Contents

PART ONE CARDIOVASCULAR SYSTEM DISORDERS, 1

Wendy A. Ware and Jessica L. Ward

1 Clinical Manifestations of Cardiac Disease, 1
2 Diagnostic Tests for the Cardiovascular System, 13
3 Management of Heart Failure, 55
4 Cardiac Arrhythmias and Antiarrhythmic Therapy, 77
5 Congenital Cardiac Disease, 100
6 Acquired Valvular and Endocardial Disease, 119
7 Myocardial Diseases of the Dog, 141
8 Myocardial Diseases of the Cat, 158
9 Pericardial Disease and Cardiac Tumors, 174
10 Pulmonary Hypertension and Heartworm Disease, 190
11 Systemic Arterial Hypertension, 211
12 Thromboembolic Disease, 221

PART TWO RESPIRATORY SYSTEM DISORDERS, 240

Eleanor C. Hawkins

13 Clinical Manifestations of Nasal Disease, 240
14 Diagnostic Tests for the Nasal Cavity and Paranasal Sinuses, 247
15 Disorders of the Nasal Cavity, 257
16 Clinical Manifestations of Laryngeal and Pharyngeal Disease, 271
17 Diagnostic Tests for the Larynx and Pharynx, 273
18 Disorders of the Larynx and Pharynx, 277
19 Clinical Manifestations of Lower Respiratory Tract Disorders, 282
20 Diagnostic Tests for the Lower Respiratory Tract, 287
21 Disorders of the Trachea and Bronchi, 321
22 Disorders of the Pulmonary Parenchyma and Vasculature, 340
23 Clinical Manifestations and Diagnostic Tests of Pleural Cavity and Mediastinal Disease, 360
24 Disorders of the Pleural Cavity and Mediastinum, 371
25 Emergency Management of Respiratory Distress, 379

PART THREE DIGESTIVE SYSTEM DISORDERS, 389

Michael D. Willard

26 Clinical Manifestations of Gastrointestinal Disorders, 389
27 Diagnostic Tests for the Alimentary Tract, 412
28 General Therapeutic Principles, 432
29 Disorders of the Oral Cavity, Pharynx, and Esophagus, 447
30 Disorders of the Stomach, 462
31 Disorders of the Intestinal Tract, 474
32 Disorders of the Peritoneum, 510

PART FOUR HEPATOBILIARY AND EXOCRINE PANCREATIC DISORDERS, 518

Penny J. Watson

33 Clinical Manifestations of Hepatobiliary and Pancreatic Disease, 518
34 Diagnostic Tests for the Hepatobiliary and Pancreatic System, 531
35 Hepatobiliary Diseases in the Cat, 561
36 Hepatobiliary Diseases in the Dog, 584
37 The Exocrine Pancreas, 620

PART FIVE URINARY TRACT DISORDERS, 649

Stephen P. DiBartola and Jodi L. Westropp

38 Clinical Manifestations of Urinary Disorders, 649
39 Diagnostic Tests for the Urinary System, 658
40 Glomerular Disease, 675
41 Acute Kidney Injury and Chronic Kidney Disease, 686
42 Bacterial Cystitis, Pyelonephritis, and Prostatitis in the Dog and Cat, 704
43 Canine and Feline Urolithiasis, 712
44 Obstructive and Nonobstructive Feline Idiopathic Cystitis, 724
45 Disorders of Micturition, 730

PART SIX ENDOCRINE DISORDERS, 740

Richard W. Nelson and Ann-Marie Della Maggiore

46 Disorders of the Hypothalamus and Pituitary Gland, 740
47 Disorders of the Parathyroid Gland, 758
48 Disorders of the Thyroid Gland, 767
49 Disorders of the Endocrine Pancreas, 806
50 Disorders of the Adrenal Gland, 857

PART SEVEN METABOLIC AND ELECTROLYTE DISORDERS, 898

Jennifer A. Larsen and Ann-Marie Della Maggiore

51 Weight Loss and Obesity, 898
52 Hyperlipidemia, 908
53 Electrolyte Imbalances, 915

PART EIGHT REPRODUCTIVE SYSTEM DISORDERS, 935

Autumn P. Davidson

54 The Practice of Theriogenology, 935
55 Clinical Conditions of the Bitch and Queen, 953
56 Clinical Conditions of the Dog and Tom, 990
57 Neonatology and Pediatrics, 1007

