabolic bone disorders such as hypertrophic osteodystrophy and panosteitis can cause fever associated with bone pain. Palpation and passive motion of all joints is also indicated in search of monoarthritis, oligoarthritis, or polyarthritis. A neurologic examination should be conducted to detect signs of meningitis or other central nervous system lesions. In older cats, the ventral cervical region should be palpated to detect thyroid enlargement or nodules.

The thorax should be auscultated carefully in search of a murmur, which could indicate bacterial endocarditis. A thorough ocular examination may reveal changes suggestive of a specific cause (e.g., chorioretinitis in cats with feline infectious peritonitis or in dogs with monocytic ehrlichiosis).

Clinicopathologic Evaluation

A minimum database consisting of a CBC, serum biochemistry profile, urinalysis, urine bacterial culture, and susceptibility testing should always be carried out in dogs and cats with persistent fever. The CBC may provide important clues regarding the cause of the fever (Table 90.2). A serum biochemistry profile may also yield diagnostic information in dogs and cats with FUO and can provide indirect information on parenchymal organ function. Some laboratories include C-reactive protein (CRP) in their profile; the CRP concentration is often elevated in patients with infectious and other inflammatory diseases but is not specific. Hyperglobulinemia and hypoalbuminemia may indicate an infectious, immune-mediated, or neoplastic disorder (see Chapter 89). The finding of pyuria or white blood cell casts in a urinalysis may indicate a urinary tract infection, which may be the cause of the FUO (i.e., pyelonephritis). Proteinuria associated with inactive urine sediment should prompt the clinician to evaluate a urine protein-to-creatinine ratio to rule out glomerulonephritis or amyloidosis as the cause of the fever.

Other diagnostic tests that may be required in patients with FUO are listed in Box 90.1. Echocardiography is indicated only if the patient has a heart murmur because it rarely detects a valvular lesion in dogs without murmurs. Some of the infectious diseases listed in Table 90.1 can be diagnosed on the basis of serologic findings, culture, or PCR testing.

Fluid from several joints should be aspirated for cytologic evaluation and possibly bacterial culture because

TABLE 90.2

Hematologic Changes in Dogs and Cats With Fever of Undetermined Origin

HEMATOLOGIC CHANGE	CAUSE OF THE FEVER
Regenerative anemia	Immune-mediated disease, hemoparasites (e.g., *Mycoplasma, Babesia*), drugs
Nonregenerative anemia	Infection, chronic inflammation, immune-mediated disease, tissue necrosis, malignancy, endocarditis
Neutrophilia with left shift	Infection, immune-mediated disease, tissue necrosis, malignancy, endocarditis
Neutropenia	Leukemia, immune-mediated disease, pyogenic infection, bone marrow infiltrative disease, drugs
Monocytosis	Infection, immune-mediated disease, tissue necrosis, lymphoma, endocarditis, histiocytosis
Lymphocytosis	Ehrlichiosis, anaplasmosis, Chagas disease, leishmaniasis, chronic lymphocytic leukemia
Eosinophilia	Hypereosinophilic syndrome, eosinophilic inflammation, lymphoma
Thrombocytopenia	Rickettsiae, leukemia, lymphoma, drugs, immune-mediated disease
Thrombocytosis	Infections (chronic), immune-mediated disease

polyarthritis may be the only manifestation of a widespread immune-mediated or infectious disorder (e.g., anaplasmosis, granulocytic ehrlichiosis). Thoracic radiography and abdominal ultrasonography should be performed to search for a silent septic focus. In dogs and cats with neurologic signs associated with fever, a cerebrospinal fluid tap should be performed; in dogs, immune-mediated vasculitis or meningitis can cause marked temperature elevations. If a diagnosis has still not been reached, bone marrow aspirates for cytologic studies, and bacterial and fungal culture should also be obtained. A leukocyte or ciprofloxacin scan may reveal a hidden septic focus, but these are rarely done in practice. Finally, if a definitive diagnosis is ultimately not obtained, a therapeutic trial of specific antibacterial or antifungal agents or immunosuppressive doses of corticosteroids can be initiated.

Treatment

If a definitive diagnosis is obtained, a specific treatment should be initiated. The problem arises if the clinician cannot arrive at a definitive diagnosis. In these patients, changes in the CBC are usually the only clinicopathologic abnormality (see Table 90.2), that is, results of bacterial and fungal cultures, serologic tests, PCR assays, imaging studies, and FNAs are negative or normal. If the patient has already been treated with a broad-spectrum bactericidal antibiotic, a therapeutic trial of immunosuppressive doses of corticosteroids is warranted. However, before instituting immunosuppressive treatment, the owners should be informed of the potential consequences of this approach, mainly that a dog or cat with an undiagnosed infectious disease may die as a result of systemic dissemination of the organism after the start of treatment. Dogs and cats undergoing a therapeutic trial of corticosteroids should be kept in the hospital and monitored frequently for worsening of clinical signs, in which case steroid therapy should be discontinued. In patients with immune-mediated (or steroid-responsive) FUO, the pyrexia and clinical signs usually resolve within 24 to 48 hours of the start of treatment.

If no response to corticosteroids is observed, two courses of action remain. In one, the patient can be released and given antipyretic drugs, such as aspirin (10-25 mg/kg orally [PO] q12h in dogs, and 10 mg/kg PO q72h in cats) or other nonsteroidal antiinflammatory drugs (NSAIDs) and then returned to the clinic for a complete reevaluation in 1 to 2 weeks. Antipyretics should be used with caution, however, because fever is a protective mechanism, and lowering the body temperature may be detrimental in an animal with an infectious disease. Also of note is that some NSAIDs have ulcerogenic effects, can cause cytopenias, and may result in tubular nephropathy if the patient becomes dehydrated or receives other nephrotoxic drugs. The second course of action is to continue the trial of antibiotics by using a combination of bactericidal drugs (e.g., ampicillin and enrofloxacin) for a minimum of 5 to 7 days.

PART FOURTEEN ▪ Infectious Diseases

Michael R. Lappin

CHAPTER 91

Laboratory Diagnosis of Infectious Diseases

Clinical syndromes induced by infectious agents are common in small animal practice. A combination of signalment, history, and physical examination findings is used to develop a list of differential diagnoses ranking the most likely infectious agents involved. For example, young, unvaccinated cats with conjunctivitis are generally infected by herpesvirus type 1, *Chlamydia felis,* or *Mycoplasma felis;* if a dendritic ulcer is present, herpesvirus type 1 is most likely. Results of a complete blood count (CBC), serum biochemical panel, urinalysis, radiographs, or ultrasonography can also suggest infectious diseases. For example, a dog with polyuria, polydipsia, neutrophilic leukocytosis, azotemia, pyuria, and an irregularly marginated kidney on radiographic examination likely has pyelonephritis. After making a tentative diagnosis, the clinician then must determine whether to "test or treat." Empiric treatment is sometimes adequate in simple, first-time infections of dogs or cats without life-threatening disease (see Chapter 92). However, having a definitive diagnosis is usually preferred so that treatment, prevention, prognosis, and zoonotic issues can be addressed optimally.

Documenting that the infectious agent is still present, using cytology, culture, antigen assays, and molecular diagnostic assays is the best way to make a definitive diagnosis. Antibody detection is commonly used to aid in the diagnosis of specific infectious diseases but can be inferior to organism demonstration for three reasons: (1) Antibodies can persist long after an infectious disease has resolved, (2) positive antibody test results do not confirm clinical disease induced by the infectious agent, and (3) in peracute infections, results of serum antibody tests can be negative if the humoral immune responses have not had time to develop. This chapter discusses the common organism demonstration and antibody detection techniques used in small animal practice.

DEMONSTRATION OF THE ORGANISM

FECAL EXAMINATION

Examination of feces can be used to help diagnose parasitic diseases of the gastrointestinal (see Chapter 27) and respiratory tracts (see Chapter 20). The techniques used most frequently include direct and saline smear, stained smear, fecal flotation, and Baermann technique; each procedure can easily be performed in a small animal practice.

Direct Smear

Fresh, liquid feces or feces that contain large quantities of mucus should be microscopically examined immediately for the presence of protozoal trophozoites, including those of *Giardia* spp. in cases with small-bowel diarrhea and *Trichomonas foetus* (*T. blagburni* proposed) in cases with large-bowel diarrhea. A direct saline smear can be made to potentiate observation of these motile organisms. A 2 mm × 2 mm × 2 mm quantity of fresh feces is mixed thoroughly with 1 drop of 0.9% NaCl or water. The surface of the feces or mucus coating the feces should be used because the trophozoites are most common in these areas. After application of a coverslip, the smear is evaluated for motile organisms by examining it under ×100 magnification (i.e., using the 10× objective in most microscopes).

Stained Smear

A thin smear of feces from all dogs and cats with diarrhea can be made. Material should be collected by rectal swab, if possible, to increase the chances of finding white blood cells and some organisms like *Histoplasma capsulatum*. A cotton swab is gently introduced 3 to 4 cm through the anus into the terminal rectum, directed to the wall of the rectum, and gently rotated several times. Placing 1 drop of 0.9% NaCl on the cotton swab will facilitate passage through the anus and

not adversely affect cell morphology. The cotton swab is rolled on a microscope slide gently multiple times to give areas with varying smear thickness (Fig. 91.1). After air-drying, the slide can be stained. White blood cells and bacteria morphologically consistent with *Campylobacter* spp. (spirochetes) or *Clostridium perfringens* (spore-forming rods; Fig. 91.2) can be observed after staining with Diff-Quik or Wright or Giemsa stains (see Cytology section). However, these findings do not confirm the diagnosis as there are many spirochetes in feces and cytologic detection of suspected *C. perfringens* spores that do not always correlate to the presence of enterotoxins. *Histoplasma capsulatum* or *Prototheca* may be observed in the cytoplasm of mononuclear cells. Methylene blue in acetate buffer (pH 3.6) stains trophozoites of the enteric protozoans. Iodine and acid methyl green stains are also used for the demonstration of protozoans. Modified acid-fast staining of a thin fecal smear can be performed in dogs and cats with diarrhea to aid in the diagnosis of cryptosporidiosis. *Cryptosporidium* spp. are the only enteric organisms of approximately 4 to 6 µm in diameter that will stain pink to red with acid-fast stain (Fig. 91.3).

Fecal Flotation

Cysts, oocysts, and eggs in feces can be concentrated to increase the sensitivity of detection. A variety of techniques are available for use in veterinary clinics. Centrifugation techniques are more sensitive than passive flotation techniques. Most eggs, oocysts, and cysts are easily identified after centrifugation in zinc sulfate solution (Box 91.1) or Sheather sugar solution. These procedures are superior to passive flotation techniques for the demonstration of protozoan cysts (particularly *Giardia* spp.; Fig. 91.4). Many clinicians are now using big service laboratories for this service, but in one study, a smaller university laboratory had a greater sensitivity than a commercial laboratory for detection of *Giardia* cysts (Hascall et al., 2016). Fecal sedimentation recovers most cysts and ova but also contains debris.

Baermann Technique

This technique is used to concentrate motile larvae from feces. The feces are diluted in water, placed in a funnel clamped at the ventral end, and the larva concentrate by gravity. Some respiratory parasites are passed as larvated eggs but release larvae shortly after being passed in feces. Eggs or larvae from respiratory parasites can also be detected by cytologic evaluation of airway washings (Fig. 91.5).

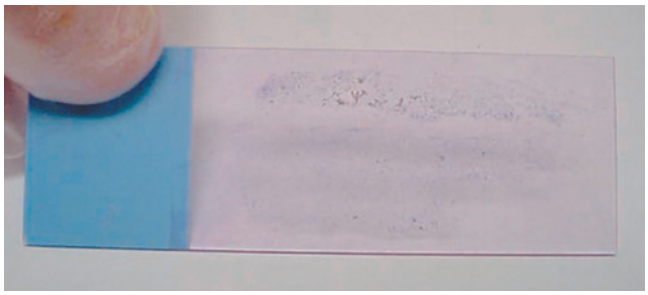

FIG 91.1
Diff-Quik–stained fecal smear showing appropriate smear thickness.

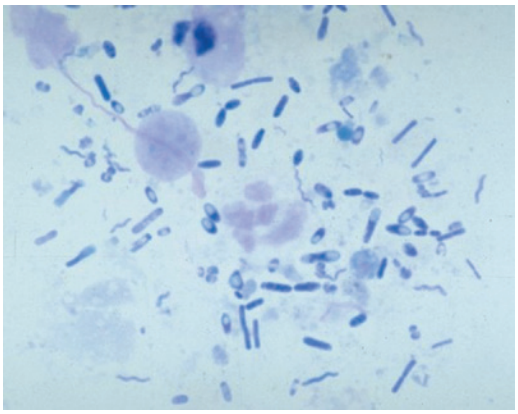

FIG 91.2
Wright-stained, thin fecal smear. A neutrophil and spore-forming rods are present in the center of the field.

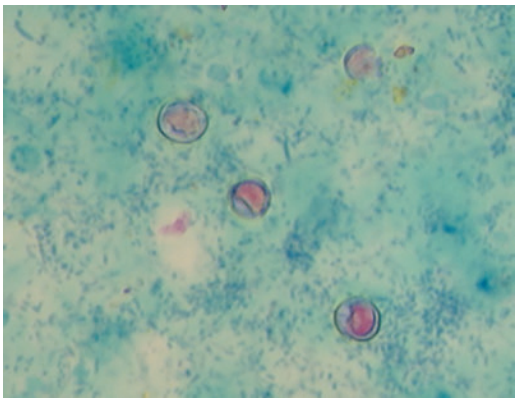

FIG 91.3
Cryptosporidium parvum oocysts stained with a modified acid-fast stain. The oocysts are approximately 4 × 6 µm.

BOX 91.1

Zinc Sulfate Centrifugation Procedure

1. Place 1 g fecal material in a 15-mL conical centrifuge tube.
2. Add 8 drops of Lugol iodine and mix well.
3. Add 7 to 8 mL of zinc sulfate (1.18 specific gravity)* and mix well.
4. Add zinc sulfate until there is a slight positive meniscus.
5. Cover the top of the tube with a coverslip.
6. Centrifuge at 1500 to 2000 rpm for 5 minutes.
7. Remove the coverslip and place on a clean microscope slide for microscopic examination.
8. Examine the entire area under the coverslip for the presence of ova, oocysts, or larvae at ×100.

*Add 330 g zinc sulfate to 670 mL distilled water.

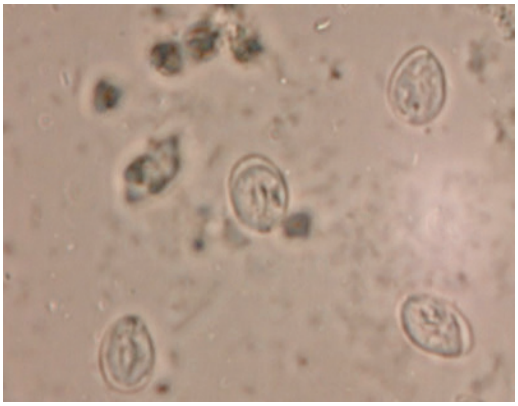

FIG 91.4
Giardia cysts after zinc sulfate flotation. The cysts are approximately 10 × 8 µm.

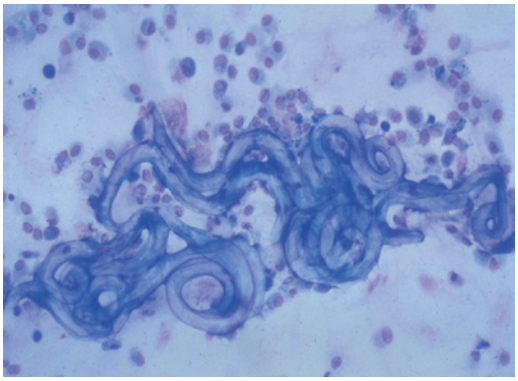

FIG 91.5
Aelurostrongylus abstrusus larvae in an airway washing collected by bronchoalveolar lavage. (Courtesy Dr. Timothy Hackett, Colorado State University, Fort Collins.)

Preservation of Feces

Feces should be refrigerated, not frozen, until assayed. If present, refrigerated *Toxoplasma gondii* oocysts will not likely sporulate and become infectious. In addition, refrigerated feces have less overgrowth of yeast, leading to fewer false-positive results. If a fecal sample is to be sent to a diagnostic laboratory for further analysis and will not be evaluated within 48 hours, it should be preserved. Polyvinyl alcohol, merthiolate-iodine-formalin, and 10% formalin preservation can be used. Ten percent formalin is commonly used because of its routine availability; the clinician should add 1 part feces to 9 parts formalin and mix well.

CYTOLOGY

Cytologic evaluation of exudates, bone marrow aspiration, blood smears, synovial fluid, gastric brushings, duodenal secretions, urine, prostatic washings, airway washings, fecal smears, tissue imprints, and aspiration biopsies is an inexpensive and extremely valuable tool for the documentation of infectious agents; see individual chapters for cytologic findings for select infectious agents. Cytologic demonstration of some infectious agents constitutes a definitive diagnosis. It is no longer recommended to use morphologic appearance and Gram stain of bacteria to aid in the selection of empiric antibiotics while waiting for results of culture and antimicrobial susceptibility testing as the results are not accurate (Lappin et al., 2017).

For demonstration of most infectious agents, thin smears are preferred. Blood can be prepared as follows: 1 drop of blood approximately the size of a match head is placed at one end of a clean microscope slide. The short edge of another slide (i.e., spreader slide) is placed against the slide at a 30-degree angle and pulled back until the blood and the spreader slide make contact. After the blood spreads across the width of spreader slide, the slide is smoothly and quickly pushed away from the blood across the length of the slide ("push" smears). For materials other than blood, the spreader slide is laid gently on top of the material; the slides are then smoothly and rapidly pulled apart on parallel planes ("pull" smears). Cells in airway washings, prostatic washings, urine, aqueous humor, and cerebrospinal fluid (CSF) should be pelleted by centrifugation at 2000 g for 5 minutes before staining. Multiple slides should always be made, if possible. After being placed on the microscope slide, the material is air-dried at room temperature, fixed if indicated by the procedure used, and stained. Slides that are not stained immediately should be fixed by dipping in 100% methanol and air-dried.

Cytologic specimens can be stained with routine stains; immunocytochemical techniques for certain pathogens are available (see Immunologic Techniques, p. 1432). Stains routinely used for the diagnosis of infectious diseases in small animal practice include Wright-Giemsa stain, Diff-Quik, Gram stain, and acid-fast stain. Immunocytochemical techniques (e.g., fluorescent antibody staining of bone marrow cells for feline leukemia virus) are only performed in reference or research laboratories (see Immunologic Techniques, p. 1432). The laboratory should be contacted for specific specimen handling information.

Bacterial Diseases

If bacterial disease is suspected, materials are collected aseptically and handled initially for culture (see Culture Techniques, p. 1431). After slides are prepared for cytologic evaluation, one is generally stained initially with Wright-Giemsa or Diff-Quik stain. If bacteria are noted, Gram stain of another slide is performed to differentiate gram-positive and gram-negative agents. If filamentous, gram-positive rods are noted, acid-fast staining can help differentiate *Actinomyces* (not acid fast) from *Nocardia* (generally acid fast). If macrophages or neutrophils are detected, acid-fast staining is indicated to assess for *Mycobacterium* spp. within the cytoplasm; *Mycobacterium* spp. can often be seen on Diff-Quik or Wright-Giemsa stained slides (see Fig. 74.2). Bacteria can be present in small numbers or can be intracellular (*Bartonella* spp.), so failure to document organisms cytologically does not totally exclude the diagnosis. Bacterial culture of all samples with increased numbers of neutrophils

or macrophages should always be considered. Some organisms such as *Mycoplasma* are rarely documented cytologically, whereas other organisms require special stains for optimal visualization. For some, bacteria culture has never been successful. For example, the hemoplasmas of dogs and cats (previously called *Haemobartonella felis* and *Haemobartonella canis*) can be detected on the surface of red blood cells (RBCs) but have never been successfully cultured. Until the advent of molecular diagnostic techniques (see p. 1432), documentation of infection was based on cytology alone; Wright-Giemsa stain is the best stain to use in practice for these organisms. However, falsely negative results based on cytology are common, and therefore molecular techniques should be considered in cytology-negative cases if the index of suspicion is high.

Rickettsial Diseases

Anaplasma spp. (Fig. 91.6) and *Ehrlichia* spp. are occasionally found within the cytoplasm of cells in the peripheral blood, lymph node aspirates, bone marrow aspirates, or synovial fluid (see Chapter 95). Morulae of these genera can be found in different cell types. Wright-Giemsa stain is superior to Wright or Diff-Quik stain for the demonstration of morulae. *Rickettsia rickettsii* in endothelial cells lining vessels can be documented by immunofluorescent antibody staining (see Immunologic Techniques, p. 1432).

Fungal Diseases

Arthrospores and conidia of dermatophytes can be identified cytologically. Hairs plucked from the periphery of a lesion are covered with 10% to 20% potassium hydroxide on a microscope slide to clear debris. The slide is then heated, but not boiled, and examined for dermatophytes. All cats with chronic, draining skin lesions should have imprints of the lesions made and stained with Wright-Giemsa stain followed by microscopic examination for the characteristic round, oval, or cigar-shaped yeast phase of *Sporothrix schenckii* within the cytoplasm of mononuclear cells (see Fig. 99.3). Periodic acid–Schiff stain is superior to Wright-Giemsa stain for the demonstration of fungi.

FIG 91.6
Anaplasma phagocytophilum morula *(arrow)* in the cytoplasm of an experimentally infected cat.

Cutaneous Parasitic Diseases

Cheyletiella spp., *Demodex* spp., *Sarcoptes scabiei, Notoedres cati,* and *Otodectes cynotis* are the most common small animal cutaneous parasites. Definitive diagnosis is based on cytologic demonstration of the organisms. *Cheyletiella* is demonstrated by pressing a piece of transparent tape against areas with crusts, placing the tape on a microscope slide, and examining it microscopically. *Demodex* spp. are most commonly detected in deep skin scrapings and follicular exudates; *Cheyletiella* spp., *S. scabiei,* and *N. cati* are detected in wide, more superficial scrapings. *O. cynotis* or its eggs are detected in ceruminous exudates from the ear canals.

Systemic Protozoal Diseases

The most common systemic protozoal diseases and the cytologic appearance and location of these agents are described in Chapter 98. Cytologic demonstration of these agents leads to a presumptive or definitive diagnosis of the disease. Wright-Giemsa or Giemsa staining of thin blood films should be used to demonstrate *Leishmania* spp., *Trypanosoma cruzi, Babesia* spp., *Hepatozoon americanum,* and *Cytauxzoon felis.* Collection of blood from an ear margin vessel may increase the chances of demonstrating the protozoans found in blood, particularly *Babesia* spp. and *C. felis. T. gondii* and *Neospora caninum* cause similar syndromes in dogs, but their tachyzoites are difficult to distinguish morphologically; immunocytochemical staining or PCR is required to differentiate these agents. These protozoans can also be distinguished by evaluating for seroconversion because antibodies are specific to each agent. With the exception of *T. gondii* and *N. caninum,* systemic protozoans are rare or regionally defined in the United States. See Chapter 98 for further discussion of these agents.

Viral Diseases

Rarely, viral inclusion bodies are detected cytologically after staining with Wright-Giemsa. Distemper virus infection causes inclusions in circulating lymphocytes, neutrophils, and erythrocytes of some dogs. Rarely, feline infectious peritonitis virus results in intracytoplasmic inclusions in circulating neutrophils. Feline herpesvirus 1 (FHV-1) transiently results in intranuclear inclusion bodies in epithelial cells.

TISSUE TECHNIQUES

Tissues collected from animals with suspected infectious diseases can be evaluated by several different techniques. Tissue samples should be aseptically placed in appropriate transport

media for culture procedures or inoculated into laboratory animals, if indicated, before further handling.

Gently blotting the cut edge of the tissue on a paper towel to remove excess blood and then lightly touching the tissue multiple times to a microscope slide make tissue impressions for cytologic examination. Tissue specimens can then be frozen, placed into 10% buffered formalin solution, or placed into glutaraldehyde-containing solutions. Frozen specimens are generally superior for immunohistochemical staining and molecular diagnostic procedures. Routine histopathologic evaluation is performed on formalin-fixed tissues. Special stains can be used to maximize the identification of some infectious agents. The clinician should alert the histopathology laboratory to the infectious agents most suspected to allow for appropriate stain selection. Glutaraldehyde-containing fixatives are superior to other fixatives for electron microscopic examination of tissues; this technique can be more sensitive than other procedures for demonstration of viral particles. Molecular diagnostic assays like fluorescence in situ hybridization (FISH) are now being used to identify nucleic acids of infectious agents within tissues (see Molecular Diagnostics, p. 1432).

CULTURE TECHNIQUES

Bacteria, fungi, viruses, and some protozoans can be cultured. In general, a positive culture can be used to establish a definitive diagnosis. Aerobic bacterial culture can be combined with antimicrobial susceptibility testing to determine optimal drug therapy. Successful culture depends on collecting the optimal materials without contamination, transporting the materials to the laboratory as quickly as possible in the most appropriate medium to minimize organism death or overgrowth of nonpathogens, and using the most appropriate culture materials.

Culture results of body systems with normal bacterial and fungal flora, including the skin, ears, mouth, nasal cavity, trachea, feces, and vagina, are the most difficult to interpret. Finding positive culture results and inflammatory cells cytologically suggests the organism is inducing disease. Culture of a single agent, particularly if the organism is relatively resistant to antimicrobials, is more consistent with a disease-inducing infection than if multiple, antibiotic-susceptible bacteria are cultured. Materials for routine aerobic bacterial culture can be placed on sterile swabs if the swabs remain moist and are placed on appropriate culture media within 3 hours of collection. If a delay of greater than 3 hours is expected, swabs containing transport medium should be used. These swabs should be refrigerated or frozen to inhibit bacterial growth if cultures are not to be started within 4 hours; some bacteria will grow more rapidly than others, potentially masking fastidious organisms. Most aerobes will survive at 4° C (routine refrigeration temperature) in tissue or on media-containing swabs for 48 hours. Solid-phase transport media that will support the growth of most aerobes, anaerobes, *Mycoplasma* spp., and fungi for several days if refrigerated are also routinely available. Routine aerobic culture is generally successful on fluid samples (e.g., urine, airway washings) stored at 20° C for 1 to 2 hours, 4° C for 24 hours, or 4° C for 72 hours if placed in transport medium.

Anaerobes can be successfully cultured from fluid collected aseptically into a syringe and the needle covered with a rubber stopper if the material is to be placed on culture media within 10 minutes of collection. Because of time limitations, transport media is generally required for samples from animals with suspected anaerobic infections. These media will support the growth of most anaerobes for 48 hours if stored at 4° C.

Samples for blood culture should be collected aseptically from a large vein after surgical preparation of the skin. In general, three 5-mL samples are collected over a 24-hour period in stable patients or at 1- to 3-hour intervals in septic patients. Unclotted whole blood is placed directly into transport media that will support the growth of aerobic and anaerobic bacteria, and it is incubated at 20° C for 24 hours. Culture for *Bartonella* spp. from blood of dogs or cats is generally performed on whole blood samples collected aseptically and placed in an EDTA-containing tube. In dogs, the combination of culture and PCR performed on 3 mL of blood in EDTA collected up to 3 days weekly may be required to detect *Bartonella* spp. infections (see Chapter 94).

Culture of feces for *Salmonella* spp. or *Campylobacter* spp. and performance of antimicrobial sensitivity testing is occasionally indicated in small animal practice, particularly if the animal has signs of sepsis or an outbreak is suspected. Approximately 2 to 3 g of fresh feces should be submitted to the laboratory immediately for optimal results; however, *Salmonella* and *Campylobacter* are usually viable in refrigerated fecal specimens for 3 to 7 days. To increase the likelihood of achieving positive culture results, a transport medium should be used if a delay is expected. The laboratory should be notified of the suspected pathogen so that appropriate culture media can be used.

Mycoplasma and *Ureaplasma* cultures are most commonly performed on airway washings, synovial fluid, exudates from chronic draining tracts in cats, urine from animals with chronic urinary tract disease, and the vagina of females with genital tract disease. Samples should be transported to the laboratory in Amies medium or modified Stuart bacterial transport medium. *Mycoplasma* spp. culture should be specifically requested.

Mycobacterium spp. grow slowly, and culture is often limited by overgrowth of other bacteria. Special medium is required; therefore the laboratory should be specifically instructed to culture for *Mycobacterium* spp. Tissue samples or exudates from animals with suspected *Mycobacterium* spp. infection should be refrigerated immediately after collection and transported to the laboratory as soon as possible. Exudates should be placed in transport media.

Cutaneous fungal agents can be cultured in the small animal office by using routinely available culture media. Materials from dogs or cats with suspected systemic fungal infection can be transported to the laboratory as described for bacteria, and the laboratory can be told specifically that fungal culture is necessary. The yeast phase of the systemic

fungi occurs in vivo and is not zoonotic; the mycelial phase of *Blastomyces, Coccidioides,* and *Histoplasma* grows in culture and will infect human beings. Thus in-house culture for these agents is not recommended.

Viral agents can be isolated from tissues or secretions at some laboratories. Contact the laboratory before submitting samples. Samples should be collected aseptically as for bacteria, placed in transport media, and immediately refrigerated to inhibit bacterial growth. The samples should be transported to the laboratory on cold packs but not frozen.

IMMUNOLOGIC TECHNIQUES

Infectious agents or their antigens can be detected in body fluids, feces, cells, or tissues by using immunologic techniques. In general, polyclonal or monoclonal antibodies against the agent in question are used in a variety of different test methods, including direct fluorescent antibody assay with cells or tissue, agglutination assays, and enzyme-linked immunosorbent assay (ELISA). Sensitivities and specificities vary by test but are generally high for most assays. Positive results with these tests generally prove infection; this is in contrast to antibody detection procedures, which only document exposure to an infectious agent. Contact the laboratory for details concerning specimen transport before collection.

Commercially available assays for the detection of antigens of *Dirofilaria immitis, Cryptococcus neoformans, Blastomyces dermatitidis,* and feline leukemia virus (FeLV) are used most frequently with blood from small animal patients. The *Cryptococcus neoformans* latex agglutination procedure can also be performed on aqueous humor, vitreous humor, and CSF (see Chapter 97).

Parvovirus *Giardia* spp. antigen detection procedures are available for use with feces of dogs and cats. Parvovirus assays detect both canine and feline parvovirus antigen and may be affected transiently by administration of modified-live vaccines (Abd-Eldaim, 2009; Freisl et al., 2017). Both CPV2c and CPV2b are detected by currently available assays (Markovich et al., 2012). Most *Giardia* antigen tests marketed for use with human or pet feces detect the *Giardia* assemblages that infect dogs or cats (Rishniw et al., 2010). Samples are occasionally antigen positive but cyst negative on fecal flotation. In this situation either the antigen test is falsely positive or the fecal flotation is falsely negative, and both tests should be repeated on a new fecal sample. Alternately, the feces can be evaluated further for *Giardia* cysts by fluorescent antibody assay (next paragraph) or polymerase chain reaction. None of the currently available ELISA-based *Cryptosporidium parvum* antigen tests marketed for use with human feces consistently detects *Cryptosporidium felis* or *Cryptosporidium canis* and should therefore not be used with feces from dogs and cats.

Immunocytochemistry and immunohistochemistry techniques are widely available for the documentation of a variety of infectious diseases. These procedures are particularly valuable for the detection of viral diseases, detection of agents present in small numbers, and for differentiation among agents with similar morphologic features. In general, these techniques are more sensitive and specific than histopathologic techniques and are comparable with culture. For example, focal feline infectious peritonitis granulomatous disease can be documented by immunohistochemical staining (see Chapter 96). A fluorescent antibody-based assay (Merifluor *Cryptosporium/Giardia*, Meridian Bioscience Inc., Saco, ME) for the detection of *Giardia* spp. cysts and *Cryptosporidium* spp. oocysts in feces is commonly used to aid in the diagnosis of these infections in dogs and cats (Mekaru et al., 2007).

MOLECULAR DIAGNOSTICS

A number of different techniques can be used to amplify the DNA or RNA of infectious agents (Veir and Lappin, 2010). Polymerase chain reaction is used frequently for DNA amplification (Fig. 91.7). With a reverse transcriptase step, RNA is converted to DNA; therefore the technique

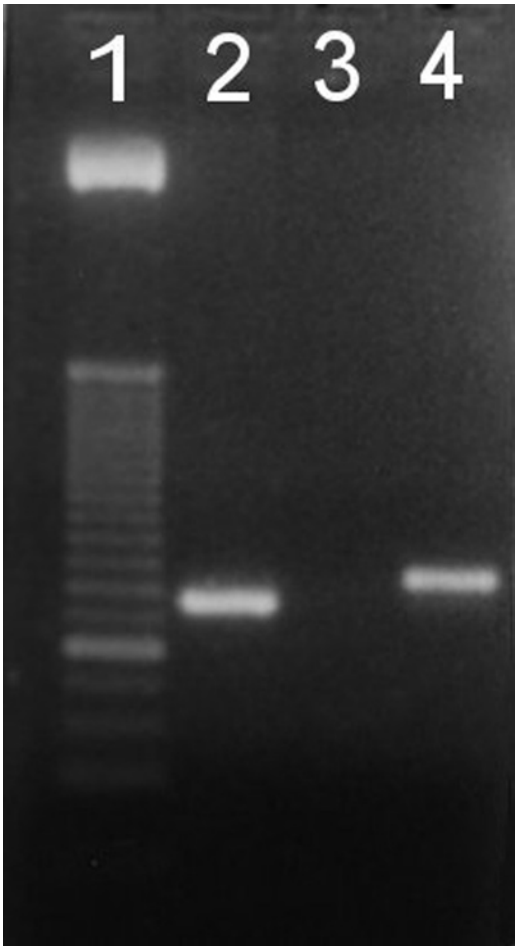

FIG 91.7
Photograph of a polymerase chain reaction assay for hemoplasmas showing the two different band sizes that help differentiate species: *Mycoplasma haemofelis (Lane 2)* and *Candidatus M. haemominutum (Lane 4). Lane 1* is a base pair ladder, and *Lane 3* is a negative sample. In this assay, *Candidatus M. turicensis* is included in the *M. haemofelis* amplicon.

can also be used to amplify RNA (RT-PCR). In general, molecular diagnostic assays are usually more sensitive than other organism demonstration techniques. These assays can be of great benefit for documentation of infectious agents that are difficult to culture (e.g., *Ehrlichia* spp.) or cannot be cultured (e.g., hemoplasmas). Specificity can be quite high depending on the primers used in the reaction. For example, primers can be designed to detect one genus but not others. Primers can also be designed to identify only one species. For example, a PCR assay can be developed to detect all *Ehrlichia* spp. and *Anaplasma* spp. or just one species such as *Ehrlichia canis*. Assays that contain multiple sets of primers to detect nucleic acids of many different infectious agents can also be used.

Another use of molecular diagnostics is FISH. In this molecular technique, nucleic acids of infectious agents can be identified within tissues. One recent infectious disease example using FISH showed that *Borrelia burgdorferi* was not in the renal tissues of dogs with presumed Lyme nephropathy, supporting the hypothesis that this clinical syndrome is likely to have an immune-mediated component (Hutton et al., 2008). In addition, FISH was used to help prove that Boxer colitis was a syndrome associated with *Escherichia coli* (Simpson et al., 2006).

Because of the inherent sensitivity of the reaction, molecular diagnostic assays can give false-positive results if sample contamination occurs during collection or at the laboratory performing the procedure. False-negative results can occur if the sample is handled inappropriately or if the patient is receiving antibiotics that are effective against that specific organism; this is of particular importance for detection of RNA viruses by reverse transcriptase polymerase chain reaction (RT-PCR). Results may also be affected by treatment. Another potential problem is that minimal standardization exists among commercial laboratories offering molecular diagnostic assays.

Although molecular diagnostic assays can be one of the most sensitive for documentation of infections, positive test results do not always prove that the infection is causing clinical illness. For example, because the technique detects DNA of both live and dead organisms, positive test results may be achieved even if the infection has been controlled. When the organism being tested for commonly infects the background population of healthy pets, interpretation of results for a single animal can be difficult. For example, FHV-1 commonly infects cats and is commonly carried by healthy cats. Thus although PCR is the most sensitive way to document infection by FHV-1, the positive predictive value for disease of a FHV-1 PCR result is actually quite low. In one study, more positive FHV-1 PCR results were detected in the healthy control group than in the group with conjunctivitis (Burgesser et al., 1999). In addition, the currently available PCR assays for FHV-1 also amplify modified-live vaccine strains, so a positive result does not even indicate presence of a pathogenic strain. Real-time PCR can be used to determine the amount of microbial DNA or RNA in a sample. The nucleic acid load may correlate to the presence of disease or therapeutic responses for some agents (Low et al., 2007; Veir and Lappin, 2010). However, minimal data exist for use of quantitative PCR for these purposes and the reader is directed to specific agent chapters for further information. Because of these findings, small animal practitioners must carefully assess the predictive values of currently available PCR assays and the expertise and reliability of the laboratory that will be performing the assays.

ANIMAL INOCULATION

Animal inoculation can be used to identify some infectious diseases. For example, oocysts of *T. gondii* cannot be distinguished morphologically from those of *Hammondia hammondi* or *Besnoitia darlingi;* only *T. gondii* is infectious for human beings. *T. gondii* can be differentiated from the other coccidians by inoculation of sporulated oocysts into mice and monitoring for *T. gondii*–specific antibody production. However, because live animals are required, animal inoculation is rarely used in small animal practice.

ELECTRON MICROSCOPY

Electron microscopy is a highly sensitive procedure for organism identification in body fluids and tissues. Glutaraldehyde-containing fixatives are used most commonly. One of the most clinically relevant uses of electron microscopy is for the detection of viral particles in feces of animals with gastrointestinal signs of diseases.

ANTIBODY DETECTION

SERUM

A variety of different methods exists for detecting serum antibodies against infectious agents; complement fixation, hemagglutination inhibition, serum neutralization, agglutination assays, agar gel immunodiffusion, indirect fluorescent antibody assay (IFA), ELISA, and Western blot immunoassay are commonly used methods. Complement fixation, hemagglutination inhibition, serum neutralization, and agglutination assays generally detect all antibody classes in a serum sample. Western blot immunoassay, IFA, and ELISA can be adapted to detect specific immunoglobulin (Ig) M, IgG, or IgA responses. Western blot immunoassay can be used to identify the immunodominant antigens recognized by the humoral immune responses (Fig. 91.8).

Comparison of IgM, IgA, and IgG antibody responses against an infectious agent can be used to attempt to prove recent or active infection. In general, IgM is the first antibody produced after antigenic exposure. Antibody class shift to IgG occurs in days to weeks. Serum and mucosal IgA immune responses have also been studied for some infectious agents, including *T. gondii,* feline coronaviruses, and *Helicobacter felis.*

Timing of antibody testing is important. In general, serum antibody tests in puppies and kittens cannot be interpreted as specific responses until at least 8 to 12 weeks of age because of the presence of antibodies from the dam passed

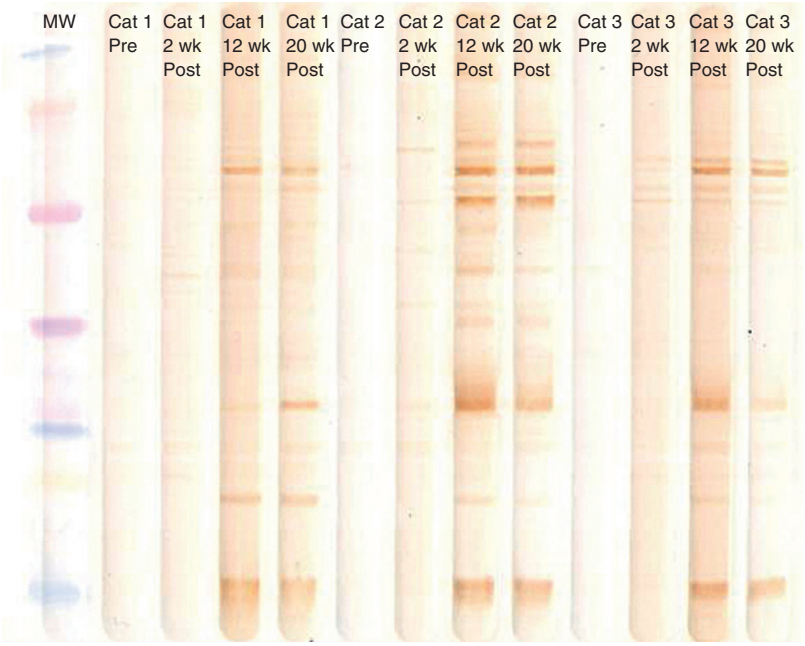

FIG 91.8
Bartonella spp. antigen recognition pattern by feline serum antibodies determined by Western blot immunoassay. *MW,* Molecular mass standards; *Post,* weeks after infection.

to the puppy or kitten in the colostrum. Most infectious agents can induce disease within 3 to 10 days of initial exposure; with many assays serum IgG antibodies are usually not detected until 1 to 2 weeks after initial exposure. On the basis of these facts, falsely negative serum antibody tests during acute disease can be common in small animal practice. If specific serum antibody testing is initially negative in an animal with acute disease, repeat antibody testing should be performed in 2 to 3 weeks to assess for seroconversion. Documentation of increasing antibody titers is consistent with recent or active infection. Assessment of both the acute and convalescent sera in the same assay on the same day is preferable to avoid interassay variation.

Sensitivity is the ability of an assay to detect a positive sample; specificity is the ability of an assay to detect a negative sample. Sensitivity and specificity vary with each assay. Positive predictive value is the ability of a test result to predict presence of disease; negative predictive value is the ability of a test result to predict absence of disease. Many of the infectious agents encountered in small animal practice infect a large percentage of the population, resulting in serum antibody production. However, they only induce disease in a small number of animals in the infected group. Examples include coronaviruses, canine distemper virus, *T. gondii, Bartonella* spp., and *Borrelia burgdorferi.* For these examples, even though assays with good sensitivity and specificity for the detection of serum antibodies are available, the predictive value of a positive test for presence of disease is extremely low. This is because antibodies are commonly detected in healthy carriers. Diagnostic utility of some serologic tests is also limited because of the presence of antibodies induced by vaccination. Examples include feline coronaviruses, some *B. burgdorferi* assays, some *Leptospira* spp. assays as well as those for FHV-1, parvoviruses, FIV calicivirus, and canine distemper virus.

The clinician should interpret positive results in serum antibody tests only as evidence of present or prior infection by the agent in question. Recent or active infection is suggested by the presence of IgM, an increasing antibody titer over 2 to 3 weeks, or seroconversion (negative antibody result on the first test and positive antibody result on convalescent testing). However, detection of recent infection based on antibody testing does not always prove disease. Conversely, failure to document recent or active infection based on serologic testing does not exclude a diagnosis of clinical disease. For example, many cats with toxoplasmosis develop clinical signs of disease after serum antibody titers have reached their plateau. The magnitude of antibody titer does not always correlate with active or clinical disease. For example, many cats with clinical toxoplasmosis have IgM and IgG titers that are at the low end of the titer scale; conversely, many healthy cats have IgG titers greater than 1:16,384 years after infection with *T. gondii.* Similarly, *Bartonella* spp. antibody magnitude does not correlate to clinical illness in cats.

BODY FLUIDS

Some infectious agents induce disease of the eyes or central nervous system (CNS). Documentation of agent-specific antibodies in aqueous humor, vitreous humor, or CSF can be used to support the diagnosis of infection of these tissues. Quantification of ocular and CSF antibodies is difficult to

interpret if serum antibodies and inflammatory disease are present, because serum antibodies leak into ocular fluids and CSF in the face of inflammation. Detection of local production of antibodies within the eye or CNS has been used to aid in the diagnosis of canine distemper virus infection, feline toxoplasmosis, and feline bartonellosis (see Chapters 94, 96, and 98). The following is a method to prove local antibody production by the eye or CNS:

$$\frac{\text{Aqueous humor or CSF-specific antibody}}{\text{Serum-specific antibody}} \times \frac{\text{Serum total antibody}}{\text{Aqueous humor or CSF total antibody}}$$

A ratio greater than 1 suggests that the antibody in the aqueous humor or CSF was produced locally. This formula has been used extensively in the evaluation of cats with uveitis. Approximately 60% of cats with uveitis in the United States have *T. gondii*–specific IgM, IgA, or IgG values greater than 1 (see Chapter 98). The technique was also used to help prove that FHV-1 and *Bartonella henselae* are causes of uveitis in cats (Powell et al., 2010).

ANTEMORTEM DIAGNOSIS OF INFECTIOUS DISEASES

As discussed, results of organism demonstration assays can be used to prove an infectious agent is still present in the body, and results of antibody assays can be used to prove exposure to infectious agents. However, many of the infectious agents of dogs and cats also colonize the host without inducing illness. Thus the majority of assays discussed are really "infectious *agent* tests" not "infectious *disease* tests." The feline hemoplasmas are great examples of this; although these agents can cause hemolytic anemia in cats and sensitive and specific PCR assays are available to amplify hemoplasma DNA, approximately 20% of healthy cats are PCR-positive. Thus a positive PCR assay result does not document clinical hemoplasmosis but merely documents current infection. The clinical diagnosis of an infectious disease usually includes the combination of the following:

- Clinical signs referable to the agent
- Serologic evidence of exposure to the agent or evidence of infection by organism demonstration techniques
- Exclusion of other causes of the clinical syndrome
- Response to treatment

However, some clinical illnesses resolve spontaneously and some antibodies can have antiinflammatory properties; this combination of findings should only be considered a tentative diagnosis rather than definitive diagnosis for an infectious disease.

CHAPTER 92

Practical Antimicrobial Chemotherapy

Antimicrobial drugs should only be administered if the index of suspicion for an infection exists. The prescribing veterinarian should also always be cognizant of the potential for selecting for antimicrobial resistant strains of bacteria, particularly when prescribing drugs also used in human beings. Veterinarians should be familiar with judicious use of antimicrobial guidelines for the species in question; the following websites can be of benefit:

1. www.avma.org/KB/Policies/Pages/The-Role-of-the-Veterinarian-in-Animal-Antimicrobial-Use.aspx
2. https://www.avma.org/KB/Policies/Pages/AAFP-AAHA-Basic-Guidelines-of-Judicious-Therapeutic-Use-of-Antimicrobials.aspx

In small animal practice, decisions to institute antimicrobial chemotherapy are made initially without the benefit of results of culture and antimicrobial susceptibility testing. In simple, first-time bacterial infections (sporadic bacterial cystitis), culture and antimicrobial susceptibility testing is often not performed, so logical empirical choices should be made. Groups like the International Society for Companion Animal Infectious Diseases (ISCAID; www.iscaid.org) and the Swedish Veterinary Medical Association (http://www.sva.se/en/antibiotics/use-for-animals-in-sweden) write and publish specific guidelines that can help veterinarians decide when to choose to use antibiotics and which to use. In life-threatening bacterial infections, materials for culture should be collected, but decisions on the choice of antimicrobials must be made before obtaining the culture results; patient survival may depend on the selection of optimal treatment regimens. For many infectious agents such as *Borrelia burgdorferi*, *Ehrlichia* spp., hemoplasmas, *Rickettsia rickettsii*, and the gastrointestinal (GI; e.g., *Giardia*) or systemic (e.g., *Toxoplasma gondii*) protozoans, the organisms are not readily grown in culture, so empirical therapy is always used.

Recognition of the most common infectious agents associated with infection of different organ systems or associated with different clinical syndromes is imperative in the empirical selection of antimicrobials (Table 92.1). The antimicrobial selected must have an appropriate mechanism of action against the suspected pathogen and must achieve an adequate concentration in infected tissues. Bacteriostatic agents may be less effective for treatment of infections in immunosuppressed animals because normal immune responses are required for the drugs to have maximal effect. The owner must be willing to administer the drug in the appropriate interval, and the drug must be affordable. Whether the antimicrobial has potential for toxicity is also an important consideration (Table 92.2). In animals with life-threatening infections, appropriate materials should be submitted for culture and antimicrobial sensitivity testing, if possible, and antibiotics administered parenterally initially. Parenteral antibiotic administration is also indicated in animals with vomiting or regurgitation. Oral administration of antibiotics can be initiated when vomiting, regurgitation, or the life-threatening condition has resolved but only if long-term treatment is needed. In life-threatening infections, administration of antimicrobial agents to treat gram-positive, gram-negative, aerobic, and anaerobic bacteria (four-quadrant approach) is indicated initially, and then therapy can be de-escalated based on clinical response and antimicrobial susceptibility testing.

Most simple, first-time bacterial infections in immunocompetent animals respond adequately to 5 to 7 days of antibiotic therapy. Therapy is generally continued for no more than 1 to 2 days past resolution of clinical signs. Chronic infections, bone infections, infections in immunosuppressed animals, infections resulting in granulomatous reactions, and those caused by intracellular pathogens are generally treated for a minimum of 1 week beyond resolution of clinical signs of disease. Please see specific sections for a more in-depth discussion of duration of therapy.

If therapeutic response to an antibiotic in 72 hours is poor and an antibiotic-responsive infectious disease is still likely, an alternative treatment should be considered. Veterinarians should always know at least two first-line drugs for each common infectious agent or infectious disease syndrome (Tables 92.3 to 92.8) and should have access to a current formulary and the websites previously cited in this chapter.

TABLE 92.1

Antibiotics Used for the Treatment of Bacterial Infections in Dogs and Cats and General Dosing Guidelines*

DRUG	MECHANISM	SPECIES	DOSAGE	ROUTE OF ADMINISTRATION
Acetamides	Protein synthesis inhibition			
Chloramphenicol		D C	25-50 mg/kg, q8h 50 mg/cat q12h	PO PO
Florfenicol		D	20 mg/kg, q6h	PO, IM
Aminoglycosides†	Protein synthesis inhibition			
Amikacin		D C	15-30 mg/kg, q24h 10-14 mg/kg, q24h	IV, IM, SC IV, IM, SC
Gentamicin		D C	9-14 mg/kg, q24h 5-8 mg/kg, q24h	IV, IM, SC IV, IM, SC
Neomycin		B	10-20 mg/kg, q6-12h	PO
Carbapenems	Cell wall synthesis inhibition			
Imipenem-cilastatin		B	5 mg/kg, q6-8h	IV, IM
Meropenem			8.5 mg/kg, q12h (SC) or q8h (IV)	IV, SC
Cephalosporins	Cell wall synthesis inhibition			
Cefadroxil (first generation)		D C	22-30 mg/kg, q12h 22 mg/kg, q24h	PO PO
Cefpodoxime (third generation)		B	5-10 mg/kg, q24h	PO
Cephalexin (first generation)		B	10-30 mg/kg, q8-12h	PO
Cefazolin (first generation)		B	20-35 mg/kg, q6-12h	SC, IM, IV
Cefoxitin (second generation)		B	15-30 mg/kg, q6-8h	SC, IM, IV
Cefotaxime (third generation)		B	20-80 mg/kg, q8-12h	SC, IM, IV
Cefovecin		B	8 mg/kg, once, can repeat in 7-14 days	SC
Ceftiofur	Naxcel	B	2.2-4.4 mg/kg, q24h	SC
Macrolides/lincosamides	Protein synthesis inhibition			
Azithromycin		D	5-10 mg/kg, on day 1 then q3d	PO
Clindamycin		D C	10 mg/kg, q12h 5-15 mg/kg, q12h	PO, SC PO, SC
Erythromycin		B	10-20 mg/kg, q8-12h	PO
Lincomycin		B	15-25 mg/kg, q12h	PO
Tylosin		B	5-15 mg/kg, q12-24h	PO
Nitroimidazole	Protein synthesis inhibition			
Metronidazole§		B B	10-25 mg/kg, q12-24h 10 mg/kg, q8h	PO IV
Ronidazole		B	30 mg/kg, q24h	PO
Penicillins	Cell wall synthesis inhibition			
Amoxicillin		B	22 mg/kg, q12h	PO
Amoxicillin and clavulanate		D C	11 mg/kg, q8-12h 62.5 mg, q8-12h	PO PO

TABLE 92.1

Antibiotics Used for the Treatment of Bacterial Infections in Dogs and Cats and General Dosing Guidelines*—cont'd

DRUG	MECHANISM	SPECIES	DOSAGE	ROUTE OF ADMINISTRATION
Ampicillin sulbactam		B	20 mg/kg, q8-12h	IV, IM
Ampicillin sodium		B	20-30 mg/kg, q8-12h	SC, IM, IV
Oxacillin		B	22-40 mg/kg, q8h	PO
Penicillin G		B	25,000- 40,000 U/kg, q12h	IV
Ticarcillin and clavulanate		D	20-50 mg/kg, q6-8h	IM, IV
Quinolones	Nucleic acid inhibition			
Enrofloxacin		D C	5-20 mg/kg, q12-24h 5.0 mg/kg, q24h	PO, IM, SC, IV PO, IM, IV
Marbofloxacin		B	2.75-5.5 mg/kg, q24h	PO
Orbifloxacin		D C	2.5-7.5 mg/kg, q24h 7.5 mg/kg, q24h	PO PO
Pradofloxacin		D C	5.0 mg/kg, q24h 7.5 mg/kg, q24hr	PO PO
Potentiated sulfas	Intermediary metabolism inhibition			
Ormetoprim-sulfadimethoxine		D	27.5 mg/kg, q24h	PO
Trimethoprim-sulfadiazine		B	15 mg/kg, q12h	PO
Tetracyclines	Protein synthesis inhibition			
Doxycycline		B	5 mg/kg, q12h OR 10 mg/kg, q24h	PO, IV
Minocycline		D C	5-10 mg/kg, q12h 50 mg/cat, q24h	PO PO
Tetracycline		B	22 mg/kg, q8-12h	PO

B, Dog and cat; *C,* cat; *D,* dog; *IM,* Intramuscular; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.
*The dose ranges and intervals in this table are general. Please see appropriate sections to determine the optimal dose for specific syndromes or infections.
†For parenterally administered aminoglycosides, giving the total daily dose at one time may lessen the potential for renal toxicity.
§The maximal total daily dose should be 50 mg/kg.

The following is a brief discussion of the empirical antimicrobial choices for treatment of infections of various body systems or types of infections. The reader is referred to individual chapters for further information concerning adjunct treatments.

ANAEROBIC INFECTIONS

The anaerobic bacteria with the most clinical relevance in dog and cats are *Actinomyces* spp., *Bacteroides* spp., *Clostridium* spp., *Eubacterium* spp., *Fusobacterium* spp., *Peptostreptococcus* spp., and *Porphyromonas* spp. *Actinomyces* is a facultative anaerobe; the other organisms are obligate anaerobes, which cannot use oxygen metabolically and die in its presence. Anaerobic bacteria are part of the normal flora in areas with low oxygen tension and low oxygen-reduction potential, such as the mucous membranes of the oral cavity and vagina. The origin of most anaerobic infections is the animal's own flora. Anaerobic infections are potentiated by poor blood supply, tissue necrosis, prior infection, or immunosuppression. Anaerobic bacteria produce a number of enzymes and factors that induce tissue injury and promote colonization. Most infections involving anaerobes usually have coexisting aerobic bacterial infection, which should be considered when selecting antimicrobial agents.

Anaerobic infections are commonly associated with infections of the oropharynx, central nervous system (CNS), subcutaneous space, musculoskeletal system, GI tract, liver, and female genital tract, and can be associated with clinical disease in animals with aspiration pneumonia or consolidated lung lobes. Dogs and cats with gingivitis or stomatitis, rhinitis, retrobulbar abscesses, retropharyngeal abscesses, pyothorax, otitis media or interna, CNS infection, bite

TABLE 92.2

Potential Antibiotic Toxicities

TOXICITY	ANTIBIOTIC EXAMPLES
Aminoglycosides	Renal tubular disease Neuromuscular blockade Ototoxicity
Beta lactams (penicillins and cephalosporins)	Immune-mediated diseases Vomiting or diarrhea
Chloramphenicol	Bone marrow/aplastic anemia (predominantly cats and humans) Inhibition of drug metabolism
Doxycycline	Esophagitis or strictures in cats given tablets or capsules
Macrolides/ lincosamides	Vomiting or diarrhea Cholestasis Esophagitis or strictures in cats given clindamycin capsules
Nitroimidazoles	Neutropenia (metronidazole) CNS toxicity (metronidazole and ronidazole)
Quinolones	Failure of cartilage development in young, growing animals Retinal dysfunction in some cats with some formulations (enrofloxacin in particular) Potentiation of seizures
Sulfonamides	Hepatic-cholestasis or acute hepatic necrosis (rare) Macrocytic anemia (long-term administration in cats) Thrombocytopenia Suppurative, nonseptic polyarthritis (predominantly Doberman) Keratoconjunctivitis sicca Renal crystalluria (rare)
Tetracyclines	Renal tubular disease Cholestasis Fever, particularly in cats Inhibition of drug metabolism Teeth browning in puppies and kittens (not doxycycline or minocycline)

CNS, Central nervous system.

TABLE 92.3

Empirical Antibiotic Choices for Dogs and Cats With Cutaneous and Soft Tissue Infections

INFECTIOUS AGENT	FIRST CHOICE ANTIBIOTICS
Abscesses (anaerobes)[1,2]	Amoxicillin OR Clindamycin OR Metronidazole OR First- or second-generation cephalosporins
Actinomyces	Penicillins OR Clindamycin OR Chloramphenical OR Minocycline
Gram-negative or resistant pyoderma	Quinolones
Nocardia	Penicillins (high dose) OR Minocycline OR Trimethoprim-sulfonamide OR Amikacin OR Imipenem cilastatin
Staphylococcal pyoderma	Clindamycin or lincomycin OR First-generation cephalosporins OR Amoxicillin-clavulanate OR Trimethoprim-sulfonamide

[1]Cefovecin can be considered if the cat is impossible to medicate orally.
[2]Amoxicillin-clavulanate is not generally required for simple cat bite abscesses and should be considered as a second choice drug if the need is approved by culture.

FIG 92.1
Caudal stomatitis in a cat with suspected secondary anaerobic bacterial infection.

wounds, open wounds, open fractures, osteomyelitis, peritonitis, bacterial hepatitis, pyometra, vaginitis, bacteremia, and valvular endocarditis should be suspected to be infected with anaerobes (Fig. 92.1). Anaerobic infections also should be considered in animals with a history of fighting, a foreign body, recent surgery, recent dental procedures, a history of immunosuppressive drugs or diseases, infections resistant to aminoglycosides or fluoroquinolones, lesions with a putrid odor or black discharge, a painful lesion with a serosanguineous discharge, neutrophilic inflammation with cytologically evident bacteria but negative aerobic culture, and the presence of "sulfur granules" on cytology. Flaccid paralysis *(Clostridium botulinum),* rigid paralysis and trismus *(Clostridium tetani),* and subcutaneous gas production occur in association with some anaerobic infections.

TABLE 92.4

Empirical Antibiotic Choices for Dogs and Cats With CNS or Muscle Infections

SYNDROME OR ORGANISM	FIRST CHOICE ANTIBIOTICS
Bacterial encephalitis	Chloramphenicol OR Quinolone OR Trimethoprim-sulfonamide OR Metronidazole
Bacterial otitis media/interna	Amoxicillin-clavulanate OR Clindamycin OR First-generation cephalosporin OR Quinolone OR Chloramphenicol
Hepatozoon americanum	Acute: clindamycin, AND Trimethoprim – sulfonamide Chronic: decoquinate
Neospora caninum	Clindamycin AND Trimethoprim-sulfonamide
Toxoplasma gondii	Clindamycin OR Azithromycin OR Trimethoprim-sulfonamide

TABLE 92.5

Empirical Antibiotic Choices for Dogs and Cats With Hepatic and Gastrointestinal Infections[#]

INFECTIOUS AGENT	FIRST CHOICE ANTIBIOTICS
Bacterial cholangiohepatitis	Amoxicillin or amoxicillin clavulanate OR First-generation cephalosporin OR Metronidazole AND Quinolones (if septic)
Campylobacter spp.*	Azithromycin OR Erythromycin OR Quinolone
*Clostridium perfringens**	Penicillin derivative OR Tylosin OR Metronidazole
Helicobacter spp.	Metronidazole plus amoxicillin
Hepatic encephalopathy	Neomycin OR Ampicillin OR Metronidazole
Salmonella spp.*	Ampicillin or amoxicillin AND Quinolones*
Small intestinal bacterial overgrowth*	Penicillin derivative OR Metronidazole OR Tylosin

[#]See the text for a discussion of treatment of protozoal infections.
*Usually only administered parenterally for the treatment of bacteremia/sepsis. Cases with diarrhea only generally respond to dietary changes and probiotic administration.

TABLE 92.6

Empirical Antibiotic Choices for Dogs and Cats With Bone or Joint Infections

ORGAN SYSTEM OR INFECTIOUS AGENT	FIRST CHOICE ANTIBIOTICS
Bone	
Discospondylitis	Amoxicillin-clavulanate OR Clindamycin OR First-generation cephalosporin OR Chloramphenicol OR Quinolone OR
Osteomyelitis	Amoxicillin-clavulanate OR Clindamycin OR First-generation cephalosporin OR Chloramphenicol OR Quinolone
Polyarthritis	
Anaplasma (*platys* or *phagocytophilum*)	Doxycycline OR Chloramphenicol
Bartonella spp.	Doxycycline AND Quinolone OR Azithromycin
Borrelia burgdorferi	Doxycycline OR Amoxicillin
Ehrlichia canis	Doxycycline OR Chloramphenicol OR Imidocarb
Ehrlichia ewingii	Doxycycline
L-form bacteria or *Mycoplasma*	Doxycycline OR Quinolone OR Chloramphenicol
Rickettsia rickettsii	Doxycycline OR Quinolone OR Chloramphenicol

Improving the blood supply and oxygenation of the infected area is the primary goal for treatment of anaerobic infections. Antibiotic therapy should be used concurrently with drainage or debridement. Parenteral antibiotics should be administered for several days in dogs or cats with pyothorax, pneumonia, peritonitis, or clinical signs consistent with bacteremia. Beta lactam antibiotics, chloramphenicol, clindamycin, metronidazole, and penicillin G are commonly used for the treatment of anaerobic infections (see Tables 92.1 and 92.3).

BACTEREMIA AND BACTERIAL ENDOCARDITIS

Bacteremia can be transient, intermittent, or continuous. Routine dentistry is a common cause of transient bacteremia. Immunosuppressed or critically ill animals commonly

TABLE 92.7

Empirical Antibiotic Choices for Dogs and Cats With Respiratory Infections

ORGAN SYSTEM OR INFECTIOUS AGENT	FIRST CHOICE ANTIBIOTICS
Feline acute bacterial upper respiratory infection (URI)	Doxycycline OR Amoxicillin
Feline chronic bacterial URI	Doxycycline OR Based on culture and susceptibility testing
Canine infectious respiratory disease complex (bacterial component)	Doxycycline OR Amoxicillin-clavulanate
Bacterial bronchitis (dogs or cats)	Doxycycline OR Based on culture and susceptibility testing
Uncomplicated "community acquired" pneumonia	Doxycycline OR Fluoroquinolone
Pneumonia with clinical evidence of sepsis*	Enrofloxacin# and ampicillin or clindamycin AND Adjust based on culture and susceptibility testing
Pyothorax (dogs or cats)*	Enrofloxacin# and penicillin or clindamycin+ AND Adjust based on culture and susceptibility testing

*For animals with clinical findings of life-threatening disease, the consensus of the ISCAID Working Group was to administer dual agent therapy with the potential for de-escalation of therapy based on culture and antimicrobial susceptibility testing (Lappin et al., 2017).
#Enrofloxacin is often chosen as there is a veterinary product for parenteral administration to dogs and the drug has a wide spectrum against gram-negative organisms and *Mycoplasma* spp. There are other drugs with a wide spectrum against gram-negative bacteria that can be substituted based on antimicrobial susceptibility testing.