PART NINE NERVOUS SYSTEM AND NEUROMUSCULAR DISORDERS, 1037

Susan M. Taylor

58 Lesion Localization and the Neurologic Examination, 1037
59 Diagnostic Tests for Nervous System and Neuromuscular Disorders, 1063
60 Intracranial Disorders, 1074
61 Loss of Vision and Pupillary Abnormalities, 1084
62 Seizures and Other Paroxysmal Events, 1093
63 Head Tilt, 1109
64 Encephalitis, Myelitis, and Meningitis, 1117
65 Disorders of the Spinal Cord, 1130
66 Disorders of Peripheral Nerves and the Neuromuscular Junction, 1157
67 Disorders of Muscle, 1174

PART TEN JOINT DISORDERS, 1187

Susan M. Taylor

68 Clinical Manifestations of and Diagnostic Tests for Joint Disorders, 1187
69 Disorders of the Joints, 1195

PART ELEVEN IMMUNE-MEDIATED DISORDERS, 1211

Andrew Woolcock and J. Catharine R. Scott-Moncrieff

70 Pathogenesis of Immune-Mediated Disorders, 1211
71 Diagnostic Testing for Immune-Mediated Disease, 1215
72 Treatment of Primary Immune-Mediated Diseases, 1220
73 Common Immune-Mediated Diseases, 1231

PART TWELVE ONCOLOGY, 1257

C. Guillermo Couto

74 Cytology, 1257
75 Principles of Cancer Treatment, 1265
76 Practical Chemotherapy, 1269
77 Complications of Cancer Chemotherapy, 1276
78 Approach to the Patient With a Mass, 1288
79 Lymphoma, 1294
80 Leukemias, 1311
81 Selected Neoplasms in Dogs and Cats, 1322

PART THIRTEEN HEMATOLOGY, 1340

C. Guillermo Couto

82 Anemia, 1340
83 Clinical Pathology in Greyhounds and Other Sighthounds, 1360
84 Erythrocytosis, 1368
85 Leukopenia and Leukocytosis, 1371
86 Combined Cytopenias and Leukoerythroblastosis, 1381
87 Disorders of Hemostasis, 1387
88 Lymphadenopathy and Splenomegaly, 1407
89 Hyperproteinemia, 1420
90 Fever of Undetermined Origin, 1423

PART FOURTEEN INFECTIOUS DISEASES, 1427

Michael R. Lappin

91 Laboratory Diagnosis of Infectious Diseases, 1427
92 Practical Antimicrobial Chemotherapy, 1436
93 Prevention of Infectious Diseases, 1448
94 Polysystemic Bacterial Diseases, 1457
95 Polysystemic Rickettsial Diseases, 1469
96 Polysystemic Viral Diseases, 1485
97 Polysystemic Mycotic Infections, 1502
98 Polysystemic Protozoal Infections, 1514
99 Zoonoses, 1532

Section Editors

Richard W. Nelson, DVM, DACVIM (Internal Medicine), Professor Emeritus, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis. Dr. Nelson received his DVM degree from the University of Minnesota in 1979; he completed a small animal internship at Washington State University in 1980 and a medicine residency at the University of California, Davis in 1982; he then joined the small animal medicine faculty at Purdue University. In 1989 he joined the small animal medicine faculty at UC Davis. Dr. Nelson's interests lie in clinical endocrinology, with a focus on the endocrine pancreas, thyroid gland, and adrenal gland. Dr. Nelson has authored numerous scientific publications and book chapters; has co-authored two textbooks, *Canine and Feline Endocrinology and Reproduction* with Dr. Ed Feldman and *Small Animal Internal Medicine* with Dr. C. Guillermo Couto; and has lectured extensively nationally and internationally. He served as an associate editor for the *Journal of Veterinary Internal Medicine* and served as a reviewer for several veterinary journals. Dr. Nelson is a co-founder and member of the Society for Comparative Endocrinology and has served as Chair of the Department of Medicine and Epidemiology and as Director of the Small Animal Clinic at UC Davis. He has received the Norden Distinguished Teaching Award at Purdue University and at UC Davis, the BSAVA Bourgelat Award, and the ACVIM Robert W. Kirk Award for Professional Excellence.

C. Guillermo Couto, DVM, Dipl. ACVIM (Internal Medicine and Oncology) graduated from Buenos Aires University, Argentina in 1976. He spent 5 years as a private practice small animal practitioner, and then completed a clinical oncology residency at the University of California-Davis. He is co-author of the textbook, *Small Animal Internal Medicine,* with Dr. Richard W. Nelson, and he has more than 350 peer-reviewed articles and book chapters in the areas of oncology, hematology, and Greyhound medicine. Dr. Couto served as editor-in-chief of the *Journal of Veterinary Internal Medicine,* and received numerous teaching and service awards while at the university. After 30 years in academia, he is now providing consultation and educational services through Couto Veterinary Consultants, Hilliard, Ohio.

Kristen M. Couto, DVM, DACVIM (ONCOLOGY)
Vista Veterinary Specialists by Ethos Veterinary Health, Sacramento, California. Dr. Couto received her BS in Biology at The Ohio State University in 2009 and went on to receive her DVM degree at Ohio State in 2013. She completed a Small Animal Medicine and Surgery internship at North Carolina State University in 2014, and a Medical Oncology residency at the University of California, Davis in 2017. Her clinical interests include multi-modal management of oncology patients, as well as fostering the human-animal bond, especially through all aspects of a cancer diagnosis and treatment. She routinely provides continuing education for local veterinary medical associations in California on various oncology topics.

Autumn P. Davidson, DVM, MS, DACVIM Clinical Professor, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis. Dr. Davidson obtained her BS and MS at the University of California, Berkeley, with an emphasis in wildlife ecology and management. Dr. Davidson is a graduate of the School of Veterinary Medicine, University of California, Davis. She completed an internship in small animal medicine and surgery at Texas A&M University and a residency in small animal internal medicine at the University of California, Davis. She became board certified in internal medicine in 1992. Dr. Davidson specializes in small animal reproduction, pediatrics, and infectious disease. From 1998 to 2003, Dr. Davidson served as the Director of the San Rafael veterinary clinic at Guide Dogs for the Blind, Inc., overseeing the health care of 1000 puppies whelped annually, as well as a breeding colony of 350 and approximately 400 dogs in training. Dr. Davidson served on the board of directors for the Society for Theriogenology from 1996 to 1999, and the Institute for Genetic Disease Control from 1990 to 2002. Dr. Davidson consults with the Smithsonian Institution National Zoological Park in Washington, D.C., concerning theriogenology and internal medicine. She has authored numerous scientific publications and book chapters, and is a well-known international speaker on the topics of small animal theriogenology and infectious disease. She has traveled the world working with cheetahs, ring-tailed lemurs, and giant pandas in the field. Dr. Davidson was the 2003 recipient of the Hill's Animal Welfare and Humane Ethics Award, which recognizes an individual who has advanced animal welfare through extraordinary service or by furthering humane principles, education, and understanding.

Ann-Marie Della Maggiore, DVM, DACVIM (Internal Medicine) Mar-Queen Pet Emergency and Specialty Group, Roseville, California.

Dr. Della Maggiore earned her DVM degree from the University of California, Davis in 2008. She completed an internship in small animal medicine and surgery at Veterinary Medical and Surgical Group in Ventura, California. She then completed her small animal internal medicine residency at UC Davis and became ACVIM board certified in Internal Medicine. Following her residency, she took a clinical faculty position at UC Davis. In 2014 she transitioned to Assistant Professor of Clinical Internal Medicine in the Department of Medicine and Epidemiology. Her research and clinical interests are in small animal endocrinology. Dr. Della Maggiore now practices internal medicine at Mar-Queen Pet Emergency and Specialty Group in Roseville, California, a private referral practice. She has lectured both internationally and nationally in canine and feline internal medicine and primarily endocrinology.