TABLE 92.8

Empirical Antibiotic Choices for Dogs and Cats With Urogenital Infections

SYNDROME OR INFECTIOUS AGENT	FIRST CHOICE ANTIBIOTICS
Aerobic infection (uncomplicated)	Amoxicillin OR Trimethoprim-sulfonamide
Aerobic infection (complicated)	Amoxicillin OR Trimethoprim-sulfonamide AND Adjust based on culture and sensitivity results
Brucella canis	Quinolone alone OR Minocycline or doxycycline cycled with a quinolone every 2 weeks
Leptospira spp.	Penicillin G or ampicillin IV during acute phase THEN Doxycycline to eliminate carriers
Mastitis	First-generation cephalosporin OR Amoxicillin or amoxicillin-clavulanate
Mycoplasma/Ureaplasma	Doxycycline OR Quinolone
Prostatitis (gram negative agents)	Trimethoprim-sulfonamide OR Quinolone AND Adjust based on culture and susceptibility testing
Prostatitis (gram positive agents)	Clindamycin AND Adjust by culture and sensitivity results
Pyelonephritis	Fluoroquinolone AND Adjust by culture and sensitivity results
Pyometra	Trimethoprim-sulfonamide OR Quinolone and ampicillin if evidence of sepsis AND Adjust by culture and sensitivity results

IV, Intravenous; *PO,* oral.

develop intermittent bacteremia; the source of infection is commonly the genitourinary or GI systems. Continuous bacteremia occurs most frequently in association with bacterial endocarditis. Bacteremic animals can have intermittent fever, depression, and clinical signs associated with the primary organ system infected. Sepsis is the systemic response to infection and is manifested by peripheral circulatory failure (septic shock).

Staphylococcus spp., *Streptococcus* spp., *Enterococcus* spp., *Corynebacterium* spp., *Escherichia coli*, *Salmonella* spp., *Klebsiella* spp., *Enterobacter* spp., *Pseudomonas* spp., *Proteus* spp., *Pasteurella* spp., *Clostridium* spp., *Fusobacterium* spp., *Bacteroides* spp., and *Bartonella* spp. organisms are commonly isolated from the blood of bacteremic animals (Sykes et al., 2006). Bacterial endocarditis is often caused by Staphylococcus aureus, E. coli, or β-hemolytic *Streptococcus* spp.; *Bartonella* spp. are now recognized as important causes of bacterial endocarditis and myocarditis (see Chapters 6, 7 and 94) in both dogs and cats (Fenimore et al., 2011).

If the source of bacteremia or bacterial endocarditis is likely from an area with mixed flora, such as the GI tract, or if the animal has life-threatening clinical signs of disease, an antibiotic or combination of antibiotics effective against gram-positive, gram-negative, aerobic, and

anaerobic organisms should be used. An aminoglycoside or quinolone for gram-negative organisms combined with ampicillin, a first-generation cephalosporin, metronidazole, or clindamycin for gram-positive and anaerobic organisms is a commonly prescribed combination treatment with the final choice made based on the likely site of bacterial entry. Second- and third-generation cephalosporins, ticarcillin combined with clavulanate, and imipenem are some of the other antimicrobial agents with a four-quadrant spectrum.

For bacteremia, without endocarditis, antimicrobial agents should be administered intravenously for at least 1 to 3 days, and clinical and clinicopathologic evidence of response documented before conversion to oral therapy. The oral treatment is selected on the basis of culture and antimicrobial susceptibility results, and duration of therapy will vary based on the source of the bacteremia. For example, if antibiotics are used parenterally in a bacteremic parvovirus puppy, continued oral therapy is not required after resolution of clinical signs of disease.

For patients with valvular endocarditis, administration of intravenous (IV) antibiotics for at least 7 to 14 days followed by subcutaneous (SC) administration for 7 to 14 days before conversion to oral therapy is recommended by some authors (Calvert and Thomason, 2012); oral antibiotic therapy may be indicated for months. Optimal treatment for valvular endocarditis from bartonellosis in dogs has not been determined, but the combination of at least two drugs is generally required. Although optimal protocols are not known, fluoroquinolones combined with doxycycline, azithromycin, or rifampin may be required in some cases (see Chapters 6 and 94). Administration of amikacin for the first 5 to 7 days of therapy is indicated for dogs or cats with endocarditis associated with bartonellosis. For aerobic or anaerobic bacteria, the blood culture can be rechecked 1 and 4 weeks after discontinuation of therapy to confirm control of the infection. Whether there is clinical utility to performing *Bartonella* spp. serology or culture after successful treatment is unclear (see Chapter 94). The prognosis in dogs and cats with bacterial endocarditis is guarded to poor because of damage to the infected heart valves (see Chapter 6).

CENTRAL NERVOUS SYSTEM INFECTIONS

Azithromycin, chloramphenicol, trimethoprim-sulfonamide, metronidazole, and the quinolones penetrate the CNS and are often considered for empirical treatment of suspected bacterial infections of this system (see Table 92.4). Anaerobic bacterial infection and rickettsial infections (*Ehrlichia* spp. and *R. rickettsii*) of the CNS occur in some cases, making chloramphenicol a logical first choice. Multiple other drugs, including penicillin derivatives, tetracyclines (doxycycline), and clindamycin, may cross into the cerebrospinal fluid (CSF) when inflammation exists. Clindamycin achieves adequate brain tissue concentrations in normal cats and can be used for the treatment of toxoplasmosis (see Chapter 98). Azithromycin, potentiated sulfas, and potentially ponazuril are alternative anti-*Toxoplasma* drugs. Optimal treatment for dogs with *Neospora caninum* infection of the CNS is unknown, but the combination of clindamycin or azithromycin with potentiated sulfas should be considered in acutely affected dogs because of the potentially poor prognosis.

GASTROINTESTINAL TRACT AND HEPATIC INFECTIONS

Oral administration of antimicrobial agents is rarely indicated for bacterial GI infections in dogs or cats because of negative effects on the GI microbiome and availability of alternate therapies like diets and probiotics (Torres-Henderson et al., 2017). However, antibiotics are sometimes needed for the treatment of small intestinal bacterial overgrowth, hepatic encephalopathy, cholangiohepatitis, hepatic abscessation, Boxer colitis, and infection by *Helicobacter* spp., *Campylobacter* spp., *Clostridium perfringens, Giardia* spp., *Cryptosporidium* spp., *Cystoisospora* spp., *Tritrichomonas foetus,* and *Toxoplasma gondii* (see Table 92.5). Administration of parenteral antibiotics may be indicated in dogs and cats with bacteremia from translocation of enteric flora or with *Salmonella* infection. The American College of Veterinary Internal Medicine has recently published a consensus statement on the treatment of enteropathogenic bacterial infections in dogs and cats (Marks et al., 2011). For most GI infections, dietary manipulation and probiotics could also be beneficial or resolve the diarrhea so antimicrobial agents are not required.

Giardia spp. infections often respond clinically to the administration of metronidazole, but infection is usually not eliminated. Administration of a probiotic and institution of a diet change should be considered concurrently when treating dogs or cats with suspected giardiasis (Fenimore et al., 2017). Administration of metronidazole benzoate at 25 mg/kg q12h orally (PO) for 7 days was effective in suppressing cyst shedding to below detectable limits in 26 cats (Scorza and Lappin, 2004). This is the maximal dose of metronidazole that should be used; CNS toxicity can be induced by overdosing or as a cumulative neurotoxin. Fenbendazole is the most commonly used alternate drug in dogs and cats. Febantel is also potentially effective in both species and is labelled for this use in some countries (Bowman et al., 2009). Metronidazole has the advantage of helping treat secondary small intestinal bacterial overgrowth and may have antiinflammatory effects. Nitaxoxanide also can be used to treat *Giardia* spp. infected dogs and should be considered for use when *Cryptosporidium* spp. co-infection and diarrhea are detected concurrently (Moron-Soto et al., 2017). Although ronidazole can be effective for the treatment of *Giardia* spp. infection, it is generally reserved for the treatment of *T. foetus* infections (Fiechter et al., 2012).

For *T. foetus* infections of kittens (and rarely, puppies), ronidazole at 30 mg/kg PO q24h for 14 days often eliminates

clinical signs of disease and trophozoites. However, ronidazole resistance and treatment failures have been detected (Xenoulis et al., 2013). CNS toxicity is also common with ronidazole if overdosed. Fluoroquinolones may be effective in *T. foetus* infected cats that fail to respond clinically to ronidazole.

Most dogs or cats diagnosed with cryptosporidiosis are infected by *C. canis* or *C. felis*, respectively. Although infection with these host-adapted species is common, it is unclear how many infected dogs and cats actually have diarrhea directed related to the infection. Infection studies of healthy dogs or cats rarely induce diarrhea. Thus, if other potential causes of diarrhea, like *Giardia* spp., are detected in a dog or cat positive for *Cryptosporidium*, the other cause of diarrhea should be treated first to see if the diarrhea resolves. Antibiotic treatment does not eliminate *Cryptosporidium* spp. infection; it just potentially lessens clinical signs. Tylosin (10-15 mg/kg q12h PO) has apparently been successful in lessening diarrhea and oocyst shedding in cats and dogs with diarrhea that were positive for *Cryptosporidium*. Azithromycin at 10 mg/kg PO daily for 7 days may lessen diarrhea in some dogs or cats with cryptosporidiosis. If responding after 7 days, continue treatment for at least 1 week past clinical resolution. Nitazoxanide can be considered at 75 mg/kg, PO, twice, 14 days apart in dogs with *Giardia* and *Cryptosporidium* co-infections (Moron-Soto et al., 2017).

The *Toxoplasma gondii* oocyst-shedding period can be shortened by administration of clindamycin, sulfadimethoxine, or ponazuril. However, most cats have completed the oocyst-shedding period in 7 to 14 days, so treatment is not often needed. *Cystoisospora* spp. generally respond to the administration of ponazuril at 50 mg/kg, PO, daily for 3 days (Litster et al., 2014). Use of sulfadimethoxine, other sulfa-containing drugs, or clindamycin is generally not needed.

Diarrhea associated with enteric bacterial infections generally will respond to dietary changes and administration of probiotics. If antibiotics are deemed necessary, *C. perfringens* and bacterial overgrowth generally respond to treatment with tylosin, amoxicillin, or ampicillin. Dogs or cats with suspected campylobacteriosis or salmonellosis should have fecal culture performed to determine antimicrobial sensitivity if other pets or people in the family become ill. GI signs of campylobacteriosis or salmonellosis are generally self-limited with supportive care alone, so these infections are often only treated parenterally and if systemic signs of disease (e.g., fever) exist because of rapid resistance that occurs after oral administration of antibiotics. Appropriate antibiotics for the empirical treatment of salmonellosis while awaiting susceptibility testing results include ampicillin and trimethoprim-sulfonamide; quinolones are also effective. Visible *Helicobacter* spp. infections were eliminated after administration of oral metronidazole (11-15 mg/kg PO q12h), amoxicillin (22 mg/kg PO q12h), and bismuth subsalicylate suspension (0.22 mL/kg PO q6-8h) for 3 weeks (Jergens et al., 2009). Boxer colitis is likely associated with *Escherichia coli* and is generally treated with enrofloxacin administered at 10 mg/kg PO q24h for 8 weeks (Marks et al., 2011).

Dogs or cats with apparent bacteremia or sepsis from enteric bacteria should be treated with parenteral antibiotics with a spectrum against anaerobic and gram-negative organisms. The combination of enrofloxacin with a penicillin or metronidazole is generally effective. Second-generation cephalosporins or imipenem are also appropriate choices.

The most common bacteria in one study of hepatic infections were *E. coli*, *Enterococcus*, *Streptococcus*, *Clostridium*, and *Bacteroides* (Wagner et al., 2007). Dogs or cats with hepatic infections and signs of bacteremia should be treated with antibiotics that kill gram-positive, gram-negative, and anaerobic bacteria, as previously discussed. Bacteremic hepatic infections generally respond to amoxicillin-clavulanate, first-generation cephalosporins, or metronidazole; a fluoroquinolone should be added if signs of sepsis are present. Decreasing numbers of enteric flora by oral administration of penicillins, metronidazole, or neomycin can lessen the clinical signs of hepatic encephalopathy.

MUSCULOSKELETAL INFECTIONS

Osteomyelitis and discospondylitis are commonly associated with infections by *Staphylococcus, Streptococcus, Proteus, Pseudomonas* spp., *E. coli,* and anaerobes (Siqueira et al., 2014). Recently, *Bartonella* spp. infections have also been identified in cats, dogs, and humans (Varanat et al., 2009). First-generation cephalosporins, amoxicillin-clavulanate, and clindamycin are logical antibiotics for empirical therapy of these conditions because of their spectrum of activity against the gram-positive organisms and anaerobic bacteria, and their ability to achieve high concentrations in bone (see Table 92.6). Quinolones should be used if gram-negative organisms (including *Brucella canis*) or *Bartonella* spp. infections are suspected. Antibiotic treatment should be continued for a minimum of 2 weeks beyond resolution of radiographic changes. Repeated treatment may be required, as bone infections can be difficult to eliminate.

Dogs and cats with septic polyarthritis should be treated in the same way as those with osteomyelitis, and the source of infection should be removed, if possible. *Anaplasma phagocytophilum*, *E. ewingii*, *Bartonella* spp., *Borrelia burgdorferi, Ehrlichia* spp., L-form bacteria, *Mycoplasma* spp., *Rickettsia rickettsii,* and other chronic infections can induce nonseptic, suppurative polyarthritis from local infection in the joints or immune complexes. Occasionally, morulae of *A. phagocytophilum* or *E. ewingii* are identified cytologically in the joint fluid or in circulating neutrophils. In general, the cytologic findings in joint fluid induced by these agents are similar to those of immune-mediated polyarthritis. For this reason, doxycycline is a logical empirical antibiotic choice for dogs with nonseptic, suppurative polyarthritis pending the results of further diagnostic tests. Amoxicillin and cefovecin are alternative drugs for the treatment of *B. burgdorferi* infection (Wagner et al., 2015) but are not effective for the treatment of most other infections associated with polyarthritis and so should be second choices to doxycycline.

Fluoroquinolones can also be used for *R. rickettsii, Mycoplasma,* and L-form bacterial infections. *Bartonella* spp. infections generally are treated with two antimicrobial agents as discussed in the bacteremia section.

Muscle disease from *T. gondii* infection often resolves during treatment with clindamycin hydrochloride, azithromycin, or trimethoprim-sulfonamide (see Table 92.4). Ponazuril at 20 mg/kg, PO, once daily may also be effective for the treatment of toxoplasmosis. Optimal duration of therapy is unknown, and no drug consistently eliminated *T. gondii* from the tissues. Although many dogs with neosporosis die, some have survived after treatment with trimethoprim-sulfadiazine combined with pyrimethamine; sequential treatment with clindamycin hydrochloride, trimethoprim-sulfadiazine, and pyrimethamine; or clindamycin alone. For dogs with acute *Hepatozoon americanum* infection, the combination of trimethoprim-sulfadiazine, pyrimethamine, and clindamycin for 14 days is highly successful; the use of decoquinate at 10 to 20 mg/kg q12h with food lessens the likelihood of recurrence of clinical disease and prolongs survival time.

RESPIRATORY TRACT INFECTIONS

Antimicrobial use guidelines (Lappin et al., 2017) for treatment of infectious respiratory diseases in dogs and cats were recently published by the Antimicrobial Guidelines Working Group of the ISCAID. The Working Group made first-choice antimicrobial recommendations for acute bacterial upper respiratory infections (URIs) in cats, chronic bacterial URIs in cats, bacterial causes of the canine infectious respiratory disease syndrome (CIRDS), bronchitis in dogs and cats, pneumonia in dogs and cats, and pyothorax in dogs and cats (see Table 92.7).

Allergies and irritants most commonly induce serous nasal discharge, and antibiotics are not indicated in the management of these syndromes. Many causes of epistaxis are local to the nasal cavity or sinuses and include trauma, foreign bodies, masses, and fungal disease that do not respond to antibiotic therapy. However, diseases associated with vasculitis also are associated with epistaxis; *B. vinsonii, E. canis,* and *R. rickettsii* are implicated most frequently in this syndrome. Administration of doxycycline may result in resolution of disease if these organisms are involved. See Chapters 94 and 95 for a complete discussion of the diagnosis and treatment of these infectious agents.

If mucopurulent nasal discharge is present in dogs or cats with other clinical manifestations of upper respiratory disease like congestion and sneezing, there is usually a bacterial component. Primary bacterial pathogens include *Bordetella bronchiseptica, Chlamydia felis* (cats), and some *Mycoplasma* spp., *Pasteurella* spp., and *Streptococcus equi*, var. *zooepidemicus* (dogs). Many dogs or cats with suspected bacterial URIs have bacterial infections secondary to other primary diseases, including foreign bodies, viral infections, tooth root abscesses, neoplasms, trauma, and fungal infections. In these examples, the normal respiratory flora that usually only colonizes the tissues can be associated with infection. *Pasteurella* spp. *Staphylococcus* spp., *Streptococcus* spp., *Mycoplasma* spp., and a variety of gram-negative organisms and anaerobic bacterial can be involved. Because the upper respiratory passageways have a normal flora, it is difficult to assess the results of culture and antimicrobial susceptibility testing or polymerase chain reaction results from samples collected from these tissues. The source of the primary insult should always be removed if possible; see Chapter 14 for a review of respiratory diagnostic techniques.

The ISCAID Working Group recommends doxycycline at 5 mg/kg, PO, q24h or 10 mg/kg, PO, q24h for the initial treatment of cats with acute bacterial URI and dogs with suspected bacterial causes of the CIRDS (see Table 92.7). Amoxicillin in cats and amoxicillin-clavulanate in dogs were considered the alternate empirical choices. If clinical signs have not resolved within 10 days, the ISCAID Working Group guidelines suggests performing a complete workup, potentially including deep cultures, before using other antibiotics like azithromycin, amoxicillin-clavulanate, cefovecin, or fluoroquinolones (Lappin et al., 2017).

The ISCAID Working Group recommended that dogs or cats with suspected bacterial bronchitis be administered doxycycline while waiting for bacterial culture and antimicrobial susceptibility results. Dogs or cats with uncomplicated community acquired pneumonia should be administered doxycycline. Common bacteria associated with pneumonia in dogs include *E. coli, Klebsiella* spp., *Pasteurella* spp., *Pseudomonas* spp., *B. bronchiseptica, Streptococcus* spp., *Staphylococcus* spp., and *Mycoplasma* spp. In cats, *Bordetella, Pasteurella,* and *Mycoplasma* organisms are commonly isolated. Aspiration of GI contents is a common cause of bacterial pneumonia with a mixed population of bacteria. Multiple species of bacteria are typically cultured from dogs and cats with bronchopneumonia. *Bordetella bronchiseptica* and *S. equi* var. *zooepidemicus* are the most important primary pathogen in dogs and cats; most other bacteria colonize after airways have been previously damaged. If consolidated lung lobes are detected radiographically, an anaerobic infection should be assumed. Dogs or cats with pneumonia and signs of sepsis should be administered a fluoroquinolone combined with a penicillin or clindamycin parenterally while finishing the diagnostic workup and then de-escalate therapy as indicated (Lappin et al., 2017). Optimal duration of treatment for bacterial pneumonia is unknown, but the consensus at this time is to reevaluate dogs and cats with pneumonia no later than 10 to 14 days after starting treatment. Additional studies are needed to determine whether the current recommendations for a minimum of 4 weeks of therapy are needed.

Whether species of *Mycoplasma* infecting dogs and cats are capable of being primary respiratory pathogens is unknown. *Chlamydia felis* in cats is not a common cause of lower respiratory tract infection. *Yersinia pestis* causes pneumonia in cats in Western states (see Chapter 99);

aminoglycosides, tetracycline derivatives, and quinolones can be used successfully in those cats.

Toxoplasma gondii occasionally causes pneumonia in neonatally infected, transplacentally infected, and immunosuppressed cats and dogs (see Chapter 98). Clindamycin or potentiated sulfas should be used if toxoplasmosis is suspected. Azithromycin may also be effective for the treatment of toxoplasmosis. *Neospora caninum* has occasionally been associated with pneumonia in dogs and should be treated with a combination of clindamycin and potentiated sulfas.

If pyothorax is attributable to penetration of foreign material from an airway or esophagus into the pleural space, thoracotomy is usually required for removal of devitalized tissue and the foreign body (see Chapter 24). Pyothorax occasionally results from hematogenous spread of bacteria to the pleural space; this may be common in cats. Pleural lavage through chest tubes is the most effective treatment for patients with pyothorax and no obvious foreign material. Most dogs and cats with pyothorax have mixed aerobic and anaerobic bacterial infections. Animals with pyothorax and clinical signs of bacteremia should initially be administered a combination of fluoroquinolones and a penicillin or clindamycin, and then the antibiotic therapy should be adjusted based on the culture, susceptibility results, and clinical response (Lappin et al., 2017). Treatment duration is determined by clinical responses and repeated thoracic radiographs, and is usually at least 4 weeks duration.

SKIN AND SOFT TISSUE INFECTIONS

Staphylococcus pseudointermedius is the most common cause of pyoderma in dogs and cats. Any organism, including gram-negative types, can induce deep pyoderma. Most soft tissue infections, including open wounds and abscesses, are infected with a mixed population of bacteria; the aerobic and anaerobic flora from the mouth are often involved. Recommended empirical antibiotic choices for routine cases of pyoderma and soft tissue infections are listed in Table 92.3. Guidelines for the diagnosis and treatment of superficial bacterial folliculitis have been published that discuss optimal topical and systemic treatments (Hillier et al., 2014). When systemic treatment is deemed appropriate, the first-tier drugs recommended included clindamycin, lincomycin, first-generation cephalosporins, amoxicillin-clavulanate, or potentiated sulfas. Other drugs to be used as second and third tiers (third-generation cephalosporins, doxycycline, minocycline, chloramphenicol, fluoroquinolones) should also be based on antimicrobial susceptibility results (Hillier et al., 2014). Fluoroquinolones are often the antibiotic class of choice for the treatment of gram-negative infections.

The World Association for Veterinary Dermatology published recommendations for the approach to methicillin-resistant staphylococcal infections (Morris et al., 2017). Many key points were presented, including use of topical therapy with known antistaphylococcal efficacy as the primary treatment modality for any surface or superficial pyoderma involving methicillin-resistant staphylococcal infections, and empirical drug selection for systemic therapy is always contraindicated when a methicillin-resistant staphylococcal infection is suspected due to the high prevalence of multidrug resistance within these strains. The case management of suspect cases should always be guided by antimicrobial sensitivity results.

Other explanations for cutaneous and soft tissue infections that fail to respond to routine treatments include infections with gram-negative bacteria, L-form bacteria, *Mycoplasma* spp., *Mycobacterium* spp., systemic fungi, or *Sporothrix* spp. (see Fig. 99.3), These cases should undergo further diagnostic testing and appropriate treatments administered. If not previously done, microscopic examination of tissue or pustule aspirates should be performed for the presence of *Sporothrix* organisms and bacteria morphologically similar to *Mycobacterium* spp. After surgical preparation of the skin, deep tissues should be obtained for aerobic, anaerobic, *Mycoplasma,* fungal, and atypical *Mycobacterium* spp. culture (see Chapter 91).

UROGENITAL TRACT INFECTIONS

Antimicrobial use guidelines for treatment of urinary tract disease in dogs and cats were recently published by the Antimicrobial Guidelines Working Group of the ISCAID (Weese et al., 2011; Weese et al., 2017). The Working Group recommended that amoxicillin or trimethoprim-sulfonamide be prescribed to dogs or cats with uncomplicated infections (sporadic bacterial cystitis). Dogs or cats with complicated infections should be administered amoxicillin or trimethoprim-sulfonamide and then have the antimicrobial therapy guided by results of culture and antimicrobial susceptibility results. Classically, antibiotics were administered for 7 to 14 days to animals with simple urinary tract infections. However, recent evidence suggests short-term protocols could be effective. For example, in a recent study of dogs with simple urinary tract infections, administration of enrofloxacin at 18 to 20 mg/kg PO q24h for 3 days or amoxicillin-clavulanic acid at 13.75 to 25 mg/kg PO q12h for 14 days had similar microbiologic cure rates (Westropp et al., 2012). There is no indication for repeat urinalysis or culture for simple infections if clinical signs resolve and the drugs are administered as prescribed (Weese et al., 2011; Weese et al., 2017). For cases with complicated infections, antimicrobial therapy should be administered for at least 4 weeks with monitoring of clinical response, and urine culture and susceptibility testing (usually 5 days after stopping treatment). It is possible that shorter duration of therapy for complicated cases could be considered.

All dogs and cats with urinary tract infection and azotemia should be assumed to have pyelonephritis and be treated accordingly, even if further diagnostic procedures are not performed. The ISCAID Working Group recommends administration of a fluoroquinolone initially with adjustments based on susceptibility results. If *Leptospira* spp.

infection is suspected and oral doxycycline cannot be administered, intravenous administration of ampicillin at 20 mg/kg IV q6h is indicated followed by doxycycline to eliminate the renal carrier phase (Sykes et al., 2011). Treatment for pyelonephritis and other chronic, complicated urinary tract infections should be continued for at least 4 to 6 weeks. Urinalysis, culture, and antimicrobial susceptibility testing should be performed 7 days after starting treatment and 1 week after cessation of treatment. It is possible that shorter duration of therapy for complicated cases could be considered. Some infections cannot be eliminated and require administration of pulse or continuous antibiotic therapy, but an optimal protocol will need to be developed on a case-by-case basis.

Mycoplasma and *Ureaplasma* infections have been documented in dogs with clinical signs of urinary tract infections (Ulgen et al., 2006). If poor response to penicillin derivatives, cephalosporins, or trimethoprim-sulfonamide is observed, culture for *Mycoplasma* spp. should be performed. Chloramphenicol, doxycycline, or quinolone treatment should be effective for *Mycoplasma* and *Ureaplasma* infections.

Most bacterial prostatic infections involve gram-negative bacteria. During acute prostatitis, almost all antibiotics penetrate the prostate well because of inflammation; trimethoprim-sulfonamide or veterinary fluoroquinolones are usually effective. After reestablishment of the blood-prostate barrier in dogs with chronic prostatitis, the acidic prostatic fluid allows only the basic antibiotics (pK_a less than 7) to penetrate well (see Table 92.8). Chloramphenicol, because of its high lipid solubility, also penetrates prostatic tissue well. In acute prostatitis, administration of acidic antibiotics, including penicillins and first-generation cephalosporins, may initially penetrate well, lessening clinical signs of disease but not eliminating the infection. This predisposes to chronic bacterial prostatitis and prostatic abscessation. For this reason, the use of penicillins and first-generation cephalosporins is contraindicated for the treatment of urinary tract infections in male dogs. In dogs with chronic prostatitis, antimicrobial therapy should be continued for at least 6 weeks and should be based on culture and sensitivity results of urine or prostatic aspirates. Most agents isolated are susceptible to trimethoprim-sulfonamide or veterinary fluoroquinolones. Urine and prostatic fluid should be cultured 7 days and 28 days after therapy. Whether shorter durations of treatment could be considered is unknown.

Brucella canis causes a number of clinical syndromes in dogs, including epididymitis, orchitis, endometritis, stillbirths, abortion, discospondylitis, and uveitis. Ovariohysterectomy or neutering lessens contamination of the human environment. (See Chapter 99 for a discussion of the zoonotic potential.) Long-term antibiotic administration usually does not lead to a complete cure (Wanke et al., 2006). Some dogs become antibody-negative, but the organism can still be cultured from tissues. Several antibiotic protocols have been suggested for dogs with brucellosis (see Table 92.8). However, owners should be carefully counselled concerning zoonotic risks before initiating treatment.

Vaginitis generally results from overgrowth of normal flora secondary to primary diseases, including herpesvirus infection, urinary tract infection, foreign bodies, vulvar or vaginal anomalies, vaginal or vulvar masses, or urinary incontinence. In dogs and cats with bacterial vaginitis from overgrowth of flora and resolution of the primary insult, broad-spectrum antibiotics, including amoxicillin, trimethoprim-sulfonamide, first-generation cephalosporins, tetracycline derivatives, and chloramphenicol, are typically successful. Because *Mycoplasma* and *Ureaplasma* organisms are part of the normal vaginal flora, providing a clinical disease association is virtually impossible; positive cultures do not confirm disease because of the organism (see Chapter 94). Hence a positive vaginal culture from an asymptomatic dog (excluding *B. canis*) is meaningless.

In all dogs and cats with pyometra, ovariohysterectomy or medically induced drainage of the uterus is imperative. Antibiotic treatment is for the bacteremia that commonly occurs concurrently (i.e., *E. coli* and anaerobes). Animals with clinical signs of bacteremia or sepsis should be treated with a four-quadrant antibiotic choice (see Table 92.5). Broad-spectrum antibiotics with efficacy against *E. coli,* such as potentiated sulfas or amoxicillin-clavulanate, are appropriate empirical choices pending the results of culture and antimicrobial susceptibility testing. Potentiated sulfas and the quinolones commonly are effective for *E. coli* but are not as effective as other drugs for the treatment of anaerobic infections in vivo.

Ampicillin, amoxicillin, and first-generation cephalosporins achieve good concentrations in milk and are relatively safe for the neonate; therefore they can be used in the empirical treatment of mastitis. Chloramphenicol, quinolones, and tetracycline derivatives should be avoided because of potential adverse effects on the neonate.

CHAPTER 93

Prevention of Infectious Diseases

Preventing infections is always preferred over treating infections. Avoiding exposure is the most effective way to prevent infections. Most infectious agents of dogs and cats are transmitted in fecal material, respiratory secretions, reproductive tract secretions, or urine; by bites or scratches; or by contact with vectors or reservoirs. Some infectious agents such as feline herpesvirus 1 (FHV-1), *Bordetella bronchiseptica,* and influenza viruses can be transmitted by direct contact with clinically normal, infected animals. Many infectious agents are environmentally resistant and can be transmitted by contact with a contaminated environment (fomites). The avoidance of zoonotic transfer of infectious agents is extremely important because some zoonotic diseases, such as plague and rabies, are life-threatening (see Chapter 99). Recognition of risk factors associated with infectious agents is the initial step in the prevention of infectious diseases. Veterinarians should strive to understand the biology of each infectious agent so that they can counsel clients and staff on the best strategies for prevention.

There are many parasitic diseases that are of importance to pets as well as their owners due to risk of zoonotic transfer, like ascarids and hookworms. There are also multiple vector-borne diseases of importance in dogs and cats, with those associated with fleas or ticks being most common in most countries. Thus one of the most important parts of any infectious disease prevention program is to provide parasite control. As discussed in Chapter 99, routine deworming and vector control are indicated for both indoor and outdoor pets. Use of the Companion Animal Parasite Council guidelines is an easy and effective way to help avoid internal and external parasitic diseases (www.capcvet.org).

Vaccines available for some infectious agents can either prevent infection (canine distemper, canine parvovirus, feline panleukopenia) or lessen clinical illness (respiratory agents) when infection occurs. Use of vaccine guidelines from the American Association of Feline Practitioners (AAFP; www.catvets.com), the American Animal Hospital Association (www.aahanet.org), and the World Small Animal Veterinary Association (www.wsava.org) can help practicing veterinarians made logical vaccination protocols for individual pets. However, in most countries a significant proportion of dogs and cats are not vaccinated. For example, in a recent study in Great Britain, only 77.9% of dogs, cats, and rabbits seen at veterinary clinics were vaccinated (Sanchez-Vizcaino, 2018). The veterinary industry needs to continue to strive to increase vaccine compliance, particularly for rabies. In addition, vaccines are not uniformly effective, are not available for all pathogens, and sometimes induce serious adverse effects. Therefore the development of sound biosecurity procedures is also paramount to avoid exposure to infectious agents when developing a preventive medicine program.

BIOSECURITY PROCEDURES FOR SMALL ANIMAL HOSPITALS

Most hospital-borne infections (nosocomial) can be prevented by following simple biosecurity guidelines (Box 93.1). The following general guidelines to consider were adapted from those used at the Veterinary Medical Center at Colorado State University (http://csuvets.colostate.edu/biosecurity). A number of excellent reviews are also available (Stull et al., 2015; Stull and Weese, 2015).

GENERAL BIOSECURITY GUIDELINES

Contaminated hands are the most common source of infectious agent transmission in the hospital environment. Fingernails of personnel having patient contact should be cut short. Hands should be washed before and after attending to each individual animal as follows. Collect clean paper towels and use to turn on water faucets; wash hands for 30 seconds with antiseptic soap, being sure to clean under fingernails; rinse hands thoroughly; use the paper towel to dry hands; and use the paper towel to turn off the water faucets. Use of antiseptic lotion should be encouraged. Personnel should not touch patients, clients, food, doorknobs, drawer or cabinet handles or contents, equipment, or medical records with soiled hands or gloves.

All employees should wear an outer garment such as a smock or scrub suit when attending to patients. Footwear should be protective, clean, and cleanable. A minimum of two sets of outer garments should always be available, and

BOX 93.1

General Hospital Biosecurity Guidelines

- Wash hands before and after each patient contact.
- Wear gloves when handling patients when zoonotic diseases are on the list of differential diagnoses.
- Minimize contact with hospital materials (instruments, records, door handles, etc.) while hands or gloves are contaminated.
- Always wear an outer garment, such as a smock or scrub shirt, when handling patients.
- Change outer garments when soiled by feces, secretions, or exudates.
- Clean and disinfect equipment (stethoscopes, thermometers, bandage scissors, etc.) after each use with animals likely to have an infectious disease.
- Examination tables, cages, and runs should be cleaned and disinfected after each use.
- Litter boxes and dishes should be cleaned and disinfected after each use.
- Place animals with suspected infectious diseases into an examination room or an isolation area immediately on admission into the hospital.
- Treat animals with suspected infectious diseases as outpatients if possible.
- Procedures that use general hospital facilities, such as surgery and radiology, should be postponed until the end of the day if possible.
- Do not consume fluids or drink in areas where patient care is provided.

they should be changed immediately after contamination with feces, secretions, or exudates. Equipment such as stethoscopes, pen lights, thermometers, bandage scissors, lead ropes, percussion hammers, and clipper blades are suspected to serve as fomites and should be cleaned and disinfected after each use with animals likely to have a transmissible infectious disease (Haun et al., 2016). Disposable thermometer covers or thermometers should be used.

To avoid zoonotic transfer of infectious diseases, food or drink should not be consumed in areas where animal care is provided. All areas where animals are examined or treated should be cleaned and disinfected immediately after use, irrespective of infectious disease status of the individual animal.

PATIENT EVALUATION

Prevention of infectious diseases starts with the front desk personnel. Staff should be trained to recognize the presenting complaints for the infectious agents in the geographic area of the hospital. Animals with gastrointestinal signs, respiratory signs, or ectoparasites are the most likely to be contagious. Infectious gastrointestinal disease should be suspected in all dogs and cats with small- or large-bowel diarrhea whether the syndrome is acute or chronic. Infectious respiratory disease should be suspected in all dogs and cats with sneezing or coughing (Lappin et al., 2017). The index of suspicion for infectious diseases is increased for dogs or cats with acute disease and fever, particularly if the animal is from a crowded environment such as a breeding facility, boarding facility, or shelter.

Front desk personnel should indicate clearly on the hospital record that gastrointestinal signs, respiratory signs, or ectoparasites are present. If the presenting complaint is known before admission into the hospital, an optimal method would be to meet the client in the parking area to determine the infectious disease risk before the pet enters the hospital. If an infectious gastrointestinal or respiratory disease is suspected, the animal should be transported (i.e., not allowed to walk on the premises) to an examination room or the isolation facility. If a patient with acute gastrointestinal or respiratory disease or ectoparasites is presented directly to the reception desk, the receptionist should contact the receiving clinician, technician, or student immediately and coordinate placement of the animal in an examination room to minimize hospital contamination. Animals with suspected infectious diseases should be treated as outpatients if possible. If hospitalization is required, the animal should be transported to the appropriate housing area by the shortest route possible, preferably with a gurney to lessen hospital contamination. The gurney and any hospital materials in contact with potentially contaminated employees (including examination tables and doorknobs) should be immediately cleaned and disinfected as previously mentioned.

HOSPITALIZED PATIENTS

If possible, all animals with suspected infectious diseases, such as *Salmonella* spp., *Campylobacter* spp., parvovirus infection, canine infectious respiratory disease complex (CIRDC), acute feline upper respiratory disease syndrome, rabies, or plague, should be housed in an isolated area of the hospital. The number of staff members entering the isolation area should be kept to a minimum. On entry into the isolation area, outerwear should be left outside, and surgical booties or other disposable shoe covers should be placed over the shoes. Alternatively, a foot bath filled with disinfectant should be placed by the exit and used when leaving the area. The room should be entered, and a disposable gown (or smock designated for the patient) and latex gloves should be put on. A surgical mask should be worn when attending dogs or cats with suspected plague or tularemia, and extreme care should be taken to avoid being bitten. Separate equipment and disinfectant supplies should be used in the isolation area.

All biologic materials submitted to clinical pathology laboratories or diagnostic laboratories from animals with suspected or proven infectious diseases should be clearly marked as such. Fecal material should be placed in a plastic, screw-capped cup with a tongue depressor or while the clinician is wearing gloves. Place the cup in a clean area and place the lid on with a clean, gloved hand. Remove the used gloves and place the cup in a second bag clearly marked

with the name of the infectious disease suspected. The outer surface of the bag should be disinfected before leaving the isolation area.

Disposable materials should be placed in plastic bags in the isolation area. The external surfaces of the bags should be sprayed with a disinfectant before being removed from the isolation area. After attending to the patient, contaminated equipment and surfaces should be cleaned and disinfected, and contaminated outer garments and shoe covers should be removed. Hands should be washed after discarding the contaminated outerwear. Dishes and litter pans should be cleansed thoroughly with detergent before returning them to the central supply area of the hospital. Optimally, materials such as outerwear and equipment to be returned to the central supply area should be placed in plastic bags and sprayed with a disinfectant before transport. Procedures requiring general hospital facilities such as surgery and radiology should be postponed to the end of the day, if possible, and the contaminated areas disinfected before use with other animals. Animals should be discharged by the shortest path to the parking lot possible.

Some animals with infectious diseases can be maintained in the general hospital boarding or treatment areas with special management techniques. For example, cats positive for the feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) should not be placed in the isolation area, if possible, to avoid exposing them to other infectious agents. Because neither of these two viruses is transmitted by aerosolization, cats with these infectious diseases can be housed in close proximity to other cats. The cages should be labeled appropriately, and the infected cats should not be caged next to or above seronegative cats. In addition, no direct contact or sharing of litter boxes or food bowls should occur between infected and naïve cats.

BASIC DISINFECTION PROTOCOLS

To lessen the spread of potential infectious agents, hospitalized animals should never be moved from cage to cage. The key to effective disinfection is cleanliness. Cage papers and litter boxes soiled by feces, urine, blood, exudates, or respiratory secretions should be removed and placed in trash receptacles. Bulk fecal material should also be placed in trash receptacles.

Many infectious agents are resistant to disinfectants or require prolonged contact time to be inactivated (Greene, 2012). Contaminated surfaces, including the cage or run floors, walls, ceiling, door, and door latch, should be wetted thoroughly with a disinfectant that is then blotted with clean paper towels or mops. Surfaces should be in contact with the disinfectant for 10 to 15 minutes if possible, particularly if known infectious agents are present. Soiled paper towels should be placed in trash receptacles. If infectious disease is suspected, the trash bags should be sealed, the surface of the bag sprayed with a disinfectant, and the trash bags discarded.

Contaminated surfaces in examination rooms should be cleaned to remove hair, blood, feces, and exudates. Examination tables, countertops, floors, canister lids, and water taps should be saturated with disinfectant for 10 minutes. Surfaces should be blotted with paper towels until dry, and the soiled towels should be placed in a trash receptacle. Urine or feces on the floor should be contained with paper towels, blotted, and placed in trash receptacles. The soiled area of the floor should be mopped with disinfectant.

Disinfectants are relatively effective for viral and bacterial agents but require high concentrations and long contact times to kill parasite eggs, cysts, and oocysts. Cleanliness is the key to lessening hospital-borne infection with these agents; detergent or steam cleaning inactivates most of these agents. Litter pans and dishes should be thoroughly cleaned with detergent and scalding water.

BIOSECURITY PROCEDURES FOR CLIENTS

Housing animals indoors in a human environment to prevent exposure to other animals, fomites, or vectors is the optimal way to prevent infectious diseases. However, some infectious agents can be carried into the home environment with the owners, by other pets that are allowed outdoors, by vectors, or by paratenic or transfer hosts. Although most infections occur in both immunocompromised and immunocompetent animals, clinical disease is often more severe in immunocompromised animals. Puppies, kittens, old or debilitated animals, animals with immunosuppressive diseases (e.g., hyperadrenocorticism, diabetes mellitus, cancer), animals with concurrent infections, and animals treated with glucocorticoids or cytotoxic agents are examples of immunocompromised patients. Avoiding exposure to infectious agents in this group is particularly important because of the potential for increased susceptibility to disease. These animals may also be less likely to have appropriate responses to immunization. Kennels, veterinary hospitals, dog parks, dog and cat shows, and shelters have an increased likelihood for infectious agent contact because of the concentration of potentially infected animals and should be avoided when possible. Areas such as parks are common sources of infectious agents that survive for long periods in the environment; parvoviruses and enteric parasites like *Giardia* spp. are classic examples (Hascall et al., 2016). Owners should avoid bringing new animals with unknown histories into a home environment with other pets until the new animal is evaluated by a veterinarian for infectious disease risk. If people are in contact with animals outside the home environment, they should wash their hands before contact with their own pet. The owner should consult the veterinarian concerning vaccination protocols and other preventive medical procedures most indicated for each individual patient. Of most importance are flea control (*Bartonella* spp., *Rickettsia felis*); tick control (*Borrelia burgdorferi,* rickettsial agents); *Dirofilaria imitis* prevention; and strategic deworming for roundworms and hookworms.

VACCINATION PROTOCOLS

VACCINE TYPES

Vaccines are available for some infectious agents of dogs and cats and can be administered to prevent infection or limit disease depending on the agent. Vaccination can stimulate humoral, mucosal, or cell-mediated immune responses. Humoral immune responses are characterized by the production of immunoglobulin M (IgM), IgG, IgA, and IgE class antibodies, which are produced by B lymphocytes and plasma cells after being presented an antigen by macrophages. Binding of antibodies to an infectious agent or its toxins helps prevent infection or disease by facilitating agglutination (viruses), improving phagocytosis (opsonization), neutralizing toxins, blocking attachment to cell surfaces, initiating the complement cascade, and inducing antibody-dependent cell-mediated cytotoxicity. Antibody responses are most effective in controlling infectious agents during extracellular replication or toxin production. Cell-mediated immune responses are mediated principally by T lymphocytes. Antigen-specific T lymphocytes either destroy the infectious agent or mediate destruction of the agent by producing cytokines that stimulate other white blood cells, including macrophages, neutrophils, and natural killer cells. Cell-mediated immunity is required for the control of most cell-associated infections.

Currently available vaccines are either infectious (attenuated [modified-live] organisms or live virus–vectored recombinant vaccines) or noninfectious (killed virus, killed bacteria [bacterins], and subunit vaccines).

Attenuated vaccines replicate in the host to effectively stimulate an immune response and therefore generally have low antigen mass and do not require adjuvants. Different products are administered locally (e.g., modified-live *B. bronchiseptica* intranasal or oral vaccines) or parenterally (e.g., modified-live canine distemper vaccine). In live virus–vectored recombinant vaccines, the specific DNA that codes for the immunogenic components of the infectious agent is inserted into the genome of a nonpathogenic organism (vector) that will replicate in the species being vaccinated. As the vector replicates in the host, it expresses the immunogenic components of the infectious agent, resulting in the induction of specific immune responses. Because the virus-vectored vaccine is live and replicates in the host, adjuvants and high-antigen mass are not required. Because only DNA from the infectious agent is incorporated into the vaccine, no risk of reverting to the virulent parent strain exists, as occasionally occurs with attenuated vaccines. Only vectors that do not induce disease in the animal being vaccinated are used. Another advantage to vaccines of this type is the potential ability to overcome inactivation by maternal antibodies.

Killed virus, killed bacteria (bacterins), and subunit vaccines are noninfectious and therefore usually require higher antigen mass than infectious vaccines to stimulate immune responses because they do not replicate in the host. Some noninfectious vaccines may stimulate immune responses of lesser magnitude and shorter duration than infectious vaccines unless adjuvants are added. Adjuvants improve immune responses in part by stimulating uptake of antigens by macrophages that present the antigens to lymphocytes. Although adjuvants have historically been associated with vaccine adverse effects, most newer-generation adjuvants induce less inflammation than older adjuvants like those containing aluminum. Subunit vaccines can be superior to killed vaccines that use the entire organism because only the immunogenic parts of the organism are used, which may decrease the potential for vaccine reactions. However, for some infections, use of only one antigen does not induce adequate protection (e.g., feline calicivirus vaccines). Native DNA vaccines and gene-deleted vaccines are currently being evaluated for several infectious diseases.

VACCINE SELECTION

Selection of optimal vaccines for use in dogs and cats can be complicated as multiple products for most infectious agents are available, but efficacy studies that directly compare different products are often lacking. The veterinarian may need to choose from infectious and noninfectious options for the same vaccine antigen. Some vaccine antigens are for intranasal or oral administration, and others are for parenteral administration. Not all vaccines for a given infectious disease are comparable in every situation. Long-term duration of immunity studies and studies evaluating a vaccine's ability to block infection by multiple field strains are not available for all individual products. When making decisions about which products to use or when evaluating a new vaccine, the practitioner should request information concerning efficacy, challenge studies, duration of immunity studies, adverse reactions, and cross-protection capability. Vaccine issues are commonly debated in veterinary journals and continuing education meetings; these are excellent sources of current information. Use of vaccine guidelines from the AAFP (www.catvets.com; Scherk et al., 2013), the American Animal Hospital Association (www.aahanet.org), and the World Small Animal Veterinary Association (www.wsava.org) can help practicing veterinarians made logical vaccination protocols for individual pets.

Not all dogs and cats need all available vaccines. Vaccines are not innocuous and should only be given if indicated. The type of vaccine and route of administration for the disease in question should also be considered. A benefit, risk, and cost assessment should be discussed with the owner of each individual animal before determining the optimal vaccination protocol. For example, FeLV only lives outside the host for minutes; it is highly unlikely that an owner would bring the virus into the household. Therefore cats housed indoors are not likely to come in contact with the virus.

Before administering vaccines, the animal should be evaluated for factors that may influence the ability to respond to the vaccine or that may affect whether vaccination could be detrimental. For example, hypothermic animals may have poor T lymphocyte and macrophage function and may not

respond appropriately to vaccination. Immunosuppressed animals, including those with FeLV infection, FIV infection, canine parvovirus infection, *Ehrlichia canis* infection, and debilitating diseases, may not respond appropriately to vaccination, and modified-live vaccines could potentially induce the disease in these animals.

If high levels of specific antibodies are present, efficacy of some vaccines is diminished. This is a particularly important consideration when vaccinating puppies or kittens from well-vaccinated dams. Disease may also develop in vaccinated puppies and kittens because infection had already occurred and was incubating when the animal was vaccinated. Vaccines can be rendered ineffective from mishandling. As most vaccine manufacturers will support their products if administered by a veterinary health care professional, it could be advantageous for owners to not purchase and administer vaccines on their own. Vaccines should not be administered while the animal is under anesthesia because if a vaccine reaction occurs, clinical signs may not be recognized.

Adverse reactions can potentially occur with any vaccine. However, they are relatively uncommon in dogs and cats and recently have been reviewed (Gershwin, 2018). In a study of more than 1.2 million dogs, the overall rate of adverse reactions was 38.2/10,000 dogs that had received vaccines within the previous 3 days (Moore et al., 2005). In a study of 496,189 cats, the overall rate of adverse reactions was 51.6/10,000 cats that had received vaccines within the previous 30 days (Moore et al., 2007). In another study, vaccine associated hypersensitivity reactions were estimated at 6.5 per 10,000 vaccinated dogs (Yao et al., 2015). Vaccination has been associated with injection site sarcomas in some cats and can be life threatening. These tumors can occur after administration of infectious or noninfectious vaccines (Dyer et al., 2009), but to date studies attempting to link different vaccine types or individual products to tumor formation have had variable results (Kass et al., 2003; Srivastav et al., 2012). Injection site sarcomas have developed after administration of other substances including parasiticides, long-lasting glucocorticoids, meloxicam, cisplatin, antibiotics, and microchips. It is apparent that tumor development may relate to a genetic predisposition, but *P53* gene testing has not provided definitive results in all cases (Banerji et al., 2007; Mucha et al., 2012). Based in the information available to date, it is impossible to determine the risk for individual cats to develop injection site sarcomas, and the validity of current recommendations to avoid all adjuvants have been questioned (Kass, 2018). Currently, the optimal way to avoid injection site sarcomas is to administer only products absolutely indicated by this route, including using the longest vaccination interval acceptable for the vaccine used. In addition, if a cat has previously developed an injection site sarcoma, it is likely of risk of developing a second tumor, and parenteral injections should be avoided if possible.

Feline vaccines for which the viruses were grown on cell cultures induce antibodies that cross-react with feline renal tissues (Lappin et al., 2005), and some hypersensitized cats have developed lymphocytic-plasmacytic interstitial nephritis (Lappin et al., 2006b). The immunodominant cell line antigen recognized by parenterally vaccinated cats is alpha enolase, which is present in all mammalian cells (Whittemore et al., 2010). In people, anti-enolase antibodies are markers for immune-mediated disease, including nephritis. Whether postvaccination or naturally occurring anti-enolase antibodies are associated with nephritis in cats is still being studied. Intranasal products can result in transient sneezing and coughing, but in cats are not associated with the development of anti-enolase antibodies (Whittemore et al., 2010).

Suspected adverse reactions to vaccination should be reported to the vaccine manufacturer. Administration of any vaccine to animals with proven vaccine-associated sarcoma or immune-mediated diseases, such as immune-mediated polyarthritis, immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, glomerulonephritis, or polyradiculoneuritis, is questionable because immune stimulation may exacerbate these conditions. However, the potential legal ramifications of waiving vaccination in these patients should be discussed with the owners and with appropriate state and county representatives when rabies vaccination is in question.

For some infectious agents, including canine distemper virus (CDV), canine parvovirus, feline panleukopenia virus (FPV), feline calicivirus (FCV), and FHV-1, serologic test results have been shown to correlate to resistance to disease after challenge in some studies. The advantages and disadvantages of the use of serologic testing have been reviewed (Moore et al., 2004). If validated laboratories or kits are used, results can be used accurately to make vaccination decisions for some dogs and cats (Lappin et al., 2002). For example, previously vaccinated animals that were presumed to have had a vaccine reaction and are still at risk of exposure to infectious agents could be assessed by serologic testing in lieu of arbitrary vaccination. In general, the positive predictive value of these tests is good (i.e., a positive test result usually predicts resistance on challenge) for CDV, canine parvovirus, and FPV. Commercially available kits for point of care testing are available in some countries.

VACCINATION PROTOCOLS FOR CATS

A physical examination, fecal parasite screen, and assessment of vaccine needs should be performed at least yearly for all cats. The AAFP formed a Feline Vaccine Advisory Panel to produce vaccine recommendations for cats (http://www.catvets.com) in 2013 (Scherk et al., 2013). These guidelines are an excellent source of information for veterinarians when individualizing vaccination protocols. Vaccine antigens were divided into those that were considered core (FPV, FCV, FHV-1) and noncore (rabies, FeLV, FIV, *B. bronchiseptica*, *Chlamydia felis*, and feline infectious peritonitis [FIP]). In contrast to previous AAFP Panel Reports, rabies vaccines are no longer considered core because the

guidelines are meant to be suitable for cats living worldwide and rabies is not endemic in all countries. Other sources for feline vaccine administration recommendations include the ABCD guidelines in Europe (Hosie et al., 2015) and the WSAVA guidelines (http://www.wsava.org/Guidelines/Vaccination-Guidelines).

Core Vaccines

Feline panleukopenia virus, feline calicivirus, feline herpesvirus-1

All healthy kittens and adult cats without a known vaccination history should be routinely vaccinated with an intranasal or parenteral vaccine that contains FPV, FCV, and FHV-1 (FVRCP). Multiple modified-live products and killed products are available, but they vary by country. In general, modified-live FVRCP vaccines are recommended for kittens housed in environments at high risk for exposure to FPV because this type of vaccine is least likely to be inactivated by antibodies transferred to the kitten as part of maternally derived immunity. Killed FVRCP vaccines have the advantage of not replicating in the host, so they are safe for administration to pregnant queens and do not colonize the host. Modified-live FVRCP vaccines for intranasal administration can induce protection against FHV-1 as soon as 4 days after administration, so this route may be preferred for kittens housed in environments at high risk for exposure to FHV-1 (Lappin et al., 2006a). However, it was shown that significant protection against FHV-1 is induced as soon as 1 week after administration of one subcutaneous dose of a killed or modified live FHV-1 containing vaccine (Summers et al., 2017). Modified-live products should not be administered to clinically ill, debilitated, or pregnant animals. Owners should be informed that the administration of intranasal FVRCP vaccines can induce transient, mild sneezing or coughing.

For kittens believed to have no more than routine risk of exposure to FPV, FCV, or FHV-1, administration of FVRCP vaccines is recommended starting no sooner than 6 weeks of age, with boosters every 3 to 4 weeks until 16 to 20 weeks of age. Older kittens and adult cats with unknown vaccination history should be administered two killed or two modified-live FVRCP doses 3 to 4 weeks apart. A booster FVRCP vaccine should be administered 1 year later and then every 3 years, lifelong (Scherk et al., 2013). As previously discussed, serologic test results for antibodies against FPV, FCV, and FHV-1 can be used to help determine vaccine needs (Lappin et al., 2002).

Some variants of FCV induce systemic vasculitis in cats (virulent systemic calicivirus; VS-FCV), and clinical signs can be severe in some cats even if previously vaccinated with FVRCP vaccines (Hurley et al., 2004). An inactivated product containing two FCV strains, including a VS-FCV strain, is now available in the United States (CaliciVax, Elanco, Indianapolis, IN). Serum from cats vaccinated with this product has been shown to cross-neutralize more FCV field strains than serum from cats vaccinated with products containing only one FCV strain (Huang et al., 2010). Similar results have been seen in other studies in Europe and Japan.

Use of FVRCP vaccines in other situations like boarding, in shelters, and in catteries are presented in the AAFP document (Scherk et al., 2013; www.catvets.com).

Noncore Vaccines

Bordetella bronchiseptica

The currently available *B. bronchiseptica* vaccine for intranasal administration can be administered as early as 4 weeks of age, has an onset of immunity as early as 72 hours, and is believed to have a minimal duration of immunity of 1 year. Many cats have antibodies against *B. bronchiseptica,* the organism is commonly cultured from cats in crowded environments, and sporadic reports have been made of severe lower respiratory disease caused by bordetellosis in kittens and cats in crowded environments or other stressful situations. However, the significance of infection in otherwise healthy pet cats appears to be minimal. *Bordetella* vaccination should be considered primarily for use in cats at high risk for exposure and disease, such as those with a history of respiratory problems and living in shelters with culture-proven outbreaks.

Chlamydia felis

Killed and modified-live *Chlamydia felis*–containing vaccines are available. Infection of cats by *C. felis* generally results in only mild conjunctivitis, is easily treated with antibiotics, and has variable prevalence rates, and the organism is of minimal zoonotic risk to people. In addition, use of FVRCP vaccines that also contained *C. felis* was associated with more vaccine reactions in cats when compared with other products (Moore et al., 2007). Thus whether *C. felis* vaccination is ever necessary in the United States is questioned. The use of this vaccine should be reserved for cats with a high risk of exposure to other cats and in catteries with endemic disease.

Feline leukemia virus

Multiple FeLV-containing vaccines are currently available in some countries. Some contain killed FeLV with and without adjuvants, and one contains recombinant antigens of FeLV without adjuvant. Because of difficulties in assessing efficacy studies performed with different experiment designs, which FeLV vaccine is optimal is unclear. In one recent challenge study, one killed product and the recombinant product performed similarly (Grosenbaugh et al., 2017). At the 2-year challenge in one study, 83% of the vaccinated cats remained FeLV-negative (Jirjis et al., 2010). The AAFP panel recommended vaccinating kittens for FeLV because they are more susceptible than adult cats, and their housing status may not have been determined at that time. Although administration of FeLV vaccines does not block proviral integration, FeLV-associated disease was lessened (Hofmann-Lehmann et al., 2007). FeLV vaccines are most indicated in cats allowed to go outdoors or those that are exposed to cats of unknown FeLV status. Vaccinated cats should be administered two vaccinations initially and a booster 1 year later if indicated by risk assessment. The AAFP Panel recommended 1-year

boosters thereafter in high-risk cats and every 2 years in low-risk cats (Scherk et al., 2013). However, it is difficult to determine whether a cat allowed outdoors is high or low risk as the prevalence rates for FeLV may not be known in all regions. FeLV vaccines are not effective in cats with progressive viremia and are therefore not indicated. However, administration of the vaccine to viremic or latently infected cats does not pose an increased risk of vaccine reaction. FeLV testing should be performed before vaccination because the retrovirus serologic status of all cats should be known to maintain appropriate husbandry.

Feline immunodeficiency virus

A killed vaccine containing two FIV subtypes (clades A and D) is currently available in some countries. Little is known about the efficacy of this vaccine in the field. The primary problem with FIV vaccination at this time is that the vaccine induces antibodies detectable by some of the currently available antibody tests. However, one of the test kits (Witness FeLV/FIV, Zoetis Animal Health) rarely detects FIV antibodies induced by vaccination (Westman et al., 2015). Reverse-transcription polymerase chain reaction for detection of FIV provirus is available in some laboratories but, as discussed in Chapter 96, some FIV-infected cats will be falsely negative in this assay because of low-level viremia.

Feline infectious peritonitis

A relatively safe coronavirus vaccine that may protect some cats from developing FIP is currently available for administration after 16 weeks of age. The vaccine may result in mild, transient sneezing because it is administered intranasally. Antibody-dependent enhancement of infectivity has not been detected in field studies. Results of the vaccine in field studies have been variable. If cats have previously been exposed to coronaviruses, the vaccine is unlikely to be effective. Because the incidence of disease is low, cats are commonly exposed to coronaviruses before vaccination and the efficacy is questionable. The AAFP panel considered this vaccine as noncore and generally not recommended, even in breeding catteries (Scherk et al., 2013). The vaccine may be indicated for seronegative cats entering a known FIP-infected household or cattery.

Rabies

All cats in endemic countries, including the United States, should be vaccinated against rabies. Recommendations concerning rabies can vary by the state and county, and one website can be used to find most requirements (http://www.rabiesaware.org/). Rabies vaccine should be administered as early as 12 weeks of age in accordance with state and local statutes. Cats should be vaccinated 1 year later and then either annually or triennially according to state and local statutes and the vaccine product used for the initial immunization. A live virus–vectored rabies vaccine with a 1-year or 3-year label is available in some countries. This product induces less inflammation than inactivated rabies vaccines that contain adjuvants, but whether this vaccine is less likely to be associated with injection site sarcomas is currently unknown.

VACCINATION PROTOCOLS FOR DOGS

A physical examination, fecal parasite screen, and vaccine needs assessment should be performed at least yearly for all dogs. The American Animal Hospital Association recently published on line the revised version of vaccination guidelines for dogs that also included recommendations for use of canine vaccines in shelters. These guidelines are an excellent source of information for veterinarians to use when individualizing a vaccination protocol for dogs (https://www.aaha.org/guidelines/canine_vaccination_guidelines.aspx). Different forms of vaccine antigens were divided into those that were considered core or noncore. The online AAHA recommendations also have a section on recommendations for dogs that are overdue for various vaccines (www.aaha.org/CanineVaccinesOverdue). The WSAVA guidelines are another excellent source of information concerning vaccination of dogs in different parts of the world (http://www.wsava.org/Guidelines/Vaccination-Guidelines).

Core Vaccines

Canine parvovirus, canine adenovirus, and canine distemper virus

Because canine parvovirus (CPV-2), canine adenovirus 1 (CAV-1; infectious canine hepatitis), and CDV can be life-threatening diseases, all dogs should be vaccinated. For CPV-2, only modified-live products should be used because of increased risk of maternal antibody interference with killed products. Both modified-live CDV and recombinant CDV (rCDV)-containing vaccines are considered adequate by the AAHA Task Force. Because of adverse effects associated with CAV-1 vaccines and poor immune responses associated with killed CAV-2 or modified-live topical CAV-2 vaccines, only modified-live CAV-2 vaccines for parenteral administration should be used. These vaccines cross-protect against canine infectious hepatitis induced by CAV-1 and the kennel cough syndrome induced by CAV-2. All puppies should be administered at least three CPV-2, CAV-2, and CDV-containing vaccines, every 3 to 4 weeks, between 6 and 16 weeks of age, with the last booster being administered at 16 weeks of age or older. Administration of a final dose at 18 to 20 weeks of age should be considered for dogs residing in high-risk environments. Adult dogs with an unknown vaccination history can be given one dose of MLV CPV-2, CAV-2, and CDV-containing vaccines. Vaccinated dogs should receive a booster vaccine 1 year later and then boosters at intervals of 3 years. Several CDV-containing products, including the rCDV vaccine, were recently shown to protect for at least 3 years (Abdelmagid et al., 2004; Larson et al., 2007). Vaccination of dogs with CPV-2b induces neutralizing antibodies against CPV-2a and CPV-2c (Wilson et al., 2014).

Dogs should be evaluated at least yearly for risk of infection by CPV, CDV, and CAV during the physical examination, checked for enteric parasites, and evaluated for *D. immitis* infection in appropriate regions. Positive serologic tests for CDV and CPV are predictive of resistance after challenge and can be used in lieu of arbitrary vaccine

intervals if performed with validated assays. Dogs should complete the puppy series and be boosted at 1 year of age before using titers to help predict vaccine need. If the vaccination status of an adult dog is unknown, the dog should be vaccinated appropriately and then serologic assessment considered in subsequent years.

Rabies

All dogs should be administered a 1-year or 3-year rabies vaccine following the manufacturer's recommendations as early as 12 weeks of age and based on state, provincial, and/or local requirements. Both puppies and adult dogs with unknown vaccination history should receive one dose and return for a booster vaccination 1 year later. Intervals and product after that booster should be based on state and local statutes (http://www.rabiesaware.org/).

Noncore Vaccines

Bordetella bronchiseptica

In general, *B. bronchiseptica* rarely causes life-threatening disease in otherwise healthy animals and is not the only cause of the CIRDC (Lappin et al., 2017). It is therefore considered a noncore vaccine. Although parenteral products administered twice induce strong serum antibody responses, in one study intranasal administration was associated with superior protection on challenge (Davis et al., 2007). It has been shown that immunity against *B. bronchiseptica* can be induced after 1 dose of intranasal or oral vaccines. The intranasal products have a 12 to 14 month duration of immunity. The duration of immunity of parenteral or oral *B. bronchiseptica* vaccines is currently unknown. The intranasal *B. bronchiseptica* vaccines can be administered as early as 3 to 4 weeks of age in outbreaks. *Bordetella bronchiseptica* vaccines for intranasal administration are also available combined with modified live parainfluenza or parainfluenza and adenovirus 2.