Stephen P. DiBartola, DVM, DACVIM (Internal Medicine), Emeritus Professor of Medicine, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University, Columbus, Ohio. Dr. DiBartola received his DVM degree from the University of California, Davis in 1976. He completed an internship in small animal medicine and surgery at Cornell University in Ithaca, New York, in June 1977 and a residency in small animal medicine at The Ohio State University College of Veterinary Medicine from July 1977 to July 1979. He served as Assistant Professor of Medicine at the College of Veterinary Medicine, University of Illinois from July 1979 until August 1981. In August 1981, he returned to the Department of Veterinary Clinical Sciences at The Ohio State University as Assistant Professor of Medicine. He was promoted to Associate Professor in 1985 and to Professor in 1990. He received the Norden Distinguished Teaching Award in 1988 and the Zoetis Distinguished Teaching Award in 2014. His textbook *Fluid Therapy in Small Animal Practice* is in its fourth edition (2012). Dr. DiBartola currently serves as co-editor-in-chief for the *Journal of Veterinary Internal Medicine*. His clinical areas of interest include diseases of the kidney and fluid, acid-base, and electrolyte disturbances.

Eleanor C. Hawkins, DVM, Dipl. ACVIM (Internal Medicine), Professor, Department of Clinical Sciences and Director, Clinical Study Core, Comparative Medicine Institute North Carolina State University College of Veterinary Medicine. Dr. Hawkins has served as President and as Chair of the American College of Veterinary Internal Medicine (ACVIM), and as President of the Specialty of Small Animal Internal Medicine (ACVIM). She has been a board member of the Comparative Respiratory Society. She has been an invited lecturer in the United States, Europe, South America, and Japan. Dr. Hawkins is the author of many refereed publications and scientific proceedings. She has been a contributor or the respiratory editor for numerous well-known veterinary texts. Dr. Hawkins was the 2014 recipient of the ACVIM Distinguished Service Award. Her areas of research include canine chronic bronchitis, pulmonary function testing, and bronchoalveolar lavage as a diagnostic tool.

Michael R. Lappin, DVM, PhD, Dipl. ACVIM (Internal Medicine), is the Kenneth W. Smith Professor of Small Animal Clinical Veterinary Medicine at the College of Veterinary Medicine and Biomedical Sciences at Colorado State University and Director of the Center for Companion Animal Studies. After earning his DVM at Oklahoma State University in 1981, he completed a small animal internal medicine residency and earned his doctorate in parasitology at the University of Georgia. Dr. Lappin has studied feline infectious diseases and has authored more than 250 research papers and book chapters. Dr. Lappin is past associate editor for the *Journal of Veterinary Internal Medicine* and serves on the editorial board of *Journal of Feline Medicine and Surgery*. Dr. Lappin has received the Norden Distinguished Teaching Award, the Winn Feline Foundation Excellence in Feline Research Award, and the ESFM International Award for Outstanding Contribution to Feline Medicine.

Jennifer A. Larsen, DVM, MS, PHD, DACVN, Chief of Service, Nutrition Support Service, Veterinary Medicine Teaching Hospital, Professor of Clinical Nutrition, Department of Molecular Biosciences, School of Veterinary Medicine, UC Davis. Dr. Larsen holds bachelor's and master's degrees in Animal Science and a DVM from UC Davis. She completed one year in local private practice before accomplishing a clinical nutrition residency at UC Davis. In 2007, Dr. Larsen attained Diplomate status from the American College of Veterinary Nutrition and completed a PhD in Nutritional Biology in 2008. In her current role, Dr. Larsen provides clinical nutritional consulting through the Nutrition Support Service at the UC Davis Veterinary Medical Teaching Hospital. She also mentors residents and students, and she teaches in the veterinary curriculum as well as for the Graduate Group of Nutritional Biology.

J. Catharine R. Scott-Moncrieff, MA, VetMB, MS, DACVIM (SA), DECVIM (CA), Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Purdue University. Dr. Scott-Moncrieff graduated from the University of Cambridge in 1985 and completed an internship in small animal medicine and surgery at the University of Saskatchewan and a residency in internal medicine at Purdue University. In 1989, she joined the faculty of Purdue University, where she is currently Professor of small animal internal medicine and Head of the Department of Veterinary Clinical Sciences. Her clinical and research interests include immune-mediated hematologic disorders and clinical endocrinology. She is the author of numerous manuscripts and book chapters and has lectured extensively nationally and internationally.