Borrelia burgdorferi

The pros and cons of administering *B. burgdorferi* vaccines were discussed in depth in an American College of Veterinary Internal Medicine Consensus Statement (Littman et al., 2018). A total of three of six panelists recommended use of *B. burgdorferi* vaccines in endemic areas, independent of current infection status, if the dog is healthy. However, *B. burgdorferi* vaccination should be considered adjunct to use of tick control products as vaccine failures can be common. Depending on the product used, vaccination can start at 8 or 9 weeks of age, and a second dose is recommended 2 to 4 weeks later, with annual boosters.

Canine influenza

In the United States, there are monovalent vaccines for H3N8 and H3N2 as well as bivalent vaccines containing both. Canine influenza vaccines are killed virus vaccines and should be administered no earlier than 6 weeks of age, with a second dose 2 to 4 weeks later. While not all areas of the United States are considered endemic for these viruses, outbreaks can occur and spread quickly, and some dogs have prolonged shedding of viral nucleic acids (Newbury et al., 2016). Thus influenza vaccination should be discussed with all owners regardless of whether an outbreak is currently in your region. Live attenuated vaccines for these two viruses have been shown to be safe and effective after 1 dose in a mouse model (Rodriguez et al., 2017).

Leptospira spp.

Vaccines containing multiple *Leptospira interrogans* serovars *Canicola*, *Icterohaemorrhagiae*, and *Pomona*) and *Leptospira kirschneri* serovar *Grippotyphosa*, are generally recommended for dogs with high risk in known endemic areas (Sykes et al., 2010). However, some serovars in the environment are not in any vaccine, and minimal cross-protection exists between serovars. Thus clients should realize that, even though their dog has been given a *Leptospira* vaccine, 100% protection cannot be guaranteed. Newer-generation vaccines have fewer adverse effects than previous vaccines. In a recent study (Yao et al., 2015), dogs that were administered a vaccination protocol that included *Leptospira* spp. antigens had an incidence rate of reported adverse events of 53/10,000 dogs (0.53%). If the vaccines are to be used, puppies should receive the first dose as early as 8 to 9 weeks of age with a booster 2 to 4 weeks later. Annual revaccination is recommended. In one recent study of one of the *Leptospira* 4 serovar products, significant protection was present 15 months after completing the immunization protocol (Grosenbaugh and Pardo, 2018).

Parainfluenza virus

Multiple products that contain CPV-2, CDV, and CAV-2 also contain modified-live parainfluenza, so they are commonly administered at the same schedule of those core vaccine antigens. Considered alone, parainfluenza is noncore because it is not life-threatening, is not zoonotic, and is a self-limited cause of CIRDC. However, outbreaks of clinical disease attributed to parainfluenza are still reported (Weese et al., 2013). Modified-live strains for intranasal administration, with some products combined with a live avirulent strain of *B. bronchiseptica*, without or without adenovirus 2 are available. If used, the intranasal vaccine can be administered as early as 3 weeks of age; transient sneezing and coughing can occur. Annual boosters are recommended in previously vaccinated dogs.

Rattlesnake vaccine

The *Crotalus atrox* toxoid vaccine was designed to protect dogs against the venom of the Western Diamondback Rattlesnake. Some cross-protection may exist against the Eastern Diamondback Rattlesnake but not the Mojave Rattlesnake. Local reactions to this toxoid are common. If used in high-risk dogs in high-risk areas, practitioners should follow the manufacturer's label.

CHAPTER 94

Polysystemic Bacterial Diseases

CANINE BARTONELLOSIS

Etiology and Epidemiology

Bartonella vinsonii subspecies *berkhoffii* was initially isolated from a dog with endocarditis in North Carolina (Breitschwerdt et al., 1995). *Bartonella vinsonii (berkhoffii)* is thought to be tick-borne but has also been amplified from fleas collected from dogs (Yore et al., 2014). In a recent seroprevalence study of 15,451 dogs, 3.26% of dogs were *Bartonella* spp. seroreactive with *B. henselae* (2.13%), *B. koehlerae* (2.39%), or *B. vinsonii* subsp. *berkhoffii* (1.42%, $P < 0.0001$) organisms (Lashnits et al., 2018). *Bartonella henselae* and *B. koehlerae* are transmitted by fleas. In the seroprevalence study, *Bartonella* spp. antibodies were detected more often in intact males (5.04%) than neutered males (2.87%, $P < 0.0001$) or intact or spayed females (3.22%, $P = 0.0003$). This result and the documentation of *Bartonella* spp. infections in dogs in areas where vector-borne diseases are uncommon like Colorado and Wyoming suggest direct transmission may also occur (Fenimore et al., 2011). Many other *Bartonella* species have been isolated from dogs from which DNA has been amplified from blood or tissues, and include *B. clarridgeiae*, *B. washoensis*, *B. quintana*, *B. rochalimae*, and *B. elizabethae*. Each of these organisms can potentially induce illness in dogs. Dogs infected with a *Bartonella* species are commonly co-infected with other agents such as *Anaplasma* spp. or *Ehrlichia* spp., which may play a role in the pathogenesis of disease.

Clinical Features

Bartonella henselae and *B. vinsonii (berkhoffii)* seem to be the most likely species to be associated with clinical disease in dogs. Clinical findings or syndromes most frequently attributed to *Bartonella* spp. infections of dogs include endocarditis, fever, arrhythmias, hepatitis, granulomatous lymphadenitis, cutaneous vasculitis, rhinitis, polyarthritis, meningoencephalitis, thrombocytopenia, eosinophilia, monocytosis, immune-mediated hemolytic anemia, epistaxis, idiopathic cavitary effusions, and uveitis. *Bartonella* spp. infection should be considered in all dogs, cats, and human beings with evidence of infective endocarditis (Fig. 94.1) particularly if culture negative using routine media (Okaro et al., 2017; Fenimore et al., 2011; Sykes et al., 2006). Recently, ineffective erythropoiesis was detected in a dog positive for *B. henselae* that subsequently responded to antibiotics (Randell et al., 2018). In one study of valvular endocarditis, all dogs with *Bartonella* spp.–associated disease were also seropositive for *Anaplasma phagocytophilum* (MacDonald et al., 2004). Whether the co-infection potentiated the *Bartonella*-associated disease is unknown.

Diagnosis

Serum antibodies can be detected in both healthy and clinically ill dogs, so the presence of antibodies does not always correlate to illness. However, because approximately 50% of dogs with bartonellosis are seronegative, serum antibodies should never be used as the sole diagnostic method in suspect cases (www.galaxydx.com). *Bartonella* spp. can be difficult to amplify from dogs because the organism is frequently present in low numbers. Thus amplification of DNA by polymerase chain reaction (PCR) assay with or without culture is often necessary to confirm infection; blood or affected tissues may also be used for PCR (Duncan et al., 2007; www.galaxydx.com). If positive test results are detected in a clinically ill dog and no other explanation for the illness is obvious, treatment is indicated.

Treatment

Dogs with suspected bartonellosis have failed treatment with doxycycline alone; thus failure to respond to this drug should not exclude the diagnosis. Azithromycin therapy has been successful in some dogs, but it is now recognized that *B. henselae* can become resistant to this drug more quickly than fluoroquinolones (Biswas et al., 2010). Dual therapy is believed to be more effective than monotherapy by some veterinarians, but more information is necessary. Doxycycline at 5 to 10 mg/kg, orally (PO), q12h combined with a veterinary fluoroquinolone like enrofloxacin at 5 mg/kg, PO, q24h is used by most veterinarians working with *Bartonella* spp. infected dogs (Breitschwerdt, 2017). Rifampin used with

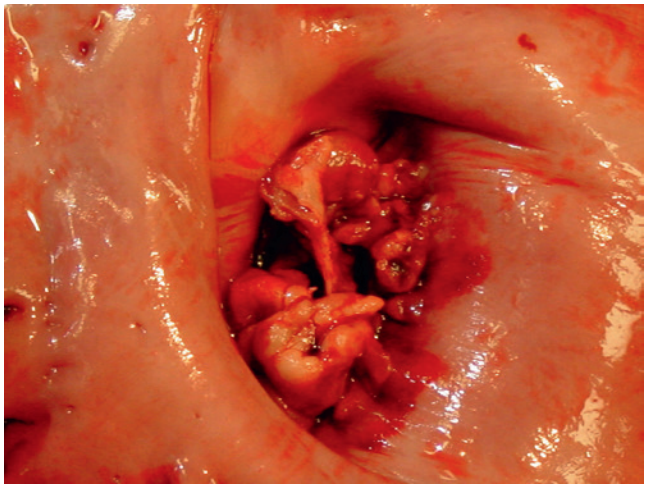

FIG 94.1
Bacterial endocarditis in a dog positive for *B. henselae* DNA in the heart value.

another drug may be required for resistant cases. Dogs with endocarditis should be given an aminoglycoside parenterally for the first week of therapy; amikacin at 20 mg/kg, intravenous (IV), q24h is commonly recommended while evaluating for renal toxicity. No matter which drug is used, a minimum of 4 to 6 weeks of treatment is usually necessary. In one study, successfully treated dogs became seronegative (Breitschwerdt et al., 2004). However, because so many dogs are initially seronegative and the organism can be difficult to grow or amplify from dogs, it is difficult to make definitive recommendations concerning use of diagnostic tests to confirm response to therapy. Thus, resolution of clinical signs and clinicopathologic abnormalities are of paramount importance, and flea and tick control should be maintained to attempt to avoid reinfection.

Zoonotic Aspects and Prevention

Many of the *Bartonella* spp. that have been detected in dogs also infect humans, in particular *B. henselae* and *B. vinsonii (berkhoffii)*. *Bartonella henselae* has been detected in dog saliva, and the cat scratch disease syndrome has been documented in human beings after exposure to dogs. Care should be taken to avoid bites, scratches, or contaminated needle sticks while handling or treating infected dogs. Flea and tick control is likely to lessen transmission of *Bartonella* species between dogs and perhaps from dogs to people. See the Zoonotic Aspects and Prevention section for feline bartonellosis for additional information.

FELINE BARTONELLOSIS

Etiology and Epidemiology

Cats have been proven to be infected by *B. henselae*, *B. clarridgeiae*, *B. koehlerae*, *B. quintana,* and *B. bovis* by culture or DNA amplification (Brunt et al., 2006; Breitschwerdt, 2017). Cats are the main reservoir hosts for *B. henselae* and *B. clarridgeiae,* and are likely the reservoir for *B. koehlerae*. *Ctenocephalides felis* plays a role in the transmission of these three species among cats. *Bartonella henselae* is the most common cause of cat scratch disease, as well as bacillary angiomatosis and peliosis hepatis, common disorders in human beings with acquired immunodeficiency syndrome (Breitschwerdt, 2017). However, multiple other *Bartonella* spp. disease associations have now been recognized, and veterinarian healthcare providers are occupationally at risk (see the Zoonoses subsection). *Bartonella* species have both intraendothelial and intraerythrocytic phases of infection (Fig. 94.2). The intracellular location may relate to the difficulties in permanently eliminating bacteremia and promotes *C. felis* taking up the organism in the blood meal. However, feline *Bartonella* spp. have not been associated with hemolytic anemia in cats, suggesting that this phase of infection is a host evasion mechanism (Ishak et al., 2007).

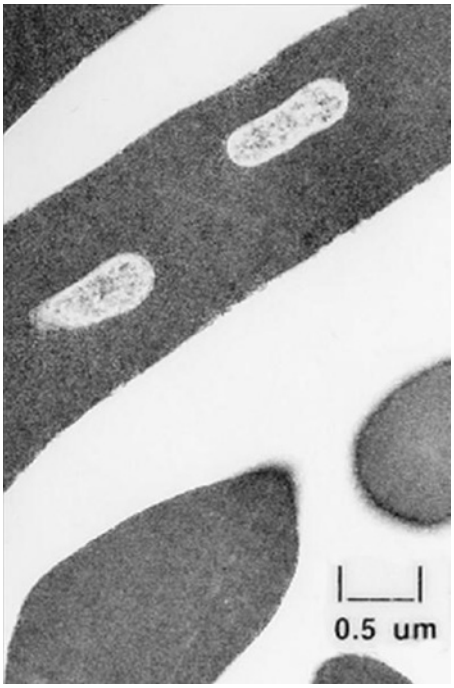

FIG 94.2
Electron micrograph of a feline erythrocyte showing intracellular *Bartonella henselae*. (Courtesy Dr. Dorsey Kordick.)

On the basis of results of seroprevalence studies, culture, or PCR assay, cats are commonly exposed to or infected by *Bartonella* species. Because feline *Bartonella* spp. are mainly transmitted by *C. felis,* prevalence is greatest in cats from regions where fleas are common. For example, although *Bartonella* spp. DNA was not amplified from any sample from cats in Colorado where fleas are rare due to the dry environment, it was commonly amplified from blood (56.9%), skin (31.4%), claws (17.6%), and gingiva (17.6%) of 51 cats housed in Alabama and Florida, where *C. felis* infestation is common (Lappin and Hawley, 2009). Results have been similar in other studies performed around the world.

Bartonella henselae survives in flea feces for days after being passed by infected *C. felis*. Infected flea feces are likely to contaminate cat claws during grooming, and then *Bartonella* species are inoculated into the person when scratched. Open wounds may also be contaminated with infected flea feces. However, *Bartonella* spp. DNA can also be amplified from the mouths of healthy cats and those with gingivostomatitis, so bites and scratches should always be avoided (Quimby et al., 2008; Lappin and Hawley, 2009). Whether clinical disease occurs from *Bartonella* spp. infection depends on a complex interaction of host and organism effects. In general, *Bartonella* spp.-associated illness is not identified in the host-adapted species (e.g., *B. henselae*, *B. clarridgeiae*, and *B. koehlerae* infections in cats) even though large numbers of the organism are detected in blood. In contrast, when *Bartonella* spp. infect non–host-adapted species like dogs and people, illness can occur with extremely low levels of bacteremia.

Clinical Features

Most cats with serologic evidence of exposure to *Bartonella* spp., *Bartonella* spp. cultured from blood, or microbial DNA amplified from blood by PCR assay are clinically normal. However, *Bartonella* spp. infection of cats has also been associated directly or indirectly with a variety of clinical manifestations like fever, lethargy, lymphadenopathy, uveitis, gingivitis, endocarditis, myocarditis, hyperglobulinemia, osteomyelitis, cutaneous vasculitis, and neurologic diseases. Fever and cardiac abnormalities are the most common manifestations in cats infected with *B. henselae* by experimental exposure to infected *C. felis* (Bradley and Lappin, 2010). How often cats become ill from *Bartonella* spp. infections is unknown, and more information is necessary.

It can be difficult to determine which cats have been exposed, and which cats are diseased. *Bartonella* spp. seroprevalence rates in shelter cats can be as high as 93% (Nutter et al., 2004). In another study, the presence of *Bartonella* species antibodies failed to correlate to the presence of most clinical syndromes in ill cats (Breitschwerdt et al., 2005b). In recent studies in the author's laboratory, the prevalence rates for *Bartonella* species antibodies in feline sera were not significantly different for cats with or without seizures (Pearce et al., 2006), cats with or without stomatitis (Dowers and Lappin, 2005), or cats with or without elevations in feline pancreatic lipase immunoreactivity (Bayliss et al., 2009). Why some cats develop *Bartonella*-associated illness and others do not is still not clear. For example, Powell et al. (2002) failed to induce *Toxoplasma gondii* or *Bartonella* species uveitis when *Bartonella* was intravenously inoculated into cats with chronic toxoplasmosis.

Diagnosis

Blood culture, PCR assay on blood, and serologic testing can be used to assess individual cats for *Bartonella* infection. Cats that are culture-negative or PCR-negative and antibody-negative, and cats that are culture-negative or PCR-negative and antibody-positive are probably not a source of flea, cat, or human infection. However, bacteremia can be intermittent, and false-negative culture or PCR results can occur, limiting the predictive value of a single battery of tests. With PCR, false-positive results can occur, and positive results do not necessarily indicate that the organism is alive. Although serologic testing can be used to determine whether an individual cat has been exposed, both seropositive and seronegative cats can be bacteremic, limiting the diagnostic utility of serologic testing when used alone. Thus testing healthy, client-owned cats for *Bartonella* spp. infection is not currently recommended in the United States (Kaplan et al., 2009). Testing should be reserved for cats with suspected clinical bartonellosis.

The combination of serology and PCR assay or culture is available in some laboratories like Antech Diagnostics, North Carolina State University, Galaxy Diagnostics (www.galaxydx.com), and Colorado State University (www.dlab.colostate.edu/). Some cats can have low-level bacteremia, and specialized media combined with PCR may be required to identify the organism (Drummond et al., 2018). If the results of *Bartonella* tests are negative in a clinically ill cat, the organism is not likely the cause of the clinical syndrome unless the infection was peracute and serologic testing was used as the diagnostic test. If the results of *Bartonella* tests are positive, the agent remains on the list of differential diagnoses, but other causes of the clinical syndrome must also be excluded.

The American Association of Feline Practitioners (AAFP) *Bartonella* Panel Report suggests that the diagnosis of clinical bartonellosis include the following combination of findings (Brunt et al., 2006):

- Presence of a syndrome reported to be associated with *Bartonella* spp. infection
- Exclusion of other causes of the clinical syndrome
- Detection of a positive *Bartonella* spp. test (culture, PCR assay, or serology)
- Response to administration of a drug with presumed anti-*Bartonella* activity

However, fulfillment of these criteria does not always prove a definitive diagnosis. The antibiotics used for the treatment of bartonellosis in cats generally have a broad spectrum, are effective for other infecting organisms that can cause syndromes resembling bartonellosis, and can also have antiinflammatory properties.

Treatment

In experimental studies, administration of doxycycline, tetracycline, erythromycin, amoxicillin-clavulanate, or enrofloxacin can limit bacteremia but does not cure infection in all cats. To date, use of antibiotics in healthy cats has not been shown to lessen the risk of cat scratch disease. Thus in the United States, treatment is generally recommended for clinically ill cats (Kaplan et al., 2009). If clinical bartonellosis is suspected, the AAFP Panel Report recommends

doxycycline at 10 mg/kg, PO, daily for 7 days as the initial therapeutic trial (Brunt et al., 2006). In the United States, doxycycline should be formulated into a flavored suspension or given with water to avoid esophagitis leading to esophageal strictures. Using the drug twice daily is also acceptable and may increase the chance of eliminating bacteremia. If a positive response is achieved, continue treatment for 2 weeks past clinical resolution of disease or for a minimum of 28 days. If a poor response is achieved by day 7 or doxycycline is not tolerated and bartonellosis is still considered a valid differential diagnosis, fluoroquinolones should be used as second choices. Enrofloxacin at 5 mg/kg, PO, daily was used in one study of cats infected by exposure to fleas (Bradley and Lappin, 2010). Recently, enrofloxacin has been used less frequently in cats due to the risk of retinal degeneration. Fever suspected to be due to *Bartonella* spp. in one field study seemingly resolved after the administration of doxycycline or orbifloxacin (Lappin et al., 2012). *Bartonella henselae* isolates from people or cats were shown to rapidly develop resistance to azithromycin, so this drug should not be used to treat feline bartonellosis (Biswas et al., 2010). Pradofloxacin is a newer generation quinolone available for use in cats in some countries, and unpublished data suggest that use of the United States formulation of this drug at 7.5 mg/kg, PO, daily may be the preferred drug to treat bartonellosis in cats. *Bartonella* spp.–positive cats that have failed to respond after administration of two different drugs with presumed anti-*Bartonella* activity generally have another cause of the clinical syndrome. There is no clinical utility in rechecking *Bartonella* serologic test or PCR test results in cats after clinical signs resolve because infection is difficult to clear and reinfection is common. Thus, successfully treated cats should have strict flea control maintained.

Zoonotic Aspects and Prevention

The clinical manifestations of bartonellosis in people are more extensive than just cat scratch disease, peliosis hepatis, bacillary angiomatosis, and valvular endocarditis. It is now apparent that immune-competent individuals can develop a number of *Bartonella* spp.–associated chronic inflammatory syndromes, and *Bartonella* spp. infections are an occupational risk for veterinary healthcare providers (Breitschwerdt et al., 2007; Breitschwerdt et al., 2011; Oteo et al., 2017). For example, *Bartonella* spp. infection was commonly confirmed in people with rheumatic symptoms in a Lyme disease–endemic region (Maggi et al., 2012). *Bartonella henselae* may have contributed to the death of two veterinarians (Breitschwerdt et al., 2015).

Veterinarians or others commonly exposed to cats or fleas that develop chronic inflammatory diseases should have *Bartonella* spp. on the list of differential diagnoses. To lessen the likelihood of acquiring a *Bartonella* species infection from a cat, the following adaptations of recommendations to HIV-infected people and other cat owners by the Centers for Disease Control and Prevention and the AAFP have been developed:

- Flea control should be initiated and maintained year round.
- If a family member is immunocompromised and a new cat is to be acquired, adopt a healthy cat older than 1 year and free of fleas.
- Immunocompromised individuals should avoid contact with cats of unknown health status.
- Declawing of cats is generally not required, but claws should be trimmed regularly.
- Bites and scratches should be avoided (including rough play with cats).
- Cat-associated wounds should be washed promptly and thoroughly with soap and water and medical advice sought.
- Although *Bartonella* species have not been shown to be transmitted by saliva, cats should not be allowed to lick open wounds.
- Keep cats indoors to minimize hunting and exposure to fleas and other possible vectors.
- Avoid needle sticks contaminated with blood from potentially infected cats or dogs.

FELINE PLAGUE

Etiology and Epidemiology

Yersinia pestis is the facultatively anaerobic gram-negative coccobacillus that causes plague. The organism is maintained in a sylvan life cycle between rodent fleas and infected rodents, including rock squirrels, ground squirrels, and prairie dogs. However, it has been shown that *C. felis* can be a competent vector, but transmission was less efficient than by a rodent flea in one experimental study (Eisen et al., 2008). Both cats and dogs are susceptible to infection. Antibodies against *Y. pestis* have also been detected in serum of nondomestic felids. Clinical disease is recognized most frequently from spring through early fall, when rodents and rodent fleas are most active. However, a recent unpublished case in Colorado was diagnosed in December of a mild winter. Most of the cases in human beings and cats in the United States have been documented in Colorado, New Mexico, Arizona, California, and Texas. Of the cases of human plague diagnosed from 1977 to 1998, 23 (7.7%) resulted from contact with infected cats (Gage et al., 2000).

Cats and dogs are infected after being bitten by infected rodent fleas, after ingestion of bacteremic rodents, or after inhalation of the organism. After ingestion, the organism replicates in the tonsils and pharyngeal lymph nodes, disseminates in the blood, and results in a neutrophilic inflammatory response and abscess formation in infected tissues. The incubation period is 2 to 6 days after a flea bite and 1 to 3 days after ingestion or inhalation of the organism. Outcomes in experimentally infected cats include death (6 of 16 cats; 38%), transient febrile illness with lymphadenopathy (7 of 16 cats; 44%), or inapparent infection (3 of 16 cats; 19%) (Gasper et al., 1993).

BOX 94.1

Clinical Findings in Cats With *Yersinia pestis* Infection (Plague)

Signalment

All ages, breeds, and gender

History and Physical Examination

Outdoor cats
Male cats
Hunting of rodents or exposure to rodent fleas
Depression
Cervical swellings, draining tracts, lymphadenopathy
Dyspnea or cough

Clinicopathologic and Radiographic Evaluation

Neutrophilia with or without a left shift
Lymphopenia
Neutrophilic lymphadenitis or pneumonitis
Homogenous population of bipolar rods cytologically (lymph node aspirate or airway washings)
Serum antibody titers, either negative (peracute) or positive
Interstitial and alveolar lung disease

Diagnosis

Culture or PCR assay of blood, exudates, tonsillar region, respiratory secretions
Fluorescent antibody identification of organism in exudates
Fourfold increase in antibody titer and appropriate clinical signs

Clinical Features

Bubonic, septicemic, and pneumonic plague can develop in infected human beings, dogs, and cats (Box 94.1). Bubonic plague is the most common form of the disease in cats, but individual cats can show clinical signs of all three syndromes. Most infected cats or dogs are allowed outdoors and have a history of hunting. Anorexia, depression, cervical swelling, dyspnea, and cough are common presenting complaints; fever is detected in most infected cats. Unilateral or bilateral enlarged tonsils, mandibular lymph nodes, and anterior cervical lymph nodes are detected in approximately 50% of infected cats. Cats or dogs with pneumonic plague commonly have respiratory signs and may cough. In a series of 62 suspected dog cases, the most common clinical signs included fever (100%), lethargy (97%), and anorexia (77%); only 23% of the dogs had lymphadenopathy (Nichols et al., 2014).

Diagnosis

Hematologic and serum biochemical abnormalities reflect bacteremia and are not specific for *Y. pestis* infection. Neutrophilic leukocytosis, left shift and lymphopenia, hypoalbuminemia, hyperglobulinemia, hyperglycemia, azotemia, hypokalemia, hypochloremia, hyperbilirubinemia, and increased activities of alkaline phosphatase and alanine transaminase are common. Pneumonic plague causes increased alveolar and diffuse interstitial densities on thoracic radiographs, and consolidated lung lobes may be detected. Cytologic examination of lymph node aspirates reveals lymphoid hyperplasia, neutrophilic infiltrates, and bipolar rods (Fig. 94.3).

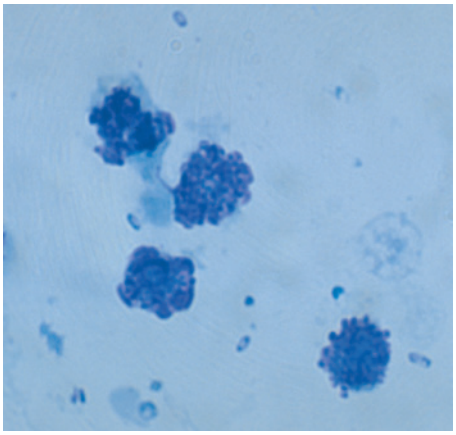

FIG 94.3
Lymph node aspirate from a cat with bubonic plague stained with Wright stain. Bipolar rods are scattered throughout the field.

Cytologic demonstration of bipolar rods on examination of lymph node aspirates, exudates from draining abscesses, or airway washings combined with a history of potential exposure, the presence of rodent fleas, and appropriate clinical signs lead to a presumptive diagnosis of feline plague. Because some cats survive infection and antibodies can be detected in serum for at least 300 days, detection of antibodies alone may indicate only exposure, not clinical infection. However, demonstration of a fourfold increase in antibody titer is consistent with recent infection. A definitive diagnosis is made by culture, fluorescent antibody demonstration of *Y. pestis* in smears of the tonsillar region, lymph node aspirates, exudates from draining abscesses, airway washings, or blood or PCR amplification of *Y. pestis* DNA from blood, fluids, or tissues.

Treatment

Supportive care should be administered as indicated for any bacteremic animal. Cervical lymph node abscesses should be drained and flushed with the clinician wearing gloves, a mask, and a gown. Parenteral antibiotics should be administered until anorexia and fever resolve. Optimal antibiotics for treatment of plague in infected cats in the United States are unknown. Streptomycin administered intramuscularly at 5 mg/kg q12h was used historically but is not widely available. Cats treated with gentamicin intramuscularly or intravenously at 2 to 4 mg/kg q12-24h, or enrofloxacin intramuscularly or intravenously at 5 mg/kg q24h, have resolved

clinical signs. Chloramphenicol administered orally or intravenously at 15 mg/kg q12h can be used in cats with central nervous system signs. Antibiotics should be administered orally for 21 days after the cat has survived the bacteremic phase; doxycycline at 5 mg/kg q12h is an appropriate choice. Care should be taken to avoid doxycycline-associated esophageal strictures in feline cases by giving water after drug administration or liquefying the product. In one study, 90.9% of cats treated with antibiotics survived, whereas only 23.8% of untreated cats survived (Eidson et al., 1991). In a dog case series, 73% of the 62 suspect cases were treated with antibiotics and 97% of the dogs survived (Nichols et al., 2014). The prognosis is believed to be worse for the pneumonic form of *Y. pestis* infection. A recent case seen at the author's institution developed a consolidated lung lobe and died after lobectomy.

Zoonotic Aspects and Prevention

Pets should be housed indoors when possible and not allowed to hunt. Flea control should be used, and the rodent population should be controlled if possible. Sleeping in the same bed with the family dog was associated with plague in one study, which suggests dogs can bring infected fleas into the human environment, and that flea control should be maintained on all pets in the home (Gould et al., 2008). Doxycycline at the doses listed for therapy should be administered for 7 days to animals with potential exposure. Human infection occurs after contact with infected fleas; contact with the tissues or exudates from infected animals, including cats and dog; and from bites and scratches from infected cats. Even though fomite transmission is unlikely, because the organism is sensitive to drying it can survive for weeks to months in infected carcasses and for up to 1 year in infected fleas. Cats and dogs from endemic areas with clinical signs of bacteremia, respiratory tract disease, or cervical draining areas or masses in the spring, summer, and early fall months should immediately be treated for fleas and handled with the clinician wearing gloves, a mask, and a gown until the diagnosis is made or discarded. While hospitalized, as few people as possible should handle infected cats and dogs while in isolation. Exposed personnel should see their physicians to discuss prophylactic antibiotic therapy; antimicrobial-resistant strains of *Y. pestis* are uncommon (Welch et al., 2007). It is believed that cats and dogs are not infectious to human beings after 3 days of antibiotic therapy. Areas where infected cats or dogs are handled should be thoroughly cleaned with routine disinfectants.

LEPTOSPIROSIS

Etiology and Epidemiology

Leptospires are motile, filamentous spirochetes that infect animals and human beings. Leptospirosis can be caused by many different serovars of *Leptospira interrogans* and *Leptospira kirschneri* (Sykes et al., 2011). Seropositive dogs have been detected in many countries, and the most prevalent serovars vary by country and regions within countries (White et al., 2017). In the United States, antibodies against *L. autumnalis, L. bratislava, L. canicola, L. grippotyphosa, L. hardjo, L. icterohaemorrhagiae,* and *L. pomona* have been detected most commonly. One study based on PCR analyses of *Leptospira* spp. DNA in urine from dogs in the United States showed *L. grippotyphosa* in 78 of the 98 positive samples (Harkin and Hays, 2016). Recently, the *L. santarosai* serogroup Sejroe was amplified from healthy dogs in Sao Paulo (Miotto et al., 2018). The *Leptospira* spp. that infect cats are less clear, and cats appear to be more resistant to clinical disease than dogs.

Prevalence and risk factors for cases of canine leptospirosis have been evaluated in several studies. In the United States the number of seropositive dogs increased between 2002 and 2004 (Moore et al., 2006). *Leptospira* spp. exposure can be common in the United States; 8.1% of 33,119 canine serum samples had titers greater than 1:1600 in one study (Gautam et al., 2010). Infection by *Leptospira* spp. occurs in both rural and suburban environments in semitropical areas of the world with alkaline soil conditions. In one study in Kansas, an association between leptospirosis in dogs and urban environments was made, so leptospirosis should be considered in all appropriate clinical situations (Raghavan et al., 2011). Exposure to water outdoors, wetlands, and public open spaces were identified as risk factors in one case-control study (Ghneim et al., 2007). Clinical cases are most commonly diagnosed in the summer and early fall, and numbers of cases often increase in years with heavy rainfall. Infection by host-adapted species results in subclinical infection; the host acts as a reservoir, shedding the organism intermittently.

Infection by non-host-adapted species results in clinical illness. *Leptospira* spp. are passed in urine and enter the body through abraded skin or intact mucous membranes. Transmission also occurs through bite wounds; by venereal contact; transplacentally; and by ingestion of contaminated tissues, soil, water, bedding, food, and other fomites. In an experimental study, *L. pomona* but not *L. bratislava* was successfully transmitted by conjunctival inoculation and resulted in fever and lethargy starting within 7 days (Greenlee et al., 2005). Hosts with preexisting antibody titers usually eliminate the organism quickly and remain subclinically infected. *Leptospira* spp. replicate in multiple tissues of nonimmune hosts or hosts infected by a non–host-adapted species; in the dog, the liver and kidneys develop the highest levels of infection. Inflammation induced by organism replication and production of toxins leads to renal, hepatic, or pulmonary disease. Dogs that are treated or develop appropriate immune responses usually survive. Some animals clear the infection 2 to 3 weeks after exposure without treatment but develop chronic active hepatitis or chronic kidney disease. Cats are generally subclinically affected but may shed the organism into the environment for variable periods after exposure and occasionally develop polyuria, polydipsia, and renal insufficiency (Arbour et al., 2012).

Clinical Findings

Dogs of any age, breed, or gender can develop leptospirosis if not previously immune. Male, middle-aged, herding dogs; hounds; working dogs; and mixed-breed dogs were at greater risk than companion dogs younger than 1 year in one study (Ward et al., 2002). But in a more recent study, small breed dogs were over-represented (Lee et al., 2014). Dogs with peracute clinical disease are usually presented for evaluation of anorexia, depression, generalized muscle hyperesthesia, tachypnea, and vomiting (Box 94.2). Fever, pale mucous membranes, and tachycardia are usually present. Petechiae, ecchymoses, melena, and epistaxis occur frequently from thrombocytopenia and disseminated intravascular coagulation. Peracute infections may rapidly progress to death before marked renal or hepatic disease is recognized.

Fever, depression, and clinical signs or physical examination findings consistent with hemorrhagic syndromes, hepatic disease, renal disease, or a combination of hepatic and renal disease are common in subacutely infected dogs. Conjunctivitis, panuveitis, rhinitis, tonsillitis, cough, and dyspnea occur occasionally. Oliguric or anuric renal failure can develop during the subacute phase. Clinical findings can vary on the basis of the infecting serovar (Goldstein et al., 2006). The pulmonary hemorrhagic syndrome described in people is likely to occur in dogs as well, so leptospirosis should be on the differential list for dogs with dyspnea (Klopfleisch et al., 2010).

Some dogs that survive peracute or subacute infection develop chronic interstitial nephritis or chronic active hepatitis. Polyuria, polydipsia, weight loss, ascites, and signs of hepatic encephalopathy secondary to hepatic insufficiency are the most common manifestations of chronic leptospirosis.

BOX 94.2

Clinical Findings in Dogs With Leptospirosis

Signalment

All ages, breeds, and gender

History

Exposure to appropriate reservoir host or contaminated environment
Urban environment common
Anorexia, depression, lethargy

Physical Examination

Fever
Anterior uveitis
Hemorrhagic tendencies, including melena, epistaxis, petechiae, and ecchymoses
Vomiting, diarrhea
Muscle or meningeal pain
Renomegaly with or without renal pain
Hepatomegaly
Polyuria/polydipsia
Icterus
Coughing or respiratory distress

Clinicopathologic and Imaging Findings

Thrombocytopenia
Leukopenia (acute)
Leukocytosis (subacute)
Azotemia
Suboptimal urine concentrating ability
Pyuria and hematuria without obvious bacteriuria
Hyperbilirubinemia and bilirubinuria
Increased activities of alanine transaminase, aspartate transaminase, alkaline phosphatase, and creatine kinase
Interstitial to alveolar lung disease
Hepatomegaly or renomegaly

Diagnosis

Culture of urine, blood, or tissues
Demonstration of the organism in urine by darkfield or phase-contrast microscopy
Demonstration of organismal DNA in urine, blood, or tissues by PCR
Combination of increasing antibody titer with clinical signs and response to therapy

PCR, Polymerase chain reaction.

Diagnosis

Multiple nonspecific clinicopathologic and imaging abnormalities occur in dogs with leptospirosis and vary depending on the host, the serovar, and whether the disease was peracute, subacute, or chronic. Leukopenia (peracute leptospiremic phase), leukocytosis with or without a left shift, thrombocytopenia, regenerative anemia (from blood loss), or nonregenerative anemia (from chronic renal or hepatic disease) are common hematologic abnormalities. Hyponatremia; hypokalemia; hyperphosphatemia; hypoalbuminemia; hypocalcemia; azotemia; hyperbilirubinemia; decreased total carbon dioxide concentrations; and increased activities of alanine transaminase, alkaline phosphatase, and aspartate transaminase are common serum biochemical abnormalities that develop from renal disease, hepatic disease, gastrointestinal losses, or acidosis. Hyperglobulinemia is detected in some dogs with chronic leptospirosis. Dogs with myositis may have increased creatine kinase activity. Urinalysis abnormalities include bilirubinuria, suboptimal urine specific gravity in the face of azotemia, granular casts, and increased numbers of granulocytes and erythrocytes. The organism is not seen in the urine sediment by light microscopy. Renomegaly, hepatomegaly, and interstitial or alveolar pulmonary infiltrates are common radiographic abnormalities. Mineralization of the renal pelves and cortices can occur with chronic leptospirosis. On histopathologic evaluation of renal tissues, mesangial proliferative glomerulonephritis with or without interstitial nephritis were the most common lesions in one study (Ortega-Pacheco, 2008).

Detection of anti-*Leptospira* antibodies is commonly performed by a microscopic agglutination test (MAT). In some countries, there are also now two commercially available point of care assays (Zoetis Animal Health; IDEXX

Laboratories). One of the commercial kits is optimized to detect immunoglobulin M (IgM) antibodies and in one study was the first to become positive in most dogs during acute infection (Lizer et al., 2018). If MAT is used, because of the wide range of leptospires infecting dogs, as many serovars as possible should be used for screening. *Leptospira bratislava, L. canicola, L. grippotyphosa, L. hardjo, L. icterohaemorrhagiae,* and *L. pomona* are commonly used. Positive titers can result from active infection, previous infection, or vaccination. Antibody titers can be negative in animals with peracute disease; seronegative dogs with classic clinical disease should be retested in 2 to 4 weeks. The serovar with the highest titer is not always the infecting serovar. The highest titer on a convalescent serum sample may be more likely the primary serovar. When the same sera were sent to different laboratories, the results were not always in agreement for the serovar giving the highest titer (Miller et al., 2011), and some vaccinated, client-owned dogs have high titer responses (Martin et al., 2014).

Documentation of seroconversion (negative result becoming positive over time), a single MAT titer greater than 1:3200, or a fourfold increase in antibody titers combined with appropriate clinicopathologic abnormalities and clinical findings, are suggestive of clinical leptospirosis. A definitive diagnosis is made by demonstrating the organism in urine, blood, or tissues. The organism can be seen in urine using darkfield or phase-contrast microscopy, but because of intermittent shedding of small numbers of organisms these procedures can be falsely negative. The organism can be cultured from urine collected by cystocentesis, blood, or renal or hepatic tissue. Materials for culture should be collected before administration of antibiotics, placed in transport media immediately after collection, and transported to the laboratory as quickly as possible. Leptospiremia can be of short duration, and urine shedding of the organism can be intermittent, giving false-negative results. PCR can be used to demonstrate the organism in urine, blood, or tissues (Harkin et al., 2003a, 2003b). In one study of 500 dogs, 41 (8.2%) were PCR-positive for a *Leptospira* spp. in urine, and some of these dogs were clinically normal (Harkin et al., 2003a). None of the PCR-positive dogs was culture-positive, and titers were not always high. *Leptospira* spp. DNA can also be amplified from renal tissues that have no evidence of inflammatory disease (Dash et al., 2018). Recent vaccination should not result in positive PCR assay results (Midence et al., 2012). Antibodies induced by *Leptospira* spp. vaccine did not cross-react with *Borrelia burgdorferi* peptides in one study (Caress et al., 2017).

Treatment

Fluid therapy is required for most dogs; intense diuresis for renal involvement may be required (see Chapter 41). Hemodialysis may increase the probability of survival in dogs with oliguric or anuric renal failure. Dogs should be treated during the initial treatment period with ampicillin administered intravenously at 22 mg/kg q8h. Some quinolones have an effect against *Leptospira* spp. and can be used in combination with penicillins during the acute phase of infection, in particular if other gram-negative organisms are on the differential list. Ampicillin and enrofloxacin were used concurrently in one study, and 83% of infected dogs survived (Adin et al., 2000). Penicillins such as amoxicillin or amoxicillin clavulanate should be administered for 2 weeks. Doxycycline administered orally at 5 mg/kg q12h for 2 weeks should be used to eliminate the renal carrier phase (Sykes et al., 2011).

Zoonotic Aspects and Prevention

All mammalian serovars should be considered potentially zoonotic to human beings. Some human beings have antibodies against canine serovars, suggesting the dog can be a reservoir for human infection (Brod et al., 2005). However, results from studies attempting to associate dog contact with leptospirosis in humans have varied. For example, 0/91 people exposed to dogs with proven leptospirosis were seropositive suggesting the risk was minimal (Barmettler et al., 2011). As leptospirosis is an occupational risk for veterinarians, the organism should be on the list of differential diagnoses if appropriate clinical signs of disease develop (Whitney, 2009). Infected urine, contaminated water, and reservoir hosts should be avoided. Infected dogs should be handled with the clinician wearing gloves. Contaminated surfaces should be cleaned with detergents and disinfected (see Chapter 93).

To lessen risk of exposure, owners should attempt to restrict dogs from drinking potentially contaminated water. Healthy dogs can shed *Leptospira* spp. in urine; 7% of 525 urine samples from dogs in Dublin were positive in one study (Rojas et al., 2010). Thus contact with dog urine should always be avoided. Vaccines available for some serovars reduce the severity of disease and lessen leptospire shedding in urine. Several products containing serovars *L. canicola, L. icterohaemorrhagiae, L. grippotyphosa,* and *L. pomona* are now available and should be used rather than two serovar vaccines to provide the greatest spectrum of protection (see Chapter 93). Numbers of long-term duration of immunity studies are small, but recently, one commercially available product was shown to induce significant protection against *L. grippotyphosa* for 15 months when compared to unvaccinated controls (Grosenbaugh and Pardo, 2018). Dogs in endemic areas should be administered at least two vaccines 2 to 4 weeks apart, and annual boosters are recommended (www.aahanet.org). Canine side effects associated with the current four serovar-containing vaccines are generally transient and mild (Spiri et al., 2017; Yao et al., 2015). In one study, hypersensitivity reactions to *Leptospira* spp. vaccines were estimated at 6.5/10,000 vaccinated dogs (Yao et al., 2015).

MYCOPLASMA AND UREAPLASMA

Etiology and Epidemiology

Mycoplasma spp. and *Ureaplasma* spp. are small, free-living microorganisms that lack a rigid, protective cell wall and

depend on the environment for nourishment. Some *Mycoplasma* spp. and *Ureaplasma* spp. are considered normal flora of mucous membranes. For example, *Mycoplasma* spp. have been isolated from the vagina of 75% of healthy dogs (Doig et al., 1981), the pharynx of 100% of healthy dogs, and the pharynx of 35% of healthy cats (Randolph et al., 1993). The hemotrophic mycoplasmas, *Mycoplasma haemofelis*, *"Candidatus* Mycoplasma haemominutum," *"Candidatus* Mycoplasma turicensis", *Mycoplasma haemocanis,* and *"Candidatus* Mycoplasma haematoparvum" are associated with erythrocytes and are discussed in Chapter 82.

Mycoplasma felis conjunctivitis in cats, *M. felis* upper respiratory tract infection in cats, *Mycoplasma gateae* polyarthritis in cats, and *Mycoplasma cynos* pneumonia in dogs have been induced experimentally. The pathogenic potential for most *Mycoplasma* spp. or *Ureaplasma* spp. is difficult to determine because the organisms can be cultured or amplified from both healthy and sick animals. In one shelter study, *M. cynos* DNA was amplified for 29.2% of healthy dogs suggesting that not all strains are pathogenic (Lavan and Knesl, 2015). For *M. cynos*, genetic heterogeneity has been documented, and some strains may be more pathogenic than others (Mannering et al., 2009).

In many cases *Mycoplasma* spp. or *Ureaplasma* spp. may be colonizing diseased tissues as opportunists as a result of inflammation induced by other causes. Other bacteria or viruses are usually identified concurrently with *Mycoplasma* spp. or *Ureaplasma* spp., making it difficult to determine which agent is inducing disease. *Ureaplasma* spp. have also been cultured from the vagina (40%) and prepuce (10%) of healthy dogs (Doig et al., 1981).

Mycoplasma spp. were isolated in pure culture from 20 of 2900 dogs with clinical signs of urinary tract inflammation (Jang et al., 1984), *Mycoplasma canis* was isolated from 4 of 100 dogs (3 in pure culture) with clinical signs of lower urinary tract disease (Ulgen et al., 2006), and *M. canis* was isolated from nine dogs with clinical signs of urogenital disease (L'Abee-Lund et al., 2003). Some *M. canis* positive dogs were azotemic, suggesting pyelonephritis (Ulgen et al., 2006), and some have been resistant to therapy (L'Abee-Lund et al., 2003).

Multiple studies suggest that some *Mycoplasma* spp. can be primary pathogens of the respiratory tract of dogs. *Mycoplasma* spp. were the only organism cultured from 7 of 93 dogs (Jameson et al., 1995), 5 of 38 dogs (Randolph et al., 1993), and 14 dogs (Chandler et al., 2002) with lower respiratory tract disease. In one study that compared *Mycoplasma* isolates from dogs with and without respiratory disease, *M. cynos* in the lower respiratory tract was statistically associated with respiratory disease (Chalker et al., 2004). In another study, 80% of dogs that developed antibodies to *M. cynos* had respiratory signs of disease (Rycroft et al., 2007).

In a recent study of cats with and without conjunctivitis, the presence of *Mycoplasma* spp. DNA was associated with the presence of conjunctivitis (Low et al., 2007). Both *M. felis* and *M. gateae* have been associated with feline ulcerative keratitis (Gray et al., 2005). *Mycoplasma gateae* and *M. felis* have been detected in cats with polyarthritis. *Mycoplasma* spp. have also been associated with the presence of rhinosinusitis, lower respiratory disease, and pyothorax. In one study of cats with upper respiratory disease in Germany, *M. felis, Mycoplasma canadense, M. cynos, M gateae, Mycoplasma lipophilum, and Mycoplasma hyopharyngis* were identified in clinically ill cats (Hartman et al., 2010).

Clinical Findings

Mycoplasma spp. infection should be considered a potential differential diagnosis for cats presented for evaluation of conjunctivitis, keratitis, sneezing and mucopurulent nasal discharge, coughing, dyspnea, fever, lameness with or without swollen painful joints, subcutaneous abscessation, or abortion. *Mycoplasma* spp. or *Ureaplasma* spp. infections were not associated with lower urinary tract disease of cats in one study (Abou et al., 2006). *Mycoplasma* spp. or *Ureaplasma* spp. infection should be considered a potential differential diagnosis for dogs presented for evaluation of coughing, dyspnea, fever, pollakiuria, hematuria, azotemia, lameness with or without swollen painful joints, mucopurulent vaginal discharge, or infertility. *Mycoplasma* spp. and *Ureaplasma* spp. are generally not recognized cytologically and usually do not grow on aerobic media; infection should be suspected in animals with neutrophilic inflammation without visible bacteria or negative aerobic culture. The index of suspicion for *Mycoplasma* spp. or *Ureaplasma* spp. infection is higher if the animal has neutrophilic inflammation and has been poorly responsive to cell wall–inhibiting antibiotics such as penicillins or cephalosporins.

Diagnosis

The clinicopathologic and imaging findings associated with *Mycoplasma* spp. or *Ureaplasma* spp. infections are similar to those induced by other bacterial infections. Neutrophilia and monocytosis are common in dogs with pneumonia; pyuria and proteinuria occur in dogs with urinary tract disease.

Preputial discharges, vaginal discharges, chronic draining wounds, airway washings, and synovial fluid from animals with *Mycoplasma* spp. or *Ureaplasma* spp. infections have nondegenerate neutrophils as the most common cell type. Dogs with lower respiratory tract disease and pure *Mycoplasma* cultures have alveolar lung patterns that cannot be differentiated from those in dogs with mixed bacterial and *Mycoplasma* cultures. In some dogs and cats with small airway disease evident radiographically, *Mycoplasma* spp. are isolated from the airways in pure culture (Chandler et al., 2002). Joint radiographs of animals with *Mycoplasma*-associated polyarthritis reveal erosive or nonerosive changes (Zeugswetter, 2007).

Specimens for *Mycoplasma* spp. or *Ureaplasma* spp. culture should be plated immediately or transported to the laboratory in Hayflicks broth medium, Amies medium with charcoal, or modified Stuart bacterial transport medium. Specimens should be shipped on ice packs if the transport time is expected to be less than 24 hours and on dry ice if

the transport time is expected to be longer than 24 hours. Most *Mycoplasma* spp. require special media, but in one report *M. canis* grew on regular blood agar plates (L'Abee-Lund et al., 2003). Because the organisms are part of the normal flora, culture of the mucous membranes of healthy animals is never indicated.

Because *Mycoplasma* spp. or *Ureaplasma* spp. can be cultured from healthy animals, interpretation of positive culture results in sick animals is difficult. Most laboratories do not report results of antibiotic susceptibility testing. The disease association is strong if *Mycoplasma* spp. or *Ureaplasma* spp. are isolated in pure culture from tissues from which isolation is unusual (lower airway, uterus, joints). Response to treatment with drugs with known activity against *Mycoplasma* spp. or *Ureaplasma* spp. may help support the diagnosis of disease induced by these agents.

PCR assays are now available for amplification of mycoplasmal DNA (Johnson et al., 2004; Chalker et al., 2004; Low et al., 2007; Zirofsky et al., 2018) in multiple diagnostic laboratories, but they have the same diagnostic limitations as cultures as positive results do not correlate to the presence of disease or response to therapy. Some laboratories use *M. felis* or *M. cynos* specific primers in the PCR assays, which will result in failure to detect other potentially pathogenic species.

Treatment

Tylosin, erythromycin, clindamycin, lincomycin, tetracyclines, chloramphenicol, aminoglycosides, and fluoroquinolones are effective for treatment of *Mycoplasma* spp. or *Ureaplasma* spp. infections (see Chapter 92). Doxycycline administered orally at 10 mg/kg q24h or at 5 mg/kg q12h is generally effective in animals with a competent immune system or without life-threatening disease (Lappin et al., 2017). In animals with mixed infections with gram-negative organisms, life-threatening disease, or suspected tetracycline-resistant strains, fluoroquinolones or azithromycin are good alternate antibiotic choices. One cat with a non-healing bite wound was positive for *M. equigenitalium* or *M. elephantis* DNA and ultimately responded to enrofloxacin and clindamycin (Torres-Henderson et al., 2014). In one study of shelter cats with suspected bacterial upper respiratory infections, the new veterinary fluoroquinolone, pradofloxacin, gave numerically higher response rates than amoxicillin (Spindel et al., 2008). Treatment for 4 to 6 weeks is usually required for lower airway, subcutaneous, or joint infections.

Zoonotic Aspects and Prevention

Although risk of zoonotic transfer is likely minimal, bite wound transmission of *Mycoplasma* spp. from an infected cat to the hand of a human being has been reported (McCabe et al., 1987). Most *Mycoplasma* spp. or *Ureaplasma* spp. infections in dogs and cats are opportunistic and associated with other causes of inflammation; thus they are not likely to be directly contagious from animal to animal unless a pathogenic strain exists. *Mycoplasma* spp. appear to have been associated with respiratory tract disease in dogs and cats as primary pathogens and may be spread from animal to animal, as with *M. pneumoniae* in human beings. Animals with conjunctivitis or respiratory tract disease should be isolated from other animals until clinical signs of disease have resolved (see Chapter 93). *Mycoplasma* spp. and *Ureaplasma* spp. are susceptible to routine disinfectants and rapidly die outside the host.

CHAPTER 95

Polysystemic Rickettsial Diseases

The most common rickettsial agents causing illness in dogs and cats are in the families Anaplasmataceae (*Anaplasma* spp., *Ehrlichia* spp., and *Neorickettsia* spp.) and Rickettsiaceae (*Rickettsia* spp.) The organisms in the *Anaplasma, Ehrlichia,* and *Neorickettsia* genera are classified genetically and by cell tropism (monocytotropic, granulocytotropic, or thrombocytotropic). The organisms of most importance to dogs and cats in the United States discussed in this chapter include *A. phagocytophilum, A. platys, E. canis, E. chaffeensis, E. ewingii, N. risticii, R. felis*, and *R. rickettsii* (Table 95.1). Prevalence rates in many countries have been determined for most agents; world maps are maintained by the Companion Vector Borne Disease group sponsored by Bayer Animal Health (http://www.cvbd.org/en/occurrence-maps/world-map/). Maps showing prevalence rates for some of the agents in the United States are published by the Companion Animal Parasite Council (www.capcvet.org). It is common for dogs and cats to be exposed to more than one vector-borne agent (Yancey et al., 2014).

CANINE GRANULOCYTOTROPIC ANAPLASMOSIS

Etiology and Epidemiology

Anaplasma phagocytophilum (previously known as *E. equi*, *E. phagocytophila*, canine granulocytic *Ehrlichia*, and human granulocytic ehrlichiosis agent) is known to infect a variety of animals, including small mammals, mountain lions, coyotes, sheep, cattle, deer, dogs, horses, and human beings. Small mammals and deer are natural reservoirs. The distribution of *A. phagocytophilum* is defined by the range of *Ixodes* ticks and in the United States is most common in California, Wisconsin, Minnesota, and the Northeastern states. This agent is common in some other areas of the world including parts of Europe, Asia, and Africa. In one study of more than 4 million canine sera tested for antibodies against *A. phagocytophilum* spp., the Northeast and upper Midwest states were most likely to have positive dogs (McMahan et al., 2016). *Borrelia burgdorferi* is also transmitted by *Ixodes* ticks, so co-infections can occur. The vector must be attached for approximately 24 to 48 hours to transmit the agent. Clinical signs usually develop approximately 1 to 2 weeks after infection. Neutrophils (and rarely other leukocytes) phagocytize the organism, and once intracellular, *A. phagocytophilum* prevents phagolysosome fusion. This mechanism allows multiplication within the phagosome, which gives the appearance of morula in neutrophils under light microscopy (Fig. 95.1). The exact pathogenesis of disease is still undetermined, and why some dogs but not others develop clinical signs of disease is unclear. However, the disease-inducing potential could be related in part to strain differences (De Arcangeli et al., 2018; Rejmanek et al., 2012).

Clinical Features

Although experimentally inoculated dogs can be PCR-positive for *A. phagocytophilum* DNA for weeks after exposure to infected *Ixodes* spp., clinical disease syndromes appear to occur primarily during the acute phase of infection. Infection has been associated most commonly with nonspecific signs of fever, lethargy, and inappetence. Stiffness and lameness consistent with musculoskeletal pain are also common, and *A. phagocytophilum* has been associated with polyarthritis (Fig. 95.2). Vomiting, diarrhea, difficult breathing, cough, lymphadenopathy, hepatosplenomegaly, and central nervous system (CNS) signs (seizures and ataxia) have also been reported. Dogs can be chronic subclinical carriers, so exacerbation of disease could occur in some dogs. However, chronic disease syndromes such as those associated with *E. canis* infection are not well documented. In a recent study of dogs with neurologic diseases in Sweden, serologic evidence of exposure to *A. phagocytophilum* and *B. burgdorferi* was common, but neither organism was linked to the presence of neurologic disease (Jaderlund et al., 2007). In one study of valvular endocarditis, all dogs with *Bartonella* spp.–associated disease were also seropositive for *A. phagocytophilum* (MacDonald et al., 2004). Whether the co-infection potentiated the *Bartonella*-associated disease is unknown. Epistaxis, which occurs with *E. canis*, *R. rickettsii*, and *Bartonella* spp. infections in some dogs, has also been reported.

TABLE 95.1

***Ehrlichia* spp., *Anaplasma* spp., and *Rickettsia* spp. of Primary Significance to Dogs or Cats**

GENUS AND SPECIES	SMALL ANIMAL HOST	CELL TROPISM	PRIMARY VECTOR	PRIMARY CLINICAL SYNDROMES
Anaplasma phagocytophilum	Dog and cat	Granulocytotropic	*Ixodes* spp.	Fever, polyarthritis
Anaplasma platys	Dog and cat	Thrombocytotropic	*Rhipicephalus sanguineus*	Fever, thrombocytopenia, uveitis
Ehrlichia canis	Dog and cat	Monocytotropic	*Rhipicephalus sanguineus; Dermacentor variabilis*	Fever and diverse manifestations
Ehrlichia chaffeensis	Dog and cat	Monocytotropic	*Amblyomma americanum, Dermacentor variabilis*	Subclinical; unclear in natural infections
Ehrlichia ewingii	Dog and cat	Granulocytotropic	*Amblyomma americanum*	Polyarthritis, fever, meningitis
Rickettsia rickettsii	Dog and cat		*Dermacentor* spp., *Amblyomma americanum, Rhipicephalus sanguineus*	Fever and diverse manifestations

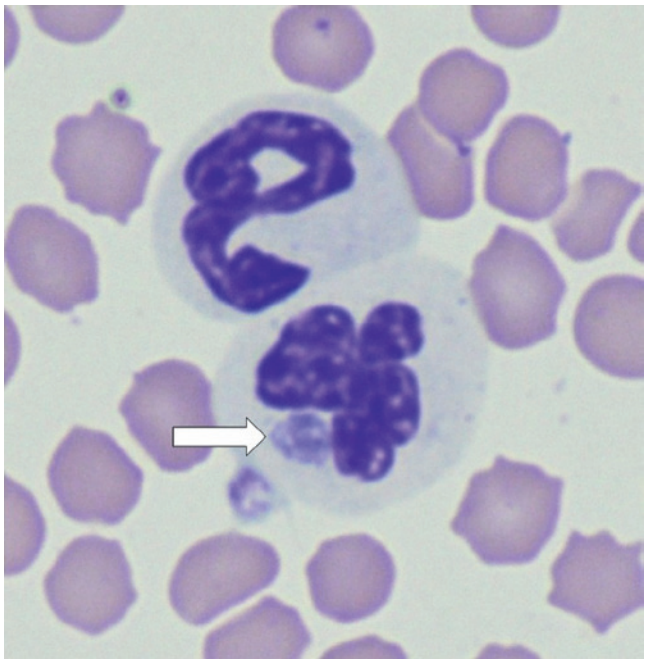

FIG 95.1
Anaplasma phagocytophilum morulae in a neutrophil of an experimentally infected cat.

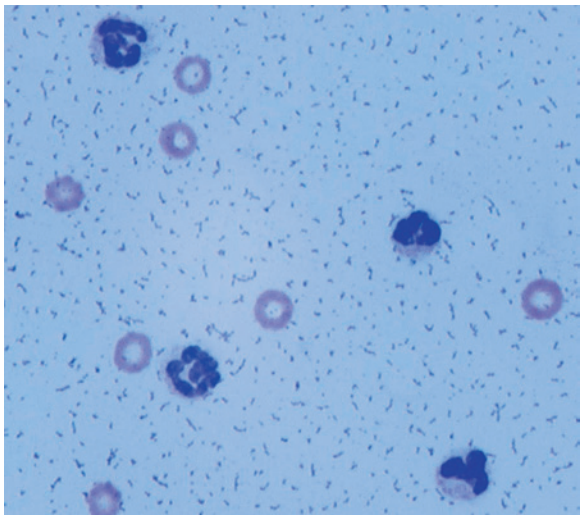

FIG 95.2
Suppurative changes consistent with polyarthritis induced by *Ehrlichia canis, E. ewingii,* or *Anaplasma phagocytophilum* infection in dogs.

Diagnosis

Morula of *A. phagocytophilum* can be detected in neutrophils of some clinically affected dogs, so infection can be strongly suspected after performance of a complete blood count (CBC) or evaluation of synovial fluid from a joint tap (see Fig. 95.2). Other CBC abnormalities recognized in some dogs include thrombocytopenia, hemolytic anemia (rarely), leukopenia, eosinopenia, lymphocytosis, and monocytosis. Reported biochemical panel and urinalysis abnormalities are mild and nonspecific. The morulae cannot be distinguished from those of *E. ewingii,* but the geographic range of the infections varies between the organisms; the travel history can help rank the differentials (see the Canine granulocytic ehrlichiosis section in this chapter).

There are multiple serum antibody tests around the world. The most common point-of-care assay that detects antibodies against *A. phagocytophilum* (SNAP 4Dx Plus, IDEXX, Westbrook, ME) also detects antibodies against *A. platys*. Many other service laboratories offer *A. phagocytophilum* antibody testing (Moroff et al., 2014). Antibody assay results can be falsely negative in acute cases, so a convalescent test 2 to 3 weeks later may be required to confirm exposure. If

an assay is being used that detects antibodies against both *A. phagocytophilum* and *A. platys*, antibodies that are detected in a dog in a region that is not endemic for *Ixodes* spp. are likely against *A. platys*. Polymerase chain reaction (PCR) assays performed on blood collected in ethylenediamine tetraacetic acid (EDTA) can be used to confirm infection and can be used to differentiate *A. phagocytophilum* infection from other infections. In one study of 19 dogs infected by *A. phagocytophilum* after infestation by wild-caught *I. scapularis*, PCR results were positive before detection of antibodies in any of the three antibody assays tested (Moroff et al., 2014).

Most dogs infected by *A. phagocytophilum* have subclinical infections and do not need to be treated. Most dogs with granulocytic anaplasmosis only have an acute phase, exposure rates in endemic areas are high, and the disease syndromes associated with infection have multiple other causes. Thus antibody test results and PCR assay results alone cannot be used to prove clinical disease associated with *A. phagocytophilum* infection. For example, although *A. phagocytophilum* is known to cause thrombocytopenia and polyarthritis in some dogs, one study failed to show an association between *A. phagocytophilum* PCR assay or serologic test results in dogs with polyarthritis or thrombocytopenia (Foley et al., 2007). Veterinarians should recognize that a clinically ill dog positive for *A. phagocytophilum* antibodies or DNA but is not responding to appropriate therapy could have another cause of the clinical syndrome, and the diagnostic workup should be continued.

Treatment

Doxycycline administered at 5 mg/kg orally (PO), q12h or at 10 mg/kg PO q24h for at least 10 days is recommended by most clinicians for the treatment of canine granulocytotropic anaplasmosis. Most dogs respond to therapy within hours to days of initiating therapy. In one group of experimentally infected dogs, administration of doxycycline did not result in decreasing antibody levels and so following antibody titers as an indication of response to therapy is likely not of clinical benefit (Chandrashekar et al., 2017). After 28 days of doxycycline administration, there was no evidence of persistent infection in one study (Yancey et al., 2018).

Zoonotic Aspects and Prevention

Anaplasma phagocytophilum infects people and dogs, and so is zoonotic. Human infections are most likely acquired by direct tick transmission, but handling infected blood and carcasses can also lead to infection. Care should also be taken when handling ticks. Infection can be avoided by tick control or prophylactic use of tetracyclines when visiting endemic areas. In at least two studies, use of acaricides prevented transmission of *A. phagocytophilum* to dogs (Honsberger et al., 2016). Dogs appear to be susceptible to reinfection, so tick control should be maintained at all times in endemic areas. Dogs used for blood donors that reside in endemic areas should be screened for *A. phagocytophilum* infections by serology and PCR assay; the American College of Veterinary Internal Medicine (ACVIM) optimally recommends using only dogs that are negative in both tests (Wardrop et al., 2016). However, if PCR assay cannot be performed, the minimal standard recommended was to use only seronegative dogs as donors.

FELINE GRANULOCYTOTROPIC ANAPLASMOSIS

Etiology and Epidemiology

As in dogs, *A. phagocytophilum* is transmitted by *Ixodes* ticks, so infections of cats are likely to be most common in these areas. Cats can be infected by *A. phagocytophilum* infection after being infested with wild-caught *I. scapularis* from Rhode Island (Lappin et al., 2015). Although rodents are commonly infected with *A. phagocytophilum,* whether ingestion or direct contact with rodents plays a role in *A. phagocytophilum* infection of cats is currently unknown. DNA of *A. phagocytophilum* can be amplified from ticks collected from cats (Duplan et al., 2018) and has been amplified from blood in naturally exposed cats with or without clinical illness in multiple countries (Adaszek et al., 2013; Bjoersdorff et al., 1999; Galemore et al., 2018; Hegarty et al., 2015; Lappin et al., 2004; Savidge et al., 2016). Cats living in endemic areas are commonly seropositive (Galemore et al., 2018; Hoyt et al., 2018). Although the pathogenesis of disease associated with *A. phagocytophilum* in cats is unknown, it is likely similar to that for dogs and human beings.

Clinical Features

Fever, anorexia, and lethargy are the most common clinical abnormalities in cats with granulocytic anaplasmosis. Ticks may or may not currently infest infected cats. Overall, clinical signs associated with *A. phagocytophilum* infection in cats are mild and resolve quickly after initiating doxycycline or minocycline therapy. Subclinical infections are the most common manifestation, like in dogs. In one study of feral cats in Massachusetts, there was no association being positive for *A. phagocytophilum* infection and anemia or thrombocytopenia in cats (Galemore et al., 2018).

Diagnosis

Approximately 50% of cats with proven clinical infections induced by *A. phagocytophilum* have a mild thrombocytopenia (66,000-118,000/μL). Neutrophilia with a left shift, lymphocytosis, lymphopenia, and hyperglobulinemia have been detected in some cats. Morulae (see Fig. 95.1) can be detected in experimentally and naturally exposed cats (Lappin et al., 2015; Savidge et al., 2016). Clinical abnormalities resolve quickly after doxycycline treatment is initiated. Biochemical and urinalysis abnormalities are uncommon. Some commercial laboratories offer serologic testing. Infected cats are negative for antibodies against *E. canis,* so *A. phagocytophilum* IFA slides should be used. Approximately 30% of cats with proven clinical infections induced by *A. phagocytophilum* are

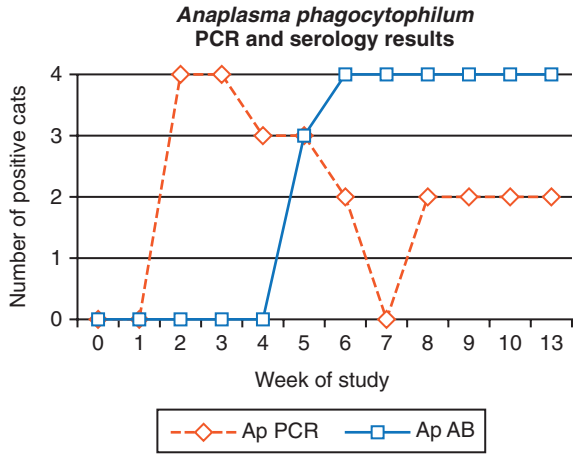

FIG 95.3
Serologic and polymerase chain reaction assay test results over time in cats infected with *Anaplasma phagocytophilum* by exposure to wild-caught *Ixodes scapularis* ticks. The four cats were exposed to wild-caught Ixodes scapularis ticks on Day 0 of the study. *AB,* Antibodies detected by the SNAP 4DX; *Ap, A. phagocytophilum; PCR,* polymerase chain reaction.

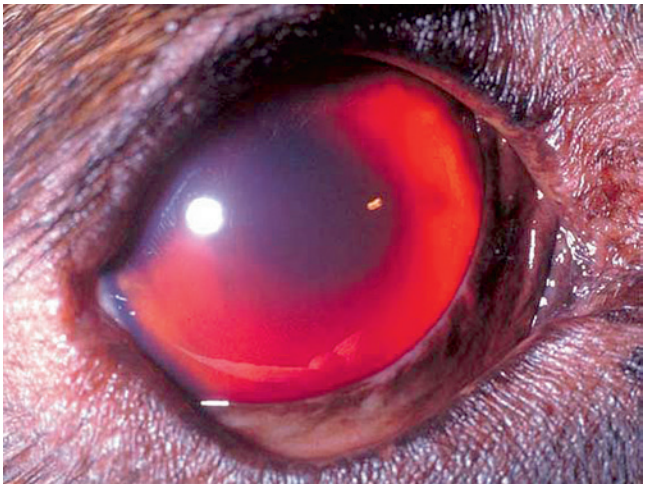

FIG 95.4
Bilateral anterior uveitis in a dog consistent with *E. canis*–associated inflammation. (Courtesy Dr. Cynthia Powell, Colorado State University.)

seronegative when first assessed serologically, but all proven cases to date have ultimately seroconverted. *Anaplasma phagocytophilum* DNA can be amplified from blood before development of detectable serum antibodies, so a single negative antibody result in an acutely infected cat does not exclude infection. Therefore cats with suspected anaplasmosis may need convalescent serum samples to prove infection. Alternately, antibody testing could be combined with PCR testing of whole blood in acute cases (Lappin et al., 2015). In a recent study of cats ($n = 4$) exposed to wild-caught *Ixodes scapularis* ticks from Rhode Island, all cats developed antibodies that were detectable in a commercially available kit labeled for use with canine serum (SNAP 4DX, IDEXX) and became PCR-positive (Lappin et al., 2015). However, none of the cats developed measurable clinical signs of disease or complete blood cell abnormalities (Fig. 95.3).

Treatment

Supportive care should be administered as needed. Several antibiotics have been administered to naturally infected cats, but most cats became clinically normal within 24 to 48 hours after initiation of tetracycline or doxycycline administration and recurrence was not reported (Adaszek et al., 2013; Bjoersdorff et al., 1999; Lappin et al., 2004; Savidge et al., 2016). Although clinically normal, two cats were still PCR-positive 17 days and 90 days after treatment (of 21-30 days' duration), respectively, which suggests that treatment with tetracyclines for 21 to 30 days may be inadequate for eliminating the organism from the body (Lappin et al., 2004).

Zoonotic Aspects and Prevention

See the section on canine granulocytic anaplasmosis for a discussion of zoonotic aspects. To prevent *A. phagocytophilum* infection in cats, acaricidal products approved for use on cats should be used. As for dogs, cats used for blood donors that reside in endemic areas should be screened for *A. phagocytophilum* infections by serology and PCR assay; the ACVIM optimally recommends using only cats that are negative in both tests (Wardrop et al., 2016). However, if PCR assay cannot be performed, the minimal standard recommended was to use only seronegative cats as donors.

CANINE THROMBOCYTOTROPIC ANAPLASMOSIS

Etiology and Epidemiology

Anaplasma platys forms morulae in circulating platelets, and this syndrome has been referred to as *canine infectious cyclic thrombocytopenia.* Infected dogs have been detected primarily in the south and southeastern United States, Australia, Africa, Caribbean Islands, the Middle East, South America, and parts of Europe. Inclusions morphologically similar to *A. platys* have been detected in one cat in Brazil, and other cats have been positive for *A. platys* DNA in blood (Hegarty et al., 2015; Lima et al., 2010; Qurollo et al., 2014; Zobba et al., 2015). However, whether this agent is associated with significant disease in cats is unknown. *Anaplasma platys* DNA has been amplified from ticks, particularly *Rhipicephalus* spp. (Foongladda et al., 2011; Geurden et al., 2018), and trans-stadial transmission has been documented in this tick (Aktas and Ozubek, 2018). High co-infection rates with *E. canis* also support the hypothesis that *Rhipicephalus* spp. ticks are the vectors of *A. platys* (Yabsley et al., 2008).

After intravenous inoculation, the incubation period is 8 to 15 days. Although cyclic thrombocytopenia and parasitemia can occur at 10- to 14-day intervals, organism numbers and severity of thrombocytopenia may lessen over time.

Later in infection, thrombocytopenia can be severe, but the organism may not be recognized cytologically or by PCR with blood (Eddlestone et al., 2007). In these experimentally infected dogs, microbial DNA could be amplified from bone marrow and splenic aspirates. Anemia and thrombocytopenia in dogs experimentally infected with either *A. platys* and/or *E. canis* were more persistent in the co-infected dogs (Gaunt et al., 2010).

Clinical Features

Dogs with *A. platys* infections in the United States are usually subclinically infected or have mild fever. More severely affected dogs have exhibited fever, uveitis, and clinical evidence of bleeding, including ecchymosis, petechia, epistaxis, melena, gingival bleeding, retinal hemorrhage, and hematoma formation. Co-infection with other tick-borne agents such as *E. canis* and *Babesia* spp. is common and may reflect a shared vector. Fatalities have been reported in the Mediterranean basin, suggested that some strains are more pathogenic than others (Bouzouraa et al., 2016).

Diagnosis

Anemia, thrombocytopenia, and neutrophilic leukocytosis can occur. Morulae may or may not be present within platelets. In endemic areas *A. platys* infection, alone or in combination with other tick-borne agents, should be suspected in dogs with anemia or thrombocytopenia. Cross-reactivity with *E. canis* is thought to be minimal, but *A. platys* antibodies are detected in some serologic assays for *A. phagocytophilum*, including one commercially available kit (SNAP 4DX Plus; Chandrashekar et al., 2010). Agreement between different tests for *A. phagocytophilum* and *A. platys* antibodies are not 100% (Liu et al., 2018). Antibody assay results can be falsely negative in acute cases, so a convalescent test 2 to 3 weeks later may be required to confirm exposure. PCR assays performed on blood collected in EDTA can be used to confirm infection and differentiate *A. platys* infections from other infections, and microbial DNA can also be amplified from healthy dogs and can be negative in clinically ill dogs (Eddlestone et al., 2007). Most dogs infected by *A. platys* have subclinical infections, most infected dogs only have an acute phase, exposure rates in endemic areas are high, and the disease syndromes associated with infection have multiple other causes. Thus antibody test results and PCR assay results alone cannot be used to prove clinical disease associated with *A. platys* infection.

Treatment

The doxycycline and tetracycline treatment protocols discussed for *A. phagocytophilum* infections of dogs should also be effective for *A. platys* infections. If co-infection with *E. canis* exists, treatment duration should be at least 4 weeks (Neer et al., 2002). In one study of dogs that were experimentally inoculated, PCR-positive test results for *A. platys* or *E. canis* remained negative after doxycycline administration in spite of attempted immune suppression (Gaunt et al., 2010).

Zoonotic Aspects and Prevention

The strategies discussed for control of *A. phagocytophilum* infection of dogs should also be effective for *A. platys*. *Anaplasma platys* DNA has been amplified from the blood of human beings, so tick control should always be maintained (Breitschwerdt et al., 2014)

CANINE MONOCYTOTROPIC EHRLICHIOSIS

Etiology and Epidemiology

Organisms that are associated with monocytotropic ehrlichiosis in naturally infected dogs include *E. canis, E. chaffeensis,* and *Neorickettsia risticii* var *atypicalis*. Cases with *E. canis* and *E. chaffeensis* are detected most frequently and will be discussed herein. An individual dog can be infected by more than one ehrlichial agent, and co-infection with other tick-borne pathogens is common.

Ehrlichia canis is the most common of these agents and causes the most severe clinical disease; it is maintained in the environment from passage from ticks to dogs. *Rhipicephalus sanguineus* and *Dermacentor variabilis* are the known vectors. The organism is not passed transovarially in the tick, so unexposed ticks must feed on a rickettsemic dog in the acute phase to become infected and perpetuate the disease (Ipek et al., 2018). Dogs seropositive for *E. canis* have been identified in most regions of the world and most of the United States, but the majority of cases occur in areas with high concentrations of *R. sanguineus,* such as the Southwest and Gulf Coast. There are different genogroups within *E. canis,* which may partially explain differences in pathogenicity (Nambooppha et al., 2018).

Ehrlichia chaffeensis is a cause of human mononuclear ehrlichiosis. White-tailed deer, voles, coyotes, and opossums are reservoirs, and *Amblyomma americanum, D. variabilis,* and some *Ixodes* ticks are vectors. Infections by *E. chaffeensis* are detected primarily in the southeastern United States. Clinical manifestations in dogs are currently being detailed (Breitschwerdt et al., 1998; Zhang et al., 2003) and appear to be rare. In experimentally infected dogs, fever is common (Nair et al., 2016). In one study of dogs infected by natural exposure to ticks in Oklahoma, clinical abnormalities were not detected in the dogs that became positive for *E. chaffeensis* (Starkey et al., 2014). In two large serological surveys of 8662 and 6582 dog serum samples in North America and the Caribbean, antibody prevalence rates for *E. canis* and *E. chaffeensis* were approximately 1% and 3%, respectively (Beall et al., 2012; Qurollo et al., 2014). As little is known about clinical disease associated with *E. chaffeensis*, the following discussion focuses on *E. canis*.

Ehrlichia canis infection causes acute, subclinical, and chronic phases of disease. Infected mononuclear cells marginate in small vessels or migrate into endothelial tissues, inducing vasculitis during the acute phase. The acute phase begins 1 to 3 weeks after infection and lasts 2 to 4 weeks; most immunocompetent dogs survive. The subclinical phase

lasts months to years in naturally infected dogs. Although some dogs clear the organism during the subclinical phase, the organism persists intracellularly in some, leading to the chronic phase of infection. Many of the clinical and clinicopathologic abnormalities that develop during the chronic phase are from immune reactions against the intracellular organism. The variable duration of the subclinical phase of disease explains why *E. canis* infection does not have a distinct seasonal incidence as does Rocky Mountain spotted fever (RMSF). However, acute-phase disease is recognized most frequently in the spring and summer when the vectors are most active. The pathogenesis of acute and chronic ehrlichiosis is complex and composed of both agent and host effects.

Clinical Features

Clinical disease from ehrlichial infection can occur in any dog, but its severity varies depending on the organism, host factors, and presence of co-infections like *A. platys* and *Bartonella* spp. Virulence is thought to vary with different field strains of *E. canis*. Dogs with depressed cell-mediated immunity develop severe disease. However, *E. canis* itself did not cause immunosuppression in young, experimentally infected dogs within the first several months of infection (Hess et al., 2006).

Clinical findings in dogs with *E. canis* infections vary with the timing of infection (Table 95.2). The clinical manifestations of acute-phase disease are quite similar to those of RMSF as a result of the development of vasculitis. Ticks are most commonly found on dogs during the acute phase of infection. Fever can occur in both clinical phases of infection but is more common in dogs with acute ehrlichiosis. Petechiae or other evidence of bleeding noted during the acute phase is generally caused by a combination of mild thrombocytopenia (consumption or immune-mediated destruction) and vasculitis; thrombocytopenia (consumption, immune-mediated destruction, sequestration, decreased production), vasculitis, and platelet function abnormalities (Brandao et al., 2006) occur in the chronic phase. The thrombocytopenia in the acute phase is generally not severe enough to result in spontaneous bleeding, so bleeding may be primarily from vasculitis and decreased platelet function. Some dogs with *E. canis* infection induced experimentally show activated platelets, which may lessen the tendency to bleed in some dogs (Shropshire et al., 2018).

Pale mucous membranes usually only occur in the chronic phase during the development of pancytopenia. Hepatomegaly, splenomegaly, and lymphadenopathy are from chronic immune stimulation (i.e., lymphoreticular hyperplasia) and are detected most frequently in dogs in the chronic phase. Interstitial or alveolar edema secondary to vasculitis or inflammation, pulmonary parenchymal hemorrhage secondary to vasculitis or thrombocytopenia, or secondary infections from neutropenia are mechanisms resulting in dyspnea or cough in some dogs with ehrlichiosis. Pulmonary hypertension may occur in some dogs with chronic disease (Locatelli et al., 2012). Polyuria, polydipsia, and proteinuria are reported in some dogs that develop renal insufficiency.

TABLE 95.2

Clinical Abnormalities Associated With *Ehrlichia canis* Infection in Dogs

STAGE OF INFECTION	ABNORMALITIES
Acute	Fever Serous or purulent oculonasal discharge Anorexia Weight loss Dyspnea Lymphadenopathy Tick infestation often evident
Subclinical	No clinical abnormalities Ticks often not present
Chronic	Ticks often not present Depression Weight loss Pale mucous membranes Abdominal pain Evidence of hemorrhage: epistaxis, retinal hemorrhage, etc. Lymphadenopathy Splenomegaly Dyspnea, increased lung sounds, interstitial or alveolar lung infiltrates Ocular: perivascular retinitis, hyphema, retinal detachments, anterior uveitis, corneal edema Central nervous system: meningeal pain, paresis, cranial nerve deficits, seizures Hepatomegaly Arrhythmias and pulse deficits Polyuria and polydipsia Stiffness and swollen, painful joints

Stiffness, exercise intolerance, and swollen, painful joints occur in some dogs with suppurative polyarthritis (see Fig. 95.2). Most dogs with polyarthritis from which the organism has been demonstrated have been infected with *E. ewingii* or *A. phagocytophilum*. Ophthalmic manifestations of disease are common; tortuous retinal vessels, perivascular retinal infiltrates, retinal hemorrhage, anterior uveitis (see Fig. 95.4), and exudative retinal detachment occur (Komnenou et al., 2007). CNS signs can include depression, pain, ataxia, paresis, nystagmus, and seizures.

Diagnosis

Clinicopathologic and radiographic abnormalities consistent with *E. canis* infection are summarized in Table 95.3. Neutropenia may occur during acute-phase vasculitis and after bone marrow suppression in the chronic phase. Chronic immune stimulation causes monocytosis and lymphocytosis; lymphocytes often have cytoplasmic azurophilic

TABLE 95.3

Clinicopathologic Abnormalities Associated With *Ehrlichia canis* Infection in Dogs

STAGE OF INFECTION	ABNORMALITIES
Acute	Thrombocytopenia Leukopenia followed by neutrophilic leukocytosis and monocytosis Morulae Low-grade, nonregenerative anemia unless hemorrhage has occurred Variable *Ehrlichia* titer PCR-positive
Subclinical	Hyperglobulinemia Thrombocytopenia Neutropenia Lymphocytosis Monocytosis Positive *Ehrlichia* titer PCR-positive
Chronic	Monocytosis Lymphocytosis Thrombocytopenia Nonregenerative anemia Hyperglobulinemia Hypocellular bone marrow Bone marrow/spleen plasmacytosis Hypoalbuminemia Proteinuria Polyclonal or immunoglobulin G monoclonal gammopathy Cerebrospinal fluid mononuclear cell pleocytosis Nonseptic, suppurative polyarthritis Rare azotemia Increased alanine aminotransferase and alkaline phosphatase activities Positive *Ehrlichia* titer Variable PCR positive

PCR, Polymerase chain reaction.

granules (i.e., large granular lymphocytes). *Ehrlichia canis* infection results in changes in lymphocyte subsets in dogs, sometimes mimicking chronic lymphocytic leukemia (i.e., clonal proliferation); further data are needed to determine the clinical significance of these findings (Villaescusa et al., 2012). Regenerative anemia is from blood loss (acute and chronic phases); normocytic, normochromic nonregenerative anemia is from bone marrow suppression or anemia of chronic disease (chronic phase). Thrombocytopenia can occur with either acute or chronic ehrlichiosis but is generally more severe in the chronic phase disease. Thrombocytopathies from hyperglobulinemia potentiate bleeding in some dogs with chronic ehrlichiosis. Chronic ehrlichiosis is classically associated with pancytopenia, but any combination

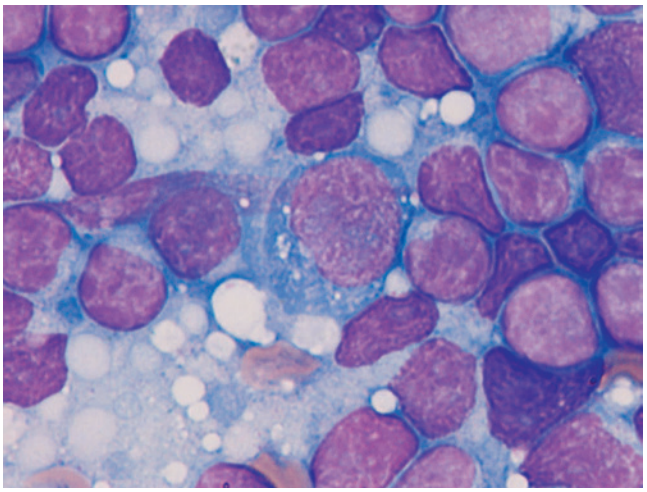

FIG 95.5
Lymph node cytology from a dog with chronic *Ehrlichia canis* infection.

of neutropenia, thrombocytopenia, and anemia can occur. Changes in bone marrow cell lines associated with ehrlichiosis vary from hypercellular (acute phase) to hypocellular (chronic phase). Bone marrow plasmacytosis is common in dogs with subclinical and chronic ehrlichiosis, and the disease can be confused with multiple myeloma, particularly in dogs with monoclonal gammopathies. However, dogs with ehrlichiosis are typically normocalcemic and do not have lytic bone lesions.

Hypoalbuminemia in the acute phase is probably caused by third spacing of albumin in tissues because of vasculitis or due to the acute phase response (i.e., albumin is a negative acute phase protein [APP]), whereas in the chronic-phase disease it is caused by glomerular loss from immune complex deposition or chronic immunostimulation (i.e., monoclonal or polyclonal gammopathy). Prerenal azotemia can occur with acute or chronic disease; renal azotemia develops in some dogs with severe glomerulonephritis from chronic ehrlichiosis. The combination of hyperglobulinemia and hypoalbuminemia is consistent with subclinical or chronic ehrlichiosis. Polyclonal gammopathies are most common, but monoclonal (e.g., immunoglobulin G) gammopathies can also occur. Serum cardiac troponin I concentration is increased in dogs with ehrlichiosis compared with healthy controls, but concentrations did not correlate to clinical outcome (Koutinas et al., 2012). The positive APP C-reactive protein (CRP), serum amyloid A (SAA), and haptoglobin (Hp) and the negative APP albumin concentrations were measured in 27 dogs with nonmyelosuppressive chronic monocytropic ehrlichiosis, 29 dogs with myelosuppressive chronic monocytropic ehrlichiosis, and 7 healthy dogs. The APP levels correlated to type of clinical syndrome but not to clinical outcome (Mylonakis et al., 2011a).

Aspirates of enlarged lymph nodes and spleen reveal reactive lymphoreticular and plasma cell hyperplasia (Fig. 95.5). In one study, plasma cells were more commonly detected in

lymph nodes of dogs with chronic monocytotropic ehrlichiosis than other causes of lymphadenopathy (Mylonakis et al., 2011b). Polyarthritis due to *E. canis* was not detected in one experimental study (Theodorou et al., 2015). If nondegenerate neutrophils are detected in synovial fluid from dogs with polyarthritis, *E. ewingii* and *A. phagocytophilum* may be the more likely causes. Bone marrow aspirates in dogs with chronic ehrlichiosis typically reveal myeloid, erythroid, and megakaryocytic hypoplasia in association with lymphoid and plasma cell hyperplasia. However, myelofibrosis was not detected in one study of 10 affected dogs (Mylonakis et al., 2010). Morulae from *E. canis* are rarely detected in the cytoplasm of mononuclear cells. Ehrlichiosis generally causes mononuclear pleocytosis and increased protein concentrations in cerebrospinal fluid. Antiplatelet antibodies, antinuclear antibodies, antierythrocyte antibodies (by direct Coombs test), and rheumatoid factors are detected in some dogs with ehrlichiosis, leading to an inappropriate diagnosis of primary immune-mediated disease (Smith et al., 2004).

No pathognomonic radiographic signs appear in dogs with ehrlichiosis. The polyarthritis is nonerosive, and dogs with respiratory signs most commonly have increased pulmonary interstitial markings, but alveolar patterns can occur.

Identification of morulae in cells documents *Ehrlichia* infection, but it is uncommon with monocytotropic strains. Examination of buffy coat smears or blood smears made from blood collected from an ear margin vessel may increase the chances of finding morulae. Some *Ehrlichia* spp. can be grown on cultured cells, but the procedure is low yield and expensive and so is not clinically useful.

Most commercial laboratories (using IFAs) and point-of-care diagnostic tests use reagents that detect antibodies against *E. canis* in serum. These tests are generally used as the first screening procedures in dogs suspected to have ehrlichiosis. If serum antibodies against *E. canis* are detected in a dog with clinical findings consistent with ehrlichiosis, a presumptive diagnosis of canine ehrlichiosis infection should be made and appropriate treatment begun. However, detection of antibodies alone is not diagnostic of ehrlichiosis because many dogs are subclinically infected. In addition, negative test results do not totally exclude ehrlichiosis from the list of differential diagnoses because clinical disease can be detected before seroconversion and not all *Ehrlichia* spp. induce antibodies that are consistently detected in all *E. canis* assays. If not stated by the company, veterinarians should contact specific test providers to determine whether the assay to be used detected antibodies against *E. canis, E. chaffeensis*, and *E. ewingii*.

PCR assays are now available commercially and can be used to detect organism-specific DNA in peripheral blood. It can be performed on joint fluid, aqueous humor, cerebrospinal fluid, and tissues. Blood PCR assay results can be positive before seroconversion in some experimentally inoculated dogs and positive results document infection, whereas positive serologic tests only document exposure (Moroff et al., 2014). Because antibiotic treatment rapidly induces negative blood PCR results, the clinician should draw the blood sample for testing and place it in an EDTA tube before treatment. In one recent study tissues (lymph nodes, spleen, liver, bone marrow, and blood) from naturally infected dogs were assayed by PCR. Blood and lymph nodes were the most likely to be positive but were falsely negative in approximately 30% of the samples (Gal et al., 2007). In one study, PCR performed on blood and splenic aspirates were equivalent for making the diagnosis of *E. canis* infection (Faria et al., 2010). Repeated testing with serology and PCR assays may be required to accurately determine the infection status of some individual dogs (Kidd et al., 2017) and is recommended in general for most vector borne diseases (Maggi et al., 2014).

Treatment

Supportive care should be provided as indicated. Several different tetracycline, doxycycline, chloramphenicol, and imidocarb diproprionate protocols have been used. The ACVIM Infectious Disease Study Group currently recommends doxycycline (10 mg/kg PO q24h for at least 28 days). Doxycycline administered at 5 mg/kg, PO, q12h has also been studied and can be effective. In one study of experimentally infected dogs, ticks still could acquire *E. canis* from feeding on dogs previously treated with doxycycline for 14 days (Schaefer et al., 2007). In an experimental study, minocycline at 10 mg/kg, PO, twice daily for 28 days had similar results to doxycycline at 10 mg/kg, PO, once daily for 28 days (Jenkins et al., 2018). Whether *E. canis* infection persists appears to vary in part on the basis of when treatment is initiated. For example, experimentally infected dogs treated during the acute or subclinical phases became PCR-negative as clinical parameters improved, but dogs treated during the chronic phase were intermittently PCR-positive after treatment (McClure et al., 2010).

Clinical signs and thrombocytopenia should rapidly resolve. If clinical abnormalities are not resolving within 7 days, other differential diagnoses should be considered. Results of studies that used imidocarb diproprionate (5-7 mg/kg intramuscular (IM) or SC repeated in 14 days) to treat canine ehrlichiosis have been variable. Some patients develop pain at the injection site, salivation, oculonasal discharge, diarrhea, tremors, and dyspnea after administration of this drug. Quinolones are not effective for the treatment of *E. canis* infections in dogs.

Positive antibody titers have been detected for up to 31 months after therapy in some naturally infected dogs. Dogs with low (<1:1024) antibody titers generally revert to negative by 1 year after therapy. Dogs with antibody titers greater than 1:1024 often maintain positive antibody titers after therapy. Whether these dogs are persistent carriers of the organism is undetermined. On the basis of these findings antibody titers are considered to be ineffective for monitoring response to therapy. Monitoring resolution of thrombocytopenia and hyperglobulinemia as markers of therapeutic elimination of the organism may be more effective.

Results of studies have been variable on whether ehrlichial infections are cleared by treatment and repeated infections

can occur. Thus whether to treat seropositive healthy dogs is controversial. Arguments for and against testing or treating healthy dogs were reviewed by the ACVIM Infectious Disease Study Group (Neer et al., 2002). The primary reason to treat a seropositive healthy dog is to try to eliminate infection before development of chronic-phase disease. However, treatment of healthy dogs is controversial for at least six reasons: (1) whether treatment halts progression to the chronic phase is unknown; (2) not all seropositive dogs are infected; (3) not all seropositive dogs progress to the chronic phase; (4) whether treatment eliminates infection is unknown; (5) even if infection is eliminated, reinfection can occur; and (6) treatment of healthy carriers may result in antimicrobial resistance. Because further data are necessary to make definitive recommendations, owners should be given the pros and cons and asked to make treatment decisions.

The prognosis is good for dogs with acute ehrlichiosis, and it is variable to guarded for those with chronic ehrlichiosis. Fever, petechiae, vomiting, diarrhea, epistaxis, and thrombocytopenia often resolve within days after initiation of therapy in acute cases. Bone marrow suppression from chronic-phase ehrlichiosis may not respond for weeks to months, if at all. Anabolic steroids and other bone marrow stimulants can be administered but are unlikely to be effective because precursor cells are often lacking. Immune-mediated events resulting in the destruction of red blood cells or platelets are likely to occur with ehrlichiosis, leading to the recommendation to administer antiinflammatory or immunosuppressive doses of glucocorticoids to acutely affected animals. Prednisone (2.2 mg/kg PO divided q12h during the first 3 to 4 days after diagnosis) may be beneficial in some cases, but controlled data are lacking.

Zoonotic Aspects and Prevention

Dogs and human beings are both infected by *E. canis* and *E. chaffeensis*. Although people cannot acquire ehrlichiosis from handling an infected dog, dogs may be reservoirs for these agents and may play a role in the human disease by bringing vectors into the human environment. Ticks should be removed and handled with care. Tick control should be maintained at all times; administration of fipronil was shown to lessen transmission in one study (Davoust et al., 2003). In another study, administration of imidacloprid 10% and permethrin 50% to young dogs lessened prevalence of *E. canis* infections by 94.6% (Otranto et al., 2010). Because *E. canis* is not passed transovarially in the tick, it can be eliminated in the environment by tick control or by treating all dogs through a generation of ticks. *Ehrlichia canis* can be transmitted within 3 hours of tick attachment so use of products that repel or very quickly kill the ticks may be superior to products with a slower kill rate (Jongejan et al., 2016). *Rhipicephalus* can only transmit *E. canis* for approximately 155 days; if tick control is not feasible tetracycline can be administered (6.6 mg/kg PO daily for 200 days). During this time, infected dogs will not infect new ticks, and previously infected ticks will lose the ability to transmit the organism. Doxycycline given at 100 mg/dog/day was used successfully as a chemopreventative (Davoust et al., 2005). Dogs used for blood donors should be screened for *E. canis* infections by serology and PCR assay; the ACVIM optimally recommends using only dogs that are negative in both tests (Wardrop et al., 2016). However, if PCR assay cannot be performed, the minimal standard recommended was to use only seronegative dogs as donors.

Some countries have published guidelines to be used by veterinarians to aid in the management of ehrlichiosis and anaplasmosis (Neer et al., 2002; Sainz et al., 2015).

FELINE MONOCYTOTROPIC EHRLICHIOSIS

Etiology and Epidemiology

Ehrlichia-like bodies or morulae have been detected in peripheral lymphocytes or monocytes of naturally exposed cats in a number of countries, including the United States, Kenya, France, Brazil, and Thailand. DNA consistent with *E. canis* has been amplified from blood of naturally infected cats in multiple surveys (Aguirre et al., 2004; Braga et al., 2013; Braga et al., 2012; Breitschwerdt et al., 2002; de Oliveira et al., 2009; Hegarty et al., 2015). In Brazil, cats at high risk for *R. sanguineus* infestation had a PCR-positive rate for *E. canis* DNA of 9.4% (Braga et al., 2014). In addition, *E. chaffeensis* DNA has been amplified from the blood of naturally exposed cats in the United States (Hegarty et al., 2015). In Europe, *Ehrlichia canis* DNA has been amplified from ticks collected from some cats (Pennisi et al., 2015). In the United States, *Amblyomma americanum* removed from cats were shown to occasionally contain DNA of *E. chaffeensis* (Little et al., 2018). Cats have also been shown to have antibodies that react to specific peptides of *E. canis* and *E. chaffeensis* (Hegarty et al., 2015). These studies document that cats can be exposed to mononuclear *Ehrlichia* spp. and become infected. However, other studies of cats in endemic areas (Arizona, Florida, Louisiana) have failed to amplify *Ehrlichia* spp. DNA from the blood of cats (Eberhardt et al., 2006; Levy et al., 2011; Luria et al., 2004;). In one study of naturally exposed cats, *E. canis* DNA was amplified from the blood, but antibodies were never detected (Breitschwerdt et al., 2002). Pathogenesis of disease associated with monocytotropic ehrlichiosis in cats is unknown but is likely to be similar to that for *E. canis* infection of dogs. Guidelines for cats with *Ehrlichia* spp. infections have been published in Europe (Pennisi et al., 2017).

Clinical Features

All ages of cats have been infected; most cats were domestic short-haired, and both males and females have been affected. Anorexia, fever, inappetence, lethargy, weight loss, hyperesthesia or joint pain, pale mucous membranes, splenomegaly, dyspnea, and lymphadenopathy were the most common historic and physical examination abnormalities. Dyspnea, petechiae, retinal detachments, vitreous hemorrhages, and

pale mucous membranes were other reported physical examination abnormalities. Concurrent diseases are rarely reported but have included hemoplasmas (previously *Haemobartonella felis*), *Cryptococcus neoformans*, feline leukemia virus and feline immunodeficiency virus infections, and lymphoma.

Diagnosis

Anemia is common and usually nonregenerative. Leukopenia; leukocytosis characterized by neutrophilia, lymphocytosis, and monocytosis; and intermittent thrombocytopenia have been reported in some cats. Bone marrow evaluation of cats with cytopenias has revealed primarily hypoplasia of the affected cell line. However, one cat had bone marrow cytologic characteristics consistent with myeloid leukemia (Breitschwerdt et al., 2002). Hyperglobulinemia was reported in multiple cats; protein electrophoresis usually reveals a polyclonal gammopathy. An epidemiologic link has been made between the presence of *Ehrlichia* spp. antibodies in serum and monoclonal gammopathy (Stubbs et al., 2000). On the basis of the cases reported to date, ehrlichiosis should be considered on the list of differential diagnoses for cats with unexplained leukocytosis (primarily lymphocytosis), cytopenias, and hyperglobulinemia. Biochemical abnormalities were infrequently reported in cats with suspected monocytotropic ehrlichiosis and were nonspecific. The three cats with *E. canis*–like DNA in the blood also had antinuclear antibodies, similar to results reported for infected dogs (Breitschwerdt et al., 2002).

Some cats with suspected clinical ehrlichiosis seroreacted to *E. canis* or *N. risticii* morulae in indirect fluorescent antibody assays. Antibodies that seroreact to more than one *Ehrlichia* spp. are sometimes detected in cat sera. Some cats with *E. canis*–like DNA in blood were seronegative (Breitschwerdt et al., 2002), so suspect cases should be screened concurrently by PCR assays. Information concerning accuracy of results from commercial kits optimized for the detection of *E. canis* antibodies in canine serum when used with feline serum is not currently available. Positive serologic test results occur in both healthy and clinically ill cats, so a diagnosis of clinical ehrlichiosis should not be based on serologic test results alone. A tentative diagnosis of clinical feline ehrlichiosis can be based on the combination of positive serologic test results or PCR assay results, clinical signs of disease consistent with *Ehrlichia* infection, exclusion of other causes of the disease syndrome, and response to anti-*Ehrlichia* drugs.

Treatment

Clinical improvement after therapy with tetracycline, doxycycline, or imidocarb dipropionate was reported for most cats. However, for some cats a positive response to therapy was a criterion for the diagnosis of ehrlichiosis. As for dogs, administration of doxycycline at 5 mg/kg, PO, q12h or 10 mg/kg, PO, q24h should be effective. Doxycycline has been associated with esophageal strictures and so should be formulated into a liquid for use in cats or followed by at least 2 mL of a liquid (Bennett et al., 2010). Optimal treatment duration is unknown, but 28 days is generally recommended provided there is resolution of clinical and laboratory abnormalities. For cats with treatment failure or those intolerant of doxycycline, imidocarb diproprionate can be given safely (5 mg/kg IM or SC twice, 14 days apart). Salivation and pain at the injection site are the common adverse effects, and imidocarb efficacy is in question for the treatment of canine monocytotropic ehrlichiosis (Eddlestone et al., 2007).

Zoonotic Aspects and Prevention

Although cats and human beings can both be infected by *E. canis* and *E. chaffeensis,* direct transmission is not known to occur. Care should be taken when removing ticks, and arthropod control should be maintained at all time for cats, particularly if allowed outdoors.

CANINE GRANULOCYTOTROPIC EHRLICHIOSIS

Etiology and Epidemiology

Ehrlichia ewingii forms morulae in neutrophils and eosinophils, and has been detected in dogs and human beings that reside in the central region, as well as the Southern and Southeastern United States. In one seroprevalence study of dogs in North America and the Caribbean, positive dogs were most common in Oklahoma (14.3%) and North Carolina (10.3%) (Qurollo et al., 2014). *Ehrlichia ewingii* has been detected most commonly in *A. americanum* (Wright et al., 2014), and deer are reservoirs (Yabsley et al., 2002). In one study of dogs naturally exposed to ticks in Oklahoma, all 10 dogs became positive for *E. ewingii* DNA, but clinical abnormalities were not detected (Starkey et al., 2014). The incubation period after tick exposure is approximately 13 days. Pathogenesis of disease is unknown but is likely to be similar to other *Ehrlichia* spp. In general, clinical signs of *E. ewingii* infection are less severe than those of *E. canis*. Concurrent disease or infections may play a role in the pathogenesis of *E. ewingii* infection.

Clinical Features

Nonspecific signs of *E. ewingii* infection include fever, lethargy, anorexia, depression, and signs consistent with polyarthritis, such as stiffness. Other clinical signs include vomiting, diarrhea, and peripheral edema and neurologic signs such as ataxia, paresis, and vestibular disease. Clinical signs can be mild, self-limited, or inapparent (Goodman et al., 2003). Similar to *R. rickettsii*, acute disease seems to be most common, so *E. ewingii* infection should be highest on the list of differential diagnoses from the spring through autumn when *A. americanum* is most active.

Diagnosis

Suppurative polyarthritis is most common. Other clinicopathologic findings typically associated with acute *E. canis* infection (see Table 95.3), such as mild to moderate

thrombocytopenia and anemia, also occur. Morulae can be detected in neutrophils and eosinophils in peripheral blood and in neutrophils from synovial fluid. However, presence of morulae is transient and so easily missed cytologically. A peptide-based, *E. ewingii* serologic assay is now available (O'Connor et al., 2010; SNAP 4DX Plus, IDEXX Laboratories, Portland, ME). However, because antibodies can be detected in healthy as well as diseased dogs, presence of *E. ewingii*–specific antibodies cannot be used alone to diagnose clinical granulocytotropic ehrlichiosis. If not stated by the company, veterinarians should contact specific test providers to determine whether the assay to be used detected antibodies against *E. canis, E. chaffeensis*, and *E. ewingii*.

Some dogs with acute disease will have negative test results on presentation, so a convalescent test to shown seroconversion is required for diagnosis. PCR assays are now used to differentiate between members of the *Ehrlichia*, *Anaplasma*, and *Neorickettsia* genera, and should be performed on blood collected in EDTA before administration of antibiotics in acute cases or those negative for specific antibodies. However, healthy dogs can be positive for *E. ewingii* DNA in blood so positive test results do not prove the clinical syndrome was from the infection (Starkey et al., 2014).

Treatment

Supportive care should be provided as indicated. The tetracycline, doxycycline, and chloramphenicol protocols recommended for *E. canis* infections are generally effective. Doxycycline administered at 5 mg/kg PO q12h or at 10 mg/kg PO q24h for at least 14 days is recommended by most clinicians for the treatment of canine granulocytotropic ehrlichiosis. However, few data from the field are available that document treatment efficacy of these protocols.

Zoonotic Aspects and Prevention

Dogs and human beings are both infected by *E. canis*, *E. ewingii*, and *E. chaffeensis* (Buller et al., 1999). Although people cannot acquire ehrlichiosis from handling an infected dog, dogs may be reservoirs for these agents and may play a role in the human disease by bringing vectors into the human environment. Ticks should be removed and handled with care. The ACVIM recommended to optimally use only seronegative and PCR-negative dogs as blood donors, particularly in areas endemic for *Amblyomma americanum* (Wardrop et al., 2016). Whether to treat healthy, seropositive dogs has pros and cons similar to those for *E. canis* infections of healthy dogs but is probably not needed (see the Canine Monocytotropic Ehrlichiosis section).

ROCKY MOUNTAIN SPOTTED FEVER

Etiology and Epidemiology

In the United States, the spotted fever group (SFG) organism most likely to be associated with clinical disease in dogs is *R. rickettsii*, the cause of RMSF. Other SFG organisms like *R. parkeri* and *R. felis* are known to infect dogs, but disease associations are less apparent (see the Other Rickettsial Infections section). In one survey of ticks in Missouri, *R. amblyommatis* was the predominant SFG species, and it was detected in *Amblyomma americanum*, *Dermacentor variabilis*, and *Ixodes scapularis* (Santanello et al., 2018). Other members of the SFG that infect dogs may induce antibodies that cross react with *R. rickettsii* (see Diagnosis later), which may lessen the risk of developing RMSF (Santanello et al., 2018). Canine RMSF is recognized predominantly in the Southeastern states from April through September when the tick vectors are most active. *Dermacentor andersoni* (American wood tick), *Dermacentor variabilis* (American dog tick), and *A. americanum* (Lone Star tick) are the principal vectors, host, and reservoir of *R. rickettsii.* A reemergence of RMSF in the southwestern states has recently occurred, and *R. sanguineous* ticks are the vector (Demma et al., 2005, 2006; Nicholson et al., 2006). *Rickettsia rickettsii* has also been detected in *R. sanguineous* in California, and infection of this tick has been confirmed experimentally (Piranda et al., 2011; Wikswo et al., 2007). Strains of *R. rickettsii* that infect dogs and human beings are closely related genetically (Kidd et al., 2006). Seroprevalence rates for antibodies against SPG organisms are high in endemic areas. In one study of dogs in the southeastern United States 14.1% and 29.7% of healthy and clinically ill dogs, respectively, had antibodies that reacted to *R. rickettsii* (Solano-Gallego et al., 2004).

The organism is maintained in nature in a cycle between ticks and small mammals such as voles, ground squirrels, and chipmunks, and it is transmitted transovarially in some ticks, so nymphs and larvae can be infected without feeding. *Rickettsia rickettsii* replicates in endothelial tissues (causing vasculitis) and can lead to diverse and sometimes severe clinical manifestations of disease as soon as 2 to 3 days after exposure. Antiplatelet antibodies can be detected in many infected dogs, suggesting an immune-mediated component to the thrombocytopenia that is frequently present (Grindem et al., 1999). The course of RMSF in dogs experimentally by tick infestation was recently described (Levin et al., 2014). Although seropositive cats have been detected, whether clinical illness occurs is unclear (Bayliss et al., 2009; Case et al., 2006).

Clinical Features

Any dog not previously exposed to *R. rickettsii* can develop RMSF. The tick frequently feeds on and leaves the dog before the development of clinical signs. In one study, only 5 of 30 owners knew their dogs had been infested by ticks (Gasser et al., 2001). After infection, the majority of dogs are subclinical; some develop acute disease with a clinical course of approximately 14 days. No age or sex predilection exists.

In dogs infected with *R. rickettsii* after tick infestation, the most significant findings were fever (starting 3-7 days after infestation), lethargy, anorexia, ocular lesions, tremors, skin rash, thrombocytopenia and leukocytosis (Levin et al., 2014). In naturally occurring cases, interstitial pulmonary disease, dyspnea, and cough have been reported as well as vomiting or diarrhea. Because the disease is generally acute,

lymphadenopathy and splenomegaly are not as common as in dogs with ehrlichiosis. Petechiae, epistaxis, subconjunctival hemorrhage, hyphema, anterior uveitis, iris hemorrhage, retinal petechiae, and retinal edema occur frequently. Cutaneous manifestations can include hyperemia, petechiae, edema, and dermal necrosis. Hemorrhage likely results from vasculitis, thrombocytopenia from consumption of platelets at sites of vasculitis, thrombocytopenia from immune destruction, and, in some dogs, disseminated intravascular coagulation. CNS signs include vestibular lesions (nystagmus, ataxia, head tilt); seizures; paresis; tremors; changes in mentation; and hyperesthesia (Mikszewski and Vite, 2005). Fatal RMSF is generally secondary to cardiac arrhythmias and shock, pulmonary disease, acute renal failure, or severe CNS disease.

Diagnosis

Clinicopathologic and radiographic abnormalities are common but do not definitively document RMSF. Neutrophilic leukocytosis, with or without a left shift and toxic cells, is found in most clinically affected dogs. Platelet counts are variable, but in one study 14 of 30 dogs had less than 75,000 platelets/μL without evidence of disseminated intravascular coagulation (Gasser et al., 2001). Leukocytosis and thrombocytopenia were the most common laboratory findings in experimentally infected dogs (Levin et al., 2015). In some naturally infected dogs, hemostatic abnormalities consistent with disseminated intravascular coagulation occur. Anemia occurs in some dogs, primarily from blood loss. Increased activities of alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase, as well as hypoalbuminemia, occur frequently. Because *R. rickettsii* does not result in chronic intracellular infection as does ehrlichiosis, hyperglobulinemia is rare. Renal insufficiency in some dogs causes azotemia and metabolic acidosis. Serum sodium, chloride, and potassium concentrations decrease in many dogs with gastrointestinal tract signs or renal insufficiency. Compared with dogs with chronic ehrlichiosis, chronic proteinuria from glomerulonephritis is rare. Positive direct Coombs test results occur in some dogs.

CNS inflammation usually causes increased protein concentrations and neutrophilic pleocytosis in cerebrospinal fluid; some dogs may have mononuclear cell pleocytosis or mixed inflammation. No pathognomonic radiographic abnormalities are associated with RMSF, but both experimentally and naturally infected dogs commonly develop unstructured pulmonary interstitial patterns.

A presumptive diagnosis of canine RMSF can be based on the combination of appropriate clinical, historic, and clinicopathologic evidence of disease; serologic test results; exclusion of other causes of the clinical abnormalities; and response to antirickettsial drugs. Documentation of seroconversion or an increasing titer 2 to 3 weeks after initial serologic testing suggests recent infection. Positive serum antibody test results alone do not prove RMSF because subclinical infection is common. In addition, positive serum antibody tests do not document infection by *R. rickettsii* because infection with nonpathogenic SFG agents can induce cross-reacting antibodies. Demonstration of *R. rickettsii* by inoculating affected tissues or blood into susceptible laboratory animals or by documenting the organism in endothelial cells by using direct fluorescent antibody staining leads to a definitive diagnosis of RMSF but is not clinically practical. PCR assay can be used to document the presence of *R. rickettsii* DNA in blood, other fluids, or tissues and document infection. But results from naturally occurring cases are rarely positive in PCR panels. In experimentally infected dogs, *R. rickettsii* DNA was inconsistently amplified from the blood of the dogs one to four times between day 5 and 13 after tick infestation (Levin et al., 2015). As with other vector-borne testing recommendations, the combination of serology and PCR assay should be used in dogs with suspected RMSF (Maggi et al., 2014).

Treatment

Supportive care for gastrointestinal tract fluid and electrolyte losses, renal disease, disseminated intravascular coagulation, and anemia should be provided as indicated. Overzealous fluid therapy may worsen respiratory or CNS manifestations of disease if vasculitis is severe.

Tetracycline derivatives, chloramphenicol, and quinolones are the antirickettsial drugs used most frequently. Doxycycline (5-10 mg/kg PO q12h for 21-28 days) is the preferred treatment. In one study of experimentally infected dogs, treatment for 16 days resulted in temporary clinical improvement in one dog that then relapsed (Levin et al., 2014). In one study of 30 dogs with RMSF, all dogs survived and no apparent differences in response rate occurred among tetracycline, doxycycline, chloramphenicol, or enrofloxacin (Gasser et al., 2001). Fever, depression, and thrombocytopenia often begin to resolve within 24 to 48 hours after starting therapy. Administration of prednisolone at anti-inflammatory or immunosuppressive doses in combination with doxycycline did not potentiate RMSF in experimentally infected dogs. The prognosis for canine RMSF is fair; it has been estimated that death occurs in less than 5% of affected dogs.

Zoonotic Aspects and Prevention

Because RMSF has not been reported twice in the same dog, permanent immunity is likely. Providing strict tick control can prevent infection. Human beings probably do not acquire *R. rickettsii* from contact with dogs, but dogs may increase human exposure to RMSF by bringing ticks into the human environment. People can also be infected when removing ticks with activated *R. rickettsii* from the dog by hand. Two dogs and the owner all died of RMSF in one study (Elchos and Goddard, 2003). As in dogs, RMSF in people is most commonly diagnosed from April to September when most of the tick vectors are most active. However, in areas endemic for *R. rickettsii* and *Rhipicephalus sanguineus*, RMSF could be diagnosed year round. RMSF can be fatal in some infected people, particularly if treatment is not started soon after clinical signs are recognized (Drexler et al., 2017; Helmick et al., 1984).

OTHER RICKETTSIAL INFECTIONS

Rickettsia felis was originally detected in a commercial cat flea *(Ctenocephalides felis)* colony and has been shown to belong in the SFG. Fever, headache, myalgia, and macular rash in human beings have been attributed to *R. felis* infection around the world (Angelakis et al., 2016). *Rickettsia felis* has been amplified from fleas collected from dogs or cats around the world including Australia, France, Israel, New Zealand, Thailand, the United Kingdom, and the United States. For example, in one study of 92 pairs of cat blood and flea extracts from Alabama, Maryland, and Texas, 62 (67.4%) of flea extracts and none of the cat blood samples were positive for *R. felis* DNA (Hawley et al., 2007). Recently, it has been suggested that dogs may prove to be important in the biology of *R. felis* (Hii et al., 2011). Because clinical illness in cats or dogs has not been documented, optimal treatment is unknown. However, on the basis of results for RMSF in dogs, doxycycline or a fluoroquinolone would be logical choices. Prevention in cats and dogs should include flea control, which may lessen exposure to people.

Rickettsia massiliae was amplified from *R. sanguineus* ticks in an area of southern California (Beeler et al., 2011). A clinical syndrome thought to be RMSF had been recognized in two dogs on the property. Antibodies against *R. massiliae, Rickettsia rhipicephali,* and *R. rickettsii* were detected by IFA in all four dogs, but each was negative for rickettsial DNA in blood by PCR. *Rhipicephalus sanguineus* collected from dogs and cats in Hungary, France, Italy, Belgium (dogs only), and Germany (cats only) were found to be positive for three *Rickettsia* species (*R. massiliae, R. raoultii,* and *R. rhipicephali*) as well as *A. platys* and *Hepatozoon canis* (Geurden et al., 2018). *Rickettsia conorii* causes Mediterranean Spotted Fever and has been associated with fever in southern Italy (Solano-Gallego, 2015). SFG *Rickettsia* DNA was amplified from *Dermacenter* collected from cats (Little et al., 2018). Further research is needed to determine disease association amongst these other SPG organisms and dogs or cats. However, on the basis of results for RMSF in dogs, doxycycline or a fluoroquinolone would be logical treatment choices. Prevention in cats and dogs should include flea and tick control, which may lessen exposure to people.

Neorickettsia helminthoeca (salmon poisoning) causes enteric signs of disease in dogs from the Pacific Northwest. *Coxiella burnetii* infection is associated with parturient or aborting cats and is primarily a zoonotic disease (see Chapter 99).

CHAPTER 96

Polysystemic Viral Diseases

Many viruses infect dogs and cats. Several, including canine distemper virus (CDV), some feline coronaviruses, feline immunodeficiency virus (FIV), and feline leukemia virus (FeLV) can cause systemic signs of disease. See other chapters for discussions of viral diseases primarily associated with disease of specific organ systems.

CANINE DISTEMPER VIRUS

Etiology and Epidemiology

CDV induces disease predominantly in terrestrial carnivores, but many other species, including seals, ferrets, skunks, badgers, porpoises, and exotic Felidae, have been infected by either CDV or related morbilliviruses. Virulence of the CDV strains varies by genetic lineage. Strains of CDV occurring in dogs in North America now vary genetically from isolates evaluated in the 1900s, and there are now antigenic variants that may affect current vaccine efficacy (Anis et al., 2018; Kapil et al., 2008). In addition, more than one strain of CDV can be present in the same area (Wostenberg et al., 2018). The virus replicates in lymphoid, nervous, and epithelial tissues, and is shed in respiratory exudates, feces, saliva, urine, and conjunctival exudates for up to 60 to 90 days after natural infection. After inhalation, the virus is engulfed by macrophages and within 24 hours is carried by the lymphatics to tonsillar, pharyngeal, and bronchial lymph nodes, where replication occurs. Central nervous system (CNS) and epithelial tissues are infected approximately 8 to 9 days after initial infection.

The degree of clinical illness and the tissues involved vary depending on the strain of the virus and the immune status of the host. Nonimmune dogs of any age are susceptible, but the disease is most common in puppies between 3 and 6 months of age. Massive replication of the virus in the epithelial cells of the respiratory tract, gastrointestinal system, and genitourinary system occurs in dogs with poor immune responses by postinfection days 9 to 14; these dogs usually die from polysystemic disease. In dogs with moderate immune responses by postinfection days 9 to 14, the virus replicates in epithelial tissues and may result in clinical signs of disease. Dogs with good cell-mediated responses and virus-neutralizing antibody titers by postinfection day 14 clear the virus from most tissues and may not be clinically affected. Most infected dogs develop CNS infection, but clinical signs of CNS disease occur only in dogs with low or no antibody response. Acute demyelination results from restrictive infection of oligodendrogliocytes and subsequent necrosis; chronic demyelination is caused by immune-mediated mechanisms, including antimyelin antibodies and CDV immune complex formation and removal.

Clinical Features

Many clinically affected dogs are unvaccinated, failed to receive colostrum from an immune bitch, were inappropriately vaccinated, or are immunosuppressed and also have a history of exposure to infected animals. Owners generally present affected dogs for evaluation of depression, malaise, oculonasal discharge, cough, vomiting, diarrhea, or CNS signs. Dogs with poor immune responses generally have the most severe signs and progress rapidly to life-threatening disease. Some partially immune dogs have only mild respiratory disease, presumptively diagnosed as canine infectious respiratory disease complex. Tonsillar enlargement, fever, and mucopurulent ocular discharge are common physical examination findings. Increased bronchial sounds, crackles, and wheezes are usually auscultated in dogs with bronchopneumonia.

Hyperesthesia, seizures, cerebellar or vestibular disease, paresis, and chorea myoclonus are common CNS signs that generally develop within 21 days of recovery from systemic disease (Table 96.1). CNS disease is generally progressive and carries a poor prognosis; it can develop in some dogs that never had systemic signs of disease recognized. Old dog encephalitis is a chronic, progressive panencephalitis in dogs older than 6 years thought to be attributable to CDV infection in which microglial proliferation and neuronal degeneration in the cerebral cortex result in depression, circling, head pressing, and visual deficits (see Chapter 64 for more information on CNS distemper).

TABLE 96.1

Clinical Manifestations of CDV Infection

In utero infection	Stillbirth Abortion Fading puppy syndrome in the neonatal period CNS signs at birth
Gastrointestinal tract disease	Vomiting Small-bowel diarrhea
Respiratory tract disease	Mucoid to mucopurulent nasal discharge Sneezing Coughing with increased bronchovesicular sounds or crackles on auscultation Dyspnea
Ocular disease	Retinochoroiditis, medallion lesions (see Fig. 96.1), optic neuritis Keratoconjunctivitis sicca Mucopurulent ocular discharge
Neurologic Disease	
Spinal cord disease	Paresis and ataxia
Central vestibular disease	Head tilt, nystagmus, other cranial nerve and conscious proprioception deficits
Cerebellar disease	Ataxia, head bobbing, hypermetria
Cerebral disease	Generalized or partial seizures ("chewing gum fits") Depression Unilateral or bilateral blindness
Chorea myoclonus	Rhythmic jerking of single muscles or muscle groups
Miscellaneous	Fever Anorexia Tonsillar enlargement Dehydration Pustular dermatosis Hyperkeratosis of the nose and footpads Enamel hypoplasia in surviving puppies

CDV, Canine distemper virus; *CNS,* central nervous system.

Ocular abnormalities associated with CDV infection include anterior uveitis, optic neuritis with resultant blindness and dilated pupils, and retinochoroiditis. The combination of retinochoroiditis and encephalitis is detected in approximately 40% of affected dogs. Keratoconjunctivitis sicca and hyperreflective retinal scars called *medallion lesions* occur in some dogs with chronic infection (Fig. 96.1).

Other less common syndromes have been attributed to CDV infection. Dogs infected before the development of permanent dentition usually have enamel hypoplasia.

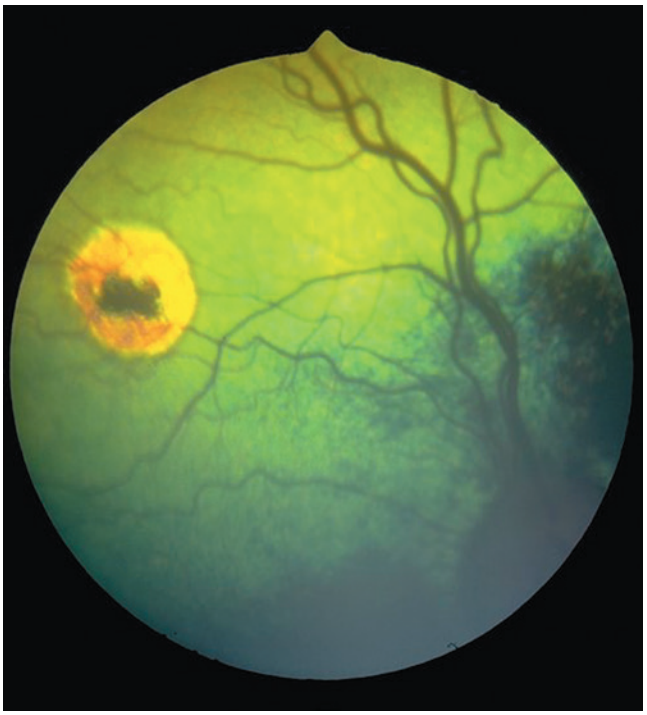

FIG 96.1
Medallion lesions resulting from canine distemper virus infection. (Courtesy Dr. Cynthia Powell, Colorado State University, Fort Collins.)

Hyperkeratosis of the nose and footpads and pustular dermatitis are the most common dermatologic abnormalities. Puppies infected transplacentally can be stillborn, aborted, or born with CNS disease.

Diagnosis

The combination of clinical findings and routine clinicopathologic and radiographic evaluation usually leads to a presumptive diagnosis of CDV infection. Lymphopenia and mild thrombocytopenia are consistent hematologic abnormalities. Interstitial and alveolar pulmonary infiltrates are common radiographic findings in dogs with respiratory disease. Although some dogs with CNS infection have normal cerebrospinal fluid (CSF) analyses, most have mononuclear cell pleocytosis and increased protein concentrations. The ratio of serum/CSF immunoglobulin G (IgG) and albumin is commonly high in dogs with encephalitis, but this only documents inflammation of the CNS, not CDV infection.

Measurement of serum or CSF antibody titers can aid in the diagnosis of CDV infection. Documentation of a fourfold increase in the serum IgG titer over a 2- to 3-week period or detection of IgM antibodies in serum is consistent with recent infection or recent vaccination but does not prove clinical disease. CSF antibody titers to CDV are increased in some dogs with encephalitis. False-positive results can occur in CSF samples contaminated with blood. If CSF antibody titers are greater than those in serum, the

antibody in the CSF had to be produced locally and is consistent with CNS CDV infection. If increased CSF protein concentrations, mononuclear pleocytosis, and antibodies against CDV are detected in a CSF sample not contaminated with peripheral blood, a presumptive diagnosis of CDV encephalitis can be made.

Definitive diagnosis of CDV infection requires demonstration of viral inclusions by cytologic examination, direct fluorescent antibody (DFA) staining of cytologic or histopathologic specimens, histopathologic evaluation, virus isolation, or reverse transcriptase polymerase chain reaction (RT-PCR) documentation of CDV RNA in peripheral blood, CSF, or conjunctival scrapings. Viral inclusions are rarely found in erythrocytes, leukocytes, and leukocyte precursors of infected dogs. Inclusions are generally present for only 2 to 9 days after infection and therefore often are not present when clinical signs occur. Inclusions may be easier to find in smears made from buffy coats or bone marrow aspirates than in those made from peripheral blood. Viral particles can be detected by DFA in cells from the tonsils, respiratory tree, urinary tract, conjunctival scrapings, and CSF for 5 to 21 days after infection. In areas molecular assays are expensive or not available, DFA assays can be performed with a moderate sensitivity (79%) when compared with molecular assays (Athanasiou et al., 2018). However, false-positive results have been detected occasionally in DFA performed on conjunctival cells from specific pathogen-free puppies, so results of these tests should be interpreted cautiously (Burton et al., 2008). Recent administration of modified-live CDV-containing vaccines can lead to positive results in DFA and some RT-PCR assays so vaccination history is important to consider with assessing the results of these assays. It is possible to differentiate wild strains and vaccine strains of CDV by RT-PCR; veterinarians should ask the preferred service laboratory whether the assay being used can provide this discrimination (Yi et al., 2012).

Treatment

Although a number of substances like ribraviron, interferon alpha, and caffeic acid inhibit CDV in vitro, therapy for CDV infection is nonspecific and supportive (Carvalho et al., 2014). Secondary bacterial infections of the gastrointestinal tract and respiratory system are common and, if indicated, should be treated as indicated. Anticonvulsants are administered as needed to control seizures (see Chapter 62), but chorea myoclonus has no known effective treatment. Glucocorticoid administration may be beneficial in some dogs with CNS disease from chronic CDV infection, but it is contraindicated in acutely infected dogs. The prognosis for dogs with CNS distemper is poor.

Prevention and Zoonotic Aspects

The CDV survives in exudates only for approximately 1 hour at body temperature and 3 hours at room temperature and is susceptible to most routine hospital disinfectants. Dogs with gastrointestinal or respiratory signs of disease should be housed in isolation to avoid aerosolization to susceptible populations. Care should be taken to avoid transmission by contaminated fomites (see Chapter 93). All puppies should be administered at least three CPV-2, CAV-2, and CDV-containing vaccines, every 3 to 4 weeks, between 6 and 16 weeks of age, with the last booster administered at 16 weeks of age (see Chapter 93). Administration of a final dose at 18 to 20 weeks of age should be considered for dogs residing in high-risk environments. Modified-live CDV vaccines and the recombinant CDV (rCDV) vaccine are considered effective by the AAHA task force (https://www.aaha.org/guidelines/canine_vaccination_guidelines.aspx). The rCDV vaccine can be used to break through maternal antibodies that can block CDV vaccines. In one recent study, almost all vaccinated dogs in a shelter achieved protective serum antibody titers within 13 to 15 days after receiving a modified live CDV vaccine (Litster et al., 2012a). Vaccines should be boosted at 1 year of age. After the 1-year booster, repeat boosters are not needed again for a minimum of 3 years and protection after challenge has been documented for more than 4 years (Jensen et al., 2015). Serologic studies have shown that vaccination induces long-term protection against CDV (Killey et al., 2018).