Susan M. Taylor, DVM, DACVIM (Internal Medicine), Professor of Small Animal Medicine, Department of Small Animal Clinical Sciences, Western College of Veterinary Medicine, University of Saskatchewan. Dr. Taylor has received several awards for teaching excellence, including the Norden Distinguished Teaching Award. She has authored numerous refereed manuscripts and book chapters and one textbook (*Small Animal Clinical Techniques*, Elsevier 2016). She is also the co-creator of a web-based program for teaching clinical neurology and neuroanatomy (WCVM NeuroVet). Dr. Taylor has presented research and continuing education lectures throughout Canada, the United States, and abroad. Clinical, academic, and research interests include neurology, neuromuscular disease, clinical immunology, and infectious disease. Dr. Taylor has an active research program investigating medical and neurologic disorders affecting canine athletes, particularly the inherited syndromes of dynamin-associated exercise-induced collapse in Labrador Retrievers (d-EIC) and Border Collie collapse.

Jessica L. Ward, DVM, DACVIM (Cardiology), Assistant Professor, Department of Veterinary Clinical Sciences, Iowa State University. Dr. Ward obtained her DVM degree from North Carolina State University in 2011. After a small animal rotating internship at The Ohio State University, she returned to NC State to complete her residency training in Cardiology. Dr. Ward joined the faculty at Iowa State University in 2015, where she teaches clinical cardiology and recently received the college's Award for Early Achievement in Teaching. She has authored a number of manuscripts and scientific proceedings, and she has given invited lectures in the United States and China. Her research interests include point-of-care ultrasound, the cardiovascular effects of steroids, and the scholarship of teaching and learning.

Wendy A. Ware, DVM, MS, DACVIM (Cardiology), Professor, Departments of Veterinary Clinical Sciences and Biomedical Sciences, Iowa State University. Dr. Ware earned her DVM degree and completed her residency training at The Ohio State University. At Iowa State, she taught clinical cardiology and cardiovascular physiology, and she served as clinical cardiologist in the ISU Lloyd Veterinary Medical Center for many years. Dr. Ware authored the highly illustrated clinical textbook *Cardiovascular Disease in Small Animal Medicine* and is preparing an expanded second edition (*Cardiovascular Disease in Companion Animal Medicine*). She also has written and edited the case-based *Self-Assessment Color Review of Small Animal Cardiopulmonary Medicine* (2012, Manson Publishing), as well as numerous journal articles and more than 60 book chapters. Dr. Ware has been an invited speaker at many continuing education programs. Her other professional activities have included service as President and Chairman of the Board of Regents of the American College of Veterinary Internal Medicine, associate editor for Cardiology for the *Journal of Veterinary Internal Medicine*, and reviewer for several veterinary scientific journals.

Penny J. Watson, MA, Vet.MD, CertVR, DSAM, DECVIM, MRCVS, Senior Lecturer in Small Animal Medicine, Queen's Veterinary School Hospital, University of Cambridge, United Kingdom. Dr. Watson received her veterinary degree from the University of Cambridge. She spent four years in private veterinary practice in the United Kingdom before returning to Cambridge Veterinary School, where she now helps run the small animal internal medicine teaching hospital. She is both a member of the Royal College of Veterinary Surgeons and a European recognized specialist in small animal internal medicine. Dr. Watson was on the examination board of the European College of Veterinary Internal Medicine (ECVIM) for five years, two as Chair. Her clinical and research interests are focused on gastroenterology, hepatology, pancreatic disease, and comparative metabolism. She gained a doctorate for studies of canine chronic pancreatitis in 2009 and continues to research, lecture, and publish widely on aspects of canine and feline pancreatic and liver disease.

Jodi L. Westropp, DVM, PhD, DACVIM (Internal Medicine), Associate Professor, School of Veterinary Medicine, University of California, Davis. Dr. Westropp received her DVM degree, as well as her residency training in internal medicine, and PhD from The Ohio State University prior to joining the faculty at UC Davis in 2003. Her clinical and research interests include feline idiopathic cystitis, urinary tract infections, urinary incontinence, and urolithiasis. She is the author of numerous manuscripts and book chapters and has lectured extensively nationally and internationally. She is also the director of the G.V. Ling Urinary Stone Analysis Laboratory at UC Davis.

Michael D. Willard, DVM, MS, DACVIM (Internal Medicine), Senior Professor, Department of Veterinary Small Animal Medicine and Surgery, Texas A&M University. Dr. Willard is an internationally recognized veterinary gastroenterologist and endoscopist. He has received the National SCAVMA Teaching Award for clinical teaching and the National Teaching Award. A past President of the Comparative Gastroenterology Society and past Secretary of the specialty of Internal Medicine, his main interests are clinical gastroenterology and endoscopy (flexible and rigid). Dr. Willard has published more than 85 journal articles and 140 book chapters on these topics and has given more than 3600 hours of invited lectures on these subjects around the world. Dr. Willard is an associate editor for *Journal of Veterinary Internal Medicine*.