Disease from CDV infection has occurred in some vaccinated dogs and rarely is attributed to modified-live virus vaccination. Clinical disease in vaccinated dogs develops if the host was immunocompromised, infected with the virus before vaccination, had vaccine-suppressive levels of maternal antibodies, or was incompletely vaccinated. Alternately, the vaccine may have been inactivated by improper handling or may not have protected against all field strains of CDV (Anis et al., 2018). Distemper virus encephalitis develops after modified-live vaccination of some dogs co-infected with canine parvovirus; administration of modified-live CDV vaccines should be delayed in dogs with clinical signs of disease consistent with parvovirus infection. Mild, transient thrombocytopenia can be induced by modified CDV vaccination but has not been associated with spontaneous bleeding unless the patient has an underlying subclinical coagulopathy. No proven public health risks are associated with CDV.

Serum antibody titers that predict resistance to challenge with CDV are known. Samples can be submitted to a validated laboratory for assessment of vaccination needs. Alternately, in some countries, assays designed to be used in the clinic are available and have been used to assess animals for CDV susceptibility in outbreak situations or for individual pet dogs (Gray et al., 2012; Litster et al., 2012ab). Some vaccinated dogs are negative for CDV antibodies 3 years after vaccination, depending on the assay used (Mahon et al., 2017). These findings support the use of serology in determining CDV vaccination need, which can be used yearly in lieu of vaccination to determine when the titer goes below protection levels. Serology can also be used to determine areas within a community that are the likely source of dogs in CDV outbreaks and drive targeted vaccination programs and lessen the potential for local outbreaks (Spindel et al., 2018).

FELINE CORONAVIRUS

Etiology and Epidemiology

Coronaviruses causing disease in cats include feline infectious peritonitis virus (FIPV) and feline enteric coronavirus (FECV). The virology and immunopathogenesis of feline coronaviruses has been reviewed (Pedersen et al., 2014a). Enteric infection generally results in mild gastrointestinal signs; systemic infection can induce a clinical syndrome with diverse manifestations commonly referred to as feline infectious perinotitis (FIP). Most current work suggests that the mutations associated with the FIPV strains are in the 3c and spike protein genes (Bank-Wolf et al., 2014; Lewis et al., 2015; Rottier et al., 2005). Enteric coronaviruses are commonly shed in feces and are highly contagious. By RT-PCR testing, coronaviruses can be detected in feces as early as 3 days after infection. In studies of FECV-infected, closed cat colonies, almost every cat becomes infected. In one study of 155 pet cats with naturally occurring FECV infection, viral RNA was shed continuously ($n = 18$) or intermittently ($n = 44$) in the feces of some cats (Addie et al., 2001). Others were initially shedding viral RNA and then ceased shedding ($n = 56$), and some were resistant to infection ($n = 4$). The cats that stopped viral shedding were susceptible to reinfection. Viral RNA was detected in the ileum, colon, and rectum of cats with persistent shedding.

Most cases of FIP develop in multiple-cat households or catteries. Theoretically, the effusive form of disease develops in cats with poor cell-mediated immune responses; the noneffusive form ("dry") develops in cats with partial cell-mediated immunity. The effusive form of disease is an immune complex vasculitis characterized by leakage of protein-rich fluid into the pleural space, the peritoneal cavity, the pericardial space, and the subcapsular space of the kidneys. In the noneffusive form pyogranulomatous or granulomatous lesions develop in multiple tissues, particularly the eyes, brain, kidneys, omentum, and liver. Some affected cats have characteristics of both forms of FIP. Using reverse transcriptase quantitative PCR (RT-qPCR) assay and immunohistochemical staining, it was shown that experimentally inoculated cats have FIPV genomic RNA mainly in macrophages in diseased tissues and effusions (Pedersen et al., 2015).

Clinical disease associated with FIP virus may be influenced by a number of factors, including the virulence of the strain, the dose of the virus, the route of infection, the immune status of the host, genetically determined host factors, the presence of other concurrent infections, and whether the cat had been previously exposed to a coronavirus. Some breeds, including British Shorthair, Devon Rex, and Abyssinian, appear to be predisposed to the development of FIP in some studies (Pedersen et al., 2014a; Pesteanu-Somogyi et al., 2006; Worthing et al., 2012;). However, it has been difficult to determine the genetic basis for increased susceptibility or resistance (Pedersen et al., 2014c). In a study of 40 of 111 cats that survived experimental inoculation with FIPV, there was no sex association, but resistance increased after 6 months of age (Pedersen et al., 2014c). FeLV infection and respiratory tract infection increase the risk for FIP, suggesting that the immune status of the host is important in determining the development of clinical disease. Cats concurrently infected with FIV shed 10 to 100 times more FECV in stool than FIV-naive cats. Previous exposure to non-FIP-inducing feline coronaviruses before challenge with virulent FIPV can result in acceleration of the disease process (Pedersen et al., 2014c). Experimentally infected, coronavirus seropositive kittens can develop accelerated FIP compared with seronegative kittens when exposed to FIPV. This antibody-dependent enhancement of virus infectivity occurs because macrophages are more effectively infected by virus complexed with antibody than by virus alone, but this phenomenon appears to be rare in naturally infected cats.

Clinical Features

Enteric replication of coronaviruses commonly results in fever, vomiting, and mucoid diarrhea. With FECV infection, clinical signs are self-limiting and generally respond to supportive care within days. Fulminant FIP can occur in cats of any age but is generally recognized in cats younger than 5 years; most cases are younger than 1 year. Intact males are over-represented in some studies. In cattery outbreaks, usually only one or two kittens in a litter are clinically affected. This may relate to poor transmissibility of strains capable of inducing FIP. Anorexia, weight loss, and general malaise are common presenting complaints (Box 96.1). Icterus, ocular inflammation, abdominal distension, dyspnea, or CNS abnormalities are occasionally noted by the owner.

Fever and weight loss are common. Pale mucous membranes or petechiae are noted in some cats. FIP is one of the most common causes of icterus in cats younger than 2 years; liver size can be normal or enlarged, and the margins are usually irregular. Abdominal distension is common, a fluid wave can often be balloted, and occasionally masses (pyogranulomas or lymphadenopathy) can be palpated in the omentum, mesentery, or intestines. A solitary ileocecocolic or colonic mass, resulting in obstruction leading to vomiting and diarrhea, occurs in some cats (Harvey et al., 1996). Kidneys can be small (chronic disease) or large (acute disease or subcapsular effusion); renal margins are usually irregular. Pleural effusion can result in dyspnea and a restrictive breathing pattern (shallow and rapid), as well as muffled heart and lung sounds. Male cats sometimes have scrotal enlargement from fluid accumulation.

Anterior uveitis and chorioretinitis occur most frequently with the noneffusive form of the disease and can be its only manifestation. Pyogranulomatous disease can develop anywhere in the CNS, leading to a variety of neurologic signs that include seizures, posterior paresis, and nystagmus. Seizures secondary to FIP are a poor prognostic indicator (Timmann et al., 2008).

Feline coronaviruses have been suggested as a cause of failure to conceive, abortion, stillbirth, and congenital defects, as well as the fading kitten syndrome (kitten mortality complex). However, one epidemiologic study failed to

BOX 96.1

Clinical Findings Suggestive of FIP in Cats

Signalment and History

Cats < 5 years or >10 years of age
Purebred cat
Purchased from a cattery or housed in a multiple-cat household
Previous history of a mild, self-limiting gastrointestinal or respiratory disease
Serologic evidence of infection by FeLV
Nonspecific signs of anorexia, weight loss, or depression
Seizures, nystagmus, or ataxia
Acute, fulminant course in cats with effusive disease
Chronic, intermittent course in cats with noneffusive disease

Physical Examination

Fever
Weight loss
Pale mucous membranes with or without petechiae
Dyspnea with a restrictive breathing pattern
Muffled heart or lung sounds
Abdominal distension with a fluid wave with or without scrotal swelling
Abdominal mass from focal intestinal granuloma or lymphadenopathy
Icterus with or without hepatomegaly
Chorioretinitis or iridocyclitis
Multifocal neurologic abnormalities
Irregularly marginated kidneys with or without renomegaly
Splenomegaly

Clinicopathologic Abnormalities

Nonregenerative anemia
Neutrophilic leukocytosis with or without a left shift
Lymphopenia
Hyperglobulinemia characterized as a polyclonal gammopathy; rare monoclonal gammopathies
Nonseptic, pyogranulomatous exudate in pleural space, peritoneal cavity, or pericardial space
Increased protein concentrations and neutrophilic pleocytosis in CSF
Positive coronavirus antibody titer in the majority (especially noneffusive)
Pyogranulomatous or granulomatous inflammation in perivascular location on histologic examination of tissues
Positive results of immunofluorescence or RT-PCR performed on pleural or peritoneal exudate

CSF, Cerebrospinal fluid; *FeLV,* feline leukemia virus; *FIP,* feline infectious peritonitis; *RT-PCR,* reverse transcriptase polymerase chain reaction.

link feline coronavirus with reproductive failure or neonatal kitten death.

Diagnosis

Multiple hematologic, serum biochemical, urinalysis, diagnostic imaging, and CSF abnormalities develop in cats with FIP. There have been multiple review articles and case series evaluating diagnostic procedures (Pedersen 2014b; Stranieri et al., 2018; Tasker et al., 2018). Other than histopathology, the positive predictive values of tests used to aid in the diagnosis of FIP are less than 100%. A presumptive diagnosis of FIP is usually based on the combination of clinical and clinicopathologic findings.

Normocytic, normochromic, nonregenerative anemia; neutrophilic leukocytosis; and lymphopenia are common. Disseminated intravascular coagulation resulting in thrombocytopenia and, rarely, hemolytic anemia occurs in cats with FIP. Hyperglobulinemia is one of the most common abnormalities and occurs in up to 89% of cases. Hyperglobulinemia can be detected with or without hypoalbuminemia (Riemer et al., 2016). In some studies, the ratio of albumin to globulins of <0.4 was supportive of a diagnosis of FIP, and a ratio >0.8 excluded the diagnosis. Polyclonal gammopathies from increases in α_2-globulin and γ-globulin concentrations are most commonly detected; monoclonal gammopathies are rare. A number of acute phase proteins like α_1-acid glycoprotein have been evaluated in the blood of cats with and without FIP. In one small study of 12 cats with FIP, serum concentrations of α_1-acid glycoprotein had high sensitivity (100%) and specificity for the diagnosis of FIP (Giori et al., 2011). Most of these findings are consistent with chronic inflammation and do not prove FIP.

Hyperbilirubinemia with variable increases in alanine aminotransferase and alkaline phosphatase activities occurs in some cats with hepatic disease. Prerenal azotemia, renal azotemia, and proteinuria are the most common renal abnormalities. Radiographs can reveal pleural, pericardial, or peritoneal effusions; hepatomegaly; or renomegaly. Mesenteric lymphadenopathy may result in mass lesions in some cats. Ultrasonography can be used to confirm the presence of abdominal fluid in cats with minimal fluid volumes and to evaluate the pancreas, liver, lymph nodes, and kidneys (Lewis and O'Brien, 2010). Protein concentrations and nucleated cell counts (neutrophils predominate in most cases) are commonly increased in CSF from cats with CNS involvement. Although high coronavirus antibody titers are common in the CSF of cats with neurologic FIP, the antibodies appear to be derived from blood and, as the authors of one study concluded, were of equivocal value (Boettcher et al., 2007).

Feline coronavirus antibody tests that were available at the time were evaluated and how to use the results of the assays in feline practice were reviewed (Addie et al., 2015). There are multiple potential reasons to use coronavirus antibody tests, particularly in breeding catteries. In the diagnosis of clinical FIP, the greatest clinical value of coronavirus antibody tests is the detection of a negative

result. If the test used is very sensitive, a negative test result helps exclude the diagnosis of FIP because most cats with effusive or noneffusive disease are serum antibody-positive. However, cats with FIP are occasionally serologically negative because of rapidly progressive disease, with a delayed rise in titer, disappearance of antibody in terminal stages of the disease, or immune complex formation. Positive coronavirus serologic test results are more difficult to use for a number of reasons. Infection of cats by any coronavirus can cause cross-reacting antibodies; therefore a positive antibody titer does not diagnose FIP, protect against disease, or predict when a cat may develop clinical FIP. Presence of maternal antibodies can confuse the diagnosis in very young kittens. However, this is age dependent as maternal antibodies decline to undetectable concentrations by 4 to 6 weeks of age; kittens infected in the postnatal period become seropositive at 8 to 14 weeks of age. Because coronavirus antibody tests are not standardized, results from different laboratories commonly do not correlate (Addie et al., 2015).

Immunocytochemistry has been developed to detect coronavirus antigen in CSF, aqueous humor, and effusions (Doenges et al., 2016; Felten et al., 2017; Felten et al., 2018). The assay can be very sensitive, but the specificity is low in most studies because some cats without FIP can be positive. Immunohistochemistry documenting the presence of coronavirus in tissues concurrently with characteristic histopathologic findings can be used to prove the diagnosis of FIP (Harvey et al., 1996).

Because virus isolation is not practical clinically, RT-qPCR is used most frequently to amplify coronaviruses in feces, blood, effusions, CSF, aqueous humor, and tissues. Multiple different molecular targets have been employed with varying sensitivity and specificity. Use of these assays on blood or feces generally do not differentiate FIPV from FECV and so positive results to not prove FIP. Use of these assays on effusions appear to have the most clinical utility. If effusions are not present, use of an RT-qPCR on circulating peripheral blood mononuclear cells was more sensitive than use of serum (Doenges et al., 2017). In cats with neurologic and/or ocular signs, the sensitivity of a real-time RT-PCR on CSF was 85.7% in one study (Doenges et al., 2016)

Effusions from cats with FIP are sterile, colorless to straw-colored, may contain fibrin strands, and may clot when exposed to air (Fig. 96.2). The protein concentration on fluid analysis commonly ranges from 3.5 g/dL to 12 g/dL and is generally higher than that associated with other diseases. Mixed inflammatory cell populations of lymphocytes, macrophages, and neutrophils occur most commonly; neutrophils predominate in most cases, but in some cats macrophages are the primary cell type seen. In some cats, the coronavirus antibody titers are greater in the effusion than in serum. Measurement of protein concentrations in effusions and calculation of the albumin/globulin ratio (AGR) can aid in the diagnosis of effusive FIP. In one study, an AGR of 0.5 had a positive predictive value of 89%, and an AGR of 1.0 had a negative predictive value of 91%. Coronavirus antigens are commonly detected by immunocytochemistry in the effusions of cats with FIP, but the sensitivity is less than 100% as antigens have also been detected in the effusions of some cats with other diseases (Felten et al., 2017). If molecular assays are available, they should be performed on cats with effusions consistent with FIP becasue viral RNA can be amplified from effusions in most cats with FIP by RT-qPCR and is unlikely to be amplified from effusions from other causes.

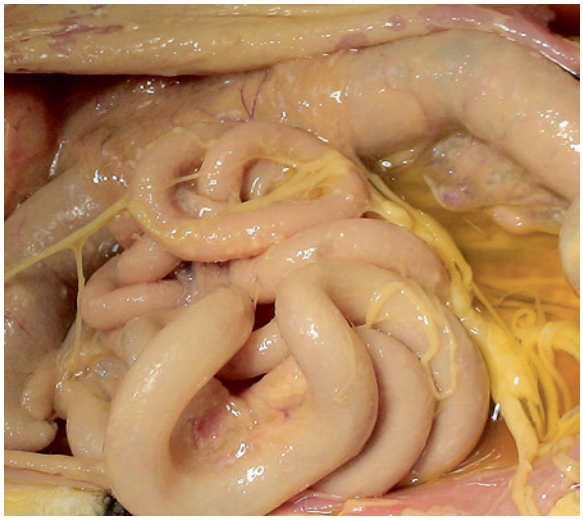

FIG 96.2
Abdominal effusion consistent with the effusive form of feline infectious peritonitis identified on necropsy of an affected cat.

The most definitive diagnosis of FIP is based on combination of characteristic histopathologic findings with the presence of coronavirus by virus isolation, immunocytochemical or immunohistochemical staining, or amplification of viral RNA in effusions, other fluids like CSF or aqueous humor or tissues by RT-qPCR.

Treatment

Because an antemortem diagnosis of FIP is difficult to make, assessment of studies reporting successful treatment is virtually impossible. Treatments for FIP have been reviewed, and there is no protocol that is consistently effective (Hartmann and Ritz, 2008; Pedersen et al., 2014b). A small percentage of cats have spontaneous remission, adding to the confusion concerning therapeutic response. Supportive care, including correction of electrolyte and fluid balance abnormalities, and lessening stress should be provided to cats with FIP as needed.

Feline coronaviruses are dependent on 3C-like protease for replication (Kim et al., 2015). The use of one 3C-like protease inhibitor showed promise in the treatment of FIP but is not currently on the market (Pedersen et al., 2017). In vitro inhibition of FIP virus replication has also been demonstrated with a number of drugs, including ribavirin, human interferon-α, feline fibroblastic interferon-β, adenine arabinoside, and amphotericin B. However, to date no

uniformly successful antiviral treatment has been developed, and the drugs typically have potentially serious adverse effects. Cyclosporine A inhibits replication of feline coronaviruses in vitro, but it is currently unknown whether this drug can be used successfully as a treatment of FIP (Tanaka et al., 2012). Small interfering RNA (siRNA) can be synthesized and target different regions of the coronavirus genome to inhibit viral replication in vitro and is another potential future treatment modality (McDonagh et al., 2011).

Because disease from FIP is secondary to immune-mediated reactions against the virus, modulation of the inflammatory reaction is the principal form of palliative therapy. Low-dose prednisolone (1-2 mg/kg orally [PO] q24h) may lessen clinical manifestations of noneffusive FIP. However, the use of immunosuppressive drugs is controversial because cats with FIP have impaired immune responses. Prednisolone and feline recombinant interferon were used in combination for the treatment of both effusive and noneffusive FIP in small numbers of cats (Ishida et al., 2004). In that study, four cats with effusive disease believed to be from FIP virus had prolonged remission. It is impossible to determine whether the effect was from the prednisolone or interferon because both drugs were administered to all cats. In another study, administration of interferon-ω was ineffective for the treatment of FIP (Ritz et al., 2007). In the future, veterinarians may be able lessen inflammation and disease induced by FIP by administering anti-feline tumor necrosis factor monoclonal antibodies (Doki et al., 2016). Immune modulation with polyprenyl immunostimulant may induce beneficial effects in some cats with noneffusive FIP (Legendre and Bartges, 2009; Legendre et al., 2017).

Antibiotics do not have primary antiviral effects but may be indicated for the treatment of secondary bacterial infection. Other supportive care treatments such as anabolic steroids (stanozolol, 1 mg PO q12h), aspirin (10 mg/kg PO q48-72h), and ascorbic acid (125 mg PO q12h) have also been recommended for the treatment of FIP. Most cats with systemic clinical signs of FIP die or require euthanasia within days to months of diagnosis. The effusive form of disease carries a grave prognosis. The drug propentofylline, used to treat vasculitis, was evaluated in a placebo-controlled study of naturally infected cats with effusive disease. However, the propentofylline protocol assessed did not improve the quality of life or lessen the effusion (Fischer et al., 2011). Depending on the organ system involved and the severity of polysystemic clinical signs, cats with noneffusive FIP have variable survival times. Cats with only ocular FIP may respond to antiinflammatory treatment or enucleation of the affected eye(s) and have a better prognosis than cats with systemic FIP.

Prevention and Zoonotic Aspects

Prevention of coronavirus infections is best accomplished by avoiding exposure to the virus. Although viral particles coronaviruses can survive in dried secretions for up to 7 weeks, routine disinfectants inactivate the viruses. Some cats eliminate FECA coronavirus infections, and not all cats exposed to FIPV develop the syndrome of FIP. However, some research cats that survived FIPV infection on primary exposure developed FIP on subsequent inoculation suggesting that immunity is not permanent (Addie et al., 2001; Pedersen et al., 2014a). Although the genetics of FIPV resistance is complex, cats with progeny that died of FIP should be avoided for use for breeding programs in pedigreed catteries (Pedersen et al., 2014).

An intranasally administered, mutant strain of coronavirus that induces mucosal immune response but minimal systemic immune response is available in some countries (Primucell FIP, Zoetis Animal Health). This strain does not induce FIP; the majority of cats with adverse effects have exhibited only mild signs associated with placement of liquid in the nares, and the vaccine does not appear to potentiate antibody-dependent enhancement of virus infectivity when administered to previously seropositive cats. The vaccine appears to be effective in at least some cats, but whether it protects against all field strains, mutations, or recombinants is unknown, so it is considered as noncore by the American Association of Feline Practitioners (see Chapter 93). Zoonotic transfer of FIP virus or FECV to human beings has not been documented.

FELINE IMMUNODEFICIENCY VIRUS

Etiology and Epidemiology

FIV is an exogenous, single-strand RNA virus in the family Retroviridae, subfamily Lentivirinae. The virus is morphologically similar to the human immunodeficiency virus (HIV), but it is antigenically distinct. Like FeLV, FIV produces reverse transcriptase to catalyze the insertion of viral RNA into the host genome. Multiple clades of the virus exist, and some isolates have differing biologic behavior. For example, immune deficiency is induced much more quickly by some isolates, and clinical diseases such as uveitis are induced by some but not all isolates. The prevalence of FIV antibodies in United States and Canada was 3.6% in a 2017 study (Burling et al., 2017), which is higher than the 2.5% in a study reported in 2006 (Levy et al., 2006). Regional variations in prevalence rates for both FIV and FeLV exist (Chhetri et al., 2013).

FIV replicates readily in the oral lymphoid tissues (Miller et al., 2017). Aggressive biting behavior is thought to be the primary route of transmission of FIV; older, male, outdoor cats with clinical signs of disease are most commonly infected. Plasma viral loads increase as the FIV disease severity increases (Kann et al., 2014). Vertical transmission appears to be unlikely to occur based on a study of group housed shelter cats (Litster et al., 2014). FIV is present in semen and can be transmitted by artificial insemination. Transplacental and perinatal transmission occurs from infected queens to kittens. Arthropod transmission appears to be unlikely. Transmission by routes other than biting is less common because high levels of viremia are of short duration. FIV infection of cats has worldwide distribution,

and prevalence rates vary greatly by region and the lifestyle of the cats tested. FIV replicates in several cell types, including T lymphocytes ($CD4^+$ and $CD8^+$), B lymphocytes, macrophages, and astrocytes. The primary phase of infection occurs as the virus disseminates throughout the body, initially leading to low-grade fever, neutropenia, and generalized reactive lymphadenopathy. A subclinical, latent period of variable length then develops; the length of this period is related in part to the strain of virus and the age of the cat when infected. The median ages of healthy, naturally infected cats and clinically ill naturally infected cats are approximately 3 years and 10 years, respectively, suggesting a latent period of years for most strains of FIV. Chronic experimental and naturally occurring infection results in a slow decline in circulating $CD4^+$ lymphocyte numbers, response to mitogens, and decreased production of cytokines associated with cell-mediated immunity, such as interleukin (IL)-2 and IL-10; neutrophil function and natural killer cell function are also affected. Humeral immune responses are often intact, and a polyclonal gammopathy develops from nonspecific B-lymphocyte activation. Within months to years, an immune deficiency stage similar to acquired immunodeficiency syndrome (AIDS) in human beings develops. Coinfection with FeLV potentiates the primary and immune deficiency phases of FIV. However, co-infection with *Mycoplasma haemofelis, Toxoplasma gondii,* feline herpesvirus, and feline calicivirus, as well as immunization, failed to potentiate FIV-associated immunodeficiency in research studies. However, FIV antibodies and hemoplasma infections are associated in some studies, which may just reflect that both agents are transmitted directly (Sarvani et al., 2018). Recently, *Felis catus* gammaherpesvirus has been be detected in FIV-infected cats, and the role co-infection with the two viruses plays in pathogenesis or progression of disease is being studied (McLuckie et al., 2017). Infection with FIV may be associated with T-cell lymphomas (Murphy et al., 2018). Many cats with FIV antibodies survive for years after diagnosis, and in one study, there was no difference in long-term survival between cats that were or were not FIV infected (Liem et al., 2013). However, cats with FeLV infection or FeLV and FIV co-infections had significantly shorter life spans than cats infected with FIV alone (Spada et al., 2018). The oral and rectal microbiota of FIV-infected cats varies from healthy controls, which may relate to chronic diarrhea and stomatitis that develops in some infected cats (Weese et al., 2015ab).

Clinical Features

Clinical signs of infection with FIV can arise from direct viral effects or secondary infections that ensue after the development of immunodeficiency (Table 96.2). Most of the clinical syndromes diagnosed in FIV-seropositive cats also occur in FIV-naïve cats, which makes proving disease causation difficult during the subclinical stage of infection. A positive FIV antibody test does not prove immunodeficiency or disease from FIV and does not necessarily indicate a poor prognosis. The only way to determine accurately whether an FIV-seropositive cat with a concurrent infectious disease has a poor prognosis is to treat the concurrent infection.

Primary (acute) FIV infection is characterized by fever and generalized lymphadenopathy. Owners commonly present FIV-infected cats in the immunodeficiency stage for evaluation of nonspecific signs such as anorexia, weight loss, and depression or for evaluation of abnormalities associated with specific organ systems. When a clinical syndrome is diagnosed in a cat seropositive for FIV, the workup should include diagnostic tests for other potential causes (see Table 96.2).

Clinical syndromes reportedly from primary viral effects include chronic small-bowel diarrhea, nonregenerative anemia, thrombocytopenia, neutropenia, lymphadenopathy, pars planitis (inflammation in the anterior vitreous humor), anterior uveitis, glomerulonephritis, renal insufficiency, and hyperglobulinemia. Oral cavity inflammatory diseases occur in both FIV and FeLV infected cats (Kornya et al., 2014). In one report of naturally infected cats, FIV was associated with proteinuria but not renal azotemia (Baxter et al., 2012). In another study, proteinuria and low specific gravity were common in FIV-positive cats (Taffin et al., 2017). FIV may play a role in the development of hypertrophic cardiomyopathy in some cats (Rolim et al., 2016). However, secondary infections associated with myocarditis like *T. gondii* and *Bartonella* spp. should also always be excluded in these cases. Behavioral abnormalities, with dementia, hiding, rage, inappropriate elimination, and roaming, are neurologic manifestations of FIV infection. Seizures, nystagmus, ataxia, and peripheral nerve abnormalities may occasionally be attributable to primary viral effects, but secondary infections associated with neurologic disease like *T. gondii* should always be excluded as well (Power et al., 2018). Lymphoid malignancies, myeloproliferative diseases, and several carcinomas and sarcomas have been detected in FIV-infected, FeLV-naïve cats, suggesting a potential association between FIV and malignancy; FIV-infected cats are at higher risk for the development of lymphoma (Magden et al., 2011; Murphy et al., 2018).

Diagnosis

Neutropenia, thrombocytopenia, and nonregenerative anemia are common hematologic abnormalities associated with FIV infection. Monocytosis and lymphocytosis occur in some cats and may be caused by the virus or chronic infection with opportunistic pathogens. Cytologic examination of bone marrow aspirates may reveal maturation arrest (i.e., myelodysplasia), lymphoma, or leukemia. A progressive decline in $CD4^+$ lymphocytes, a plateau or progressive increase in $CD8^+$ lymphocytes, and an inversion of the $CD4^+$/$CD8^+$ ratio occurs in experimentally infected cats over time. A multitude of serum biochemical abnormalities is possible depending on what FIV-associated syndrome is occurring. Polyclonal gammopathy can occur in some FIV-infected cats. No pathognomonic imaging abnormalities are associated with FIV infection.

TABLE 96.2

Clinical Syndromes Associated With FIV Infection and Possible Opportunistic Agents

CLINICAL SYNDROME	PRIMARY VIRAL EFFECT	OPPORTUNISTIC AGENTS
Dermatologic/otitis externa	None	Bacterial; atypical *Mycobacterium; Otodectes cynotis; Demodex cati; Notoedres cati;* dermatophytosis; *Cryptococcus neoformans;* cowpox
Gastrointestinal	Yes; small-bowel diarrhea	*Cryptosporidium* spp.; *Cystoisospora* spp.; *Giardia* spp.; *Salmonella* spp.; *Campylobacter spp.* others
Glomerulonephritis	Yes	Bacterial; FeLV, FIP, SLE
Hematologic	Yes; nonregenerative anemia; neutropenia; thrombocytopenia	*Mycoplasma haemofelis*; FeLV; *Bartonella henselae?*
Myocarditis; hypertropic cardiomyopathy	Yes	*Bartonella* spp., *T. gondii*
Neoplasia	Yes; myeloproliferative disorders and lymphoma	FeLV
Neurologic	Yes; behavioral abnormalities	*Toxoplasma gondii; C. neoformans*; FIP; FeLV, *B. henselae?*
Ocular	Yes; pars planitis, anterior uveitis	*T. gondii;* FIP; *C. neoformans,* FHV-1, *B. henselae*
Pneumonia/pneumonitis	None	Bacterial; *T. gondii; C. neoformans*
Pyothorax	None	Bacterial
Renal failure	Yes	Bacterial; FIP; FeLV
Stomatitis	None	Calicivirus; overgrowth of bacteria flora; candidiasis, *B henselae?*
Upper respiratory tract	None	FHV-1; calicivirus; overgrowth of bacterial flora; *Cryptococcus neoformans*
Urinary tract infection	None	Bacterial

FeLV, Feline leukemia virus; *FHV-1,* feline herpesvirus type 1; *FIP,* feline infectious peritonitis; *FIV,* feline immunodeficiency virus; *SLE,* systemic lupus erythematosus.

Antibodies against FIV are detected in serum in clinical practice most frequently by enzyme-linked immunosorbent assay (ELISA). Saliva can be used instead of serum in fractious cats or in facilities that do not have a veterinarian available at all times (Westman et al., 2016a). Test results for FIV antibody can vary amongst test kits (Levy et al., 2017; Westman et al., 2017). Whether antibodies induced by the FIV vaccine available in some countries also varies by test kit (Westman et al., 2017). Results of PCR or virus isolation can be used to distinguish a previously vaccinated cat if the history is not known (Nichols et al., 2017). Clinical signs can occur before seroconversion in some cats, and some infected cats never seroconvert; thus false-negative reactions can occur. Results of virus isolation or RT-PCR on blood are positive in some antibody-negative cats. False-positive reactions can occur with ELISA; therefore positive ELISA results in healthy or low-risk cats should be confirmed by Western blot immunoassay or RT-PCR. Kittens can have detectable, colostrum-derived antibodies for several months. Kittens younger than 6 months that are FIV seropositive should be tested every 60 days until the result is negative. If antibodies persist at 6 months of age, the kitten is likely infected. Virus isolation or PCR on blood can also be performed to confirm infection. The biggest problem with FIV RT-PCR assays to date is lack of standardization among laboratories and the potential for both false-positive and false-negative results (Crawford et al., 2005).

Detection of antibodies against FIV in the serum of cats that have not been vaccinated against FIV documents exposure and correlates well with persistent infection but does not correlate with disease induced by the virus. Because many clinical syndromes associated with FIV can be caused by opportunistic infections, further diagnostic procedures may determine treatable etiologies (see Table 96.2). For example, some FIV-seropositive cats with uveitis are coinfected by *T. gondii* and often respond to the administration of anti-*Toxoplasma* drugs (see Chapter 98).

Treatment

Because FIV-seropositive cats are not necessarily immunosuppressed or diseased from FIV, the cat should be evaluated and treated for other potential causes of the clinical syndrome (Tasker et al., 2006a). Some FIV-seropositive cats are immunodeficient; if infectious diseases are identified, bacteriocidal drugs administered at the upper end of the dosage should be chosen. Long-term antibiotic therapy or multiple

treatment periods may be required. The only way to determine if an FIV-seropositive cat with a concurrent infection has a poor prognosis is to treat the concurrent infection.

A number of antilentiviral drugs may be effective for the treatment of FIV-infected cats, but controlled studies are largely lacking (Hartmann et al., 2015; Mohammad and Bienzle, 2012). Administration of interferons has shown clinical benefit in some studies. Oral administration of 10 IU/kg of human interferon-α led to improved clinical signs and prolonged survival compared with a placebo-treated control group in one study (Pedretti et al., 2006). In another study, feline recombinant interferon was administered at 10^6 U/kg/day subcutaneously (SC) for 5 days in three series (starting on days 0, 14, and 60) and was shown to improve clinical signs early in the study and prolong survival in treated cats (de Mari et al., 2004). In another study with recombinant feline interferon omega, neither a subcutaneous protocol nor an oral protocol lessened FIV viremia, but IL-6 was decreased (Leal et al., 2015). The use of feline interferon and potential immunomodulatory effects on FIV infection have been reviewed (Leal and Gil, 2016). Administration of bovine lactoferrin by mouth was beneficial in the treatment of intractable stomatitis in FIV-seropositive cats (Sato et al., 1996). Removal of all premolar and molar teeth has also been effective for treatment of intractable stomatitis in some FIV-seropositive cats.

Other substances like the reverse transcriptase inhibitor azidothymidine (AZT), melittin, and phosphonate 9-(2-phosphonylmethoxypropyl)-2,6-diaminopurine, 9-(2-phosphonylmethoxyethyl) adenine, or plerixafor have had mixed success in the treatment of FIV and are generally not used clinically in the United States for management of FIV cats. Human recombinant erythropoietin administration increased red blood cell and white blood cell counts, did not increase viral load, and had no measurable adverse clinical effects in FIV-infected cats compared with placebo (Arai et al., 2000) and could be considered for management of anemia in FIV-infected cats. In contrast, although administration of human recombinant granulocyte-monocyte colony-stimulating factor (GM-CSF) to FIV-infected cats increased white blood cell counts in some treated cats, it also induced fever, anti–GM-CSF antibodies, and increased viral load; GM-CSF therefore appears to be contraindicated for this syndrome. Cats with FIV and hospitalized cats had lower serum 25-hydroxyvitamin D [25(OH)D] concentrations than healthy cats in one study (Titmarsh et al., 2015). Whether supplementation will have clinical benefit in the management if FIV infections remains to be proven.

Prevention and Zoonotic Aspects

Housing cats indoors to avoid fighting and testing new cats before introduction to an FIV-seronegative, multiple-cat household will prevent most cases of FIV. Transmission by fomites is unusual because the virus is not easily transmitted by casual contact, is susceptible to most routine disinfectants, and dies when out of the host after minutes to hours, especially when dried. Cleaning litter boxes and dishes shared by cats with scalding water and detergent inactivates the virus. Cats with potential exposure from fighting should be retested 60 days after the exposure (Goldkamp et al., 2008). Cats that are FIV-infected should be housed indoors at all times to avoid exposing FIV-naïve cats in the environment to the virus and to lessen the affected animal's chance of acquiring opportunistic infections. Kittens queened by FIV-infected cats should not be allowed to nurse to avoid transmission by ingestion of milk; they should be shown to be serologically negative at 6 months of age to document failure of lactogenic or transplacental transmission before being sold or adopted. In one study, FIV-positive cats housed in groups of ≤ 2 cats had better long-term outcomes than FIV-positive cats housed in large groups (Beczkowski et al., 2015). A killed vaccine containing immunogens from two FIV isolates is licensed for use in some countries. However, the efficacy of the vaccine is in question (Westman et al., 2016b).

HIV and FIV are morphologically similar but antigenically distinct. Antibodies against FIV have not been documented in the serum of human beings, even after accidental exposure to virus-containing material (Butera et al., 2000; Dickerson et al., 2012). Cats with FIV infection resulting in immunodeficiency may be more likely to spread other zoonotic agents into the human environment; clinically ill, FIV-seropositive cats should therefore undergo a thorough diagnostic evaluation (see Chapter 99).

FELINE LEUKEMIA VIRUS

Etiology and Epidemiology

FeLV is a single-strand RNA virus in the family Retroviridae, subfamily Oncovirinae. The virus produces reverse transcriptase, which catalyzes the reaction, resulting in the formation of a DNA copy (provirus) of FeLV viral RNA in the cytoplasm of infected cells; the provirus is inserted into the host cell genome. On subsequent host cell divisions the provirus serves as a template for new virus particles formed in the cytoplasm and is released across the cell membrane by budding. FeLV is composed of several core and envelope proteins. Envelope protein p15e induces immunosuppression. Core protein p27 is present in the cytoplasm of infected cells, peripheral blood, saliva, and tears of infected cats; detection of p27 is the basis of most FeLV antigen tests. The envelope glycoprotein 70 (gp70) contains the subgroup antigens A, B, or C, which are associated with the infectivity, virulence, and disease caused by individual strains of the virus. Neutralizing antibodies are produced by some cats after exposure to gp70. Antibodies against feline oncornavirus-associated cell membrane antigen (FOCMA) are formed by some cats but are generally not used clinically.

The principal route of infection by FeLV is prolonged contact with infected cat saliva and nasal secretions; grooming or sharing common water or food sources effectively results in infection. Because the organism does not survive in the environment, feces, urine, fomite, and aerosol

transmission is unlikely. Transplacental, lactational, and venereal transmission are less important than casual contact. FeLV infection has worldwide distribution; the seroprevalence of infection varies geographically and by the population of cats tested. Infection is most common in outdoor male cats between ages 1 and 6 years. The prevalence of FeLV antigen in North America and Canada was 3.1% in a 2017 study (Burling et al., 2017), which is higher than the 2.3% in a study reported in 2006 (Levy et al., 2006). FeLV can be detected in feces of infected fleas for 2 weeks (Vobis et al., 2005). However, the prevalence rates for FeLV vary little across regions of the United States with high and low prevalence rates of fleas, so this is an unlikely route of infection.

The virus replicates first in the oropharynx, followed by dissemination through the body to the bone marrow (Table 96.3). If persistent bone marrow infection occurs, infected white blood cells and platelets leave the bone marrow with ultimate infection of epithelial structures, including salivary and lacrimal glands. Whether infection occurs after natural exposure to FeLV is determined by the virus subtype or strain, the virus dose, the age of the cat when exposed, and the cat's immune responses. Using real-time PCR and antigen ELISA results, four classes of FeLV infection (Torres et al., 2005; Levy et al., 2008) were defined (see Table 96.3). Some FeLV-exposed cats can eliminate the infection (abortive), whereas others progress to clinical illness and persistent viremia (progressive). Other FeLV-exposed cats will develop regressive infection characterized by antigen-negative results and lower transiently positive real-time PCR results. Focal infections are transiently antigen-positive but have persistently positive real-time PCR results. Focal and regressive infections can be potentially activated by the administration of glucocorticoids or other immunosuppressive drugs. Blood from cats with regressive infection (provirus-positive) can infect previously naïve cats (Nesina et al., 2015).

The pathogenesis of various syndromes induced by FeLV is complex but includes induction of lymphoma from activation of oncogenes by the virus or insertion of a provirus into the genome of lymphoid precursors; subgroup C induction of aplastic anemia from increased secretion of tumor necrosis factor-α; immunodeficiency attributable to T-lymphocyte depletion (both $CD4^+$ and $CD8^+$ lymphocytes) or dysfunction; neutropenia; neutrophil function disorders; malignant transformation; viral induction of bone marrow growth-promoting substances leading to myeloproliferative diseases; and potentially co-infections with other retroviruses like FIV and feline foamy virus (FFV). Cats with FeLV infection or FeLV and FIV infections had significantly shorter life spans than cats infected with FIV alone (Spada et al., 2018). In one study, differences in viral RNA and provirus tissue loads influenced the different infection outcomes like lymphoma, leukemia, and nonregenerative anemia (Helfer-Hungerbuehler AK, et al., 2015). In that study, FeLV viral RNA and provirus DNA were detected in cats with regressive infection for up to 12 years. A closed colony of research cats was used to evaluate for associations amongst FeLV, FFV, feline gammaherpesvirus, and feline coronavirus. In that study, progressive FeLV infection and FeLV-B presence were associated with higher FeLV proviral and plasma viral loads. Female cats were more likely to have progressive infections, and males were more likely to have abortive infections. Higher proviral loads of FFV associated with higher FeLV proviral and plasma viral loads, FeLV-B, and feline coronavirus. FcaGHV-1 co-infections were more likely to occur in male cats (Powers et al., 2018). Future FeLV field studies should also include comparison with FFV and feline gammaherpesvirus test results.

Clinical Features

Owners generally present FeLV-infected cats for evaluation of nonspecific signs such as anorexia, weight loss, and depression, or abnormalities associated with specific organ systems. Of the FeLV-infected cats evaluated at necropsy, 23% had evidence of neoplasia (96% lymphoma/leukemia); the remainder died from nonneoplastic diseases (Reinacher, 1989). Specific clinical syndromes can result from specific effects of the virus or from opportunistic infections caused

TABLE 96.3

Outcomes of FeLV Infection

OUTCOME OF FELV EXPOSURE	FELV P27 ANTIGEN IN BLOOD	VIRAL BLOOD CULTURE	VIRAL TISSUE CULTURE	VIRAL RNA IN BLOOD	PROVIRAL DNA IN BLOOD	VIRAL SHEDDING	FELV-ASSODATED DISEASE
Progressive infection	Positive	Positive	Positive	Positive	Positive	Positive	Likely
Regressive infection	Negative or transiently positive	Negative or transiently positive	Negative or transiently positive	Transiently or persistently positive	Positive	Negative	Unlikely
Abortive exposure	Negative	Negative	Negative	Not tested	Negative	Negative	Unlikely
Focal infection	Negative	Negative	Positive	Not tested	Not tested	Variable	Unlikely

by immunosuppression. A positive FeLV test result does not prove disease induced by FeLV. When a clinical syndrome is diagnosed in a FeLV-seropositive cat, the workup should include diagnostic tests for other potential causes. The opportunistic agents discussed for FIV are also common in FeLV-infected cats (see Table 96.2).

Bacterial or calicivirus-induced stomatitis occurs in some FeLV-infected cats as a result of immunosuppression. FeLV infection can result in vomiting or diarrhea from a form of enteritis clinically and histopathologically resembling panleukopenia, from alimentary lymphoma, or from secondary infections attributable to immunosuppression. Icterus in FeLV-infected cats can be prehepatic from immune-mediated destruction of red blood cells induced by FeLV or secondary infection by *M. haemofelis* or *"Candidatus Mycoplasma haemominutum";* hepatic from hepatic lymphoma, hepatic lipidosis, or focal liver necrosis; or posthepatic from alimentary lymphoma. Some FeLV-infected cats with icterus may be concurrently infected by FIP virus or *T. gondii.*

Clinical signs of rhinitis or pneumonia occur in some FeLV-infected cats as a result of secondary infections. Dyspnea or dysphagia from mediastinal lymphoma occurs in some cats. These cats are generally younger than 3 years and may have decreased cranial chest compliance on palpation, as well as muffled heart and lung sounds if pleural effusion is present.

Mediastinal, multicentric, and alimentary lymphomas are the most common neoplasms associated with FeLV; lymphoid hyperplasia also occurs. Alimentary lymphoma most commonly involves the small intestine, mesenteric lymph nodes, kidneys, and liver of older cats; however, most cats with alimentary lymphoma are FeLV-negative. Renal lymphoma can involve one or both kidneys, which are usually enlarged and irregularly marginated on physical examination. For additional discussion, please see Chapter 79. Fibrosarcomas occasionally develop in young cats co-infected with FeLV and feline sarcoma virus (see Chapter 81). Lymphocytic, myelogenous, erythroid, and megakaryocytic leukemia all are reported with FeLV infection; erythroleukemia and acute myelomonocytic leukemia are the most common (see Chapter 80). The history and physical examination findings are nonspecific.

Renal failure occurs in some FeLV-infected cats from renal lymphoma or glomerulonephritis. Affected cats are presented for evaluation of polyuria, polydipsia, weight loss, and inappetence during the last stages of disease. Urinary incontinence from sphincter incompetence or detrusor hyperactivity occurs in some cats; small-bladder nocturnal incontinence is reported most frequently.

Some FeLV-infected cats are presented for miosis, blepharospasm, or cloudy eyes from ocular lymphoma. Aqueous flare, mass lesions, keratic precipitates, lens luxations, and glaucoma are often found on ocular examination. FeLV does not likely induce uveitis without lymphoma. Neurologic abnormalities associated with FeLV infection include anisocoria, ataxia, weakness, tetraparesis, paraparesis, behavioral changes, and urinary incontinence. Nervous system disease is likely to develop as a result of polyneuropathy or lymphoma. Intraocular and nervous system disease in FeLV-infected cats can occur from infection with other agents, including FIPV, *Cryptococcus neoformans,* or *T. gondii.*

Abortion, stillbirth, or infertility occurs in some FeLV-infected queens. Kittens infected in utero that survive to birth generally develop accelerated FeLV syndromes or die as part of the kitten mortality complex.

Some FeLV-seropositive cats present for lameness or weakness from suppurative nonseptic polyarthritis attributed to immune complex deposition. Multiple cartilaginous exostoses occur in some cats and may be FeLV related.

Diagnosis

A variety of nonspecific hematologic, biochemical, urinalysis, and radiographic abnormalities occur in FeLV-infected cats. Nonregenerative anemia alone or in combination with decreases in lymphocyte, neutrophil, and platelet counts is common. The presence of increased numbers of circulating nucleated red blood cells or macrocytosis in association with severe nonregenerative anemia occurs frequently; examination of bone marrow often documents a maturation arrest in the erythroid line (erythrodysplasia). Immune-mediated destruction of erythrocytes can be induced by FeLV and occurs in cats co-infected with hemoplasmas; regenerative anemia, microagglutination or macroagglutination of erythrocytes, and a positive result on the direct Coombs test are common in these cats. Neutropenia and thrombocytopenia occur from bone marrow suppression or immune-mediated destruction. In one study, 37 cats with nonregenerative cytopenias were evaluated for focal FeLV in the bone marrow by RT-PCR assay and 2 cats were positive (Stützer et al., 2010). FeLV-infected cats with the panleukopenia-like syndrome have gastrointestinal tract signs and neutropenia and are difficult to differentiate from cats with panleukopenia virus infection or salmonellosis. However, cats with FeLV-induced panleukopenia-like syndrome usually have anemia and thrombocytopenia, abnormalities rarely associated with panleukopenia virus infection. In one study, FeLV-positive cats with anemia at the time of initial diagnosis had shorter life span than FeLV-positive cats with normal red blood cells (Spada et al., 2018).

Azotemia, hyperbilirubinemia, bilirubinuria, and increased activity of liver enzymes are common biochemical abnormalities. Proteinuria occurs in some FeLV-infected cats with glomerulonephritis. Cats with lymphoma have mass lesions radiographically depending on the organ system affected. Mediastinal lymphoma can result in pleural effusion; alimentary lymphoma can cause obstructive intestinal patterns.

Lymphoma can be diagnosed by cytologic or histopathologic evaluation of affected tissues (see Chapters 74 and 79). Because lymphoma can be diagnosed cytologically and treated with chemotherapy, cats with mediastinal masses, lymphadenopathy, renomegaly, hepatomegaly, splenomegaly, or intestinal masses should be evaluated cytologically before surgical intervention. Malignant lymphocytes are also

occasionally identified in peripheral blood smears, effusions, and CSF.

Most cats with suspected FeLV infection are screened for FeLV antigens in neutrophils and platelets by immunofluorescent antibody (IFA) testing or in whole blood, plasma, serum, saliva, or tears by ELISA. Blood or plasma may be the most accurate fluids to assess in ELISA tests. There are multiple point of care tests around the world, and results can vary between tests and between the same test in two different studies (Hartmann et al., 2007; Westman et al., 2017; Levy et al., 2017; Liu et al., 2016; Krecic et al., 2018). IFA results are not positive until the bone marrow has been infected. Generally, the results of IFA testing are accurate more than 95% of the time. False-negative reactions may occur when leukopenia or thrombocytopenia prevents evaluation of an adequate number of cells. False-positive reactions can occur if the blood smears submitted for evaluation are too thick. A positive IFA result indicates that the cat is viremic and contagious; approximately 90% of cats with positive IFA results are viremic for life. The rare combination of IFA-positive and ELISA-negative results suggests technique-related artifact.

The virus can be detected in serum by ELISA before infection of bone marrow and can therefore be positive in some cats during early progressive stages of infection or during early latent infection, even though IFA results are negative. Other possibilities for discordant results (ELISA-positive, IFA-negative) are false-positive ELISA results or false-negative IFA results. Cats with positive ELISA results and negative IFA results should be isolated until retested 4 to 6 weeks later because progression to persistent viremia and epithelial cell infection may be occurring.

ELISA-positive cats that revert to negative have developed focal (latent) infections or regressive infection. Virus isolation, IFA performed on bone marrow cells, immunohistochemical staining of tissues for FeLV antigen, and PCR can be used to confirm focal or regressive infection in some cats. Cats with focal or regressive infection are not likely contagious to other cats by direct contact, but infected queens may pass the virus to kittens during gestation or parturition, or by milk. Cats with regressive or focal infection can be immunodeficient and may become viremic (IFA- and ELISA-positive) after administration of glucocorticoids, or after extreme stress.

A delay of 1 to 2 weeks generally occurs after the onset of viremia before ELISA tear and saliva test results become positive; therefore these test results can be negative even when results with serum are positive and so are not generally not recommended for use unless blood cannot be collected. Antibody titers to FeLV envelope antigens (neutralizing antibody) and against virus-transformed tumor cells have been detected in research studies, but the diagnostic and prognostic significance of results from these tests is unknown. Real-time PCR assays are more sensitive than conventional PCR for FeLV infections, but testing is not standardized amongst most laboratories in the United States (Torres et al., 2005).

FeLV has been transmitted by blood from some cats that are FeLV provirus-positive, p27 antigen-negative (Nesina et al., 2015). Thus results support the recommendation to optimally use FeLV antigen-negative and provirus DNA-negative cats as blood donors (Wardrop et al., 2016)

Treatment

Antiretroviral drugs that could be potentially used for the management of cats with clinical disease related to FeLV have been reviewed (Hartmann et al., 2015). Several antiviral agents have been proposed for the treatment of FeLV; the reverse transcriptase inhibitor AZT has been studied the most. Unfortunately, administration of AZT to persistently viremic cats does not appear to clear viremia in most, and it had minimal benefits for clinically ill cats in a study (Hartmann et al., 2002). Interferons have an effect against FeLV in vivo and in vitro (Collado et al., 2007; de Mari et al., 2004) and lessen clinical disease in FeLV-infected cats by immune modulation as described for FIV (Domenech et al., 2011; Leal and Gil, 2016; Pedretti et al., 2006). Immunotherapy with drugs compounds such as *Staphylococcus* protein A, *Propionibacterium acnes,* or acemannan have been purported to improve clinical signs in some cats, but controlled studies are lacking.

Chemotherapy should be administered to cats with FeLV-associated neoplasia (see Chapters 76 and 79). Opportunistic agents should be managed as indicated; the upper dose range and duration of antibiotic therapy are generally required. Supportive therapies such as hematinic agents, vitamin B_{12}, folic acid, anabolic steroids, and erythropoietin generally have been unsuccessful in the management of nonregenerative anemia. Blood transfusion is required in many cases. Cats with immune-mediated hemolytic anemia require immunosuppressive therapy, but this may activate virus replication. The prognosis for persistently viremic cats is guarded; the majority die within 2 to 3 years.

Prevention and Zoonotic Aspects

Avoiding contact with FeLV by housing cats indoors is the best form of prevention. Potential fomites such as water bowls and litter pans should not be shared by seropositive and seronegative cats. Testing and removal of seropositive cats can result in virus-free catteries and multiple-cat households.

Because of variations in challenge study methods and the difficulty of assessing the preventable fraction of a disease with a relatively low infection rate, long subclinical phase, and multiple field strains, the efficacy of individual vaccines continues to be in question (see Chapter 93). In one recent study, all three FeLV vaccines studied gave similar efficacies (Grosenbaugh et al., 2017). Vaccination of cats not previously exposed to FeLV should be considered in cats at high risk (i.e., contact with other cats), but owners should be warned of the potential efficacy of less than 100%. Cats with persistent FeLV viremia do not benefit from vaccination. Vaccination is related to the development of fibrosarcoma in some cats (see Chapter 93). Cats developing these tumors may be genetically predisposed.

FeLV-infected cats should be housed indoors to avoid infecting other cats and avoid exposure to opportunistic agents. Flea control should be maintained to avoid exposure to hemoplasmas, and *Bartonella* spp. FeLV-infected cats should not be allowed to hunt or be fed undercooked meats to avoid infection by *T. gondii, Cryptosporidium parvum, Giardia* spp., and other infectious agents carried by transport hosts.

Antigens of FeLV have never been documented in the serum of human beings, suggesting that the zoonotic risk is minimal. However, FeLV-infected cats may be more likely than FeLV-naïve cats to pass other zoonotic agents, such as *C. parvum* and *Salmonella* spp., into the human environment.

CHAPTER 97

Polysystemic Mycotic Infections

BLASTOMYCOSIS

Etiology and Epidemiology

Blastomyces dermatitidis is a saprophytic yeast found primarily in the Mississippi, Missouri, and Ohio River valleys; the mid-Atlantic states; and southern Canada. An extracellular yeast form (5-20 µm in diameter) with broad-based budding develops in the vertebrate host (Table 97.1). The infectious mycelial phase occurs in the soil and in culture.

Blastomycosis develops most frequently in areas exposed to high humidity, fog, excavation sites, and sandy, acidic soils near bodies of water. Potential for disease may vary with the virulence of the field strain, the inoculum dose, and the immune status of the host. Most clinical cases occur from point source exposure; multiple cases are diagnosed in an area, and clusters of infection in people and dogs have been reported. Seasonal, weather, and environmental variables influence prevalence rates. Transmission is from inhalation or contamination of open wounds with spores from the environment. Nasal culture failed to identify the fungus on samples collected from 110 clinically normal dogs living in an endemic area, suggesting colonization of this site is not common (Varani et al., 2009). After inhalation, the organism probably replicates in the lungs initially and then spreads hematogenously to other tissues, including the skin and subcutaneous tissues, eyes, bones, lymph nodes, external nares, brain, testes, nasal passages, prostate, liver, mammary glands, vulva, and heart. However, central nervous system (CNS) disease may result from extension from the nasal cavity. The organism can be swallowed and passed in feces. Incomplete clearance of the organism by individuals with poor cell-mediated immune responses results in pyogranulomatous inflammation in affected organs, which can cause clinical signs of disease. Subclinical infection is believed to be uncommon in dogs and cats.

Clinical Features

Large-breed, young, male, sporting dogs are infected most commonly by *B. dermatitidis* most likely because of an increased chance for exposure to the organism. Anorexia, cough, dyspnea, exercise intolerance, weight loss, ocular disease, skin disease, depression, lameness, and syncope are the most common presenting complaints.

Fever occurs in approximately 40% of affected dogs. Interstitial lung disease and hilar lymphadenopathy result in cough, dry and harsh lung sounds, and dyspnea; hypertrophic osteopathy occurs in some dogs. Infection of the nasal cavity, the nasopharynx, and the retrobulbar area occurs rarely and can extend intracranially. Dyspnea from chylothorax caused by cranial vena cava syndrome has been described. Valvular endocarditis occurs as well, and conduction disturbances from myocarditis are detected in some dogs with cardiac blastomycosis. Lymphadenopathy and cutaneous or subcutaneous nodules, abscesses, plaques, or ulcers occur in 20% to 40% of infected dogs. Splenomegaly is common. Lameness from fungal osteomyelitis of the spine or appendicular skeleton occurs in approximately 30% of dogs with blastomycosis. Infection of the testes, prostate, urinary bladder, mammary glands, and kidneys occurs rarely.

Ocular manifestations are recognized in approximately 30% of dogs with blastomycosis; anterior uveitis, endophthalmitis, posterior segment disease, and optic neuritis occur. Cataracts can result from chronic inflammation or rupture of the lens capsule. Fungal infections of the CNS were recently reviewed (Bentley et al., 2018). Blastomycosis of the CNS often is an intracranial mass or a cause of ventriculitis. Depression and seizures from diffuse or multifocal CNS involvement occur in some dogs.

Blastomycosis can occur in any cat but is most common in young males. Both cats housed indoors and cats allowed outdoors can develop disease. Infected cats develop respiratory tract disease, CNS disease, regional lymphadenopathy, dermatologic disease, ocular disease, gastrointestinal tract disease, and urinary tract disease. Pleural or peritoneal effusion resulting in dyspnea or abdominal distension occurs in some cats. Ocular disease usually involves the posterior segment.

Diagnosis

Hematologic abnormalities commonly identified in dogs or cats with blastomycosis are normocytic normochromic

TABLE 97.1

Morphologic Appearance of Systemic Canine and Feline Fungal Agents

AGENT	CYTOLOGIC APPEARANCE
Blastomyces dermatitidis	Extracellular yeast, 5-20 µm in diameter; thick, refractile, double-contoured wall; broad-based bud; routine stains are adequate
Cryptococcus spp.	Extracellular yeast, 3.5-7.0 µm in diameter; thick, unstained capsule; thin-based bud; violet color with light-red capsule with Gram stain; unstained capsule with India ink
Coccidiodes spp.	Extracellular spherules (20-200 µm in diameter) containing endospores; deep red to purple double outer wall with bright red endospores with PAS stain
Histoplasma capsulatum	Intracellular yeast in mononuclear phagocytes, 2-4 µm in diameter, basophilic center with lighter body with Wright stain
Sporothrix schenckii	Intracellular yeast in mononuclear phagocytes, 2-3 µm × 3-6 µm in diameter; round, oval, or cigar-shaped

PAS, Periodic acid–Schiff.

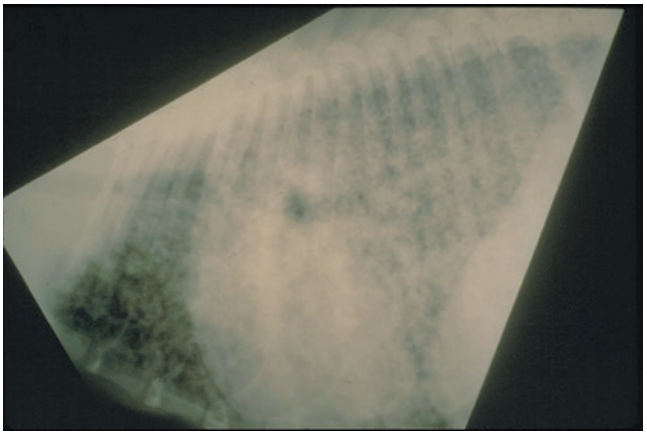

FIG 97.1

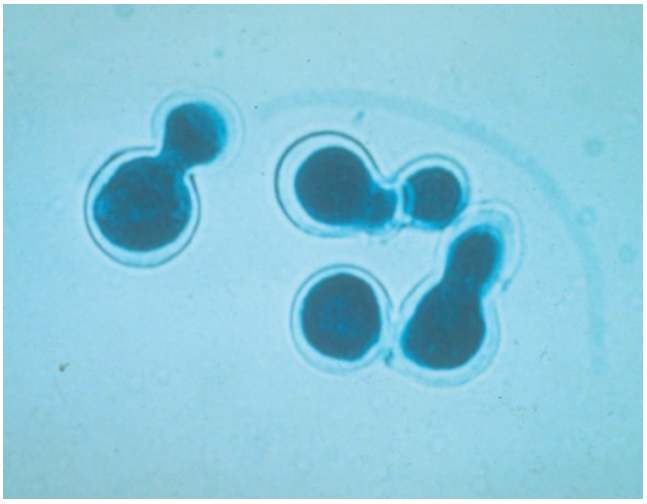

FIG 97.2
Cytologic appearance of the budding yeast, *Blastomyces dermatitidis*. The organism is 5 to 20 µm in diameter with a thick, refractile, double-contoured wall. (Courtesy Dr. Dennis Macy, College of Veterinary Medicine and Biomedical Sciences, Colorado State University.)

nonregenerative anemia, lymphopenia, neutrophilic leukocytosis with or without a left shift, and monocytosis. Hypoalbuminemia and hyperglobulinemia (i.e., polyclonal gammopathy) caused by chronic inflammation are common serum biochemical abnormalities; hypercalcemia occurs rarely in dogs. Most infected dogs and cats with respiratory disease have diffuse, miliary, or nodular interstitial lung patterns and intrathoracic lymphadenopathy on thoracic radiographs (Fig. 97.1); single masses and pleural effusion from chylothorax sometimes occur. Alveolar lung disease occurs in some cats. Bone lesions induced by blastomycosis are lytic with a secondary periosteal reaction and soft tissue swelling. Intracranial blastomycosis generally reveals evidence of extension from the nasal cavity on diagnostic imaging but solitary CNS granulomas do occur (Bentley et al., 2018).

Serum antibodies develop in some infected animals; agar gel immunodiffusion (AGID) or a commercially available canine assay (www.miravistalabs.com) is frequently used. Because blastomycosis rarely causes subclinical infection, positive serum antibody assay results combined with appropriate clinical signs and radiographic abnormalities allow presumptive diagnosis if the organism cannot be demonstrated. Antibody titers do not always revert to negative after successful treatment. False-negative results can occur in animals with peracute infection, immunosuppression, or advanced infection that overwhelms the immune system; many cats with blastomycosis are seronegative.

Detection of the organism in a clinically ill animal with the appropriate presentation can give a definitive diagnosis of blastomycosis. The organism can be demonstrated by cytology, histopathology, culture, antigen test, or amplification of specific DNA by polymerase chain reaction (PCR) assay. Impression smears from skin lesions and aspirates from enlarged lymph nodes and focal lung lesions usually reveal pyogranulomatous inflammation and organisms that can usually be seen at low power (Fig. 97.2). Recovery of organisms from urine is less consistent. Bronchoalveolar

lavage is more sensitive than transtracheal aspiration for organism demonstration; organisms can also be found in samples obtained by percutaneous lung aspirates. However, in one study, *B. dermatitidis* was identified in 13 of 17 dogs after transtracheal aspiration (McMillan and Taylor, 2008). Growth in culture requires 10 to 14 days and is of lower yield than cytology or biopsy.

A *Blastomyces* antigen assay is available for human samples and has been evaluated in small numbers of dogs (MVista *Blastomyces* Antigen EIA; www.miravistalabs.com). The assay is sensitive but not specific for *B. dermatitidis*. In a study of 46 dogs with confirmed blastomycosis, the sensitivities of the antigen test using urine or serum were 93.5% and 87.0%, respectively (Spector et al., 2008). In contrast, the sensitivity of serum antibody results by AGID was 17.4%. In another study, *Blastomyces* antigen was detected in urine of all 21 dogs tested as well as in 18 of 20 sera (Foy et al., 2014). In that study, 71% of the dogs with clinical relapse were positive for *Blastomyces* antigen in urine. *Blastomyces dermatitidis* DNA can also be amplified from cerebrospinal fluid (CSF) of dogs with neurologic disease (Han et al., 2015).

Treatment

Amphotericin B, ketoconazole, both amphotericin B and ketoconazole, and itraconazole alone are used most frequently for the treatment of blastomycosis in dogs (Table 97.2). Amphotericin B is generally used in animals with life-threatening disease; the lipid or liposomal encapsulated product is less likely to cause toxicity. If regular amphotericin B is used, the animal should be well hydrated with 0.9% sodium chloride before treatment, and treatment should be discontinued if the patient becomes azotemic. Because itraconazole is as effective as amphotericin B and ketoconazole alone or in combination and has fewer adverse effects, it has

TABLE 97.2

Antifungal Drugs Used in the Management of the Systemic Canine and Feline Fungal Diseases

DRUG	SPECIES	DOSAGE	ORGANISM
Amphotericin B deoxycholate	D	1 mg/kg, IV, up to 3 times weekly[a] to a cumulative dose of 4-8 mg/kg. 0.5-0.8 mg/kg SC 2-3 times weekly to a cumulative dose of 4-8 mg/kg.[b]	Bl, H, Cr, Co
	C	0.25 mg/kg IV up to 3 times weekly,[c] to a cumulative dose of 4-6 mg/kg 0.5-0.8 mg/kg SC 2-3 times weekly[b] to a cumulative dose of 4-6 mg/kg	Bl, H, Cr, Co
Amphotericin B (lipid complex)	D	2-3 mg/kg, IV, 3 times weekly[d] to a cumulative dose of 12-27 mg/kg	Bl, H, Cr, Co
	C	1 mg/kg IV infusion 3 times weekly to a cumulative dose of 12 mg/kg	
Fluconazole	D	5-10 mg/kg PO or IV q12-24h	Bl, H, Cr, Co
	C	25 or 50 mg/cat PO q12-24h	Cr, Bl, H, Co
Flucytosine[e]	C	50 mg/kg PO q6-8h	Cr
Ketoconazole	D	10 mg/kg PO q12-24h	Bl, H, Cr, Co, Sp
	C	5-10 mg/kg, PO, q24h	Bl, H, Cr, Co, Sp
Itraconazole	D	5-10 mg/kg, PO, q12-24h	Bl, Cr, H, Co, Sp
	C	50-100 mg/cat/day PO	Bl, Cr, H, Co, Sp
Posaconazole	C	30 mg/kg, PO loading dose followed by 15 mg/kg, PO, q48h	Bl, Cr, H, Co, Sp
Terbinafine	D	30-35 mg/kg, PO, q24h	Cr, Bl, H, Co
Voriconazole[f]	D	4 mg/kg, PO, q12h	Bl, Cr, H, Co

[a]In dogs with normal renal function, dilute in 60-120 mL 5% dextrose and administer IV over 15 minutes; in dogs with renal insufficiency but with a blood urea nitrogen level <50 mg/dL, dilute in 500 mL to 1 L 5% dextrose and administer IV over 3-6 hours.
[b]Mix in 400 mL (cats) or 500 mL (dogs) of 0.45% saline and 2.5% dextrose solution, and administer SQ.
[c]In cats with normal renal function, dilute in 50-100 mL 5% dextrose and administer IV over 3-6 hours.
[d]Dilute the contents of a vial with 5% dextrose to a final concentration of 1 mg/mL and shake for 30 seconds. Draw up needed volume and filter through an 18-gauge Monoject filter needle into 100 mL of 5% dextrose. Infuse intravenously over 15 minutes.
[e]Should be used in combination with amphotericin B.
[f]Has been used in cats as well, but is associated with neurotoxicity (Quimby et al., 2010).

been the drug of choice for the treatment of blastomycosis (see Table 97.2). Dogs should be treated with 5 mg/kg/day twice daily for the first 5 days and then 5 mg/kg once daily. Treatment should be continued for 60 to 90 days or for 4 weeks beyond resolution of measurable disease (i.e., thoracic radiographic abnormalities or skin lesions). A bioequivalence study showed that generic intraconazole was not bioequivalent to the approved product but was close enough to be used clinically (Mawby et al., 2014). In contrast, one source of compounded itraconazole was not suitable for use. Fluconazole can also be used and may be effective for CNS, ocular, and urinary system blastomycosis. In one retrospective study, overall responses to fluconazole or itraconazole in dogs with blastomycosis were similar. However, dogs treated with fluconazole had a higher mortality rate in the first 2 weeks of therapy, suggesting differences between the drugs in early efficacy (Mazepa et al., 2011).

Relapses occur in 20% to 25% of treated dogs. When they occur, a complete course of therapy should be reinstituted. Posterior segment ocular disease responds well to itraconazole, but anterior uveitis and endophthalmitis often require enucleation of the affected eye. In dogs with ocular blastomycosis resulting in euthanasia or enucleation of the affected eye, differences in the presence of the organism was not noted between treated and untreated dogs (Hendrix et al., 2004). In one study of 23 cats with blastomycosis, successful results were reported for two cats treated with amphotericin B and ketoconazole, one cat treated with amputation, and one cat treated with potassium iodide. In a more recent study of eight cats, two cats treated with itraconazole and one cat treated with fluconazole had clinical resolution of their disease (Gilor et al., 2006).

After treatment, decreases in *B. dermatitidis* serum antibody levels are variable. In contrast, in one study of 46 treated dogs, urine antigen concentrations decreased with treatment and so may be of benefit for monitoring therapy with clinical and radiographic parameters (Spector et al., 2008).

Zoonotic Aspects and Prevention

Genetic analyses have confirmed three haplotypes of *B. dermatitidis* that are common to both dogs and humans (Anderson et al., 2013). Direct zoonotic transmission from infected animals is unlikely because the yeast phase is not as infectious as the mycelial phase. One veterinarian was infected after material from a pulmonary aspirate from an infected dog was injected intramuscularly, and another developed disease after being bitten by an infected dog. The mycelial phase develops at temperatures lower than body temperature; positive cultures and contaminated bandages are infectious. Multiple reports have been made of canine and human blastomycosis that developed from the same environmental exposure. Decreasing potential for exposure by avoiding lakes and creeks in endemic areas is the only way to prevent the disease. A vaccine made of a genetically engineered live-attenuated strain of *B. dermatitidis* shows promise for use in dogs (Wüthrich M et al., 2011).

COCCIDIOIDOMYCOSIS

Etiology and Epidemiology

Coccidioides immitis is a dimorphic fungus found deep in sandy alkaline soils in regions with low elevation, low rainfall, and high environmental temperatures, including the southwestern United States, California, Mexico, Central America, and South America. In the United States coccidioidomycosis is diagnosed most frequently in California, Arizona, New Mexico, Utah, Nevada, and southwest Texas. *Coccidioides posadasii* has also been proven in some regions that are endemic for *C. immitis* (Brown et al., 2013; Luna-Isaac et al., 2014). The environmental mycelial phase produces arthrospores (2-4 µm wide, 3-10 µm long) that enter the vertebrate host by inhalation or wound contamination. Large numbers of arthrospores return to the surface after periods of rainfall and are dispersed by the wind; the prevalence of coccidioidomycosis increases in the years after a high rainfall. Most cases of feline coccidioidomycosis are diagnosed between December and May. In one study of dogs residing in an endemic area (Arizona), the cumulative probability of infection (evidenced by seroconversion) by 2 years of age was 28%, and the cumulative probability of clinical infection by 2 years of age was 6% (Shubitz et al., 2005). In another recent study that included 41 dogs with coccidioidomycosis and 79 control dogs, younger age, digging behavior, and travel to Arizona or the California central valley were associated with infection (Gayzel et al., 2017).

Inhaled arthrospores induce neutrophilic inflammation followed by infiltrates of histiocytes, lymphocytes, and plasma cells. The lymphocytic infiltrates associated with infection sites are predominantly T cells. Infection is cleared if cell-mediated immune responses are normal; most people, dogs, and cats exposed to the organism are subclinically affected. The organism disseminates to mediastinal and tracheobronchial lymph nodes, bones and joints, visceral organs (liver, spleen, kidneys), heart and pericardium, testicles, eyes, brain, and spinal cord of some individuals. Spherules (20-200 µm in diameter) containing endospores (see Table 97.1) form in tissues of infected hosts. Endospores are released by cleavage and produce new spherules. Respiratory signs and signs of disseminated disease occur 1 to 3 weeks and 4 months after exposure, respectively.

Clinical Features

Clinical disease in dogs is most common in young, male, large-breed dogs. Dogs that are allowed to roam or walk in the desert in endemic areas, particularly if they also exhibit digging behavior are most likely to be exposed. Approximately 90% of clinically affected dogs have lameness with swollen, painful bones or joints. Cough, dyspnea, anorexia, weakness, weight loss, lymphadenopathy, clinical signs of ocular inflammation, and diarrhea are other presenting complaints. Crackles, wheezes, or muffled lung sounds from pleural effusion are common. Restrictive pericarditis presenting with evidence of right heart failure, such as hepatomegaly, pleural effusion, and ascites, can also occur.

Heart base masses developed in two dogs in a recent report (Ajithdoss et al., 2011). Dermatologic findings in both dogs and cats are most commonly subcutaneous nodules (Simoes et al., 2016). If subcutaneous abscesses, nodules, ulcers, and draining tracts occur, they are usually associated with infected bones. Over 50% of the cats with skin lesions and over 75% of the dogs with cutaneous manifestations also have systemic illness (Simoes et al., 2016). In some dogs, coccidioidomycosis has been initially misdiagnosed as a malignancy (Ramirez-Romero et al., 2016). Of the three cases described in this report, one was infected by *C. posadasii*. Myocarditis, icterus, renomegaly, splenomegaly, hepatomegaly, orchitis, epididymitis, keratitis, iritis, granulomatous uveitis, and glaucoma are detected in some dogs. Depression, seizures, ataxia, central vestibular disease, cranial nerve deficits, and behavioral changes are the most common signs of CNS infection. Solitary CNS granulomas can occur (Bentley et al., 2015).

In one review, the median age of cats with coccidioidomycosis was 5 years; no obvious sex or breed predilection existed (Greene et al., 1995). The most common clinical manifestations include skin disease (56%), respiratory disease (25%), musculoskeletal disease (19%), and either ophthalmic or neurologic disease (19%). If ocular disease occurs, granulomatous chorioretinitis and anterior uveitis occur in most infected cats.

Diagnosis

Normocytic, normochromic nonregenerative anemia; leukocytosis; leukopenia; and monocytosis are the most common hematologic abnormalities. Hyperglobulinemia (i.e., polyclonal gammopathy), hypoalbuminemia, renal azotemia, and proteinuria occur in some infected animals. In one study of 87 dogs with coccidioidomycosis, azotemia (13%) and proteinuria (63%) were common (Mehrkens et al., 2016). Of the 24 dogs with renal histopathology performed, 13 dogs had lesions suggestive of immune complex glomerulonephritis. Thus dogs with proteinuria that have visited endemic areas like Arizona and California should be evaluated for infection.

Diffuse interstitial lung patterns are more common than bronchial, miliary interstitial, nodular interstitial, or alveolar patterns radiographically in dogs and cats with respiratory coccidioidomycosis. Pleural effusion from pleuritis, right-sided heart failure, or constrictive pericarditis can occur. Hilar lymphadenopathy is common in dogs and cats; however, sternal lymphadenopathy or calcification of lymph nodes is not. Bone lesions usually involve the distal diaphysis, epiphysis, and metaphysis of one or more long bones, and they are more proliferative than lytic. It can be difficult to differentiate neoplasia from *Coccidioides* spp. granulomas based on MRI findings (Bentley et al., 2015).

There are currently several methods for detection of serum antibodies against *C. immitis*, including AGID, complement fixation, and enzyme linked immunoassays, and tube precipitin (TP) tests. False-negative results can occur in dogs and cats with early *C. immitis* infections (<2 weeks), chronic infection, rapidly progressive acute infection, and primary cutaneous coccidioidomycosis. The assays can cross-react with antibodies against *Histoplasma capsulatum* and *B. dermatitidis*.

Serum antibodies develop in dogs with and without clinical signs of disease, and titer magnitude failed to correlate with the presence of illness in one study (Shubitz et al., 2005). Thus results of antibody test results alone should not be used to make a definitive diagnosis. The combination of positive serologic test results and radiographic signs of interstitial lung disease, dermatologic disease, or osteomyelitis in animals from endemic areas can be used to make a presumptive diagnosis if the organism cannot be demonstrated. In one study of 131 dogs, hilar lymphadenopathy was assessed as a predictor of a positive serum antibody titer and was shown to have a sensitivity, specificity, positive predictive value, and negative predictive value of 28%, 91.5%, 43.8%, and 84.4%, respectively (Crabtree et al., 2008). The authors concluded that, in endemic areas, the presence of hilar lymphadenopathy in dogs in endemic areas suggested treatment was indicated while waiting for serum antibody test. Titers may persist for months to years after resolution of clinical disease.

Definitive diagnosis requires demonstration of the organism by cytology, biopsy, antigen assay, culture, or amplification of specific DNA. The organism is often difficult to demonstrate by cytology; transtracheal aspiration or bronchoalveolar lavage is commonly negative. Extracellular spherules (Fig. 97.3) are most commonly found in lymph node aspirates, draining masses, and pericardial fluid; wet mount examination of unstained smears or periodic acid–Schiff-stained smears are more suitable than dry mounts.

For *B. dermatitidis* and *H. capsulatum,* detection of antigens of the fungi in serum or urine has shown some clinical utility (see appropriate sections of this chapter). In humans, detection of *C. immitis* antigen in serum or urine shows promise as a diagnostic procedure. However, when *C. immitis*

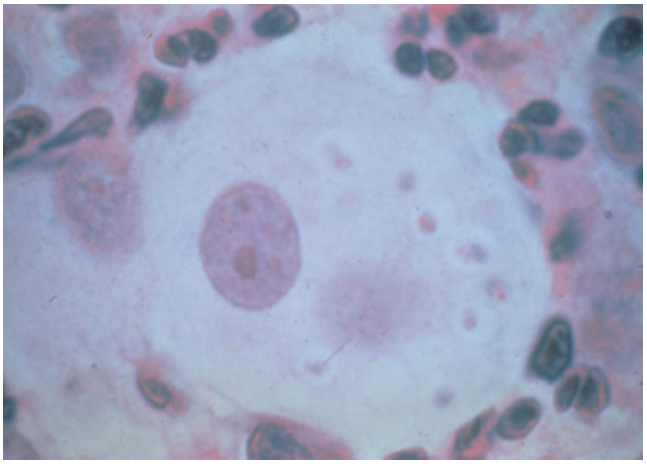

FIG 97.3
Coccidiodes immitis spherule (20-200 µm in diameter) in muscle tissue.

antigen was measured in samples from 60 dogs with antibody titers 1:16 or greater, the sensitivity was low for both serum (19%) and urine (3.5%), suggesting this assay should not be used in dogs (Kirsch et al., 2012).

Treatment

Ketoconazole is inexpensive and a drug of choice for treatment of coccidioidomycosis in dogs (see Table 97.1). However, this drug commonly leads to inappetence, vomiting, diarrhea, weight loss, and increases in liver enzyme activities in some dogs and cats. In dogs, long-term use of ketoconazole can suppress testosterone and cortisol production and has been associated with cataracts. Amphotericin B should be used if life-threatening disease is present or if response to ketoconazole is poor. Itraconazole can be used in animals with toxicity from ketoconazole. Fluconazole should be considered for animals with meningoencephalitis. Posaconazole has fungistatic activity against *Coccidioides* spp. and has been used successfully in management of human cases with refractory respiratory disease. Pharmacokinetic information is now available for this drug in cats (Mawby et al., 2016).

Cats and dogs should be treated for 60 to 90 days or until clinical illness has been resolved for at least 1 month. Bone infections are often incurable; therefore repeated treatments are often required. When treated with ketoconazole, itraconazole, or fluconazole, 32 of 44 cats with coccidioidomycosis were asymptomatic during or after treatment; relapse occurred in 11 cats during or after treatment (Greene et al., 1995). Voriconazole is a newer fluconazole derivative that achieves high concentrations in the CNS and so could be considered for dogs with CNS involvement. Neurologic adverse effects appear to be common in cats but have not been well defined in dogs (Quimby et al., 2010).

Daily administration of lufenuron, a chitin synthesis inhibitor, has been evaluated in a limited number of dogs with coccidioidomycosis. Nikkomycin Z (NikZ) is another chitin synthase inhibitor that was used to treat 12 dogs with *Coccidioides* spp.-associated respiratory disease for an average of 3 months (Shubitz, 2013). Seven of the nine dogs that completed the protocol had clinical and laboratory evidence of improvement. Pharmacologic studies with terbinafine have been completed (Sakai et al., 2011), and it could be considered as another option for the treatment of coccidioidomycosis (30-35 mg/kg, orally [PO], daily).

Zoonotic Aspects and Prevention

One study showed an association between the location of canine and human coccidioidomycosis in California suggesting dogs could be used as sentinels for infection in people (Grayzel et al., 2017). People exposed to *C. immitis* develop asymptomatic infection or mild, transient respiratory signs. The organism is not transmitted from infected animals to people. However, the mycelial phase occurs outside the vertebrate host, so fomites such as bandage material and cultures should be handled carefully. Avoiding endemic areas is the only way to prevent the disease.

CRYPTOCOCCOSIS

Etiology and Epidemiology

Cryptococcus neoformans is a 3.5- to 7.0-µm yeast-like organism with worldwide distribution. It has a thick polysaccharide capsule and reproduces by narrow-based budding (see Table 97.1). *Cryptococcus gattii* is also common in some regions and is associated with disease. Clinical findings with either infection are similar. Many cases have been described in California, British Columbia, and both coasts of Australia. An outbreak of *Cryptococcus* spp. infections recently occurred in people, dogs, cats, ferrets, and a bird in British Columbia (Lester et al., 2004; MacDougall et al., 2007). Most cases were on Vancouver Island and were caused by *C. gattii*. The organisms are acquired from the environment; risk factors significantly associated with infection in animals in the British Columbia outbreak included living near a site of soil disturbance such as logging sites, having an above-average level of activity, hunting, and having owners who hiked or visited a botanic garden (Duncan et al., 2006b). There may be breed predispositions; in one study in California, American Cocker Spaniels were more likely to have cryptococcosis than other breeds (Trivedi et al., 2011a). In the same study, most cats were infected by *C. gattii* and most dogs were infected by *C. neoformans*. Whether disease occurs is dependent on both host and organism factors (Ma and May, 2009).

The route of transmission for *Cryptococcus* spp. is believed to be inhalation. Nasal and pulmonary disease manifestations are common; however, on the basis of culture and serologic studies of healthy animals, an inapparent carrier state also occurs. The organism probably spreads to extrapulmonary sites hematogenously; the CNS may also be infected by direct extension across the cribriform plate from the nasal cavity. Immunity is cell mediated; individuals with incomplete responses do not completely remove the organism, thus resulting in granulomatous lesions. The polysaccharide capsule of the organism inhibits plasma cell function, phagocytosis, leukocyte migration, and opsonization, potentiating infection.

Cryptococcus spp. can be primary pathogens. However, preexisting immunosuppressive conditions are documented in approximately 50% of people with cryptococcosis. Serologic evidence of co-infection with feline immunodeficiency virus or feline leukemia virus occurs in some cats with cryptococcosis. Potentially immunosuppressive conditions such as administration of corticosteroids, ehrlichiosis, heartworm disease, and neoplasia are identified in a small percentage of dogs with cryptococcosis.

Clinical Features

Cryptococcosis is the most common systemic fungal infection of cats and should be considered a differential diagnosis for cats with clinical evidence of upper or lower respiratory tract disease, subcutaneous nodules, lymphadenopathy, intraocular inflammation, fever, or CNS disease. Lower urinary tract disease has also been described. All ages of cats

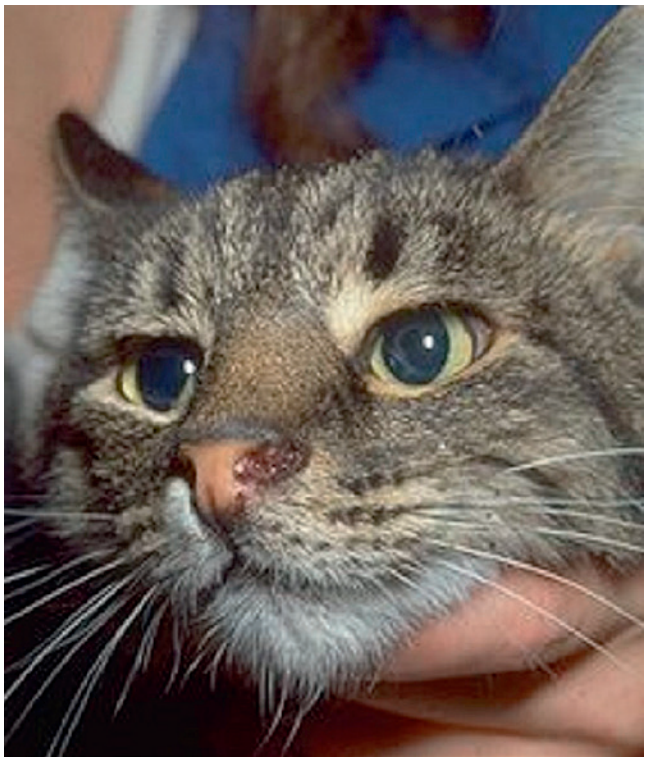

FIG 97.4
Nasal cryptococcosis in a cat in Colorado.

have been infected, but young cats are generally overrepresented. In one study in Australia, Siamese, Himalayan, and Ragdoll breeds were overrepresented (O'Brien et al., 2004). Infection of the nasal cavity, resulting in sneezing and nasal discharge (Fig. 97.4), is reported most frequently. The nasal discharge can be unilateral or bilateral, range from serous to mucopurulent, and often contains blood. Granulomatous lesions extruding from the external nares, facial deformity over the bridge of the nose, and ulcerative lesions on the nasal planum are common; mandibular lymphadenopathy is detected in most cats with rhinitis. These signs are also common in cats with upper airway lymphoma and feline aspergillosis, so every effort should be made to obtain a diagnosis before instituting treatment. The nasopharynx is the primary site of involvement in some infected cats and dogs, resulting in snoring and stertor as the predominant clinical signs. *Cryptococcus gattii* has also been detected in pleural effusion (Barrs et al., 2005).

Single or multiple, small (<1 cm), cutaneous or subcutaneous masses also have been reported commonly in cats infected with *C. neoformans*. The masses can be either firm or fluctuant and have a serous discharge if ulcerated. Anterior uveitis, chorioretinitis, or optic neuritis occurs in association with ocular infection; lens luxations and glaucoma are common sequelae. Chorioretinitis lesions can be punctate or large; suppurative retinal detachment occurs in some infected cats.

CNS signs of disease result from diffuse or focal meningoencephalitis or focal granuloma formation. Manifestations include depression, behavioral changes, seizures, blindness, circling, ataxia, loss of sense of smell, and paresis depending on the location of the lesion; peripheral vestibular disease can also occur. When pain from cryptococcosis occurred in cats, it was generalized or localized to the thoracolumbar spine or pelvic limbs in one study (Sykes et al., 2010). Nonspecific signs of anorexia, weight loss, and fever occur in some infected cats.

Clinical findings in dogs with cryptococcosis depend on the organ systems involved and are similar to those that occur in the cat. Cryptococcosis is diagnosed most commonly in young purebred dogs. Clinical manifestations include signs of upper or lower respiratory tract infection, disseminated disease including intraabdominal masses, CNS disease, disease of the orbit or eye, skin lesions, nasal cavity disease, and lymph node involvement. Seizures, ataxia, central vestibular syndrome, cranial nerve deficits, and clinical signs of cerebellar disease are the common CNS manifestations in dogs (Sykes et al., 2010). Dogs with *Cryptococcus* spp.–associated pyelonephritis (Newman et al., 2003) and gastrointestinal disease (Graves et al., 2005) have been reported. Abdominal cryptococcosis, responsive to fluconazole therapy without surgery, was recently reported in two dogs (Tangeman et al., 2015). One dog had primary alimentary cryptococcosis alone and the other dog pancreatic and disseminated cryptococcosis.

Diagnosis

Nonregenerative anemia and monocytosis are the most common hematologic abnormalities; neutrophil counts and biochemical panels are generally normal. In dogs with CNS involvement, CSF protein concentrations vary from normal to 500 mg/dL and cell counts vary from normal to 4500/μL; neutrophils and mononuclear cells predominate, but eosinophils are present in some cases. Imaging changes consistent with cryptococcosis include increased soft tissue density in the nasal cavity caused by fungal granuloma formation, as well as nasal bone deformity and lysis. Hilar lymphadenopathy and diffuse to miliary pulmonary interstitial patterns are common thoracic radiographic abnormalities.

Because circulating *Cryptococcus* spp. antibodies can be detected in both healthy and diseased animals, their presence does not document clinical disease. In addition, in one study all infected cats were seronegative (Flatland et al., 1996). Cryptococcal antigen can be detected in serum, aqueous humor, or CSF by a number of methods; serum antigen tests are positive in most cats and dogs infected by *C. neoformans*. For example, 51 of 53 cats and 15 of 18 dogs tested were positive for serum antigen in a retrospective study in California (Trivedi et al., 2011a). However, animals with acute disease, chronic low-grade infections, drug-induced remission, localized disease, or infection by *C. gattii* can be latex agglutination (LA) test-negative (Tintelnot et al., 2015). The LA performed on CSF is positive in almost all animals with CNS cryptococcosis. Because of the problems associated with detection of *C. gattii* antigen by some assays, culture or PCR assays should be considered in

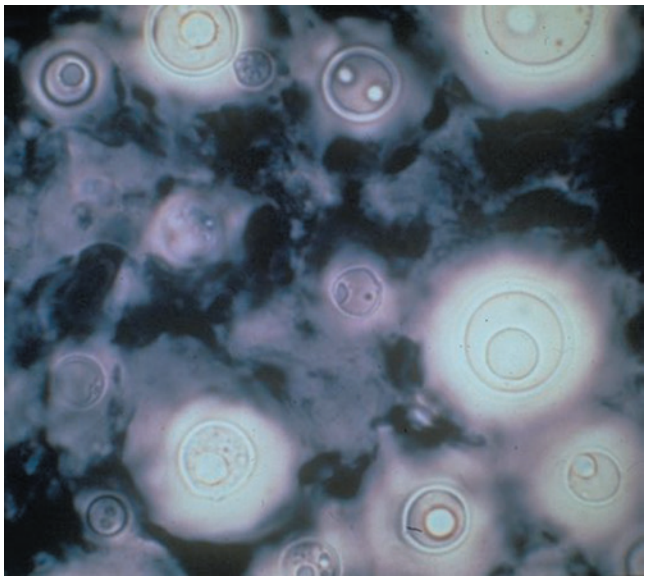

FIG 97.5
Cytologic appearance of *Cryptococcus neoformans*. The organism is 3.5 to 7.0 µm in diameter and has a thick polysaccharide capsule. (Courtesy Dr. Dennis Macy, College of Veterinary Medicine and Biomedical Sciences, Colorado State University.)

cases with characteristic clinical and laboratory findings but negative antigen test results.

A definitive diagnosis of cryptococcosis is based on positive antigen testing, cytologic, histopathologic, culture, or PCR assay demonstration of the organism (Fig. 97.5) combined with appropriate clinical manifestations of disease. The organism is found during cytologic evaluation of nasal lesions, cutaneous lesions, lymph node aspirates, CSF, and bronchoalveolar lavage fluid in most affected animals; it can also be cultured. The agents can be cultured from the nasal cavity of some asymptomatic animals, so positive culture results do not always correlate to disease. One study evaluating subclinical carriage of *C. gattii* showed some animals eliminated the infection, some remained persistently colonized, and some progressed to clinical illness (Duncan et al., 2005a). If organism numbers are low in tissues and are not detected cytologically or histopathologically, immunohistochemistry, PCR, and fungal culture can be used to confirm infection (Myers et al., 2017).

Treatment

There are molecular types of *C. neoformans* and *C. gattii* that affect antifungal drug susceptibility (Singer et al., 2014). In one study of 42 isolates, it was shown that, when compared with the mean inhibitory concentration (MIC) for *C. neoformans*, *C. gattii* MICs were lower for flucytosine and strain VGIII MICs (all from cats) were lower for flucytosine and itraconazole. In addition, for all drugs except itraconazole, *C. gattii* isolates exhibited a wider range of MICs than *C. neoformans*. In addition, it is now known that resistance to fluconazole can develop in infected animals and the mechanisms confirmed with molecular assays (Sykes et al., 2017). Thus treatment responses in individual animals may be variable.

Dogs and cats with cryptococcosis have been treated with amphotericin B, ketoconazole, itraconazole, fluconazole, posaconazole, voriconazole, or 5-flucytosine alone and in various combinations (see Table 97.2). Amphotericin B is usually not indicated unless life-threatening disseminated disease requiring rapid response to therapy is required. If amphotericin B is deemed necessary, lipid or liposomal encapsulated amphotericin is likely optimal because fewer adverse effects are associated with these formulations compared with regular amphotericin B. However, for owners who cannot afford this therapy, a less expensive subcutaneous protocol for administration of regular amphotericin B has been used successfully for the treatment of cryptococcosis in dogs and cats and may be effective for other systemic fungi susceptible to the drug (Malik et al., 1996; see Table 97.2).

Ketoconazole, itraconazole, or fluconazole are used as a single agent in dogs or cats without life-threatening disease. Ketoconazole is inexpensive but commonly leads to inappetence, vomiting, diarrhea, weight loss, and increases in liver enzyme activities in some dogs and cats. In dogs, long-term use of ketoconazole can suppress testosterone and cortisol production and has been associated with cataracts. Because of these problems, ketoconazole is used less frequently than itraconazole and fluconazole. Fluconazole should be considered for dogs or cats with ocular or CNS infection. If clinical signs of toxicity develop (inappetence; drug eruptions) or increased activity of alanine aminotransferase is detected, drug therapy should be stopped and then reinstituted at 50% of the original dose after signs of toxicity abate. In one study, *C. neoformans* minimum inhibitory concentrations for itraconazole and voriconazole were similar (Okabayashi et al., 2009). Because voriconazole has been associated with CNS toxicity in cats, it should probably not be selected over fluconazole or itraconazole for the treatment of this disease (Quimby et al., 2010).

Flucytosine crosses the blood-brain barrier better than ketoconazole or amphotericin B, so it has been used primarily for the treatment of CNS cryptococcosis. It must be used in combination with other antifungal drugs and has many adverse effects, including vomiting, diarrhea, hepatotoxicity, cutaneous reactions, and bone marrow suppression. One dog with protein-losing enteropathy from intestinal cryptococcosis responded to administration of terbinafine after failing treatment with amphotericin B and fluconazole (Olsen et al., 2012).

Clinical signs of nasal and cutaneous cryptococcosis generally resolve with treatment, but dogs or cats with CNS or ocular disease are less likely to respond. In one study of dogs and cats with CNS cryptococcosis, 32% of the treated animals survived longer than 6 months; presence of decreased mentation was a poor prognostic indicator (Sykes et al., 2010). Administration of glucocorticoids was associated with increased short-term survival in this study and one other (Vorathavorn et al., 2013).

Treatment should continue for at least 1 to 2 months past resolution of clinical disease. Serum and CSF LA antigen titers can diminish with therapy and have been used to monitor response. Antigen titers fail to decrease in some animals without clinical evidence of disease, suggesting persistence of the organism in tissues.

Zoonotic Aspects and Prevention

People and animals can have the same environmental exposure to *Cryptococcus* spp., but zoonotic transfer from contact with infected animals is unlikely. Prevention is achieved by decreasing potential for exposure.

HISTOPLASMOSIS

Etiology and Epidemiology

Histoplasma capsulatum is a saprophytic dimorphic fungus found in the soil in all regions with tropical and subtropical climates; histoplasmosis is diagnosed most frequently in the Mississippi, Missouri, and Ohio River valleys and in the mid-Atlantic states. The organism is considered endemic in 31 of the 48 contiguous United States. The organism has also been associated with disease in dogs in some other countries. The microconidia (2-4 µm) and macroconidia (5-18 µm) of the mycelial phase are found in the environment. In the vertebrate host, the 2- to 4-µm yeast phase is found in the cytoplasm of mononuclear phagocytes (see Fig. 97.6 and Table 97.1).

Histoplasma capsulatum is concentrated most heavily in soil contaminated with bird or bat excrement. Point sources for infection are found in endemic areas; two dogs and 20 people developed pulmonary histoplasmosis after removing a tree that had served as a bird roost (Ward et al., 1979). Subclinical infections are common in dogs. Dogs in endemic areas are commonly exposed, but the prevalence of disease is low. Immunosuppression may predispose to clinical infection in dogs and cats. In one study of 30 cats, 11 cats were housed strictly indoors with potted plants (5 cats) or unfinished basements (6 cats) being the possible sources of infection (Reinhart et al., 2012).

Infection is by ingestion or inhalation of microconidia from the environment. The organism is engulfed by mononuclear phagocytes, transformed to the yeast phase, and transported throughout the body in the blood and lymph. Granulomatous inflammation results in persistently infected organs and clinical signs of disease. Disseminated disease is common in cats.

Clinical Features

Most dogs with histoplasmosis are outdoor sporting breeds younger than 7 years. Subclinical infection, pulmonary infection, and disseminated infection are recognized most frequently. Most affected dogs are presented for evaluation of anorexia, fever, depression, weight loss, cough, dyspnea, or diarrhea. Large-bowel diarrhea is most common, but small-bowel diarrhea, mixed-bowel diarrhea, and protein-losing enteropathy occur in some.

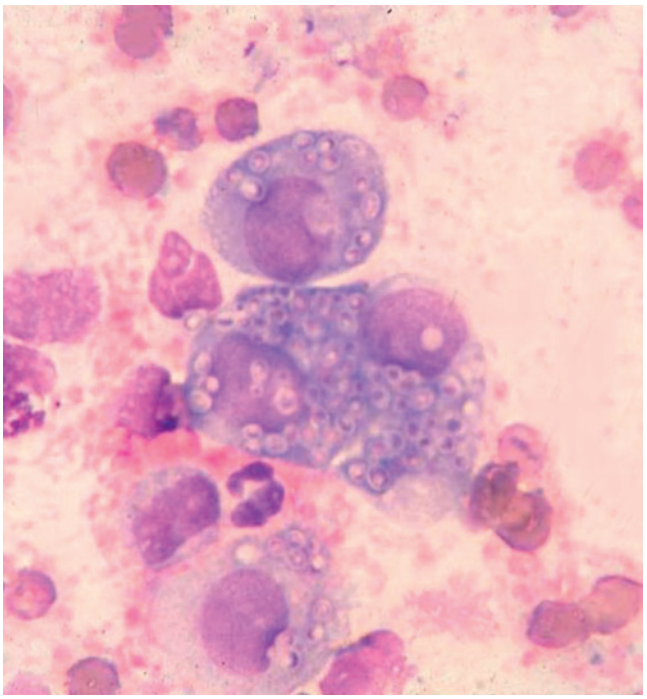

FIG 97.6
Histoplasma capsulatum (2-4 µm in diameter) in mononuclear cells. (Courtesy Dr. Dennis Macy, College of Veterinary Medicine and Biomedical Sciences, Colorado State University.)

Physical examination abnormalities often include depression, increased bronchovesicular sounds, respiratory wheezes, fever, evidence of diarrhea, pale mucous membranes, hepatomegaly, splenomegaly, icterus, ascites, and intraabdominal lymph node enlargement. Airway obstruction from massive hilar lymphadenopathy occurs in some dogs. Lameness from bone infection or polyarthritis, peripheral lymphadenopathy, chorioretinitis, CNS disease, and skin disease occur occasionally. Subcutaneous nodules rarely drain or ulcerate and are less common than in dogs with cryptococcosis or blastomycosis.

Infected cats are either normal or develop disseminated disease. Most clinically affected cats are younger than 4 years, and some are co-infected with feline leukemia virus. Depression, weight loss, anorexia, lameness, and dyspnea are common presenting complaints. Weight loss can be severe and develop in as little as 2 weeks. Fever, pale mucous membranes, abnormal lung sounds, oral erosions or ulcers, peripheral or visceral lymphadenopathy, icterus, soft tissue swelling around osseous lesions, hepatomegaly, skin nodules, and, rarely, splenomegaly are physical examination abnormalities potentially consistent with histoplasmosis. Disseminated disease has a grave prognosis in cats. Osseous histoplasmosis is most common in bones of the appendicular skeleton distal to the stifle or elbow joints, and one or more limbs can be involved. Feline ocular histoplasmosis manifests with conjunctivitis, chorioretinitis, retinal detachment, or optic

neuritis and may result in glaucoma and blindness. Other than depression, CNS signs are uncommon.

Diagnosis

A variety of nonspecific clinicopathologic and radiographic abnormalities are associated with histoplasmosis. Normocytic, normochromic, nonregenerative anemia is the most common hematologic abnormality in both dogs and cats. Neutrophil counts can be normal, increased, or decreased. Unlike the other systemic fungi, *H. capsulatum* is occasionally seen in circulating cells, particularly on examination of a buffy coat smear; mononuclear cell infection is most common, followed by eosinophils. Thrombocytopenia from disseminated intravascular coagulation or microangiopathic destruction occurs in approximately 50% of dogs and some cats. Some affected cats develop pancytopenia from bone marrow infection. Hypoproteinemia and increased activities of alkaline phosphatase and alanine aminotransferase occur in some infected animals.

Lysis predominates in animals with bone infection; periosteal and endosteal new bone production occurs in some cases. In dogs with pulmonary infection, radiographic abnormalities include diffuse interstitial, miliary-to-nodular interstitial disease; hilar lymphadenopathy; pleural effusion; and calcified pulmonary parenchyma caused by chronic disease. In some dogs, massive hilar lymphadenopathy is the only radiographic finding. Alveolar lung disease, tracheobronchial lymphadenopathy, and calcified lymph nodes are uncommon in cats. Colonoscopic findings in dogs with gastrointestinal infection include increased mucosal granularity, friability, ulceration, and thickness.

Several tests have been evaluated for the detection of circulating antibodies against *H. capsulatum* in the serum of dogs and cats, but the sensitivity and specificity are poor for all. Serologic diagnosis is unreliable and should be used only to establish a presumptive diagnosis when the organism cannot be demonstrated by cytology, histopathology, culture, or PCR assay, and the clinical signs are suggestive of the disease.

Definitive diagnosis requires demonstration of the organism by cytology, antigen assay, biopsy, culture, or amplification of specific DNA by PCR assay (see Fig. 97.6). The organism is found most frequently in rectal scrapings or biopsies from dogs with large-bowel diarrhea, in bone marrow or buffy coat cells from cats with disseminated disease, and in other locations (e.g., lymph nodes, lung, spleen, liver, skin nodules). The organism has also been identified in pleural and peritoneal effusions and in CSF.

In one retrospective study, results of a urine antigen assay were compared with standard diagnostic methods in 18 cats with clinical signs and clinicopathologic findings supportive of histoplasmosis (MVista *Histoplasma* Antigen EIA; www.miravistalabs.com). Antigen was detected in the urine of 17 of 18 cats, suggesting this assay may be useful for diagnosing this disease in cats. However, in cats with ocular histoplasmosis, false negative antigen test results occurred using serum, urine, and subretinal fluid (Smith et al., 2017). In one feline case, H. capsulatum antigen was detected in serum but not urine. In dogs, the urine antigen assay has been evaluated in several studies. In one study of 17 confirmed cases of histoplasmosis and 41 cases with other diseases, there were 2 false-negative antigen assay results but no false-positive results (Cunningham et al., 2015).

Treatment

Because of its effectiveness and minimal toxicity, itraconazole is the initial drug of choice for dogs and cats with histoplasmosis (see Table 97.2). Animals should be treated for 60 to 90 days or until clinical evidence of disease has been resolved for at least 1 month. Amphotericin B can be used in animals with life-threatening disease or in those unable to absorb oral medications because of intestinal disease. Ketoconazole and fluconazole are also effective in some animals. However, ketoconazole has more adverse effects than itraconazole, and some cases that do not respond to fluconazole respond to intraconazole. The overall success rate for the treatment of histoplasmosis in cats was 33% in one study (Clinkenbeard et al., 1989). In another study, all eight cats treated with itraconazole (5 mg/kg PO q12h) were eventually cured (Hodges et al., 1994). Pulmonary disease in dogs has a fair to good prognosis, whereas disseminated disease has a poor prognosis. In one study, clinical outcomes were similar for 17 cats treated with fluconazole and 13 cats treated with itraconazole (Reinhart et al., 2012). *Histoplasma capsulatum* may develop resistance to fluconazole during treatment (Renschler et al., 2017) as documented for *C. gattii* (Sykes et al., 2017). Use of serum and urine antigen testing has been used to monitor response to treatment or recurrence in one series of 15 cats and showed potential clinical utility (Hanzlicek et al., 2016).

Administration of glucocorticoids with or without antifungal drugs lessened clinical signs associated with chronic hilar lymphadenopathy much more quickly than did administration of antifungal drugs alone and did not result in disseminated histoplasmosis (Schulman et al., 1999). However, if the infection is active, administration of glucocorticoids may exacerbate clinical disease.

Zoonotic Aspects and Prevention

Like blastomycosis, direct zoonotic transmission from infected animals is unlikely because the yeast phase is not as infectious as the mycelial phase. Care should be taken when culturing the organism. Prevention includes the avoidance of potentially contaminated soil. Organism numbers in contaminated areas can be decreased by application of 3% formalin.

CHAPTER 98

Polysystemic Protozoal Infections

BABESIOSIS

Etiology and Epidemiology

Babesiosis in dogs is most commonly associated with *Babesia canis*, *B. rossi*, *B. vogeli*, *B. gibsoni,* and *B. conradae*. These protozoans parasitize red blood cells (RBCs) and are most frequently associated with development of anemia and associated signs. The worldwide distribution, vectors, and virulence of *Babesia* spp. varies. *B. rossi* is transmitted by *Haemaphysalis elliptica* (previously *leachi*) and is the most pathogenic; *B. canis* is transmitted by *Dermacentor* spp. and *Rhipicephalus sanguineus* and is moderately pathogenic; *B. vogeli* is the least pathogenic and is transmitted by *R. sanguineus*. *Babesia vogeli* is the most common *B. canis* subspecies infecting dogs in the United States. *B. gibsoni* is transmitted by *Haemaphysalis longicornis* and *Haemaphysalis bispinosa* in some countries; the vector in the United States is unknown, but *R. sanguineus* has been proposed. Presence of *B. gibsoni* DNA in blood of dogs in the United States has been associated with a history of a dog bite, especially by an American Pit Bull Terrier, suggesting that fighting is a route of transmission (Birkenheuer et al., 2003b). *Babesia conradae* induces hemolytic anemia in dogs in southern California; the vector is unknown but is suspected to be *R. sanguineous* (Kjemtrup et al., 2006). *Theleiria annae* and *B. vulpes* are *Babesia microti*-like organisms that has been detected in dogs of Europe and North America that may be transmitted by *Ixodes* spp. (Solano-Gallego and Baneth, 2011; Solano-Gallego et al., 2016).

In one survey in North America, *Babesia* spp. infections were detected in 29 states and Ontario (Birkenheuer et al., 2005). Other novel *Babesia* spp. that genetically vary considerably from other *B. canis* or *B. gibsoni* isolates have been described in the United States; however, the prevalence rate for these infections is unknown (Meinkoth et al., 2000; Birkenheuer et al., 2004a). *Babesia* spp. can also be transmitted by blood transfusions so screening is recommended for blood donors (Wardrop et al., 2016).

Babesiosis in cats appears to be less common than in dogs. Cats have been shown to be infected by *B. cati* (India), *B. felis* (Africa, southern Asia, Europe; Qatar), *B. herpailuri* (South America, Africa), *B. canis presentii* (Israel), *B. canis* (Europe), and *B. vogeli* (Brazil, Thailand, Qatar, United States). *Babesia vogeli* DNA was amplified from *Ctenocephalides felis* collected from cats in Jerusalem (Kamani et al., 2018). Whether this just reflects ingestion of *B. vogeli* in blood by the flea or whether the flea is involved in transmission of *B. vogeli* has not been determined.

After infection with pathogenic strains of *B. canis, B. vogeli*, or *B. gibsoni,* the incubation period varies from several days to several weeks. The degree of parasitemia varies by the organism studied but can be detected transiently in some dogs as soon as day 1. The organisms replicate intracellularly in RBCs, resulting in intravascular or extravascular hemolytic anemia. Immune-mediated reactions against the parasites or altered self-antigens worsen the hemolytic anemia and commonly result in a positive direct Coombs test. Activation of macrophages leads to fever and hepatosplenomegaly. Severe hypoxia occurs because of rapid breakdown of RBCs. Disseminated intravascular coagulation occurs in some infected dogs during acute infection.

The severity of disease depends on the species and strain of *Babesia* and the host's immune status; chronic, subclinical infection is common. Administration of glucocorticoids or splenectomy may reactivate chronic carriers into an acute disease state. Splenectomized experimentally infected dogs develop more severe *B. vogeli* clinical and laboratory manifestations of disease (Wang et al., 2018). Presence of coinfections such as *Bartonella* spp. may increase the pathogenic potential.

Clinical Features

The clinical features most commonly associated with *Babesia* spp. infecting dogs worldwide have been reviewed (Solano-Gallego and Baneth, 2011). In the United States, subclinical *Babesia* spp. infections are most common. Peracute or acute *Babesia* spp. infections result in anemia and fever, leading to pale mucous membranes, tachycardia, tachypnea, depression, anorexia, and weakness. Icterus, petechiae, and hepatosplenomegaly are present in some dogs depending on the stage of infection and the presence of disseminated intravascular coagulation. Severe anemia, disseminated

intravascular coagulation, metabolic acidosis, and renal disease are most common during acute infection and are generally most severe with *B. rossi* infections in South Africa. Tissue hypoxemia is important in the pathogenesis of disease in severely affected dogs. The main differential diagnoses for acute babesiosis is primary immune-mediated hemolytic anemia and immune-mediated thrombocytopenia. Chronically infected dogs commonly have weight loss and anorexia. Ascites, gastrointestinal signs, central nervous system (CNS) disease, edema, and clinical evidence of cardiopulmonary disease occur in some dogs with atypical infection. *Babesia canis* or *B. gibsoni* DNA has been amplified from the blood or effusion (one dog; *B. gibsoni*) of some dogs with pericardial effusion (Tabar et al., 2018).

Diagnosis

Spherocytic regenerative anemia, hyperbilirubinemia, bilirubinuria, hemoglobinuria, thrombocytopenia, metabolic acidosis, azotemia, polyclonal gammopathy, proteinuria, and cylindruria are common in dogs infected with pathogenic *Babesia* spp. Presence of the organism in RBCs detected by Wright or Giemsa stains on thin blood smears (see Chapter 91) can be used to support the diagnosis, but parasitemia can be intermittent, giving falsely negative results; capillary blood is the preferred source for blood smear evaluation. In the United States, *B. vogeli* is typically found as single or paired, piriform bodies measuring 2.5 × 4.5 µm, *B. gibsoni* is typically found as single annular bodies (more than one per cell are common) measuring 1.0 × 3.0 µm, and *B. conradae* is typically found as ring or ameboid bodies measuring 0.3 × 3 µm.

Serologic and polymerase chain reaction (PCR) assays are usually used in the diagnosis of babesiosis. Indirect fluorescent antibody tests for *B. vogeli* and *B. gibsoni* are available commercially in the United States. However, serologic cross-reactivity can exist, so antibody test results cannot be used to determine the infective species definitively. Demonstration of increasing titers over 2 to 3 weeks is consistent with recent or active infection. No standardization between laboratories exists, so suggested positive cutoff titers vary. False-negative serologic test results can occur in some dogs, particularly in those with peracute disease or concurrent immunosuppression. Many dogs are seropositive but clinically normal, so serology alone cannot be used to make a definitive diagnosis of clinical babesiosis.

Positive results in PCR assays performed on blood prove current infection and can be used to differentiate amongst the *Babesia* spp. However, as subclinical carriers exist, positive results do not always correlate with clinical illness. In addition, not all PCR assays performed in commercial laboratories are equivalent.

The acute phase proteins like serum amyloid A, haptoglobin, and paraoxonase-1 have been studied in small numbers of animals in an attempt to differentiate subclinical *Babesia* spp. carriers from those with clinical manifestations of disease. In naturally infected cats with *B. vogeli* infections, serum haptoglobin concentrations were increased and paraoxonase-1 concentrations were decreased when compared with healthy client-owned cats (Vilhena et al., 2017). These types of assays may prove to be of clinical benefit in the future.

Treatment

Supportive care, including blood transfusions, sodium bicarbonate therapy for acidosis, and fluid therapy, should be administered as indicated. A number of drugs, including diminazene aceturate, phenamidine, pentamidine isethionate, parvaquone, atovaquone, and niridazole, have also been used in an attempt to treat different *Babesia* spp. infections. In the United States, if clinical disease associated with *B. vogeli* is suspected, imidocarb diproprionate may be effective when administered (5-6.6 mg/kg subcutaneously or intramuscularly) twice, 14 days apart or (7.5 mg/kg subcutaneously or intramuscularly) once. Adverse effects include transient salivation, diarrhea, dyspnea, lacrimation, necrosis at the injection site, and depression.

Imidocarb as a single agent is not as effective for the treatment of *B. gibsoni* infection. In the United States, if clinical disease associated with *B. gibsoni* or *B. conradae* is suspected, azithromycin (10 mg/kg by mouth [PO] q24h for at least 10 days) and atovaquone (13.3 mg/kg PO q8h for at least 10 days) is currently recommended. However, this combination does not always result in elimination of infection, and *B. gibsoni* resistance to these drugs has been recognized (Birkenheuer et al., 2004b; Di Cicco et al., 2012; Jefferies et al., 2007). In Asia the combination of clindamycin, diminazene, and imidocarb was used successfully for the treatment of *B. gibsoni* infection in 11 of 13 dogs (Lin et al., 2012) and should be considered for atovaquone resistant strains (Baneth, 2018). Oral administration of a doxycycline-enrofloxacin-metronidazole combination led to clinical improvement in 85.7% of dogs infected with Asian strains of *B. gibsoni* (Lin and Huang, 2010). Although success rates with this protocol have not been reported with North American strains, it could be considered for use with infected dogs if atovaquone or diminazene are not immediately available or is ineffective. Because no drugs are known to eliminate infection consistently, treatment of healthy, seropositive dogs is unlikely to be of benefit.

Zoonotic Aspects and Prevention

No evidence currently exists to suggest that *Babesia* spp. infecting dogs and cats can cause human disease. However, some *Babesia* spp. that infect people *(B. microti)* are genetically similar to those infecting dogs, so ticks should be controlled if possible. Minimal cross-protection exists between species; a dog that has recovered from babesiosis may still become ill if infected with another species. Administration of immunosuppressive drugs or splenectomy should be avoided in previously infected dogs. Dog bites should be avoided. Vaccines against some *Babesia* spp. are available in some countries but not the United States. For blood donor programs, high-risk breeds (American Pit Bull Terrier; Greyhounds) or dogs from endemic areas should be screened for

Babesia spp. infection by serology or PCR assays, and positive dogs should be excluded from the program (Wardrop et al., 2016).

Babesia canis has been shown to be transmitted to 50% of experimentally infected dogs by *D. reticulatus* after 8 hours of feeding (Varloud et al., 2018). Thus acaricides that repel or have a rapid kill time are indicated in endemic areas. In one field study, an imidacloprid/flumethrin collar was 99.7% against tick infestation, and had an efficacy of 91.6% for the prevention of *A. platys* and 91.6% for *B. vogeli* (Dantas-Torres et al., 2013).

CYTAUXZOONOSIS

Etiology and Epidemiology

Cytauxzoon felis is a protozoal disease of cats in the southeastern, mid-Atlantic, and south-central United States that is often fatal when clinical illness occurs unless appropriate treatment is administered. *Cytauxzoon* spp. infection has also been documented in a number of other countries including Italy (Carli et al., 2012), France (Legroux et al., 2017), Spain (Díaz-Regañón et al., 2017), and Portugal (Alho et al., 2016). However, clinical illness has only occasionally been detected in the cats infected in Europe suggesting it is a different strain or variant of *C. felis* (Gallusová et al., 2016).

In contrast, isolates from domestic cats have been genetically similar between studies in the United States (Birkenheuer et al., 2006b). Bobcats are usually subclinically affected and may therefore be the natural host of the organism. Recent genetic analysis performed on *C. felis* from bobcats and pumas suggests multiple strains of the organism exist in wild felids (Shock et al., 2012). Domestic cats can be infected by different genotypes, alone or in combinations (Cohn et al., 2011). The organism can be passed experimentally from infected bobcats to domestic cats by *Dermacentor variabilis* (American dog tick) and *Amblyomma americanum* (Lone Star tick), but based on geographical distribution of infected cats, *A. americanum* is likely most important. Clinical illness occurs after an incubation period of 5 to 20 days. The majority of cases are diagnosed in April, May, and June (Reichard et al., 2008). After infection, schizonts and macroschizonts form in mononuclear phagocytes. The infected macrophages line the lumen of veins throughout the body. Merozoites released from the infected macrophages infect erythrocytes. Clinical disease results from obstruction of blood flow through tissues by the mononuclear infiltrates and from hemolytic anemia. Domestic cats occasionally survive infection, suggesting that variants that are less virulent to cats also exist in the United States. Perinatal infection did not occur from 2 queens to their 14 kittens (Lewis et al., 2012).

Clinical Features

Most cases of cytauxzoonosis are in cats allowed to go outdoors. Fever, anorexia, dyspnea, depression, icterus, pale mucous membranes, and death are the most common clinical findings. A primary differential diagnosis is hemoplasmosis. Ticks are rarely identified on affected cats.

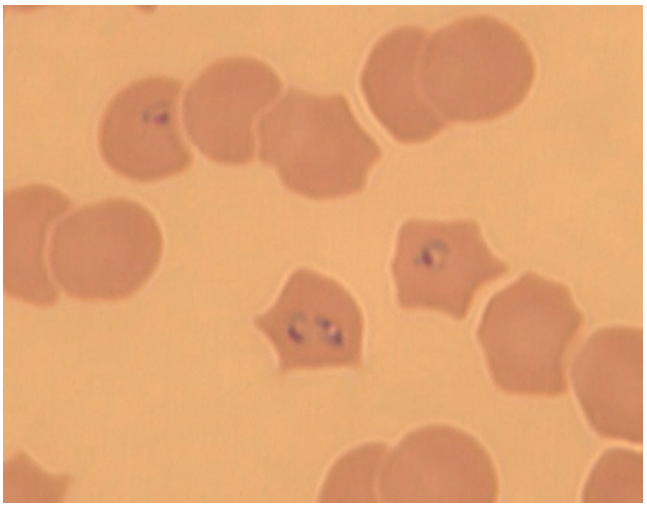

FIG 98.1
Cytauxzoon felis in the red blood cells of a cat. (Courtesy Dr. Terry M. Curtis, Gainesville, FL.)

Diagnosis

Regenerative anemia, pancytopenia, and neutrophilic leukocytosis are the most common hematologic findings; thrombocytopenia occurs in some cats. Hemoglobinemia, hemoglobinuria, hyperbilirubinemia, and bilirubinuria are uncommon. Antemortem diagnosis is based on demonstration of the erythrocytic phase on thin blood smears (Fig. 98.1) stained with Wright or Giemsa stains (see Chapter 91). Infected macrophages can be detected cytologically in bone marrow, spleen, liver, or lymph node aspirates. The organism is easily identified on histopathologic evaluation of most organs. Serologic testing is not commercially available. PCR can be used to amplify organism DNA from blood, and positive test results prove current infection.

Treatment

Supportive care includes fluid therapy and blood transfusion administered as indicated. Recently, a prospective study compared survival in cats treated with atovaquone at 15 mg/kg PO q8h and azithromycin at 10 mg/kg PO q24h to cats treated with imidocarb at 3.5 mg/kg IM (Cohn et al., 2011). The survival rates for the atovaquone/azithromycin combination and imidocarb were 60% and 26%, respectively. Diminazene administered at 2 mg/kg IM twice, 7 days apart was used in five cats that survived infection (Greene et al., 1999). However, some cases fail treatment with diminazene, and side-effects including monoparesis at the injection site, signs of nausea, and potential hepatotoxicity can occur (Lewis et al., 2014).

Zoonotic Aspects and Prevention

Cytauxzoon felis is not known to be zoonotic. The disease can only be prevented by avoiding exposure.

Ticks should be controlled, and cats in endemic areas should be housed during periods of peak tick activity. *Cytauxzoon felis* has been shown to be transmitted by *A. americanum* between 36 and 48 hours after feeding (Thomas et al., 2018). An imidacloprid/flumethrin collar was effective at blocking transmission by *A. americanum* in one experimental study (Reichard et al., 2013). Known *C. felis*-positive cats should not be used as blood donors, and cats to be used as blood donors in endemic areas should be shown negative by PCR assay (Wardrop et al., 2016).

HEPATOZOONOSIS

Etiology and Epidemiology

Hepatozoonosis in dogs is caused by the protozoal agents *Hepatozoon canis* and *Hepatozoon americanum.* In North America, *H. americanum* predominates, is transmitted by *Amblyomma maculatum* (Gulf Coast tick), and is most common in the Texas Gulf Coast, Mississippi, Alabama, Georgia, Florida, Louisiana, and Oklahoma. In Africa, southern Europe, and Asia, *H. canis* predominates and is transmitted by *R. sanguineus* (brown dog tick). In South America, *H. canis* is transmitted by *R. sanguineus* and *A. ovale*. *Hepatozoon canis* can also be transmitted transplacentally. Cystozoites are an infectious stage of *Hepatozoon* spp. that form in the tissue of paratenic hosts like rabbits, mice, and some rats and can initiate infection in dogs after predation (Johnson et al., 2009a,b). In one study of 614 dogs with suspected hepatozoonosis in the United States, the prevalence rates for *H. americanum, H. canis,* or both were 27.2%, 2.3%, and 2.3%, respectively (Li et al., 2008).

At least three *Hepatozoon* species can be detected in the blood of cats in Europe (Díaz-Regañón et al., 2017; Giannelli et al., 2017), and the organism can be amplified from ticks removed from cats (Duplan et al., 2018). The routes of transmission and clinical disease associations are currently unclear, but the cats are commonly co-infected with feline leukemia virus or feline immunodeficiency virus.

Vertebrate hosts develop macrogametes and microgametes in neutrophils and monocytes after infection by a *Hepatozoon* spp. The tick ingests the organism during a blood meal and oocysts develop. After a dog ingests an infected tick, sporozoites are released and infect mononuclear phagocytes and endothelial cells of the spleen, liver, muscle, lungs, and bone marrow, and ultimately form cysts containing macromeronts and micromeronts. Micromeronts develop into micromerozoites, which infect leukocytes and develop into gamonts. Tissue phases induce pyogranulomatous inflammation, resulting in clinical disease. Glomerulonephritis or amyloidosis may occur as a result of chronic inflammation and immune complex disease. Infected dogs can serve as a source of infection for ticks for months to years (Ewing et al., 2002).

Clinical Features

Although subclinical infection is common, both *H. americanum* and *H. canis* can be primary pathogens, resulting in clinical illness without concurrent immune deficiency. Clinically affected dogs have been in all age groups, but disease is most commonly recognized in puppies. Fever, weight loss, and severe hyperesthesia over the paraspinal regions are common findings. Anorexia, pale mucous membranes from anemia, depression, oculonasal discharge, meningoencephalomyelitis, and bloody diarrhea occur in some dogs. Cutaneous lesions consisting of a pruritic swelling were described in one dog (Little and Baneth, 2011). Clinical signs can be intermittent and recurrent.

Diagnosis

Neutrophilic leukocytosis (20,000-200,000 cells/μL) with a left shift is the most common hematologic finding for dogs infected with *H. americanum*. Thrombocytopenia is unusual unless co-infection with *Ehrlichia canis*, *Anaplasma* spp., or *Leishmania* spp occurs. Normocytic, normochromic, nonregenerative anemia is common and is likely from chronic inflammation. Increased activity of alkaline phosphatase but not creatine kinase occurs in *H. americanum*–infected dogs. Hypoalbuminemia, hypoglycemia, and, rarely, polyclonal gammopathy occur in some dogs. Periosteal reactions from the inflammatory response directed at tissue phases in muscle can occur in any bone except the skull, are most common in young dogs, do not occur in every case, and are not pathognomonic for hepatozoonosis. Definitive diagnosis is based on identification of gamonts in neutrophils or monocytes in Giemsa or Leishman stained blood smears or by demonstration of the organism in muscle biopsy sections. However, the organisms can be detected in the blood of healthy dogs and cats. Serologic tests are available in some countries and because the tissue phases are not cleared, positive test results suggest that the dog is infected. However, because subclinical infection can occur, presence of serum antibodies does not prove the clinical manifestations are from *Hepatozoon* spp. infection. PCR assays are now available in some laboratories, and positive results confirm infection (Li et al., 2008; Modrý et al., 2017). Quantitative PCR assay results may be used to follow treatment responses in the future.

Treatment

No therapeutic regimen has been shown to eliminate *H. canis* or *H. americanum* infection from tissues. However, clinical disease resolves rapidly with several drug protocols. For treatment of *H. americanum,* the combination of trimethoprim-sulfadiazine (15 mg/kg PO q12h), pyrimethamine (0.25 mg/kg PO q24h), and clindamycin (10 mg/kg PO q8h) for 14 days is highly successful in the acute stage (Macintire et al., 2001). Use of decoquinate (10-20 mg/kg q12h) with food lessens the likelihood of recurrence of clinical disease and prolongs survival time. Imidocarb dipropionate (5-6 mg/kg intramuscularly or subcutaneously) administered once or twice 14 days apart is the drug of

choice for treatment of *H. canis* and may also be effective for *H. americanum*. A recent study showed administration of ponazuril as a single therapeutic agent did not clear the infection (Allen et al., 2010). Administration of nonsteroidal antiinflammatory agents may lessen discomfort for some dogs. Administration of doxycycline or oxytetracycline has been used in some cats in Europe suspected as having hepatozoonosis (Lloret et al., 2015).

Zoonotic Aspects and Prevention

No evidence exists for zoonotic transfer of *H. americanum* or *H. canis* from infected dogs to people. Tick control is the best form of prevention. Glucocorticoid administration should be avoided because it may exacerbate clinical disease. However, prednisone was used in the management of one case with meningoencephalomyelitis without obvious exacerbation of infection (Marchetti et al., 2009).

LEISHMANIOSIS

Etiology and Epidemiology

Leishmania spp. are flagellates that cause cutaneous, mucocutaneous, and visceral diseases in dogs, human beings, and other mammals. Rodents and dogs are primary reservoirs of *Leishmania* spp., people and cats are probably incidental hosts, and sandflies are the vector in most endemic regions other than the United States. Cats are also commonly exposed in areas with endemic canine infection. In one study, sandflies could be infected by feeding on a naturally infected cat, suggesting this species should be further evaluated as a potential reservoir (Maroli et al., 2007).

Leishmaniosis was considered unimportant in the United States until recently, with cases only reported occasionally. In 1999, *Leishmania infantum* infection was confirmed in multiple dogs in a Foxhound kennel in New York State (Gaskin et al., 2002). Further investigation of more than 12,000 Foxhounds and other canids documented *L. infantum* infection in 18 states and two Canadian provinces (Duprey et al., 2006). Infection of canids other than Foxhounds appears to be uncommon in North America. In the United States, *Leishmania* spp. appear to be transmitted vertically (Freeman et al., 2010).