Andrew Woolcock, DVM, DACVIM (Internal Medicine), Assistant Professor, Department of Veterinary Clinical Sciences, School of Veterinary Medicine, Purdue University. Dr. Woolcock graduated from Michigan State University in 2011; he completed an internship in small animal medicine and surgery at North Carolina State University and a residency in small animal internal medicine at the University of Georgia. Dr. Woolcock joined the faculty of Purdue University in 2015, where he is currently Assistant Professor of small animal internal medicine. His clinical and research interests include immune-mediated hematologic disorders and oxidative stress in inflammatory disease states.

We dedicate this book to Kay and Graciela. This project would not have been possible without their continued understanding, encouragement, and patience. I (Guillermo) also dedicate this book to Jason and Kristen, who in following my path have made me the proudest dad. Having co-authored the oncology section with Kristen is one of the highlights of my career.

This page intentionally left blank

Preface

In the sixth edition of *Small Animal Internal Medicine*, we have retained our original goal of creating a practical text with a strong clinical slant that is useful for both practitioners and students. We have continued to limit authorship, with each author selected for her or his clinical expertise in their field, to ensure consistency within each section and allowing differences to be expressed when topics overlap between sections of the book; this illustrates that frequently different approaches get us to the same destination: a diagnosis. We have continued to focus on the clinically relevant aspects of the most common problems in internal medicine, presenting information in a concise, understandable, and logical format. Extensive use of tables, algorithms, cross-referencing within and among sections and a comprehensive index help make *Small Animal Internal Medicine* a quick, easy-to-use reference textbook.

ORGANIZATION

As before, the book contains 14 sections organized by organ systems (e.g., cardiology, respiratory) or when multiple systems are involved, by discipline (e.g., oncology, infectious diseases, immune-mediated disorders). Each section, when possible, begins with a chapter on clinical signs and differential diagnoses and is followed by chapters on indications, techniques, and interpretation of diagnostic tests; general therapeutic principles; specific diseases; and finally a table listing recommended drug dosages for drugs commonly used to treat disorders within the appropriate organ system or discipline. Each section is supported extensively by tables, photographs, schematic illustrations, videos, and algorithms, which address clinical presentations, differential diagnoses, diagnostic approaches, and treatment recommendations. Selected references and recommended readings are provided under the heading "Suggested Readings" at the end of each chapter. In addition, specific studies are cited in the text by author name and year of publication and are included in the Suggested Readings.

KEY FEATURES OF THE SIXTH EDITION

We have retained all of the features that were popular in the first five editions and have significantly updated and expanded the new sixth edition. Features in the sixth edition include:

- Thoroughly revised and updated content, with expanded coverage of hundreds of topics throughout the text
- The expertise of several new authors
- The addition of a new chapter on neonatology in the reproduction section of the book
- The addition of short video clips of physical examination, diagnostic, and treatment techniques
- The creation of a bank of multiple-choice questions to test student understanding of material contained in the book
- Extensive cross-referencing to other chapters and discussions, providing a helpful roadmap and reducing redundancy within the book
- Hundreds of functionally color-coded summary tables and boxes to draw the reader's eye to quickly accessible information such as:

Etiology

Differential Diagnoses

Drugs (appearing within chapters)

Drug formularies (appearing at the end of sections)

Treatment

General Information (e.g., formulas, clinical pathology values, manufacturer information, bred predispositions)

Finally, we are grateful to the many practitioners, faculty, and students worldwide who provided constructive comments on the first five editions, thereby making it possible to design an even stronger sixth edition. We believe the expanded content, features, and visual presentation will be positively received and will continue to make this book a valuable, user-friendly resource for all readers.

Richard W. Nelson
C. Guillermo Couto

Acknowledgments

We would like to extend our sincerest thanks to Wendy, Eleanor, Mike, Penny, Sean, Sue, Michael, Catharine, Jodi, and Autumn for their continued dedication and hard work to this project; to Kristen, Ann-Marie, Jennifer, Jessica, Michael, and Andrew for their willingness to become involved in this project; and to Jennifer Catando, Rich Barber, and many others at Elsevier for their commitment and latitude in developing this text.