In other countries, flagellated promastigotes develop in the sandfly and are injected into the vertebrate host when the sandfly feeds. Promastigotes are engulfed by macrophages and disseminate through the body. After an incubation period of 1 month to 7 years, amastigotes (nonflagellate) form and cutaneous lesions develop; sandflies are infected during feeding. In Foxhounds in the United States transmission appears to be primarily from dog to dog (Duprey et al., 2006). Transmission by fighting, shared needles, blood transfusions, breeding, and vertical transmission can occur (Boggiatto et al., 2011; Duprey et al., 2006; de Freitas et al., 2006). *Leishmania infantum* DNA has been amplified from *Rhipicephalus sanguineous* ticks collected off naturally infected dogs; further study of this potential route of transmission is necessary (Solano-Gallego et al., 2012). The intracellular organism induces extreme immune responses; polyclonal gammopathies (and occasionally monoclonal); proliferation of macrophages, histiocytes, plasma cells, and lymphocytes in lymphoreticular organs; and immune complex formation resulting in glomerulonephritis and polyarthritis are common. Co-infections like Ehrlichia canis may potentiate the development of clinical manifestations of disease (Attipa et al., 2018).

Cats have generally been believed to be more resistant that dogs to leishmaniosis. However, when illness occurs, the syndrome usually includes cutaneous lesions (Pennisi et al., 2015).

Clinical Features

Dogs generally develop visceral leishmaniosis. A subclinical phase of infection may persist for months or years. Weight loss in the face of a normal to increased appetite, polyuria, polydipsia, muscle wasting, depression, vomiting, diarrhea, cough, petechiae, ecchymosis, epistaxis, sneezing, and melena are common presenting complaints. Splenomegaly, lymphadenopathy, facial alopecia, fever, rhinitis, dermatitis, increased lung sounds, icterus, swollen painful joints, uveitis, and conjunctivitis are commonly identified on physical examination. Cutaneous lesions are characterized by hyperkeratosis, scaling, thickening, mucocutaneous ulcers, and intradermal nodules on the muzzle, pinnae, ears, and foot pads (Fig. 98.2). Bone lesions are detected in some dogs. Infertility and prostatitis were detected in a chronically infected dog (Mir et al., 2012). Most dogs die or are euthanized as a consequence of chronic kidney disease. Cats are usually subclinically infected; when infection occurs, the major clinical manifestations are cutaneous. The skin lesions are usually nodular and ulcerative on the pinnae and less commonly on the muzzle and periorbital skin (Navarro et al., 2010; Trainor et al., 2010). Histopathology reveals

FIG 98.2
Characteristic *Leishmania* spp.–associated skin lesion on the foot of a dog in Spain. (Courtesy Dr. Arturo Font, Barcelona, Spain.)

granulomatous inflammation with numerous amastigotes within macrophages.

Diagnosis

The principal clinicopathologic abnormalities include hyperglobulinemia, hypoalbuminemia, proteinuria, increased liver enzyme activities, anemia, thrombocytopenia, azotemia, lymphopenia, and leukocytosis with left shift. The hyperglobulinemia is usually polyclonal, but an immunoglobulin G (IgG) monoclonal gammopathy has been reported. Neutrophilic polyarthritis occurs in some dogs as a manifestation of a type III hypersensitivity reaction. Demonstration of amastigotes (2.5-5.0 μm × 1.5-2.0 μm) in lymph node aspirates, bone marrow aspirates, or skin imprints stained with Wright or Giemsa stain gives a definitive diagnosis (Fig. 98.3). The organism can also be identified by histopathologic or immunoperoxidase evaluation of skin or organ biopsy, culture, inoculation of hamsters, or PCR. Antibodies against *Leishmania* can be detected in serum by a variety of techniques and point care assays are available in some countries. In general, IgG titers develop 14 to 28 days after infection and decline 45 to 80 days after treatment. Serologic cross-reactivity occurs between *Trypanosoma cruzi* and *Leishmania,* so positive antibody test results do not always correlate with *Leishmania* infection. Use of vaccines against *Leishmania* spp. in some countries has complicated the diagnosis of leishmaniosis by use of antibody tests in vaccinated dogs (Solano-Gallego et al., 2017). Because dogs are unlikely to eliminate infection spontaneously, most true-positive antibody test dogs are currently infected. PCR can be performed on ethylenediamine tetraacetic acid anticoagulated blood, bone marrow, spleen, or lymph node aspirates. Real-time PCR assays can be used to monitor response to therapy (Francino et al., 2006).

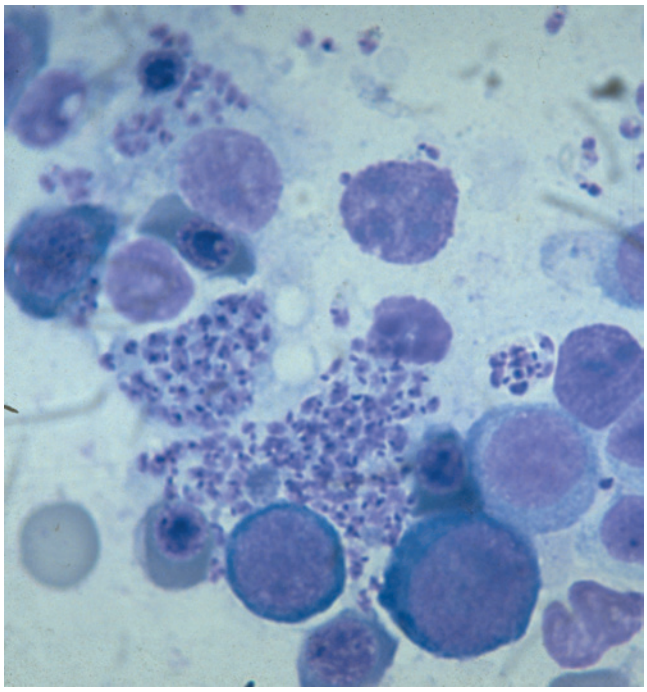

FIG 98.3
Impression smear of a lymph node of a *Leishmania* spp.–infected dog showing intracellular amastigotes. (Courtesy Dr. Arturo Font, Barcelona, Spain.)

Treatment

The management of canine leishmaniosis can be completed and the LeishVet group has published recommendations (Solano-Gallego et al., 2012). Dogs that are seropositive, cytologically positive, or PCR-positive with clinical disease manifestations consistent with leishmaniosis should be treated. Although clinical signs of disease often improve with drug administration, the prognosis for visceral leishmaniosis in dogs is variable; most cases are recurrent. No drug or drug combination has been used to clear *Leishmania* from the body successfully. The combination of antimony compounds and allopurinol (15 mg/kg PO q12h) was superior to treatment with either drug alone (Denerolle et al., 1999), but even long-term therapy does not always eliminate infection (Manna et al., 2008). In one study of dogs treated with meglumine antimoniate (50 mg/kg subcutaneously q12h) until clinical and clinicopathologic abnormalities resolved and allopurinol (15 mg/kg PO q12h administered for 6 months), relapses were not reported in 1 year of monitoring, and the disease-free interval for some dogs was as long as 65 months (Paradies et al., 2012). Miltefosine and domperidone are available in some countries. Miltefosine when given with allopurinol (Miró et al., 2009) and domperidone given as a single agent also have shown therapeutic efficacy for canine leishmaniosis (Gómez-Ochoa et al., 2009). Because antimony drugs are not available in the United States, infected dogs should be started on allopurinol therapy initially. In one study, marbofloxacin was effective in vitro and may be considered for the treatment of infected dogs if other drugs are not available (Vouldoukis et al., 2006). Liposomal or lipid-emulsified amphotericin B at varying doses (0.8-3.3 mg/kg IV for varying numbers of treatments) has been prescribed with good clinical results, but recurrences can still occur (Cortadellas, 2003). Dogs with chronic kidney disease have a poor prognosis, but one study showed administration of allopurinol to be beneficial (Plevraki et al., 2006). In cats, long-term administration of allopurinol at 10-20 mg/kg PO q12h or q24h can be clinically beneficial (Pennisi et al., 2015).

Zoonotic Aspects and Prevention

Reviews of control measures for leishmaniosis are available (Solano-Gallego et al., 2011; Miro et al., 2017). The primary zoonotic risk for canine leishmaniosis is from dogs acting as a reservoir host for the organism. Direct contact with amastigotes in draining lesions is unlikely to result in human infection. None of the 185 persons with potential exposure to infected Foxhounds had evidence of infection (Duprey et al., 2006). Avoidance of infected sandflies is the primary means of prevention in endemic areas. In endemic areas, animals should stay indoors during night hours and breeding places of sandflies should be controlled. Use of 10%

imidacloprid/50% permethrin may lessen transmission in sandfly-endemic areas (Otranto et al., 2007). In one study, the authors suggested that 65% permethrin applied every 2 to 3 weeks would be efficacious (Molina et al., 2012). Many vaccines have been studied and are available for use with dogs in some countries (Dantas-Torres, 2006; Fernández Cotrina, et al., 2018; Palatnik-de-Sousa, 2012). For blood donor programs, high-risk breeds (e.g., Foxhounds) or dogs from endemic areas should be screened for *Leishmania* spp. infection by serology or PCR assays, and positive dogs should be excluded from the program (Wardrop et al., 2016).

NEOSPOROSIS

Etiology and Epidemiology

Neospora caninum is a coccidian previously confused with *Toxoplasma gondii* because of similar morphology. The sexual cycle is completed in the gastrointestinal tract of canids and results in the passage of oocysts in feces. Oocyst shedding can continue for several months in some dogs (McGarry et al., 2003). Sporozoites develop in oocysts within 24 hours of passage. Tachyzoites (rapidly dividing stage) and tissue cysts containing hundreds of bradyzoites (slowly dividing stage) are the other two life stages. In one study, dogs fed sporulated oocysts were infected and seroconverted but did not shed oocysts (Bandini et al., 2011). Dogs are infected by ingestion of bradyzoites but not tachyzoites. Infection has been documented after ingestion of a number of different infected bovine tissues. Dogs can also become infected from ingesting intermediate hosts such as white-tailed deer, and the organism has been detected in the tissues of free-ranging chickens (Gondim et al., 2004; Gonçalves et al., 2012). Thus free-roaming dogs appear to be at increased risk of infection. Transplacental infection has been well documented; dams that give birth to infected offspring can repeat transplacental infection during subsequent pregnancies. Because repeated transplacental infections occur, puppies from a bitch who previously birthed infected puppies are at an increased risk. Canine neosporosis has been reported in many countries around the world. Seroprevalence of infection has varied from 0% to 100% depending on the country and lifestyle of the dog (Dubey et al., 2007a). In one paper from Australia, the canine prevalence rate increased over a 20-year period (Sloan et al., 2017). Oocysts are rarely reported in fecal surveys; in one study of 24,677 dog samples, oocysts consistent with *N. caninum* were detected in 0.3% (Barutzki and Schaper, 2011). DNA of *N. caninum* has been amplified from feces of coyotes as well (Klein et al., 2018). The pathogenesis of the disease is primarily related to the intracellular replication of tachyzoites. Although organism replication occurs in many tissues, including the lungs, in dogs clinical illness is primarily neuromuscular. Administration of glucocorticoids may activate bradyzoites in tissue cysts, resulting in clinical illness.

Encephalomyelitis and myositis develop in experimentally infected kittens, and seropositive, naturally exposed cats have been detected (Bresciani et al., 2007), but clinical disease in naturally infected cats has not been reported. *N. caninum* seropositive, nondomestic felids also have been reported (Spencer et al., 2003; Sedlák et al., 2014). *Neospora caninum* infection can lead to great economic losses as a result of abortion in cattle. Strategies for control of the infection in cattle have been reviewed (Dubey et al., 2007a).

Clinical Features

Ascending paralysis with hyperextension of the hindlimbs in congenitally infected puppies is the most common clinical manifestation of the disease. Muscle atrophy occurs in many cases. Polymyositis and multifocal CNS disease can occur alone or in combination. Cerebral ataxia and atrophy is a recently recognized clinical syndrome associated with neosporosis (Garosi et al., 2010). Clinical signs can be evident soon after birth or may be delayed for several weeks. Neonatal death is common. Although disease tends to be most severe in congenitally infected puppies, dogs as old as 15 years have been clinically affected. In one dog presented primarily for respiratory disease, cough was the principal sign. Myocarditis, dysphagia, ulcerative dermatitis, pneumonia, and hepatitis occur in some dogs. Whether clinical disease in older dogs is from acute, primary infection or exacerbation of chronic infection is unknown. Administration of glucocorticoids with or without cyclosporine may activate bradyzoites in tissue cysts, resulting in clinical illness. Disease is caused by intracellular replication of *N. caninum* tachyzoites. Infection of CNS structures generally causes mononuclear cell infiltrates, which suggests an immune-mediated component to the pathogenesis of disease. Intact tissue cysts in neural structures are generally not associated with inflammation, but ruptured tissue cysts induce inflammation. Untreated disease generally results in death.

Diagnosis

Hematologic and biochemical findings are nonspecific. Myositis commonly results in increased creatine kinase and aspartate aminotransferase activities. Cerebrospinal fluid (CSF) abnormalities include increased protein concentration (20-50 mg/dL) and a mild, mixed pleocytosis (10-50 cells/μL) consisting of monocytes, lymphocytes, neutrophils, and, rarely, eosinophils. Interstitial and alveolar patterns can be noted on thoracic radiographs. Magnetic resonance imaging of seven dogs with cerebellar disease showed marked bilaterally symmetric cerebellar atrophy surrounded by an area T2-weighted hyperintense and T1-weighted hypointense signal (Garosi et al., 2010).

Definitive diagnosis is based on demonstration of the organism in CSF or tissues. Tachyzoites are rarely identified on cytologic examination of CSF, imprints of dermatologic lesions, and bronchoalveolar lavage. Mixed inflammation with neutrophils, lymphocytes, eosinophils, plasma cells, macrophages, and tachyzoites was noted on transthoracic aspirate of one dog with lung disease. *N. caninum* tissue cysts have a wall thicker than 1 μm; *T. gondii* tissue cysts have a wall thinner than 1 μm (Fig. 98.4). Oocysts can be detected

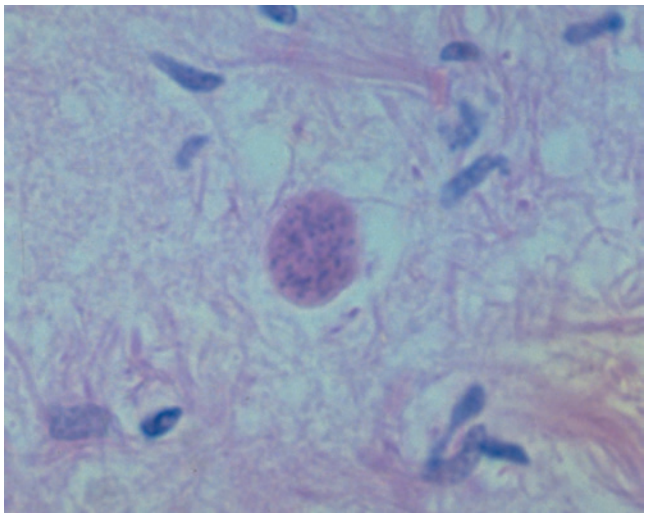

FIG 98.4
Neospora caninum cyst filled with bradyzoites in canine central nervous system tissue.

in feces by microscopic examination after flotation or by PCR. The organism can be differentiated from *T. gondii* by electron microscopy, immunohistochemistry, and PCR. A multiplex PCR assay that detects both *T. gondii* and *N. caninum* for use with tissues or CSF has been reported (Schatzerg et al., 2003). In a group of dogs with cerebellar disease related to *N. caninum* infection, four of five dogs tested were positive for DNA of the organism by PCR assay performed on CSF.

A presumptive diagnosis of neosporosis can be made by combining appropriate clinical signs of disease and positive serology or presence of antibodies in CSF with the exclusion of other etiologies inducing similar clinical syndromes, particularly *T. gondii*. Serologic cross-reactivity between *T. gondii* and *N. caninum* exist in some assays. IgG antibody titers of at least 1:200 have been detected in most dogs with clinical neosporosis; minimal serologic cross-reactivity occurs with *T. gondii* at titers of 1:50 or higher when using the immunofluorescent assay test.

Treatment

Although many dogs with neosporosis die, some have survived after treatment with trimethoprim-sulfadiazine combined with pyrimethamine; sequential treatment with clindamycin hydrochloride, trimethoprim-sulfadiazine, and pyrimethamine; or clindamycin alone. While different doses of have recommended by different authors, administration of trimethoprim-sulfadiazine (15 mg/kg PO q12h) with pyrimethamine (1 mg/kg PO q24h) for 4 weeks or clindamycin (10 mg/kg PO q8h) for 4 weeks has been used frequently treatment of canine neosporosis. If improvement is noted, treatment should be continued. A 7-week-old Irish Wolfhound with *N. caninum*–associated myositis had significant clinical improvement after 18 weeks of treatment with clindamycin (Crookshanks et al., 2007). In one recent study of naturally infected Beagle puppies, administration of clindamycin alone (75 mg/puppy at 9 weeks of age PO q12h [dose doubled at 13 weeks] for 6 months) lessened clinical signs of disease but did not eliminate the infection (Dubey et al., 2007b). Four of six dogs with cerebellar disease associated with *N. caninum* infection treated with different combinations of clindamycin, trimethoprim, sulfadiazine, and pyrimethamine had a positive response (Garosi et al., 2010). Ponazuril is a cidal drug and may prove to be effective for the treatment of neosporosis at 20 mg/kg, PO, daily (Silva et al., 2016). Treatment of clinically affected dogs should be initiated before the development of extensor rigidity, if possible. The prognosis for dogs presented with severe neurologic involvement is grave.

Zoonotic Aspects and Prevention

Neospora caninum antibodies have been detected in people, but in one study no link was found to repeated abortion (Petersen et al., 1999). In addition, the organism has not been isolated from human tissues, so the zoonotic potential is still unproven. An epidemiologic link has been shown between dogs and cattle; efforts should be made to lessen dog fecal contamination of livestock feed, and dogs should not be allowed to ingest bovine placentas. Consuming raw meat is a risk factor for dogs and should be avoided (Reichel et al., 2007). Hunting behavior of dogs should be restricted if possible. Bitches that whelp clinically affected puppies should not be bred. Glucocorticoids should not be administered to seropositive animals, if possible, because a potential exists for activation of infection.

FELINE TOXOPLASMOSIS

Etiology and Epidemiology

Toxoplasma gondii is one of the most prevalent parasites infecting warm-blooded vertebrates. Only cats complete the coccidian life cycle and pass environmentally resistant oocysts in feces. Sporozoites develop in oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity. Tachyzoites disseminate in blood or lymph during active infection and replicate rapidly intracellularly until the cell is destroyed. Bradyzoites are slowly dividing, persistent tissue stages that form in the extraintestinal tissues of infected hosts as immune responses attenuate tachyzoite replication. Tissue cysts form readily in the CNS, muscles, and visceral organs. Bradyzoites may persist in tissues for the life of the host. There are different genotypes of *T. gondii,* which may vary in pathogenic potential, partially explaining why even some immunocompetent cats can become ill.

Infection of warm-blooded vertebrates occurs after ingestion of any of the three life stages of the organism or transplacentally. Most cats are not coprophagic and so are infected most commonly by ingesting *T. gondii* bradyzoites during carnivorous feeding; oocysts are shed in feces from 3 to 21 days. Sporulated oocysts can survive in the environment for months to years and are resistant to most disinfectants

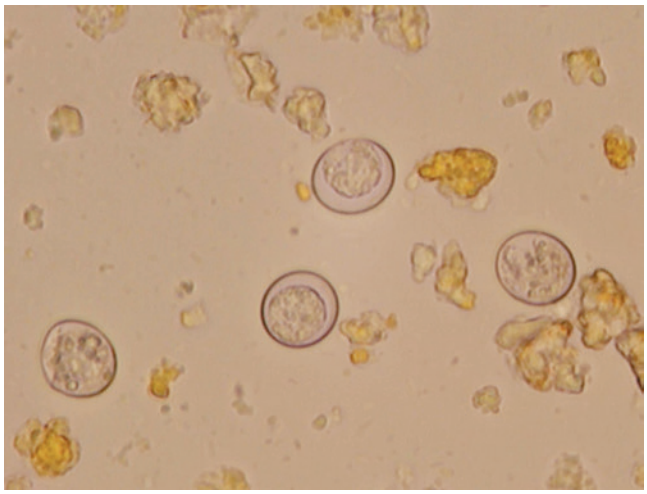

FIG 98.5
Unstained *Toxoplasma gondii* unsporulated oocysts. The oocysts are 10 × 12 µm.

(Fig. 98.5). Results of a research study confirm that the *T. gondii* oocyst-shedding prepatent period is stage-dependent (ingestion of bradyzoites has a shorted prepatent period than ingestion of sporozoites) and not dose-dependent (Dubey et al., 2006). In addition, transmission of *T. gondii* is most efficient when cats consume tissue cysts (carnivorism) and when intermediate hosts consume oocysts (fecal-oral transmission). *Toxoplasma gondii* infection of rodents changes the behavior of the prey species, making it less averse to cats, potentially increasing the likelihood the definitive host (felid) will become infected and potentiate the sexual phase of the organism (Vyas et al., 2007). A number of studies have now evaluated whether *T. gondii* infection is associated with behavioral abnormalities in people with mixed results (see Chapter 99). In one study of clinically ill cats in the United States, *T. gondii* antibodies were detected in 31.6% of the 12,628 cats tested (Vollaire et al., 2005) so cats are commonly exposed to the agent, likely from predation in most.

Clinical Features

Approximately 10% to 20% of experimentally inoculated cats develop self-limiting, small-bowel diarrhea for 1 to 2 weeks after primary oral inoculation with *T. gondii* tissue cysts; this is presumed to be from enteroepithelial replication of the organism. However, detection of *T. gondii* oocysts in feces is rarely reported in studies of naturally exposed cats with or without diarrhea because of the short shedding period. For example, in a study in Germany the oocyst-shedding rate was estimated at 0.8% in 8640 cats (Barutzki and Schaper, 2011). *Toxoplasma gondii* enteroepithelial stages were found in intestinal tissues from two cats with inflammatory bowel disease. Positive response to anti-*Toxoplasma* drugs in these two cats suggests that toxoplasmosis may occasionally induce inflammatory bowel disease.

Fatal extraintestinal toxoplasmosis can develop from overwhelming intracellular replication of tachyzoites after primary infection; hepatic, pulmonary, CNS, and pancreatic

FIG 98.6
Punctate chorioretinitis caused by *Toxoplasma gondii* in an experimentally inoculated cat.

tissues are commonly involved. Kittens infected by the transplacental or transmammary routes develop the most severe signs of extraintestinal toxoplasmosis and generally die of pulmonary or hepatic disease. Common clinical findings in cats with disseminated toxoplasmosis include depression, anorexia, and fever followed by hypothermia, peritoneal effusion, icterus, and dyspnea.

If a host with chronic toxoplasmosis is immunosuppressed, bradyzoites in tissue cysts can replicate rapidly and disseminate again as tachyzoites; this is common in people with acquired immunodeficiency syndrome (AIDS). Disseminated toxoplasmosis has been documented in cats concurrently infected with feline leukemia, feline immunodeficiency, or feline infectious peritonitis viruses, as well as after cyclosporine administration for skin disease or after renal transplantation (Barrs et al; 2006). The acute respiratory distress syndrome was recently documented in a cat with disseminated toxoplasmosis (Evans et al., 2017).

Sublethal, chronic toxoplasmosis occurs in some cats. *Toxoplasma gondii* infection should be on the list of differential diagnoses for cats with anterior or posterior uveitis, cutaneous lesions, fever, muscle hyperesthesia, myocarditis with arrhythmias, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, or pancreatitis (Fig. 98.6). Cutaneous toxoplasmosis is characterised by hyperemic nodules that may or may not be ulcerated. On the basis of results of *T. gondii*–specific aqueous humor antibody and PCR studies, toxoplasmosis appears to be a common infectious cause of uveitis in cats. Distal polyneuropathies can occur in dogs or cats (Mari et al., 2016).

Kittens infected transplacentally or lactationally commonly develop ocular disease. Immune complex formation and deposition in tissues and delayed hypersensitivity reactions may be involved in chronic, sublethal clinical toxoplasmosis. Although chronic tissue infection and immune complex formation are common, there was no association between *T. gondii* antibodies and chronic kidney disease in one study (Hsu et al., 2011). None of the anti-*Toxoplasma* drugs totally clear the body of the organism, so recurrence of disease may occur in some cats, and serum IgG titers rarely become negative.

Diagnosis

Cats with clinical toxoplasmosis can have a variety of clinicopathologic and radiographic abnormalities, but none documents the disease. Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, neutropenia, eosinophilia, proteinuria, and bilirubinuria, as well as increases in serum protein and bilirubin concentrations, creatinine kinase, alanine aminotransferase, alkaline phosphatase, and lipase activities occur in some cats. Pulmonary toxoplasmosis most commonly causes diffuse interstitial to alveolar patterns or pleural effusion. Mass lesions may be detected on computed tomography or magnetic resonance imaging examinations. CSF protein concentrations and cell counts are often higher than normal. The predominant white blood cells in CSF are small mononuclear cells, but neutrophils are also commonly found.

The antemortem definitive diagnosis of feline toxoplasmosis can be made if the organism is demonstrated; however, this is uncommon, particularly in association with sublethal disease. Bradyzoites or tachyzoites are rarely detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF. Visualization of 10×12 µm oocysts in feces in cats with diarrhea suggests toxoplasmosis but is not definitive because *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts.

Toxoplasma gondii–specific antibodies (IgM, IgG, IgA), antigens, and immune complexes can be detected in the serum of normal cats, as well as in those with clinical signs of disease, so antemortem diagnosis of clinical toxoplasmosis is impossible on the basis of these tests alone. Of the serum tests, IgM correlates the best with clinical feline toxoplasmosis because this antibody class is rarely detected in serum of healthy cats. The antemortem diagnosis of clinical toxoplasmosis can be tentatively based on the combination of the following:

- Demonstration of antibodies in serum, which documents exposure to *T. gondii*
- Demonstration of an IgM titer above 1:64 or a fourfold or greater increase in IgG titer, which suggests recent or active infection
- Clinical signs of disease referable to toxoplasmosis
- Exclusion of other common causes for the clinical syndrome
- Positive response to appropriate treatment

Some cats with clinical toxoplasmosis will have reached their maximal IgG titer or have undergone antibody class shift from IgM to IgG by the time they are serologically evaluated, so the failure to document an increasing IgG titer or a positive IgM titer does not exclude the diagnosis of clinical toxoplasmosis. Because some healthy cats have extremely high serum antibody titers and some clinically ill cats have low serum antibody titers, the magnitude of titer is relatively unimportant in the clinical diagnosis of toxoplasmosis. Because the organism cannot be cleared from the body, most cats will be antibody positive for life, so repeating serum antibody titers after the clinical disease has resolved is not necessary.

The combination of aqueous humor or CSF *T. gondii*–specific antibody detection and *T. gondii* DNA amplification by PCR is the most accurate way to diagnose ocular or CNS toxoplasmosis (www.dlab.colostate.edu; Diagnostic Laboratory, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins). For example, in one study of six cats with uveitis, five had *T. gondii* DNA in blood or aqueous humor but were seronegative for *T. gondii* antibodies (Powell et al., 2010). Whereas *T. gondii*–specific IgA, IgG, and *T. gondii* DNA can be detected in aqueous humor and CSF of both normal and clinically ill cats, *T. gondii*–specific IgM has only been detected in the aqueous humor or CSF of clinically ill cats and therefore may be the best indicator of clinical disease. Because *T. gondii* DNA can be amplified from the blood of healthy cats, positive PCR results do not always correlate to clinical disease (Burney et al., 1999).

Treatment

Supportive care should be instituted as needed. Clindamycin hydrochloride (10-12 mg/kg PO q12h) administered for 4 weeks has been used most frequently by the author for the treatment of clinical feline toxoplasmosis. Azithromycin (10.0 mg/kg PO q24h) has been used successfully in a limited number of cats, but the optimal duration of therapy is unknown. Ponazuril was apparently successful for the treatment of *T. gondii* infection in a dog and also has been shown to have anti-*T. gondii* effects in a mouse model (Mitchell et al., 2004). Ponazuril is known to be safe in cats for the treatment of *Isospora* spp. infection and should be studied further for use in affected cats. Trimethoprim-sulfonamide combination has been used at 15 mg/kg PO q12h for 4 weeks in some cats with toxoplasmosis but is not tolerated by many cats. Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in vomiting or inappetance and can cause anemia in cats. Cats with systemic clinical signs of toxoplasmosis, such as fever or muscle pain combined with uveitis, should be treated with anti-*Toxoplasma* drugs in combination with topical, oral, or parenteral corticosteroids to avoid secondary lens luxations and glaucoma. *Toxoplasma gondii*–seropositive cats with uveitis that are otherwise normal can be treated with topical glucocorticoids alone unless the uveitis is recurrent or persistent. In these situations,

administration of a drug with anti–*T. gondii* activity may be beneficial.

Clinical signs not involving the eyes or the CNS usually resolve within the first 2 to 3 days of clindamycin or azithromycin administration; ocular and CNS toxoplasmosis respond more slowly to therapy. If fever or muscle hyperesthesia does not decrease after 3 days of treatment, other causes should be considered. Recurrence of clinical signs may be more common in cats treated for less than 4 weeks. No evidence suggests that any drug can totally clear the body of the organism, so recurrences are common and infected cats will always be seropositive. The prognosis is poor for cats with hepatic or pulmonary disease caused by organism replication, particularly in those that are immunocompromised.

Zoonotic Aspects and Prevention

Toxoplasma gondii is a major zoonosis. Primary infection of mothers during gestation can lead to clinical toxoplasmosis in the fetus; stillbirth, CNS disease, and ocular disease are common clinical manifestations. Primary infection in immunocompetent individuals results in self-limiting fever, malaise, and lymphadenopathy. As T-helper cell counts decline, approximately 10% of people with AIDS develop toxoplasmic encephalitis from activation of bradyzoites in tissue cysts.

People most commonly acquire toxoplasmosis transplacentally or by ingesting sporulated oocysts or tissue cysts. Avoiding the ingestion of undercooked meats and carefully washing or cooking produce are two of the most important ways to prevent toxoplasmosis (Box 98.1). In a study of 6282 meat samples from 698 retail meat stores, *T. gondii* was not found in any of the beef or chicken samples tested (by bioassay in cats) and only a small number of pork samples were positive (Dubey et al., 2005). However, the organism has been detected in tissues from free-ranging chickens that were likely infected by ingestion of sporulated oocysts (Gonçalves et al., 2012). Sporulated oocysts are also infectious, so ingestion of materials that may be contaminated with old cat feces (e.g., contaminated soil or unwashed vegetables) should be avoided. There is also an association between toxoplasmosis and ingestion of certain uncooked shellfish that can concentrate the organism from contaminated water (Jones et al., 2009). Touching individual cats is probably not a common way to acquire toxoplasmosis for the following reasons:

- Cats generally only shed oocysts for days to several weeks after primary inoculation.
- Reactivation of oocyst shedding is rare in cats with chronically infected healthy cats, even in cats treated with clinical doses of glucocorticoids or cyclosporine, or in those infected with feline immunodeficiency virus or feline leukemia virus.
- Repeat shedding can occur if chronically infected cats are re-exposed, but generally smaller numbers of oocysts are shed (Zulpo et al., 2018).

BOX 98.1

Prevention of Human Toxoplasmosis

Prevention of Oocyst Ingestion

Avoid feeding undercooked meats to cats.
Do not allow cats to hunt.
Clean the litter box daily, and incinerate or flush the feces.
Clean the litter box periodically with scalding water or use a litter box liner.
Wear gloves when working with soil.
Wash hands thoroughly with soap and hot water after gardening.
Wash fresh vegetables well or cook before ingestion.
Keep children's sandboxes covered.
Boil water for drinking that has been obtained from the general environment.
Control potential transport hosts.
Treat oocyst shedding cats with anti-*Toxoplasma* drugs.

Prevention of Tissue Cyst Ingestion

Cook all meat products to 66° C.
Wear gloves when handling meats.
Wash hands thoroughly with soap and hot water after handling meats.
Freeze all meat for a minimum of 3 days before cooking.

- Cats are quite fastidious and usually do not allow feces to remain on their skin for periods long enough to lead to oocyst sporulation; the organism was not isolated from the fur of cats shedding millions of oocysts 7 days previously.
- Increased risk of acquired toxoplasmosis was not associated with cat ownership in people with AIDS or in most studies of veterinary health care providers.

However, in the minority of studies evaluating risk factors, the association between cat contact and toxoplasmosis has been made. For example, the risk was associated with owning three or more kittens in one study (Jones et al., 2009). Thus hands should always be washed after handling kittens and cat feces. If a fecal sample from a cat is shown to contain oocysts measuring 10 × 12 µm, the organism is assumed to be *T. gondii.* The feces should be collected daily until the oocyst-shedding period is complete. Historically, administration of clindamycin (25-50 mg/kg PO divided q12h) can reduce levels of oocyst shedding. Because human beings are not commonly infected with *T. gondii* from contact with individual cats, testing healthy cats for toxoplasmosis is not recommended. Fecal examination is an adequate procedure to determine when cats are actively shedding oocysts but cannot predict when a cat has shed oocysts in the past. No serologic assay accurately predicts when a cat shed *T. gondii* oocysts in the past, and most cats that are shedding oocysts are seronegative. Most seropositive cats have completed the oocyst shedding period and are unlikely to repeat shedding;

most seronegative cats would shed the organism if infected. If owners are concerned that they may have toxoplasmosis, they should see their physician for testing.

CANINE TOXOPLASMOSIS

Etiology and Epidemiology

Dogs do not produce *T. gondii* oocysts like cats, but they can mechanically transmit oocysts after ingesting feline feces. The tissue phases of *T. gondii* infection occur in dogs and can induce clinical disease. Approximately 20% of dogs in the United States are seropositive for *T. gondii* antibodies (Levy et al., 2011). Before 1988, many dogs diagnosed with toxoplasmosis based on histologic evaluation were truly infected with *Neospora caninum* (see Neosporosis section). Transplacental infection occurs in dogs with both *T. gondii* and *N. caninum*. In one study of 41 stillborn puppies, 78.6% were positive for *T. gondii* (Taques et al., 2016). Toxoplasma gondii strains from dogs in Brazil were shown to be from four different genotypes of which all were proven to be virulent to mice (da Silva et al., 2017).

Clinical Features

Respiratory, gastrointestinal, or neuromuscular infection resulting in fever, vomiting, diarrhea, dyspnea, and icterus occurs most commonly in dogs with generalized toxoplasmosis. Generalized toxoplasmosis is most common in immunosuppressed dogs such as those with canine distemper virus infection or those receiving cyclosporine to prevent rejection of a transplanted kidney. Neurologic signs depend on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis present with weakness, stiff gait, or muscle wasting. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. One study associated *T. gondii* antibodies with polyradiculoneuritis in dogs (Holt et al., 2011). Some dogs with suspected neuromuscular toxoplasmosis probably have neosporosis. Myocardial infection resulting in ventricular arrhythmias occurs in some infected dogs. Dyspnea, vomiting, or diarrhea occurs in dogs with polysystemic disease. Retinitis, anterior uveitis, iridocyclitis, and optic neuritis occur in some dogs with toxoplasmosis, but they are less common than in cats. Cutaneous disease has also been reported.

Diagnosis

As in cats, clinicopathologic and imaging abnormalities are not specific. Hyperglobulinemia can occur in dogs with chronic infection (Yarim et al., 2007). Increased protein concentrations and mixed inflammatory cell infiltrates occur in dogs with CNS toxoplasmosis.

Demonstration of the organism associated with inflammation in tissues or exudates can lead to a definitive diagnosis. More commonly an antemortem diagnosis is based on the combination of appropriate clinical signs, exclusion of other likely etiologies, positive serum antibody tests, exclusion of *N. caninum* infection by serologic testing, and response to an anti-*Toxoplasma* drug. Interpretation of serum, aqueous humor, and CSF antibody and PCR test results is as discussed for toxoplasmosis in cats.

Treatment

Clindamycin hydrochloride (10-12 mg/kg PO q12h) has been used most frequently for treatment of canine toxoplasmosis by the author. Trimethoprim-sulfa (15 mg/kg PO q12h) is an alternative protocol. Treatment should be continued for a minimum of 4 weeks. Ponazuril at 20 mg/kg PO q24h for 28 days was used successfully to treat a dog with suppurative keratitis and necrotizing conjunctivitis (Swinger et al., 2009). If uveitis is detected, topical glucocorticoid treatment should also be used.

Zoonotic Aspects and Prevention

Dogs do not complete the enteroepithelial phase of *T. gondii* but can mechanically transmit oocysts after ingesting feline feces. Like all other warm-blooded vertebrates, dogs are infected by the ingestion of sporulated oocysts or tissue cysts. Repeated infection can occur in dogs, and it appears that venereal infection can also occur (Arantes et al., 2009; Taques et al., 2016). Toxoplasmosis in dogs can be prevented by not allowing dogs to be coprophagic and to feed only cooked meat and meat by-products.

AMERICAN TRYPANOSOMIASIS

Etiology and Epidemiology

Trypanosoma cruzi is a flagellate that infects many mammals and causes American trypanosomiasis. The disease is diagnosed primarily in South America, but multiple cases have been detected in dogs of North America. *Trypanosoma caninum* is a new species identified in dogs in Brazil (Madeira et al., 2014). Continued work is needed to determine the prevalence of this agent in the United States and to define the clinical importance of the agent. *Trypanosoma cruzi* is molecularly diverse, but isolates from California have been shown to be similar to those of Latin America and so are likely of being capable of inducing disease (Shender et al., 2016). The triatomine vectors (reduviid [kissing] bugs) of *T. cruzi* are common in parts of the United States including Texas and California and frequently live in homes and dog kennels (Curtis-Robles et al., 2018). Even though infected reservoir mammals (dogs, cats, raccoons, opossums, armadillos) and vectors are found in the United States, infection in dogs or people is rare; this may relate to differences in vector behavior and sanitation standards in the United States. In one study in Texas, the number of serologically positive dogs increased between 1987 and 1996 (Meurs et al., 1998). Foxhounds infected with *Leishmania* spp. are commonly shown to be co-infected with *T. cruzi* (Duprey et al., 2006). In a study of 860 dogs in Tennessee, 6.4% had positive serum antibody titers suggesting exposure was common (Rowland et al., 2010). In another smaller study, the seroprevalence

rate in Virginia was 1%. Although some cats in Mexico are known to be seropositive, clinical disease in cats has not been characterized (Longoni et al., 2012).

The organism has three life stages: trypomastigotes (flagellated stage found free in blood), amastigotes (nonflagellated intracellular form), and epimastigotes (flagellated form found in the vector). When infected kissing bugs defecate during feeding, epimastigotes enter the vertebrate host, infect macrophages and myocytes, and transform into amastigotes. Amastigotes divide by binary fission until the host cell ruptures, releasing trypomastigotes into the circulation. The vector is then infected by ingesting trypomastigotes during a blood meal. Transmission can also occur transplacentally by vector ingestion, blood transfusion, or ingestion of infected tissues or milk. Coinfection with parasites like *Ancylostoma caninum* may potentiate *T. cruzi* infection (Enriquez et al., 2016). Peak parasitemia occurs 2 to 3 weeks after infection, causing acute disease. Disease in dogs is primarily a cardiomyopathy that develops from parasite-induced damage to myocardial cells or immune-mediated reactions.

Clinical Features

Exercise intolerance and weakness are nonspecific presenting complaints that relate to myocarditis or heart failure during acute infection. Generalized lymphadenopathy, pallor, tachycardia, pulse deficits, hepatomegaly, and abdominal distension can be detected on physical examination. Anorexia, diarrhea, and neurologic signs occasionally occur. Dogs that survive acute infection can present for evaluation of chronic dilative cardiomyopathy. In 537 dogs in Texas that were confirmed serologically or by histopathology, the primary clinical abnormalities included anorexia, ascites, cardiac conduction disturbances, cardiomegaly, lethargy, and respiratory difficulties (Kjos et al., 2008). In another study of 11 dogs with chronic infection, right-sided cardiac disease, conduction disturbances, ventricular arrhythmias, and supraventricular arrhythmias were most common (Meurs et al., 1998).

Diagnosis

Common clinicopathologic abnormalities include lymphocytosis and increased activities of liver enzymes and creatine kinase. Thoracic radiographic, abdominal radiographic, and echocardiographic findings are consistent with cardiac disease and failure but are not specific for trypanosomiasis. The primary electrocardiographic findings are ventricular premature contractions, heart block, and T-wave inversion. Definitive diagnosis is based on organism demonstration. Trypomastigotes (one flagellum, 15-20 μm long) can be identified during acute disease on thick blood film or buffy coat smears stained with Giemsa or Wright stain. The organism is sometimes detected in lymph node aspirates or abdominal effusions. Histopathologic evaluation of cardiac tissue usually reveals myocarditis (98%) and amastigotes (82%) are often identified (Kjos et al., 2008). Serologic assays can be used to prove exposure to *T. cruzi*. PCR assays can also be used to amplify *T. cruzi* DNA from tissues or blood, and positive test results prove infection. Trypomastigotes can be cultured from blood or grown by bioassay in mice.

Treatment

Nifurtimox has been prescribed for Chagas disease, but it is toxic and not readily available in the United States. In a recent study of allopurinol for the treatment of *T. cruzi* infection in an experimentally infected mouse model, a positive response was noted. Thus treating clinically affected dogs with allopurinol as described for *Leishmania* may be prudent. In recent studies, administration of benznidazole or ravuconazole lessened parasitemia but did not prevent infection in dogs (Diniz Lde et al., 2010; Kratz et al., 2018; Santos et al., 2012). Administration of the statin, simvastatin, at 20 mg PO q24h lessened cardiac dysfunction over time in an experimentally infected dog, likely from the immune modulating effects of the drug (Melo et al., 2011). Whether the same benefits will be recognized in naturally infected dogs remains to be proven. DNA vaccines for use as therapy also show promise (Quijano-Hernandez et al., 2008). Glucocorticoid therapy may improve survival of infected dogs. Therapy for arrhythmias or heart failure should be instituted as needed. Most dogs that survive acute infection develop dilative cardiomyopathy. Survival time in 11 dogs ranges from 0 to 60 months.

Zoonotic Aspects and Prevention

Infected dogs can serve as a reservoir of *T. cruzi* for vectors, and blood from infected dogs can be infectious to human beings (Travi, 2018). Vector control is the primary means of prevention. In one study, use of deltamethrin-treated collars reduced *Triatoma infestans* feeding success on dogs (Reithinger et al., 2005; Travi, 2018). However, treatment with fipronil does not provide adequate protection (Gürtler et al., 2009; Amelotti et al., 2012). Dogs should be kept from other reservoir hosts, such as opossums, and should not be fed raw meat. Potential blood donors from endemic areas should be serologically screened. For blood donor programs, high-risk breeds (e.g., Foxhounds) or dogs from endemic areas should be screened for *T. cruzi* infection by serology or PCR assays, and positive dogs should be excluded from the program (Wardrop et al., 2016). Experimental vaccine studies in dogs have been shown to lessen parasitemia and potential for development of Chagas disease.

CHAPTER 99

Zoonoses

Zoonotic diseases are defined as being common to, shared by, or naturally transmitted between humans and other vertebrates. Most of the agents discussed in this chapter can infect and cause disease in immunocompetent people, but disease is generally more prevalent or more severe in immunodeficient people. Immunosuppression is common in humans. People with acquired immunodeficiency syndrome (AIDS) are discussed most frequently, but the population also includes the very old, the very young, and those receiving chemotherapy for immune-mediated diseases, organ transplantation, or neoplasia. Immunosuppressed people are sometimes advised to give up their pets. However, humans are unlikely to contract zoonotic diseases from contact with their healthy pets, so in most cases this is not necessary. All human and other animal healthcare providers should provide accurate information to pet owners concerning the risks and benefits of pet ownership so that an informed decision about acquiring and keeping pets can be made. The Centers for Disease Control and Prevention website "Healthy Pets Health People" is an excellent source of information physicians, veterinarians, and pet owners (https://www.cdc.gov/healthypets/index.html).

Many infectious agents can infect humans by direct contact with pets, their exudates, or their excrement (Table 99.1). These agents are the most important to veterinary healthcare providers and to dog and cat owners, and are discussed in this chapter by likely route of exposure. For some zoonoses, including *Anaplasma* spp. (ticks), *Bartonella* spp. (fleas and possibly ticks), *Borrelia burgdorferi* (ticks), *Ehrlichia* spp. (ticks), and *Rickettsia* spp. (fleas for *R. felis*; ticks for *R. rickettsii*), the pet brings the vector of the organism into the environment, resulting in potential exposure of the person. With some zoonoses, including *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis,* and *Cryptococcus neoformans,* the owner and pet are infected by shared environmental exposure to the agent.

The following is a brief description of the more common canine and feline zoonoses encountered in small animal practice. General guidelines for the avoidance of zoonotic transfer of disease for veterinarians and pet owners are listed in Boxes 99.1 and 99.2, respectively.

ENTERIC ZOONOSES

Multiple infectious agents of the gastrointestinal tract can be shared between animals and humans. Many veterinarians in United States now use commercial diagnostic laboratories for fecal flotation, which has allowed for the publication of results on large sample sizes (Little et al., 2009). For example, results from 1,199,293 dog samples showed overall national prevalence rates for ascarids (2.2%), hookworms (2.5%), and *Giardia* (4.0%). Other manuscripts have shown high prevalence rates of enteric zoonotic agents in cats as well (De Santis et al., 2006a; De Santis et al., 2006b). These findings emphasize that diagnostic workups for enteric infections in pets with gastrointestinal signs of disease are indicated because of potential human health risks.

The minimal diagnostic plan to assess for enteric zoonoses in pets with diarrhea includes a fecal flotation and a *Giardia* antigen test or fluorescent antibody assay. In one study, a fecal polymerase chain reaction (PCR) assay was less sensitive than other assays, likely due to fecal PCR inhibitors, thus this technique should not be the screening procedure for *Giardia* (Hascall et al., 2016). Fecal bacterial culture should be considered if infection with *Salmonella* spp. or *Campylobacter* spp. is on the list of differential diagnoses.

NEMATODES

Visceral larva migrans can be induced by infection of humans with *Toxocara cati, Toxocara canis,* or *Baylisascaris procyonsis* (see Table 99.1). In the United States, infection of humans is still common; the age-adjusted seroprevalence is approximately 14% (Won et al., 2008). These common roundworms are passed as eggs in feces. The eggs larvate and become infectious after 1 to 3 weeks and can survive in the environment for months. Humans are infected after ingesting embryonated eggs. Embryonated *Toxocara* spp. eggs have been transmitted by earthworms, filth flies, and cockroaches, and have been found on the fur of pets (Sasmal et al., 2008; Overgaauw et al., 2009). Dogs are considered more of a significant problem than cats for the spread of eggs. However, areas such as children's sandboxes and vegetable gardens may be contaminated with *T. cati* because of

TABLE 99.1

Common Zoonotic Infections of Dogs and Cats

ROUTE OF EXPOSURE	AGENT	AFFECTED	PRINCIPLE CLINICAL SYNDROMES
Bites, Scratches, Exudates			
Bartonella spp.[a]	Bacteria	Cats and dogs	Subclinical, fever, hyperglobulinemia, uveitis, lymphadenopathy, others
		Humans	Fever, malaise, lymphadenopathy, bacillary angiomatosis, bacillary peliosis, others
Capnocytophaga canimorsus	Bacterium	Dogs and cats	Subclinical oral carriage
		Humans	Bacteremia
Dermatophytes	Fungi	Cats and dogs	Superficial dermatologic disease
		Humans	Superficial dermatologic disease
Francisella tularensis[b]	Bacterium	Cats and dogs	Septicemia, pneumonia
		Humans	Ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of inoculation)
Rabies	Virus	Cats and dogs	Progressive central nervous system disease
		Humans	Progressive central nervous system disease
Sporothrix spp.[b]	Fungal	Cats	Draining cutaneous tracts
		Humans	Draining cutaneous tracts
Yersinia pestis[b]	Bacterium	Cats and dogs	Bubonic, bacteremic, or pneumonic (depending on route of inoculation)
		Humans	Bubonic, bacteremic, or pneumonic (depending on route of inoculation)
Enteric Agents			
Ancylostoma spp.[c]	Hookworm	Dogs and cats	Blood loss anemia, diarrhea, unthrifty
		Humans	Cutaneous larva migrans; esosinophilic pain
Baylisascaris procyanosis	Roundworm	Dogs	Failure to thrive
		Humans	Visceral larva migrans; CNS disease
Campylobacter jejuni and *Campylobacter coli*	Bacteria	Dogs and cats	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Cryptosporidium spp.[d]	Coccidian	Dogs and cats	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Escherichia coli	Bacteria	Dogs and cats	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Echinococcus multilocularis	Cestode	Dogs and cats	Subclinical infection
		Humans	Polysystemic disease
Echinococcus granulosa	Cestode	Dogs and cats	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Entamoeba histolytica[e]	Amoeba	Dogs	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Giardia spp.[f]	Flagellate	Dogs and cats	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Helicobacter spp.[g]	Bacterium	Dogs and cats	Vomiting
		Humans	Reflux disease and vomiting
Salmonella spp.	Bacteria	Dogs and cats	Diarrhea and vomiting
		Humans	Diarrhea and vomiting
Strongyloides stercoralis	Hookworm	Dogs and cats	Blood loss anemia, failure to thrive
		Humans	Cutaneous larva migrans

TABLE 99.1

Common Zoonotic Infections of Dogs and Cats—cont'd

ROUTE OF EXPOSURE	AGENT	AFFECTED	PRINCIPLE CLINICAL SYNDROMES
Toxocara canis and *T. cati* (C)[c]	Roundworms	Dogs and cats Humans	Vomiting, failure to thrive Ocular and visceral larva migrans
Toxoplasma gondii[h]	Coccidian	Cats Humans	Rarely diarrhea, polysystemic disease Ocular, CNS, polysystemic disease
Uncinaria stenocephala[c]	Hookworm	Dogs and cats Humans	Blood loss anemia, diarrhea, unthrifty Cutaneous larva migrans
Yersinia enterocolitica	Bacterium	Dogs and cats Humans	Subclinical infection Diarrhea and vomiting
Respiratory or Ocular			
Bordetella bronchiseptica	Bacterium	Dogs and cats Humans	Sneeze and cough Pneumonia in immunosuppressed
Chlamydia felis	Bacterium	Cats Humans	Conjunctivitis, sneezing Conjunctivitis
Francisella tularensis[i]	Bacterium	Cats Humans	Septicemia, pneumonia Ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of infection)
Streptococcus group A	Bacterium	Dogs and cats Humans	Subclinical, transient carrier "Strep throat," septicemia
Yersinia pestis[i]	Bacterium	Cats	Bubonic, bacteremic, or pneumonic
		Humans	Bubonic, bacteremic, or pneumonic
Urogenital			
Brucella canis	Bacterium	Dogs Humans	Orchitis, epididymitis, abortion, stillbirth, vaginal discharge, uveitis, fever Fever, malaise
Leptospira spp.	Spirochetes	Dogs Humans	Fever, malaise, inflammatory urinary tract or hepatic disease, uveitis, CNS Fever, malaise
Coxiella burnetii[i]	*Rickettia*	Cats Humans	Subclinical, abortion, or stillbirth Fever, pneumonitis, lymphadenopathy, myalgia, arthritis
Flea-borne			
Bartonella spp.[a]	Bacteria	Cats and dogs Humans	Subclinical, fever, hyperglobulinemia, uveitis, lymphadenopathy, others Fever, malaise, lymphadenopathy, bacillary angiomatosis, bacillary peliosis, others
Rickettsia felis	Rickettsia	Cats Humans	Subclinical, fever Fever, CNS
Yersinia pestis	Bacterium	Cats Humans	Bubonic, bacteremic, or pneumonic (depending on the route of inoculation) Bubonic, bacteremic, or pneumonic (depending on the route of inoculation)
Tick-borne[j]			
Anaplasma phagocytophilum	Rickettsia	Dogs and cats Humans	Fever, polyarthritis Fever, polysystemic

TABLE 99.1

Common Zoonotic Infections of Dogs and Cats—cont'd

ROUTE OF EXPOSURE	AGENT	AFFECTED	PRINCIPLE CLINICAL SYNDROMES
Borrelia burgdorferi	Spirochete	Dogs	Subclinical infection, fever, polyarthritis, nephropathy
		Humans	Polyarthropathy, cardiac and CNS disease
Ehrlichia spp.	Rickettsia	Dogs	Subclinical infection, fever, polysystemic
		Humans	Fever, polysystemic
Rickettsia rickettsii	Rickettsia	Dogs	Subclinical infection, fever, polysystemic
		Humans	Fever, polysystemic

[a]*Bartonella henselae*, *Bartonella koehlerae*, and *Bartonella clarridgeaie* are transmitted among cats and dogs by *C. felis* and are therefore listed under flea-borne disease. Other *Bartonella* spp. have zoonotic implications. Cats generally develop a higher level of bacteremia than dogs and are therefore epidemiologically linked more frequently to human disease. The vector is unknown for some *Bartonella* spp.
[b]Dogs rarely shed enough organisms to be a public health risk.
[c]Larvation of eggs occurs after passage into the environment, so direct transmission is less likely than exposure through environmental contamination.
[d]Most dogs and cats are infected by *Cryptosporidium canis* or *C. felis*, respectively, and these host-adapted species are rarely associated with disease in humans.
[e]Infection of dogs in the United States is thought to be rare.
[f]Host-adapted and zoonotic assemblages exist. Dogs and cats can harbor zoonotic assemblages, but whether levels of infection result in reinfection of humans is not established.
[g]Most *Helicobacter* spp. found in dogs and cats are host-adapted species. When *Helicobacter pylori* is detected in a dog or cat, it is likely from reverse zoonotic transmission.
[h]Sporulation of oocysts occurs after passage into the environment, so direct transmission is less likely than exposure through environmental contamination.
[i]Also can be vector-borne.
[j]*Bartonella* spp. DNA have been amplified from some ticks, but the extent of the role ticks play in the transmission of these agents has not been fully ascertained.

BOX 99.1

General Guidelines for Veterinarians to Avoid Zoonotic Transfer of Disease

- Veterinarians and their staff should familiarize themselves with zoonotic issues and take an active role in discussing the health risks and benefits of pet ownership with clients so that logical decisions concerning ownership and management of individual animals can be made.
- The veterinary clinic should communicate that the staff understands conditions associated with immune deficiency, is discreet, and is willing to help; signs or posters can be effective for this purpose.
- Pet owners should be provided information concerning veterinary or public health aspects of zoonoses, but veterinarians should not diagnose diseases in humans or discuss specific treatments.
- Clinically ill pet owners should always be referred to a physician for additional information and treatment.
- Veterinarians and physicians have different experiences concerning zoonoses; veterinarians should volunteer to speak to the pet owner's physician to clarify zoonotic issues when indicated.
- When public health–related advice is offered, it should be documented in the medical record.
- When reportable zoonotic diseases are diagnosed, appropriate public health officials should be contacted.
- Diagnostic plans to assess for presence of organisms with zoonotic potential should be offered, particularly to owners with clinically ill pets.
- All dogs and cats should be vaccinated for rabies.
- Dogs and cats should be routinely administered drugs that kill hookworms and roundworms.
- Flea and tick control should be maintained at all times.
- Veterinary clinic staff members should teach owners techniques to avoid being bitten or scratched.
- Avoid needle sticks contaminated with blood or effusions.

BOX 99.2

General Guidelines for Pet Owners to Avoid Zoonotic Transfer of Disease

- If a new pet is to be adopted, the dog or cat least likely to be a zoonotic risk is a clinically normal, arthropod-free, adult animal from a private family.
- Once the animal to be adopted is identified, it should be quarantined from any immunocompromised person until a thorough physical examination and zoonoses risk assessment is performed by a veterinarian.
- Veterinary care should be sought for all clinically ill pets.
- Physical examination and fecal examination should be performed at least once or twice yearly.
- Fecal material produced in the home environment should be removed daily, preferably by someone other than an immunocompromised individual.
- Use litterbox liners and periodically clean the litterbox with scalding water and detergent.
- Do not allow dogs or cats to drink from the toilet.
- Wear gloves when gardening and wash hands thoroughly when finished.
- Filter or boil water from sources in the environment.
- Wash your hands after handling animals.
- Do not handle animals that you are unfamiliar with.
- Clinically ill animals should not be handled by immunocompromised people, if possible.
- Pets should be maintained within the home environment to lessen exposure to other animals that may carry zoonotic agents, exposure to excrement of other animals, and exposure to fleas and ticks.
- Pets should only be fed commercially processed food.
- People should not share food utensils with pets.
- Avoid being licked by animals.
- Claws of cats should be clipped frequently to lessen the risk of skin penetration.
- To lessen the risk of bites and scratches, do not tease or physically restrain dogs and cats.
- If bitten or scratched by a dog or cat, seek medical attention.
- Control potential transport hosts, such as flies and cockroaches, that may bring zoonotic agents into the home.
- Cook meat for human consumption to 80° C for 15 minutes minimum (medium-well).
- Wear gloves when handling meat and wash hands thoroughly with soap and water when finished.

the defecation habits of cats. Human infection after direct contact with dogs or cats is extremely unlikely because the eggs are not immediately infectious.

Dogs and cats can be subclinically affected or may develop poor haircoats, poor weight gain, and gastrointestinal signs. In people, eosinophilic granulomatous reactions involving the skin, lungs, central nervous system (CNS), or eyes then occur, potentially leading to clinical signs of disease. Clinical signs and physical examination abnormalities in affected individuals include skin rash, fever, failure to thrive, CNS signs, cough, pulmonary infiltrates, and hepatosplenomegaly. Peripheral eosinophilia is common. Ocular larva migrans most commonly involves the retina and can cause reduced vision; uveitis and endophthalmitis can also occur. Visceral larva migrans is most common in children between 1 and 4 years of age, whereas ocular larva migrans is most common in older children. Diagnosis in human beings is confirmed by biopsy or can be presumed in cases with classic clinical manifestations, eosinophilia, and positive serology.

Ancylostoma caninum, Ancylostoma braziliense, Ancylostoma tubaeformis, Uncinaria stenocephala, and *Strongyloides stercoralis* have been associated with cutaneous larva migrans in the United States. Prevalence rates of hookworm infection vary by the study and have changed over the years. In one large study of more than 1 million dogs examined at 547 private veterinary hospitals in 44 U.S. states, 4.5% of samples contained eggs of *Ancyclostoma* spp. (Little et al., 2009). In high-risk areas and animals, infection rates can be much higher. For example, *A. tubaeforme* and *A. braziliense* were found in feces of 26 of 40 (65%) of the feral cats tested in one study in Florida (Liotta et al., 2012). After the passage of hookworm eggs into the environment in feces, infectious larvae are released after incubating for 1 to 3 days; humans are infected by skin penetration. In addition, eosinophilic enteritis in humans was reported after ingestion of larvated *A. caninum* eggs (Landmann and Prociv, 2003).

Animals are either subclinically ill or have nonspecific signs such as poor haircoats, failure to gain weight, vomiting, or diarrhea. Heavily infected puppies and kittens may have pale mucous membranes from blood loss anemia. In humans, the larvae cannot penetrate the dermoepidermal junction and usually die in the epidermis. Clinical signs are related to migration of the larvae, which results in an erythematous, pruritic cutaneous tunnel. Cutaneous signs usually resolve within several weeks. Abdominal pain is the most common clinical sign in humans with *A. caninum* intestinal infection.

Trichuris vulpis, the dog whipworm, is most commonly associated with large-bowel diarrhea in dogs. The organism is common in dogs of the United States (overall prevalence = 1.2%; Little et al., 2009) and has been detected in feces in some people (George et al., 2017).

Prevention of hookworms and roundworms is achieved by control of animal excrement in human environments. All puppies and kittens should have a fecal flotation performed and should be routinely treated with an anthelmintic that has efficacy against roundworms and hookworms. The Companion Animal Parasite Council (http://www.capcvet.org) maintains current guidelines on how to optimally control zoonotic parasitic infections of dogs and cats.

CESTODES

Dipylidium caninum, Echinococcus granulosa, and *Echinococcus multilocularis* are cestodes of dogs or cats that can infect humans. Wild carnivores are more common definitive hosts of *Echinococcus* spp. and shed infective eggs into the environment. *Echinococcus granulosa* eggs can be transmitted in feces of dogs after ingestion of infected sheep or rabbit tissues; *Echinococcus multilocularis* can be transmitted in feces of dogs or cats after ingestion of an infected rodent. Transmission to humans occurs after ingestion of the intermediate host (flea, *Dipylidium*) or eggs (*Echinococcus* spp.). Infection of dogs and cats with cestodes is generally subclinical. *Dipylidium* infection is most common in children after accidental ingestion of fleas and can lead to diarrhea and pruritus ani. In humans, after ingestion of eggs, which are immediately infectious, *Echinococcus* enters the portal circulation and spreads throughout the liver and other tissues. *Echinococcus multilocularis* is most common in the northern and central parts of North America but seems to be spreading with the fox population (most common definitive host). Prevention or control of cestodes is based on sanitation procedures and use of taeniacides. Praziquantel is labeled for the treatment of *Echinococcus* spp. Restricting hunting behavior of dogs and cats and feeding only processed or cooked foods should lessen potential exposure to *Echinococcus* spp. Monthly administration of praziquantel should be considered in dogs and cats allowed to hunt in endemic areas. Flea control should be maintained to lessen risk of *D. caninum* infection.

COCCIDIANS

Cryptosporidium spp. inhabit the respiratory and intestinal epithelium of many vertebrates, including birds, mammals, reptiles, and fish. Once thought to be a commensal, *Cryptosporidium* spp. are now known to cause gastrointestinal tract disease in several mammalian species, including rodents, dogs, cats, calves, and humans. The organisms have an enteric life cycle similar to that of other coccidians that culminates in the production of thin-walled, autoinfective oocysts and thick-walled, environmentally resistant oocysts that are passed in feces (Fig. 99.1). Oocysts (4-6 µm in diameter) are passed sporulated and are immediately infectious to other hosts. Multiple species of *Cryptosporidium* spp. exist, including *Cryptosporidium parvum*, *Cryptosporidium hominis*, *Cryptosporidium felis,* and *Cryptosporidium canis.* Although some *Cryptosporidium* infect multiple animal species, others have a limited host range. However, strains that infect both pets and people cannot be differentiated by light microscopy from those that infect only pets, so all *Cryptosporidium* spp. should be considered potentially zoonotic. *Cryptosporidium parvum* infection of humans after exposure to infected calves has been recognized for years, and it is now known that most human infections are from *C. hominus*. The most common *Cryptosporidium* spp. isolated from dogs and cats are the host-adapted *C. canis* and *C. felis,* respectively, and so most consider pets with *Cryptosporidium* spp. infections to not be significant risks for humans (Lucio-Forster et al., 2010). In one study, cat or dog ownership was not statistically associated with cryptosporidiosis in human immunodeficiency virus (HIV)-infected people (Glaser et al., 1998).

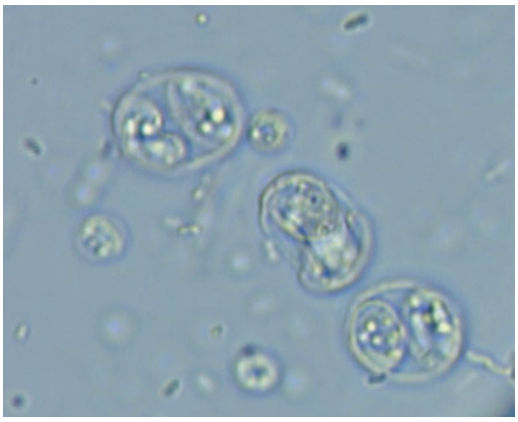

FIG 99.1
Cryptosporidium parvum and *Toxoplasma gondii* oocysts on a fecal flotation. The *C. parvum* oocysts are approximately 4 × 5 µm, and the *T. gondii* oocysts are approximately 10 × 12 µm.

Infection of dogs and cats by *Cryptosporidium* spp. is usually subclinical, but small-bowel diarrhea occurs in some cases. Immunosuppression may potentiate disease; several dogs and cats had concurrent FeLV infection, canine distemper virus infection, or intestinal lymphoma. Clinical cryptosporidiosis is characterized by small-bowel diarrhea and is generally self-limiting in immunocompetent people, but fatal infection is common in those with AIDS.

The small size (approximately 4-6 µm in diameter) of *Cryptosporidium* spp. oocysts leads to difficulty in diagnosis. Routine salt solution flotation and microscopic examination at ×100 magnification commonly lead to false-negative results. The combination of concentration techniques with fluorescent antibody staining or acid-fast staining appears to be more sensitive. Multiple enzyme-linked immunosorbent assays for the detection of *C. parvum* antigen in feces are commercially available but do not accurately detect *C. felis* or *C. canis.* PCR assay is the most sensitive test to date and is now routinely available but not standardized among laboratories.

No drug has been shown to eliminate *Cryptosporidium* spp. from the gastrointestinal tract. However, clinical signs usually resolve when azithromycin is administered orally at 10 mg/kg q24h, tylosin is administered orally at 10 to 15 mg/kg q8h, or nitazoxanide is administered orally at 37.5-75 mg/kg twice, 14 days between doses. Optimal duration of therapy is unknown; some cases have required administration of azithromycin for several weeks before clinical signs resolve. Avoiding exposure is the most effective prevention. Routine disinfectants require extremely long contact with the organism to be effective. Drying, freeze thawing, and steam cleaning can inactivate the organism. Surface water collected in the field for drinking should be boiled or filtered. If the

owner of a dog or cat with *Cryptosporidium* spp. infection would like to know whether the pet is carrying a pet species or zoonotic species, genotyping can be performed commercially in the United States (www.dlab.colostate.edu).

Toxoplasma gondii is a ubiquitous coccidian with worldwide distribution (Lappin et al., 2010). Most seroprevalence studies performed in the United States suggest that at least 30% of cats and humans have previously been exposed. Cats are the only known definitive host of the organism, completing the enteroepithelial cycle (sexual phase) that results in the passage of environmentally resistant unsporulated oocysts in feces. Oocyst sporulation occurs in 1 to 5 days in the presence of oxygen; sporulated oocysts are infectious to most warm-blooded vertebrates (see Fig. 99.1). After infection by *T. gondii,* an extraintestinal phase that ultimately leads to the formation of tissue cysts containing the organism develops. Infection by *T. gondii* occurs after ingestion of sporulated oocysts, after ingestion of tissue cysts, or transplacentally. Transplacental infection of humans and cats usually occurs only if the mother is infected for the first time during gestation.

In dogs and cats, clinical disease from *T. gondii* infection occurs occasionally and is manifested most commonly by fever, uveitis, pulmonary disease, hepatic disease, and CNS disease (see Chapter 98). Infected immunocompetent humans are generally asymptomatic; self-limiting fever, lymphadenopathy, and malaise occur occasionally. Transplacental infection of humans results in clinical manifestations, including stillbirth, hydrocephalus, hepatosplenomegaly, and retinochoroiditis. Presence of *T. gondii* antibodies has been associated with presence of behavioral abnormalities in people, but a direct cause and effect has not been established (Fuglewicz et al., 2017). Chronic tissue infection in humans can be reactivated by immunosuppression, leading to dissemination and severe clinical illness; this has been commonly associated with drug-induced immunosuppression and AIDS. Approximately 10% of humans with AIDS develop toxoplasmic encephalitis.

Toxoplasma gondii oocysts are most effectively demonstrated in cat feces after sugar or other centrifugation techniques. Clinical toxoplasmosis is difficult to diagnose in humans, dogs, and cats but usually involves the combination of clinical signs, serologic test results, organism demonstration techniques, and response to anti-*Toxoplasma* drugs (Lappin, 2010; see Chapter 98).

Although *T. gondii* is recognized as one of the most common zoonoses, humans are usually not infected by direct contact with cats. The oocyst-shedding period usually lasts several days to several weeks (≈7-10 days if the cat was infected by tissue cyst ingestion). Because oocysts have to sporulate to be infectious, contact with fresh feces cannot cause infection. Cats are quite fastidious and usually do not allow feces to remain on their skin for periods long enough to lead to oocyst sporulation. Oocysts were not isolated from the fur of cats 7 days after completion of the oocyst-shedding period in one study. Most studies evaluating cat ownership as a risk factor for human toxoplasmosis has showed minimal associations including one study of HIV-infected individuals (Wallace et al., 1993). In addition, one study of veterinary staff members who worked frequently with cats had low seroprevalence rates suggesting exposure to cats did not increase their risk for acquiring *T. gondii* infection (Shuhaiber et al., 2003). Cats infected by *T. gondii* usually do not shed or shed lower numbers of oocysts on secondary exposures (Zulpo et al., 2018) and did not have repeat oocyst shedding after being administered cyclosporine in a recent study (Lappin et al., 2015). Cats do not need to be removed from households with immunodeficient people or pregnant women because of the risk for acquiring toxoplasmosis (www.cdc.gov/parasites/toxoplasmosis/gen_info/pregnant.html). Prevention of *T. gondii* infection is summarized in Box 98.1.

FLAGELLATES, AMOEBA, AND CILIATES

Giardia spp. (flagellate), *Entamoeba histolytica* (amoeba), and *Balantidium coli* (ciliate) are enteric protozoans that can be transmitted to humans by contact with feces; the cysts do not require an incubation period to become infectious. *Entamoeba histolytica* infection is extremely rare in dogs and cats; *B. coli* infection is rare in dogs and has not been reported in cats.

Giardia spp. infection of dogs and cats is common and can be detected in feces of normal dogs and cats, and in those with small-bowel diarrhea (and occasionally mixed-bowel diarrhea in cats). Clinical signs of disease are generally more severe in immunodeficient individuals. Because the organism is immediately infectious when passed as cysts in stool, direct zoonotic transfer is possible. Genetic studies have detected multiple *Giardia* spp., and most dogs and cats are infected with the host-adapted assemblages C, D, and F (Scorza et al., 2012). However, as is the case with *Cryptosporidium,* because determining zoonotic strains of *Giardia* spp. by microscopic examination is not possible, assume that feces from all dogs and cats infected with *Giardia* spp. are a potential human health risk. Fecal examination should be performed on all dogs and cats at least yearly, and treatment with drugs with anti-*Giardia* activity, such as fenbendazole, metronidazole, or febantel/praziquantel/pyrantel, should be administered if indicated (see Chapter 28). Febantel/praziquantel/pyrantel is now labeled for the treatment of giardiasis in dogs in some countries. Centrifugation techniques (zinc sulfate or sugar) are considered by most parasitologists to be optimal for demonstration of cysts. If fresh stool is available from dogs or cats with diarrhea, examination of a wet mount to detect the motile trophozoites may improve sensitivity (see also Chapter 91). Monoclonal antibody-based immunofluorescent antibody tests, fecal antigen tests, and PCR assays are available but should be used in addition to, not in lieu of, fecal flotation, which can also reveal other parasites. The combination of a fecal centrifugation technique with a *Giardia* antigen test has approximately 97% sensitivity. Fecal PCR assay results can be less sensitive due to presence of fecal PCR inhibitors (Hascall et al., 2016). The Companion Animal Parasite Council does not recommend treating

healthy carriers with more than one drug (www.capcvet.org). If a pet is healthy but persistently *Giardia*-positive, genotyping can be performed to determine whether the assemblage is zoonotic (www.dlab.colostate.edu).

Giardia vaccines for dogs or cats are no longer commercially available in the United States. Prevention of zoonotic giardiasis includes boiling or filtering surface water for drinking and washing hands that have handled fecally contaminated material, even if gloves were worn. In dogs and cats treated for giardiasis, infection can be documented again several weeks later in approximately 75% of animals. Thus the primary goal for the treatment of giardiasis is elimination of diarrhea. Whether these cases are a treatment failure or a reinfection is unknown.

BACTERIA

Campylobacter spp., *Escherichia coli, Helicobacter* spp. *Salmonella* spp., and *Yersinia enterocolitica* can each infect dogs and cats, and can cause disease in humans. When pets with *Clostridium difficile* are identified, the animal was likely infected by a human and usually is a subclinical carrier. Transmission from animals to humans is by fecal-oral contact. Dogs can be subclinical carriers of *Shigella* spp., but humans are the natural hosts. Although *Helicobacter pylori* was isolated from a colony of cats, whether dogs and cats are a common source of *Helicobacter* infection in humans is unclear. However, on the basis of epidemiologic studies, it is unlikely. In most studies on prevalence of enteric zoonoses, *Salmonella* spp. and *Campylobacter* spp. infections were uncommon in pet dogs and cats. The prevalence of *Salmonella* and *Campylobacter* infections is greater in young animals housed in unsanitary or crowded environments.

Gastroenteritis can occur in dogs or cats after infection by *Salmonella* spp., *Campylobacter* spp., or *E. coli; Y. enterocolitica* is probably a commensal agent in animals but causes fever, abdominal pain, polyarthritis, and bacteremia in humans. *Helicobacter* infections cause gastritis, which is commonly manifested as vomiting, belching, and pica. *Salmonella* spp. infection in dogs and cats is often subclinical. Approximately 50% of clinically affected cats have gastroenteritis; many present with signs of bacteremia that usually include fever (Tauni et al., 2000). Salmonellosis of cats and humans has been associated with songbirds (songbird fever). Abortion, stillbirth, and neonatal death can result from in utero infection. Diagnosis of *Salmonella* spp., *Campylobacter jejuni, E. coli,* and *Y. enterocolitica* is based on culture of feces (see Chapter 91). A single negative culture may not rule out infection. Although PCR assays are available, culture is superior because antimicrobial susceptibility can be determined.

Antibiotic therapy can control clinical signs of disease from infection by *Salmonella* spp. or *Campylobacter* spp. (see Chapter 28) but should not be administered orally to pets because of the risk for antibiotic resistance. Parenteral drugs should be administered if bacteremia is suspected. Strains of *Salmonella* resistant to most antibiotics have been detected in several cats. Prevention of enteric bacterial zoonoses is based on sanitation and control of exposure to feces. Immunodeficient people should avoid young animals and animals from crowded or unsanitary housing, particularly if clinical signs of gastrointestinal tract disease occur.

BITE, SCRATCH, OR EXUDATE EXPOSURE ZOONOSES

BACTERIA

It is estimated that, between 2005 and 2009, there were approximately 300,000 nonfatal dog bite injuries per year in the United States (Quirk, 2012). Most of the aerobic and anaerobic bacteria associated with bite or scratch wounds cause only local infection in immunocompetent individuals. However, 28% to 80% of cat bites become infected, and severe sequelae, including meningitis, endocarditis, septic arthritis, osteoarthritis, and septic shock, can occur. The majority of the aerobic and anaerobic bacteria associated with dog or cat bite or scratch wounds lead only to local infection in immunocompetent individuals. Immunodeficient humans or those exposed to *Pasteurella* spp., *Capnocytophaga canimorsus* (DF-2), or *Capnocytophaga cynodegmi* more consistently develop systemic clinical illness. Splenectomized humans are at increased risk for developing bacteremia.

Dogs and cats are subclinical carriers of multiple bacteria in the oral cavity. After a person is bitten or scratched, local cellulitis is noted initially, followed by evidence of deeper tissue infection. Bacteremia and the associated clinical signs of fever, malaise, and weakness are common, and death can occur within hours after infection with *Capnocytophaga* spp. in immunodeficient or splenectomized humans. Diagnosis is confirmed by culture. Treatment of carrier animals is not necessary. Treatment of clinically affected humans includes local wound management and parenteral antibiotic therapy. Penicillin derivatives are highly effective against most *Pasteurella* infections; penicillins and cephalosporins are effective against *Capnocytophaga* spp. in vitro.

Normal dogs and cats, as well as those with clinical signs of disease, can carry methicillin-resistant *Staphylococcus aureus* (MRSA) and *Staphylococcus pseudintermedius* (MRSP) on the skin. These agents can be spread among veterinary or human patients and doctors, so this is a significant problem in hospitals (Febler et al., 2018; Weese et al., 2006). A recent study of nasal and perianal samples completed in an open admission shelter showed MRSA in 0.5% of cat samples, MRSA in 0.5% of dog samples, and MRSP in 3% of dog samples (Gingrich et al., 2011). These prevalence rates are generally lower than those from dogs or cats from veterinary hospitals. These animals are generally not a risk for immunocompetent and otherwise healthy people, but care should be taken to avoid contamination of open wounds if an infected animal is being cared for. It is wise for veterinary hospitals to have an MRSA and MRSP policy for staff members; if repeated infections occur in veterinary cases, a staff member could be a carrier, so testing may been necessary.

Mycoplasma spp. infections of humans resulting from cat bites, one with cellulitis and one with septic arthritis, have been reported. L-form bacteria are cell wall–deficient organisms associated with chronic draining skin wounds in cats commonly resistant to cell wall–inhibiting antibiotics such as penicillins and cephalosporins. Infection of a human being after a cat bite has been documented. Diagnosis can be confirmed only by histologic examination of tissue. Doxycycline has been used to treat cats and people successfully. Gloves should be worn when attending cats with draining tracts, and hands should be cleansed thoroughly.

Bartonella henselae can infect both dogs and cats, and is the most common cause of cat scratch disease, as well as bacillary angiomatosis and bacillary peliosis—common disorders in humans with AIDS (Breitschwerdt et al., 2010). Dogs and cats can also be infected with several other *Bartonella* spp., including *Bartonella clarridgeiae, Bartonella koehlerae, Bartonella vinsonii* (dogs), and *Bartonella quintana* (see Chapter 94). *Bartonella henselae* has been isolated from the blood of subclinically ill, seropositive cats and also from some cats with a variety of clinical manifestations such as fever, lethargy, lymphadenopathy, uveitis, gingivitis, and neurologic diseases. Infection of dogs has also been associated with clinical illness. Seroprevalence in cats varies by region, but up to 93% of cats in some geographic areas of the United States are *Bartonella* spp. seropositive. *Bartonella* spp. have also been detected in dog saliva, and dogs have been associated with bartonellosis in people (see Chapter 94). *Bartonella henselae*, *B. clarridgeiae,* and *B. koehlerae* are transmitted between cats by fleas, so the prevalence is greatest in cats from states where fleas are common (Breitschwerdt et al., 2010). Transmission to humans commonly occurs after cat bites or scratches; the disease appears to be transmitted most commonly from kittens. *B. henselae* survives in flea frass for at least 9 days, so the cat's claws and teeth are likely contaminated with *B. henselae* during grooming, which emphasizes the maintenance of flea control on dogs and cats (Fig. 99.2). In one study of cats with *C. felis* infestation, *Bartonella* spp. DNA could be amplified from the skin (31%) and claw beds (18%) of the cats (Lappin and Hawley, 2009).

Humans with cat scratch disease develop a variety of clinical signs, such as lymphadenopathy, fever, malaise, weight loss, myalgia, headache, conjunctivitis, skin eruptions, and arthralgia (Breitschwerdt et al., 2007; Breitschwerdt et al., 2010). Bacillary angiomatosis is a diffuse disease resulting in vascular cutaneous eruptions. Bacillary peliosis is a diffuse systemic vasculitis of parenchymal organs, particularly the liver. The incubation period for cat scratch disease is approximately 3 weeks. Most cases of cat scratch disease are self-limiting but may take several months to completely resolve. Recently, *B. henselae* has been documented as a cause of chronic disease syndromes like fever, headaches, polyarthritis, and chronic fatigue; immunocompetent veterinary healthcare providers or *Bartonella* researchers may be overrepresented from increased risk of exposure (Breitschwerdt et al., 2007). Most medical doctors may not recognize this differential and should be informed if a patient is exhibiting these problems.

FIG 99.2
Ctenocephalides felis frass and eggs that can contain live *Bartonella* spp. or *Rickettsia felis*. (Courtesy the HESKA Corporation.)

Blood culture, blood PCR, and serologic testing can be used to determine the risk of individual cats, dogs, or people (see Chapter 94). The use of Bartonella alpha proteobacteria growth medium (BAPGM) culture media with PCR assay has been shown to be one of the most sensitive ways to prove *Bartonella* spp. bacteremia in dogs and people. This assay is available at a commercial laboratory (www.galaxydx.com). In dogs and cats, although serologic testing can be used to determine whether an individual has been exposed, both seropositive and seronegative cats can be bacteremic, limiting the diagnostic utility of serologic testing. Thus testing healthy cats or dogs for *Bartonella* spp. infection is not currently recommended by the Centers for Disease Control and Prevention (Kaplan et al., 2009) or the American Association of Feline Practitioners (Brunt et al., 2006). Testing should be reserved for cats with suspected clinical bartonellosis.

In experimental studies, administration of doxycycline, tetracycline, erythromycin, amoxicillin-clavulanate, or enrofloxacin can limit bacteremia but does not cure infection in all cats and has not been shown to lessen the risk of cat scratch disease. Azithromycin was commonly administered to cats with suspected clinical bartonellosis but is now considered contraindicated for feline bartonellosis due to rapid induction of antimicrobial resistance (Biswas et al., 2010). Thus antibiotic treatment of healthy bacteremic cats is controversial and not currently recommended by the Centers for Disease Control (Kaplan et al., 2009) and Prevention or the American Association of Feline Practitioners (Brunt et al., 2006). Treatment should be reserved for cats with suspected clinical bartonellosis. Strict flea control should be maintained because the administration of monthly imidacloprid topically or in an 8-month collar has been shown to block transmission of *B. henselae* among cats (Bradbury and Lappin, 2010; Lappin et al., 2013). Immunodeficient people

should avoid kittens. Cat claws should be kept clipped, and cats should never be teased. Cat-induced wounds should immediately be cleansed, and medical advice sought.

Plague in cats and dogs is caused by *Yersinia pestis,* a gram-negative coccobacillus found most commonly in Midwestern and far Western states, particularly Arizona, New Mexico, and Colorado. Rodents are the natural hosts for this bacterium; cats are most commonly infected by ingestion of bacteremic rodents or lagomorphs or by being bitten by *Yersinia*-infected rodent fleas. Humans are most commonly infected by rodent flea bites, but many cases of transmission by exposure to wild animals and infected domestic cats have been documented. From 1977 to 1998, 23 cases of human plague (88% of the total cases) resulted from contact with infected cats (Gage et al., 2000). Infection can be induced by inhalation of respiratory secretions of cats with pneumonic plague, through bite wounds, or by contamination of mucous membranes or abraded skin with secretions or exudates.

Bubonic, septicemic, and pneumonic plague can develop in cats and humans; each form has accompanying fever, headache, weakness, and malaise. Because cats are most commonly infected by ingestion of bacteremic rodents, suppurative lymphadenitis (buboes) of the cervical and submandibular lymph nodes is the most common clinical manifestation. Exudates from cats with lymphadenopathy should be examined cytologically for the presence of large numbers of the characteristic bipolar rods (see Fig. 94.3). The diagnosis is usually confirmed by PCR assays that amplify the DNA of *Y. pestis* in exudates or aspirates. The diagnosis can also be confirmed by fluorescent antibody staining of exudates; culture of exudates, the tonsillar area, and saliva; and documentation of increasing antibody titers. People who are exposed to infected cats should be urgently referred to physicians for antimicrobial therapy, and public health officials should be alerted. Doxycycline, fluoroquinolones, chloramphenicol, or aminoglycosides can be used successfully for the treatment of plague. Parenteral antibiotics should be used during the bacteremic phase. Cats or dogs with suppurative lymphadenitis should be considered plague suspects, and extreme caution should be exercised when handling exudates or treating draining wounds. Suspect animals should be treated for fleas and housed in isolation. Pets are generally not considered infectious to humans after 4 days of antibiotic treatment.

Francisella tularensis is the gram-negative bacillus found throughout the continental United States that causes tularemia. The agent has several ticks capable of transmitting the agent. Human tularemia occurs most commonly after exposure to ticks and less commonly from contact with infected animals. However, human cases after exposure to dogs or cats have been reported (Capellan et al., 1993; Rimawi et al., 2015; Salit et al., 2013).

Infected cats exhibit generalized lymphadenopathy and abscess formation in organs such as the liver and spleen, which leads to fever, anorexia, icterus, and death. Ulceroglandular, oculoglandular, glandular, oropharyngeal, pneumonic, and typhoidal forms have been described in humans and develop depending on the route of exposure. Unlike the situation with plague, the organism is not often recognized in exudates or lymph node aspirates from infected cats. PCR assays, cultures, and documentation of increasing antibody titers can be used to confirm the diagnosis in pets and humans. Most cases of tularemia in pets have been diagnosed at necropsy, so optimal treatment is unknown. Streptomycin and gentamicin are the drugs used most commonly to treat humans. Tetracycline or chloramphenicol can be used in cases not requiring hospitalization but may be associated with relapses. Avoiding exposure to rabbits, ticks, and infected dogs or cats prevents the disease. All dogs or cats dying with bacteremia should be handled carefully at necropsy.

FUNGI

Of the many fungal agents that infect both humans and animals, only *Sporothrix* spp. and the dermatophytes have been shown to infect humans on direct exposure. *Histoplasma, Blastomyces, Coccidioides, Aspergillus,* and *Cryptococcus* infections of humans and animals can occur in the same household but generally result from a common environmental exposure (see Chapter 97).

Sporothrix spp. are cosmopolitan in distribution, and the soil is believed to be the natural reservoir. Early studies usually reported *S. schenckii* as the primary zoonotic agent. However, in Brazil, *S. brasiliensis* is most common and frequently a zoonosis (Della Terra et al., 2017). Dogs generally do not produce large numbers of *Sporothrix* in exudates and are not as great a zoonotic risk as cats. Infection of cats and humans usually occurs after the organism contaminates broken skin. Cats are believed to be infected by scratches from contaminated claws of other cats; infection is most common in outdoor males. Humans can be infected by contamination of cutaneous wounds with exudates from infected cats. *Sporothrix* infection in cats can be cutaneolymphatic, cutaneous, or disseminated. Chronic draining cutaneous tracts are common. Cats commonly produce large numbers of the organism in feces, tissues, and exudates; thus veterinary care personnel are at high risk when treating infected cats (Fig. 99.3). The clinical disease in humans is similar to that in cats. The organism can be demonstrated by cytologic examination of exudates or culture. Fluconazole, itraconazole, or ketoconazole are effective treatments. Gloves should be worn when attending cats with draining tracts, and hands should be cleansed thoroughly.

VIRUSES

Rabies is still the only relevant direct small animal viral zoonosis in the United States. See Chapter 64 for a discussion of this agent, as well as the Compendium on Rabies Control 2016 (Brown et al., 2016). Pseudorabies is a herpesvirus that infects pigs; dogs and humans can develop self-limiting pruritic skin disease after exposure. Dogs occasionally develop CNS disease characterized by depression and seizures. Diagnosis is suspected on the basis of the exposure history, and prevention is by avoiding exposure. To date, there is no

FIG 99.3
Sporothrix schenckii-associated skin lesions in a cat in Colorado.

evidence suggesting that the three retroviruses of cats—feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and feline foamy virus (FeFV)—infect humans. In one study, 204 veterinarians and others potentially exposed to feline retroviruses were assessed for antibodies against FIV and FeFV, FeLV p27 antigen, and FeLV provirus; test results on all were negative (Butera et al., 2000). Because both FeLV and FIV can induce immune deficiency, infected cats should be considered more likely than retrovirus-naïve cats to be carrying other potential zoonotic agents, particularly if gastrointestinal tract signs are present.

RESPIRATORY TRACT AND OCULAR ZOONOSES

BACTERIA

Bordetella bronchiseptica is a bacterium that induces respiratory tract infections in dogs and cats (see Chapter 21). The classic clinical manifestation is tracheobronchitis, but the organism can also cause pneumonia, sneezing, and nasal discharge. Humans rarely develop clinical disease caused by *B. bronchiseptica* unless they are immunologically compromised (see Table 99.1). Most cases of *B. bronchiseptica* infection in humans have been in patients that were immunodeficient (Dworkin et al., 1999; Wernli et al., 2011). *Bordetella bronchiseptica* infection in humans has been associated with cats and dogs. Amoxicillin-clavulanate, chloramphenicol, enrofloxacin, and tetracycline derivatives are all effective treatments. Animals with upper or lower respiratory tract inflammatory disease should be kept away from immunodeficient people until the animals are clinically normal. However, treated animals can still shed the organism.

Chlamydia felis (formerly *Chlamydia psittaci*) causes mild conjunctival disease and rhinitis in cats. Conjunctivitis in humans after direct contact with ocular discharges from cats has been described. A human isolate of *Chlamydia* spp. was inoculated into cats, resulting in conjunctivitis and persistent infection, suggesting that the isolate was a feline strain. Occasionally the organism is associated with systemic disease; atypical pneumonia was diagnosed in an apparently immunocompetent 48-year-old man, malaise and cough were diagnosed in an immunosuppressed woman, and endocarditis and glomerulonephritis were diagnosed in a 40-year-old woman. Diagnosis is based on organism demonstration by culture, cytologic documentation of characteristic inclusion bodies, or fluorescent antibody staining of conjunctival scrapings. Tetracycline- or chloramphenicol-containing eye ointments are generally effective in the treatment of infection. Oral administration of doxycycline is still considered the optimal way to clear the carrier state. Care should be taken to avoid direct conjunctival contact with discharges from the respiratory or ocular secretions of cats, especially by immunosuppressed persons (see Box 99.2). Employees should be directed to wear gloves or wash hands carefully when attending cats with conjunctivitis.

Humans are the principal natural hosts for *Streptococcus* group A bacteria; *Streptococcus pyogenes* is the most common cause of "strep throat" in humans. Dogs and cats in close contact with infected humans can develop transient, subclinical colonization of pharyngeal tissues and can transmit the infection to other humans. However, this is poorly documented and believed to be unusual (Wilson et al., 1995). The organism can be cultured from the tonsillar crypts. Culture-positive animals should be treated with penicillin derivatives. If animals are to be treated in a household with chronic, recurrent "strep throat," all humans should also be treated because they could be chronic subclinical carriers.

Yersinia pestis and *F. tularensis* can be transmitted from cats to humans in respiratory secretions. In endemic areas, cats with clinical signs or radiographic abnormalities consistent with pneumonia should be handled as plague or tularemia suspects. Gloves, mask, gown, and eye protection should be worn while performing transoral airway washings in suspect cats.

VIRUSES

Influenza A viral infections have been detected in some cats after close exposure to infected birds (Leschnik et al., 2007). In studies of naturally exposed and experimentally infected cats, some cats developed respiratory disease and others have become asymptomatic carriers. Results of studies assessing transmission between infected cats have been variable. Very rarely, cats infected with an influenza virus are associated with clinical disease in humans (Lee et al., 2017).

GENITAL AND URINARY TRACT ZOONOSES

Coxiella burnetii is a rickettsial agent found throughout the world, including North America (see Table 99.1). Many ticks, including *Rhipicephalus sanguineus,* are naturally infected with *C. burnetii.* Cattle, sheep, and goats are

commonly subclinically infected and pass the organism into the environment in urine, feces, milk, and parturient discharges. Seropositive dogs have been detected, but zoonotic transfer to humans from dogs has not been documented. Infection of cats most commonly occurs after tick exposure, ingestion of contaminated carcasses, or aerosolization from a contaminated environment. Fever, anorexia, and lethargy developed in some experimentally infected cats. Infection has been associated with abortion in cats, but the organism can also be isolated from normal parturient cats. Infection of cats appears to be common; 20% of cats from a shelter in southern California and 20% of cats in Maritime Canada were seropositive, the organism was grown from the vagina of healthy cats in Japan, and DNA of the organism was amplified from uterine tissues of cats in Colorado (Cairns et al., 2007).

Human illness associated with direct contact with infected cats occurs after aerosol exposure to the organism passed by parturient or aborting cats; clinical signs develop 4 to 30 days after contact. Humans commonly develop acute clinical signs similar to those associated with other rickettsial diseases, including fever, malaise, headache, pneumonitis, myalgia, and arthralgia (Marrie, 1995). After primary infection, chronic Q fever develops in approximately 1% and can manifest as hepatic inflammation or valvular endocarditis. Tetracyclines, chloramphenicol, and quinolones are usually effective therapeutic agents in humans. Gloves and masks should be worn when attending to parturient or aborting cats. People who develop fever or respiratory tract disease after exposure to parturient or aborting cats should seek medical attention.

Leptospira spp. can be transmitted in urine from infected dogs and cats to humans, resulting in clinical disease (Sykes et al., 2010). Host-adapted species cause subclinical infection; infection by non-host-adapted species commonly results in clinical illness. The organisms enter the body through abraded skin or intact mucous membranes. (See Chapter 94 for a detailed discussion of the clinical manifestations of this disease and its treatment in dogs and cats.) Human clinical syndromes vary with the serovar but are similar to those that occur in the dog. Animals with suspected leptospirosis should be handled while wearing gloves. Contaminated surfaces should be cleaned with detergents and disinfected with iodine-containing products. Vaccines containing four leptospire serovars should be considered (see Chapter 93).

Brucella canis is a bacterium that preferentially infects the testicles, prostate, uterus, and vagina of dogs (see Chapters 55 and 56). The infection is maintained in dogs primarily by venereal transmission. Humans can be infected by direct contact with vaginal and preputial discharges from dogs. Clinical syndromes in dogs are diverse but commonly include abortion, stillbirth, failure to conceive, orchitis, epididymitis, vaginal discharge, uveitis, discospondylitis, and bacteremia. Intermittent fever, depression, and malaise are common in infected people. Diagnosis is based on serologic testing or demonstration of the organism by culture or PCR assay. Dogs with clinical signs of brucellosis should be evaluated serologically for *Brucella* infection with the 2-mercaptoethanol rapid slide agglutination card test. Seronegative dogs are unlikely to harbor *Brucella* unless the clinical syndrome is peracute. Seropositive dogs should have results confirmed by tube agglutination or agar gel immunodiffusion. Long-term antibiotic treatment (tetracyclines, aminoglycosides, quinolones) usually does not clear the infection, thus some recommend euthanasia of infected dogs. Ovariohysterectomy or castration will lessen contamination of the environment. Genital tract secretions should be avoided.

SHARED VECTOR ZOONOSES

Some zoonotic agents are transmitted between animals and humans by shared vectors such as fleas, ticks, or mosquitoes. *Rickettsia rickettsii* (ticks), *Rickettsia felis* (fleas), *Ehrlichia* spp. (ticks), *Anaplasma phagocytophilum* (ticks), *Borrelia burgdorferi* (ticks), *Bartonella* spp. (fleas and ticks), *Dipylidium caninum* (fleas), *Dirofilaria immitis* (mosquitoes), and West Nile virus (mosquitoes) are examples of vector-borne zoonoses common in the United States. For the flea- and tick-borne zoonoses, the pet brings the vector of the organism into the environment, resulting in exposure of the human being. Veterinary healthcare providers could have a slightly increased risk of exposure because they handle many animals infested with fleas and ticks. However, the vector, not direct contact with the infested animal, results in infection of the person. Flea and tick control should always be maintained with animals, and infested animals seen in the clinic should be treated immediately. See other sections of this textbook for detailed discussions of these agents.

SHARED ENVIRONMENT ZOONOSES

Some agents that infect both animals and man are not commonly transmitted between the pet and the owner by direct contact but are acquired from the same environmental source. Notable examples include *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis, Cryptococcus neoformans,* and *Aspergillus* spp. See Chapter 97 for detailed discussions of these agents.

A

A-a gradient. *see* Alveolar-arterial gradient
ABCB1 gene, 1276
Abdomen
  distention of, 7*f*, 408–411, 410*b*
  enlargement of, 408–411, 410*b*
  radiographic imaging of, 419–420, 419*f*
Abdominal carcinomatosis, 513
Abdominal effusion, 407, 519
Abdominal hemangiosarcoma, 513
Abdominal pain, 408, 410*b*, 519
  cranial, 625*f*–626*f*
Abdominal ultrasonography
  cancer staging using, 1288–1289
  hyperadrenocorticism evaluations, 862–864, 862*b*, 863*f*–865*f*
Abdominocentesis, 422, 543–544, 544*t*
Abducent nerve, 1055, 1056*t*
Abiotrophy, 1080–1081
Abortifacient, 1034*t*–1036*t*
Abortion, bacteria associated with, 965–966
Abscess, 612–613, 979*f*
  carnassial tooth root, 245–246
  epididymal, 1001*f*
  prostatitis with, 1003*f*
  retrobulbar, 1124*f*
  splenic, 1412–1413
  subcutaneous, site of glucose administration, 1012*f*
Absorption tests, 423
Acanthocytosis, 1345*t*
Acanthomatous ameloblastoma, 448*t*
Accelerated idioventricular rhythm, 41
Accessory nerve, 1056*t*
Acepromazine, 19–20, 386*t*–388*t*, 733*t*–734*t*
  hypertension treated with, 217*t*
  neurologic disorders treated with, 1185*t*–1186*t*
  stress relief using, 380*t*
Acetamides, 1437*t*–1438*t*
Acetaminophen, 629*t*–630*t*
Acetazolamide, 1079–1080
Acetylcholine, 1041–1042
Acetylcholine receptors
  antibodies to, 424
  myasthenia gravis caused by deficiency of, 1250
Acetylcholinesterase, 1041–1042
Acetylsalicylic acid, 1197*t*, 1209*t*–1210*t*
Acholic feces, 529*f*
Acid-base balance
  blood gas analysis of, 318
  in Greyhounds, 1362, 1362*t*
Acquired chronic polyneuropathies, 1164–1168
Acquired endocardial disease, 119–140
Acquired esophageal weakness, 454–455, 454*f*
Acquired valvular disease, 119–140
Acromegaly, feline, 749–753
  clinical features of, 750–751, 751*f*
  clinical pathology of, 751–752
  clinical signs of, 750*b*
  diagnosis of, 752, 752*f*
  etiology of, 749–750
  hyperadrenocorticism *versus*, 752
  insulin-resistant diabetes mellitus management in, 753
Acromegaly, feline *(Continued)*
  magnetic resonance imaging of, 750*f*
  prognosis for, 753
  radiation therapy for, 753
  treatment of, 753
Acrosomes, 946–947
Activated charcoal, 1185*t*–1186*t*
Activated partial thromboplastin time, 228
Acute abdomen, 407–408, 408*b*, 409*f*
Acute addisonian crisis, 886–888
Acute bronchitis, 330*b*
Acute canine polyradiculoneuritis (ACP), 1166–1168, 1167*t*, 1168*f*
Acute diarrhea, 398–399, 398*b*, 474–476
  acute enteritis, 474–475
  dietary-induced, 475–476
  enterotoxemia and, 475
Acute enteritis, 474–475
Acute gastritis, 462
Acute hemorrhagic diarrheal syndrome (AHDS), 462–463, 482
Acute hepatitis, 598–599, 598*b*
Acute intervertebral disk disease
  cervical disk extrusion, 1138*t*, 1139
  clinical features of, 1136, 1136*f*
  description of, 1135–1141
  diagnostic approach, 1136–1137, 1137*f*–1139*f*
  magnetic resonance imaging of, 1137
  myelography for, 1137, 1138*f*
  thoracolumbar disk extrusion, 1138*t*, 1139–1141, 1140*f*, 1140*t*
  treatment of, 1137–1141
Acute kidney injury (AKI), 686–692
  causes of, 687*b*
  chronic kidney disease *versus*, 687*t*
  clinical findings of, 689
  clinicopathologic findings of, 689–690
  dialysis for, 692
  diuretics for, 691
  fluid administration for, 690
  hyperphosphatemia in, 691
  metabolic acidosis in, 691
  nonsteroidal anti-inflammatory drugs as cause of, 686–687
  oliguria in, 688*f*
  overhydration associated with, 692
  pathophysiology of, 686–689, 687*f*–688*f*
  phases of, 687, 689*f*
  prognosis for, 692
  renal biopsy of, 690
  treatment of, 690–692
  ultrasonographic findings, 690*f*
Acute leukemias
  in cats, 1313*t*, 1319–1320
    chemotherapy for, 1317*b*
    clinical features of, 1320
    diagnosis of, 1320, 1320*f*
    hematologic features of, 1320
    prevalence of, 1319–1320
    treatment of, 1320
  in dogs, 1313–1316, 1313*t*
    chemotherapy for, 1317*b*
    clinical features of, 1313, 1314*f*
    diagnosis of, 1314–1316, 1316*b*
    hematologic features of, 1313–1314, 1314*f*–1315*f*
    prevalence of, 1313
    remission of, 1316
    treatment of, 1316
Acute lower motor neuron tetraparesis, 1166, 1167*t*
Acute lung injury (ALI), 356
Acute lymphoblastic leukemia, 1312*t*, 1313
Acute myelogenous leukemia, 1312*t*, 1313
Acute myelomonocytic leukemia, 1312*t*
Acute pancreatitis
  analgesia for, 628–631, 629*t*–630*t*
  antibiotics for, 633
  antiemetics for, 632–633
  biliary tract obstruction and, 633
  in cats, 624*f*
  chronic pancreatitis *versus*, 623*t*
  clinical features of, 621–625, 623*t*, 624*f*
  description of, 620
  diagnosis of, 625–627
  diagnostic imaging of, 626–627, 627*f*
  etiology of, 621, 623*t*
  fluid analysis for, 627
  gastroprotectants for, 633
  histopathology of, 627
  intravenous fluids and electrolytes for, 628
  necrotizing, 628
  nutrition for, 631–632, 631*b*, 632*f*
  pancreatic enzyme assays, 625–626
  pathogenesis of, 621, 623*t*
  plasma transfusion for, 628
  practice for feeding in, 631*b*
  prognosis for, 627–633
  prognostic factors of, 626
  risk factors for, 623*t*
  treatment of, 627–633
  ultrasonography of, 627*f*
Acute posterior paresis, 226
Acute proctitis, 504
Acute respiratory distress syndrome (ARDS), 356
Acute septic prostatitis, 1003
Acute tubular necrosis, 687*f*
Acute tumor lysis syndrome, 1276, 1286, 1286*f*
Acute vestibular attacks, 1116

management of, 681–684, 682*b*–683*b*
pathogenesis of, 676–677, 676*f*–677*f*
physical examination of, 680
prognosis of, 685
progression of, 677–678
sodium retention in, 684
thromboembolism in, 684–685
Glomerular filtration rate, 658, 661, 688*f*, 772
Glomerular function, diagnostic tests for, 658–662
bladder tumor antigen test, 662
blood urea nitrogen, 658, 659*f*
creatinine clearance, 660–661, 661*t*
cystatin C, 659
fibroblast growth factor-23 (FGF-23), 659–660
γ-Glutamyl transferase (GGT), 660
iohexol clearance, 661
kidney injury molecule-1 (KIM-1), 660
microalbuminuria, 662
N-acetyl-β-D-glucosaminidase (NAG), 660
neutrophil gelatinase-associated lipocalin (NGAL), 660
radioisotopes, 661
serum creatinine, 658–659
symmetric dimethylarginine, 659
urine protein-to-creatinine ratio, 661–662
Glomerulonephritis
clinical features of, 1249
diagnosis of, 1248*t*, 1249–1250
etiology of, 1249
histopathologic lesions of, 678–679
immune-complex, 676–677, 676*f*
immune-mediated, 676, 678*b*, 1249–1250
membranoproliferative, 678, 693*b*
membranous, 678
pathogenesis of, 1249*b*
proliferative, 678
treatment of, 1249–1250
Glomerulotubular balance, 694–695, 695*f*
Glomerulus
filtration barrier of, 675
mesangial cells, 675, 676*f*
structure of, 675, 676*f*
Glossopharyngeal nerve, 1056*t*, 1059–1060
Glucagon, 896*t*–897*t*
Glucocorticoid(s), 441. *see also* Corticosteroid(s); *specific drug*
acute addisonian crisis treated with, 886–887, 887*b*
adverse effects of, 1223, 1223*f*
aspiration pneumonia treated with, 348
canine chronic bronchitis treated with, 331–332
chronic hepatitis treated with, 592, 592*f*
endogenous
deficiency of, 883
excess of, 1178
eosinophilic lung disease treated with, 349
feline bronchitis treated with, 331
gastrointestinal ulceration/erosion from, 470
granulomatous meningoencephalitis treated with, 1121, 1121*b*
hemolysis treated with, 1235–1236
immune-mediated disorders treated with, 1221–1223, 1222*t*
immune-mediated hemolytic anemia treated with, 1235–1236
immune-mediated polyarthritis treated with, 1203–1204, 1204*t*, 1204*b*
insulin-secreting β-cell neoplasia treated with, 852
laryngeal paralysis treated with, 278
lymphocytic-plasmacytic gastritis treated with, 463
masticatory muscle myositis treated with, 1175
optic neuritis treated with, 1088
pulmonary edema caused by, 382
steroid-responsive meningitis-arteritis treated with, 1119
thyroid gland function tests affected by, 781
Glucocorticoid resistance, 1222
Glucosamine, 1197*t*, 1209*t*–1210*t*
Glucose
blood
continuous monitoring systems for, 821, 822*f*
for diabetes mellitus monitoring
in cats, 835–836, 836–837, 836*f*
in dogs, 818
measurement of
in cats, 838*f*
methods for, 821
serial curves of, 819–822, 820*f*–821*f*, 823*f*–824*f*, 837
stress hyperglycemia effects on, 837–839
toxicity, 831–832
urine, 665
diabetes mellitus monitoring in dogs using, 819
α-Glucosidase inhibitors, 835
Glucotrol. *see* Glipizide

Human chorionic gonadotropin (hCG), 1034*t*–1036*t*
Human intravenous immunoglobulin, 1225*t*, 1228, 1236–1237, 1243, 1255*t*–1256*t*
Human toxoplasmosis, 1524*b*
Humidification, 342
Humoral hypercalcemia of malignancy, 760, 924
Hyaline cast, 667–668, 667*f*
Hydralazine, 62*b*, 63
chronic heart failure treated with, 64*t*, 71, 147
dilated cardiomyopathy treated with, 147
hypertension treated with, 217*t*
Hydrocephalus, 1078–1080, 1078*f*–1079*f*
Hydrochlorothiazide, 64*t*, 67, 718
Hydrocodone bitartrate, 386*t*–388*t*
Hydrocortisone, 1222*t*
Hydromorphone, 386*t*–388*t*, 629*t*–630*t*
analgesic uses of, 227*b*
stress relief using, 380*t*
Hydromyelia, 1155
1α-Hydroxylase, 697
17α-Hydroxyprogesterone caproate, 962–963
Hydroxyurea
chronic myelogenous leukemia treated with, 1319
erythrocytosis treated with, 116
polycythemia rubra vera treated with, 1369
Hyoscyamine
in dogs, 90*t*–91*t*
dosage of, 90*t*–91*t*
Hypalgesia, 1040–1041
Hyperadrenocorticism
acromegaly *versus*, 752
adrenal-dependent, 863*f*
in cats, 878–883
adrenalectomy for, 883
clinical features of, 879–882, 879*b*
clinical pathology of, 880–881
description of, 878
diagnosis of, 882
etiology of, 878
imaging of, 881
physical examination findings in, 879–880, 879*f*
pituitary-adrenocortical axis tests, 881–882, 881*t*
prognosis for, 883
Hyperadrenocorticism *(Continued)*
signs of, 879–880
treatment of, 882–883
description of, 654*t*–655*t*, 741*t*
diagnosis of, 1249–1250
in dogs, 857–878
abdominal ultrasonography of, 862–864, 862*b*, 863*f*–865*f*
adrenocortical tumors, 857–858, 858*f*
clinical features of, 858–871
clinical pathology of, 861–862, 861*b*
diagnostic evaluation of, 861
etiology of, 857–858
imaging of, 862–864, 862*b*
medical complications of, 860–861, 860*b*
occult hyperadrenocorticism, 878
physical examination of, 860*t*
pituitary macrotumor syndrome, 859–860, 860*f*
pituitary-dependent hyperadrenocorticism, 857, 858*f*–859*f*, 863*f*, 869*f*, 876*f*
prognosis for, 877–878
signalment for, 858
signs of, 858–859, 860*t*
treatment, 871–877
adrenalectomy, 875–876
hypophysectomy, 877
ketoconazole, 875
mitotane, 872–875, 874*b*
pituitary irradiation, 876–877, 876*f*
trilostane, 871–872, 872*f*
endocrine alopecia caused by, 748*t*
hypertriglyceridemia associated with, 910
hypothyroidism *versus*, 783–784
iatrogenic, 858, 870
occult, 878
pituitary-dependent
in cats, 869*f*, 879*f*–880*f*
in dogs, 857, 858*f*–859*f*, 863*f*, 869*f*, 876*f*
Hyperbilirubinemia, 1231, 1489
Hypercalcemia, 48, 49*b*, 761*t*, 923–927, 1268, 1298

Hyperproteinemia, 1298, 1420–1422
Hypersensitivity reactions, 1281
Hypersthenuria, 663
Hypertension
amlodipine besylate for, 215, 217*t*
angiotensin-converting enzyme inhibitors for, 215, 217*t*
antihypertensive drugs for, 215, 217*t*
cardiomegaly secondary to, 213
in chronic kidney disease, 698
clinical features of, 213
complications of, 213*b*
diabetes mellitus and, 830
diagnosis of, 213–214
dietary salt restriction for, 215–216
diseases associated with, 211–212, 212*b*
echocardiographic findings, 213–214
etiology of, 211–212
general considerations for, 211–219
in glomerular disease, 685
hyperthyroidism and, 791
idiopathic, 211–212
mild, 211
moderate, 211
ocular effects of, 212, 213*b*
organs affected by, 211
pathophysiology of, 212
portal
chronic hepatitis and, 588
congestive splenomegaly caused by, 1413
prognosis for, 215–217
renal disease and, 211–212
severe, 211
treatment of, 215–217, 216*b*, 217*t*
Hypertensive crisis, 217*t*, 219
Hypertensive emergency, 218–219
Hypertensive encephalopathy, 213, 1077
Hyperthyroidism, 654*t*–655*t*
in cats, 167–168, 788–800
carbimazole, 796*t*, 797
cervical ultrasound for, 794, 795*f*
chronic kidney disease with, 790–791
clinical features of, 789
clinical pathology of, 790–791
diagnosis of, 791–794
etiology of, 788–789, 788*f*–789*f*
gastrointestinal tract disorders and, 791
iatrogenic hypothyroidism and, 790–791
iodine-restricted diet for, 796*t*, 797–798
methimazole for, 794, 796*t*
oral antithyroid drugs for, 794–797
physical examination of, 789, 790*t*
radioactive iodine for, 796*t*, 799–800, 799*f*
serum TSH concentration, 793

Hyperthyroidism *(Continued)*
signalment of, 789
signs of, 789, 790*t*
surgery for, 798–799, 798*b*
systemic hypertension and, 791
T3 suppression test for, 793–794, 793*f*
thyroid scintigraphy, 794
thyroidectomy for, 796*t*, 798, 798*b*
thyrotoxic cardiomyopathy, 790
treatment of, 794–800
urinary tract infection with, 791
chronic kidney disease, 696*f*, 698
myocardial hypertrophy and, 162
Hypertonic enemas, 445
Hypertonic saline, 432–433, 934*t*
Hypertriglyceridemia, 909, 910*t*
Hypertrophic cardiomyopathy
in cats
breeds affected by, 158
clinical features of, 159–160
clinicopathologic findings of, 162–163
color flow Doppler imaging of, 164*f*
diagnosis of, 160, 161*f*, 163*f*
echocardiographic findings of, 160–163, 163*f*–164*f*
electrocardiographic findings of, 160, 162*f*
etiology of, 158
myocardial ischemia secondary to, 159
pathophysiology, 158–159
prevalence of, 159–160
prognosis for, 167
radiographic findings of, 160, 161*f*
treatment of, 163–164, 166*b*
color flow Doppler of, 165*f*
description of, 80
in dogs, 152–153
echocardiographic findings, 152
subclinical, 163–164
Hyperventilation, 318, 1076
Hyperviscosity
description of, 113
treatment of, 116
Hypoadrenocorticism, 654*t*–655*t*, 883–889
ACTH stimulation test for, 885–886
acute addisonian crisis, 886–888
atypical, 884, 889
breeds at increased risk for, 884*b*
clinical features of, 884–885
clinical pathology of, 884–885, 885*b*
definition of, 883
diagnosis of, 885–886
electrocardiography for, 885
etiology of, 883–884
glucocorticoid-deficient, 889
imaging of, 885
megaesophagus and, 885
physical examination of, 884
primary, 886*t*
primary adrenal insufficiency, 888–889
secondary, 884, 886*t*
signalment for, 884
signs of, 884, 884*b*
treatment of, 886–889
Hypoalbuminemia
in canine monocytotropic ehrlichiosis, 1475
in dogs, 923
nephrotic syndrome causing, 684
plasma oncotic pressure decreases caused by, 362
pulmonary edema caused by, 358
Hypoallergenic diets, 434*b*
Hypocalcemia, 48, 49*b*, 765*t*, 927–929, 928*b*

Hypocobalaminemia, 640
Hypoechoic, defined, 19
Hypogastric nerve, 995
Hypoglobulinemia, 1362–1363
Hypoglossal nerve, 1056*t*, 1059–1060, 1060*f*
Hypoglycemia, 806–809
chronic, 852
clinical features of, 807
diagnostic approach of, 807–808
etiology of, 806–807, 807*b*
iatrogenic, 806
insulin therapy and, 824, 837–838
seizures caused by, 808*b*
signs of, 807
treatment of, 808–809, 808*b*, 815
Hypoglycemic drugs, 808*b*, 835–837
Hypogonadism, 754
Hypokalemia, 47, 49*b*, 921–923, 922*b*, 923*t*
Hypokalemic polymyopathy, 1178–1179, 1178*f*
Hypokinetic, defined, 5
Hypoluteiodism, 962–963
Hypomagnesemia, 844, 931–933, 932*b*
Hypomotility, idiopathic gastric, 469–470
Hyponatremia, 74, 917–919, 918*b*
Hypo-osmolality, 918
Hypoparathyroidism, 798–799
iatrogenic, 764
primary, 763–766
clinical signs of, 764, 764*b*
diagnosis of, 764–765
etiology of, 763–764
hypocalcemia caused by, 765*t*
physical examination of, 764
prognosis for, 766
signalment, 764
treatment of, 765–766
transient, 764
Hypophosphatemia, 843–844, 930–931, 930*b*
Hypoproteinemia, 923
Hyporexia, 407, 407*b*
Hyposthenuria, 663, 742
Hypothalamic-pituitary-thyroid gland complex, 767, 768*f*
Hypothalamus, disorders of, 740–757
Hypothyroid myopathy, 770–771
Hypothyroid polyneuropathy, 1164–1165
Hypothyroidism
in cats, 785–788
congenital, 788
diagnosis of, 786–787, 787*f*
etiology of, 785–786
levothyroxine for, 787
prognosis for, 788
signs of, 786, 786*f*, 786*b*
treatment of, 787
congenital, 767–768
in dogs, 767–785
autoimmune polyendocrine syndromes associated with, 773
behavioral problems associated with, 772
clinical features of, 768–773
clinical manifestations of, 770*b*
clinical pathology of, 773–782

Infectious agents
description of, 1427
laboratory diagnosis of, fecal examination, 1427–1429
Infectious diarrhea, 476–480
canine coronaviral enteritis, 479
canine parvoviral enteritis, 476–478, 477*b*
elokomin fluke fever, 480
feline coronaviral enteritis, 479
feline immunodeficiency virus-associated diarrhea, 480
feline leukemia virus-panleukopenia-like syndrome, 479–480
feline parvoviral enteritis, 478–479
salmon poisoning, 480
Infectious diseases
antemortem diagnosis of, 1435
antibody detection
in body fluids, 1434–1435
in serum, 1433–1434
biosecurity procedures for small animals hospitals, 1448–1450, 1449*b*
disinfection protocols for, 1450
laboratory diagnosis of, 1427–1435
animal inoculation, 1433
culture techniques, 1431–1432
cytology, 1429–1430
electron microscopy, 1433
immunocytochemistry, 1432
immunologic techniques, 1432
molecular diagnostics, 1432–1433
polymerase chain reaction, 1432–1433, 1432*f*
tissue techniques, 1430–1431
prevention of
in hospitalized patients, 1449–1450
overview of, 1448–1456
patient evaluation, 1449
screening, 936*b*
zoonotic transfer of, 1449
Infectious inflammatory disease, 1142–1143
Infectious orchitis, 1000–1001
Infectious pericarditis, 182
Infectious prostatitis, 1002–1003, 1002*f*
Infective endocarditis
antibiotics for, 136–137
antimicrobial prophylaxis for, 138
bacteremia and, 132
blood culture testing for, 133–134
in cats, 132
cephalosporins for, 136–137
clinical features of, 133
congestive heart failure secondary to, 132
diagnosis of, 133–136, 135*b*
in dogs, 132
Doppler imaging of, 136, 136*f*
echocardiography of, 133–134, 136*f*
etiology of, 132–133
immune-mediated disease *versus*, 133
laboratory tests for, 134
microorganisms associated with, 132
neutrophilia associated with, 134
nonregenerative anemia associated with, 134
pathophysiology of, 132–133
prognosis for, 136–138
prophylactic antibiotics for, 138
sequelae of, 134*b*
signs of, 133
systemic effects of, 134*b*
thromboemboli caused by, 133
treatment of, 136–138
valves commonly affected by, 132
vegetations associated with, 132
Infective myocarditis, 153–154
Infertility
congenital, 1005
male. *see* Male infertility
sexual differentiation disorders, 1005–1006, 1006*f*
Infiltrative diseases
gastric, 471–472
gastrointestinal ulceration/erosion from, 470
Infiltrative splenomegaly, 1412*t*, 1413
Inflammatory bowel disease, 493–495

Leukopenia, 1248*t*, 1345*t*
Leukotriene inhibitors, 333
Levamisole, 344
Levetiracetam
neurologic disorders treated with, 1185*t*–1186*t*
seizures treated with, 1103
Levothyroxine, for hypothyroidism, 783–784, 783*b*
Leydig cell tumors, 997
L-form bacteria, 1440*t*
Lidocaine, 89–91
in cats, 90–91, 90*t*–91*t*
constant-rate infusion of, 88*b*
in dogs, 90*t*–91*t*
dosage of, 90*t*–91*t*
electrocardiographic changes associated with, 49*b*
half-life of, 89
indications for, 89
infusion of, 629*t*–630*t*
metabolism of, 89

Lidocaine *(Continued)*
seizures induced by, 90–91
toxic effects of, 90–91
ventricular tachycardia treated with, 82
Ligamentum arteriosum, 116–117
Lincomycin, 1437*t*–1438*t*
Lincosamides, 1437*t*–1438*t*
Linear foreign objects, 499–501, 500*f*
Lipemia, 911*t*
Lipoprotein(s)
classes of, 908
description of, 908
high-density, 908
low-density, 908
very-low-density, 908
Lipoprotein electrophoresis, 911
Lipoprotein lipase, 908
Liposomal amphotericin B, pythiosis treated with, 472
Liquid barium sulfate, 422–423
Lisinopril, 64*t*
Lissencephaly, 1080
Lithium carbonate, 1280
Little white shaker syndrome, 1183
Liver. *see also specific hepatic entries*
chemotherapy toxicity to, 1285
enlargement of, 524–525
size of, change in, 524–525, 525*t*
Liver biopsy, 553–559, 554*f*
indications for, 554
techniques for, 554–555, 555*f*–558*f*
Liver disease
breed-related, 586*b*
diagnostic approach to, 531–532, 532*b*
Liver enzymes, 1362
Liver fluke infestation, 568*t*, 572–573, 573*b*
Liver tumors
in cats, 576
clinical features of, 577*t*
Lobular dissecting hepatitis, 587
Lomotil. *see* Diphenoxylate
Lomustine, 587–588, 1285, 1332–1333
Lone atrial fibrillation, 85–86
Loop diuretics
acute kidney injury treated with, 691
chronic heart failure treated with, 66–67
Loperamide, 440, 440*t*, 515*t*–517*t*
Low-density lipoproteins, 908
Low-dose dexamethasone suppression test, 864–865, 866*t*, 867–868, 869*f*
Lower esophageal sphincter, 426*f*, 461*f*
Lower motor neuron (LMN)
paralysis of, 1163*f*, 1164*b*
signs, 1039–1040, 1039*f*, 1040*t*
Lower respiratory tract disorders
arterial blood gas analysis for, 286
clinical manifestations of, 282–286
complete blood count in, 286
cough associated with, 282–283
definition of, 282
diagnostic approach to, 284–286, 284*f*
diagnostic tests for, 287–320
blood gas analysis. *see* Blood gas analysis
bronchoalveolar lavage. *see* Bronchoalveolar lavage
bronchoscopy, 309*t*, 312
computed tomography, 295–296
magnetic resonance imaging, 295–296
nuclear imaging, 296
parasitology, 296–298, 297*f*, 297*t*

advanced imaging, 192
clinical features of, 354
clinical findings of, 191
clinicopathologic findings, 192
diagnosis of, 191, 354
diseases associated with, 193
in dogs, 193
echocardiographic findings, 192, 192*f*
electrocardiographic findings, 192

Pulmonary hypertension *(Continued)*
etiology of, 190–191, 353–354
heartworm disease as cause of, 193, 287
microthrombi in, 354–355
prognosis for, 192–193, 354
pulmonary thromboembolism as cause of, 224
radiographic findings, 191–192, 191*f*
with shunt reversal, 114–116, 115*f*
signs of, 130, 191
sildenafil citrate for, 116, 191, 354
treatment of, 192–193, 354
TRmax associated with, 30–31
Pulmonary infiltrates with eosinophils (PIE), 348
Pulmonary mycoses, 344
Pulmonary neoplasia, 352–353
bronchoalveolar lavage findings, 352*f*
clinical features of, 352
diagnosis of, 352–353, 352*f*
prognosis for, 353
radiographic findings, 366*f*
treatment of, 353
Pulmonary nodules, 296*f*
Pulmonary parenchymal disorders, 283*b*, 340–359
emergency management of, 381–382
eosinophilic lung disease, 348–349
parasites
Aelurostrongylus abstrusus, 345
Capillaria aerophila, 344
Crenosoma vulpis, 346
description of, 344–346
Paragonimus kellicotti, 344–345, 345*f*
pneumonias
bacterial. *see* Bacterial pneumonia
canine influenza, 340
definition of, 340
fungal, 344
fungal pneumonia, 344
viral, 340–343
pulmonary hypertension. *see* Pulmonary hypertension
pulmonary neoplasia. *see* Pulmonary neoplasia
toxoplasmosis, 343
Pulmonary thromboembolism
abnormalities associated with, 355*b*
clinical features of, 355
computed tomography pulmonary angiography of, 355–356
D-dimer measurements, 355
description of, 194, 224, 354–356
diagnosis of, 355–356
fibrinolytic agents for, 356
heartworm disease as cause of, 201–203, 224
pleural effusion caused by, 360
postadulticide, 201–203
prevention of, 356
prognosis for, 356
selective angiography of, 356
treatment of, 201–202, 356
Pulmonary toxicity, chemotherapy-induced, 1285–1286
Pulmonary vascular resistance, 190, 353–354
Pulmonary vasculature, 288
Pulmonary venous congestion, 18, 122–123
Pulmonary vessels, lobar, 17–18
Pulmonic stenosis
balloon valvuloplasty for, 108
β-blockers for, 108–109
clinical features of, 108
diagnosis of, 108
in dogs, 102*t*, 107
echocardiographic findings, 108, 110*f*
etiology of, 107–108
exercise restriction for, 108–109
murmur of, 11
pathophysiology of, 107–108
prognosis for, 108–109
radiographic findings, 103*t*, 108, 109*f*
Pulmonic stenosis *(Continued)*
single anomalous coronary artery associated with, 108
treatment of, 108–109
Pulse deficits, 79
Pulse oximetry
definition of, 318–319
indications for, 318–319
interpretation of, 319
method of, 319, 319*f*
oxygen saturation evaluations, 65
Pulsed wave Doppler echocardiography, 28–30, 29*f*–30*f*
Pulsus alternans, 6
Pulsus paradoxus, 6, 177–178

subclinical, 709
treatment of, 708–709, 1445–1446
Urinary tract zoonoses, 1542–1543
Urine
appearance of, 664
bilirubin in, 665
chemical properties of, 664–665
glucose in, 665
ketones in, 665
occult blood in, 665
pH, 664–665
physical properties of, 664
protein in, 665
sediment examination of, 665–670
casts, 667–668, 668*f*
crystals, 668–669, 669*f*–670*f*, 669*t*
epithelial cells, 666–667, 667*f*
organisms, 668, 669*f*
red blood cells, 666, 666*f*
white blood cells, 666, 666*f*
specific gravity of, 652, 662–664, 741, 743*f*, 745*f*, 861–862
Urine cortisol/creatinine ratio, 866*t*, 867, 867*f*–868*f*, 881, 881*t*
Urine protein-to-creatinine ratio, 661–662, 680–681, 698–699
Urodynamic testing, 672, 732
Urogenital disorders, 1025–1027, 1025*f*–1027*f*, 1441*t*
Urokinase, for arterial thromboembolism in cats, 227*b*, 229
Urokinase-type plasminogen activator, 1388
Urolith(s)
analysis of, 712
calcium oxalate, 717–718
removal of, 712–714, 713*f*–714*f*
struvite, 718–719, 719*f*
types of, 712
xanthine, 722
Urolithiasis, 712–723
calcium oxalate
dietary modifications for, 717–718, 718*b*
drug therapy for, 718
management of, 717*b*
prevention of, 717–718
cystine, 721–722
signs of, 712
silica, 721–722, 722*f*
urate
in cats, 721
in dogs, 719–721, 720*f*, 720*b*
xanthine, 722
Ursodeoxycholic acid
for lymphocytic cholangitis, 571–572
for neutrophilic cholangitis, 570
Ursodiol, 590
Usual interstitial pneumonia, 349–350
Uterine contractions
oxytocin effects on, 969–972
patterns of, 969
suppression of, terbutaline for, 962
Uterine inertia, 969
Uterus
postpartum disorders involving, 974–979
rupture of, 976
torsion of, 973*f*
trauma to, 976, 976*f*
Uveitis, lens-induced, 829

V

Vaccines and vaccinations
adverse reactions to, 1452
attenuated, 1451
autoimmunity and, 1214
Bordetella bronchiseptica, 1453, 1455
Borrelia burgdorferi, 1455
canine adenovirus, 1454–1455
Vaccines and vaccinations *(Continued)*
canine distemper virus, 1454–1455
canine infectious tracheobronchitis, 324
canine influenza, 1455