Contents

PART ONE CARDIOVASCULAR SYSTEM DISORDERS, 1

Wendy A. Ware and Jessica L. Ward

1 Clinical Manifestations of Cardiac Disease, 1
Signs of Heart Disease, **1**
Signs of Heart Failure, **1**
Cardiovascular Examination, **3**

2 Diagnostic Tests for the Cardiovascular System, 13
Cardiac Biochemical Markers, **13**
Cardiac Radiography, **14**
Echocardiography, **18**
Electrocardiography, **34**
Other Techniques, **52**

3 Management of Heart Failure, 55
Overview of Heart Failure, **55**
Preclinical Cardiac Disease, **60**
Treatment for Acute Congestive Heart Failure, **61**
Management of Chronic Heart Failure, **66**

4 Cardiac Arrhythmias and Antiarrhythmic Therapy, 77
General Considerations, **77**
Diagnosis and Management of Common Arrhythmias, **78**
Antiarrhythmic Agents, **88**

5 Congenital Cardiac Disease, 100
General Considerations, **100**
Extracardiac Arteriovenous Shunt, **101**
Ventricular Outflow Obstruction, **105**
Intracardiac Shunt, **109**
Atrioventricular Valve Malformation, **112**
Cardiac Anomalies Causing Cyanosis, **113**
Other Cardiovascular Anomalies, **116**

6 Acquired Valvular and Endocardial Disease, 119
Degenerative Atrioventricular Valve Disease, **119**
Diagnosis, **122**
Preclinical (Stage B) CVMD, **126**
CHF Onset in CMVD (Stage C), **128**
Common Complications, **129**
Infective Endocarditis, **132**

7 Myocardial Diseases of the Dog, 141
Dilated Cardiomyopathy, **141**
Arrhythmogenic Right Ventricular Cardiomyopathy, **148**
Secondary Myocardial Disease, **150**
Hypertrophic Cardiomyopathy, **152**
Myocarditis, **153**

8 Myocardial Diseases of the Cat, 158
Hypertrophic Cardiomyopathy, **158**
Secondary Myocardial Hypertrophy, **167**
Restrictive Cardiomyopathy, **168**
Dilated Cardiomyopathy, **169**
Other Myocardial Diseases, **171**

9 Pericardial Disease and Cardiac Tumors, 174
Congenital Pericardial Disorders, **174**
Pericardial Effusion, **176**
Constrictive Pericardial Disease, **184**
Cardiac Tumors, **185**

10 Pulmonary Hypertension and Heartworm Disease, 190
Pulmonary Hypertension, **190**
Heartworm Disease, **193**
Heartworm Disease in Dogs, **194**
Heartworm Disease in Cats, **203**
Angiostrongylosis, **207**

11 Systemic Arterial Hypertension, 211
General Considerations, **211**

12 Thromboembolic Disease, 221
General Considerations, **221**
Pulmonary Thromboembolism, **224**
Systemic Arterial Thromboembolism in Cats, **224**
Systemic Arterial Thrombosis in Dogs, **230**
Venous Thrombosis, **233**

PART TWO RESPIRATORY SYSTEM DISORDERS, 240

Eleanor C. Hawkins

13 Clinical Manifestations of Nasal Disease, 240
General Considerations, **240**
Nasal Discharge, **240**
Sneezing, **244**
Stertor, **245**
Facial Deformity, **245**

14 Diagnostic Tests for the Nasal Cavity and Paranasal Sinuses, 247
Nasal Imaging, **247**
Rhinoscopy, **250**
Frontal Sinus Exploration, **252**
Nasal Biopsy: Indications and Techniques, **253**
Nasal Cultures: Sample Collection and Interpretation, **255**

15 Disorders of the Nasal Cavity, 257
Feline Upper Respiratory Infection, **257**
Bacterial Rhinitis, **259**
Nasal Mycoses, **260**
Nasal Parasites, **263**
Feline Nasopharyngeal Polyps, **264**
Canine Nasal Polyps, **264**
Nasal Tumors, **265**
Allergic Rhinitis, **266**
Idiopathic Rhinitis, **266**
16 Clinical Manifestations of Laryngeal and Pharyngeal Disease, 271
Clinical Signs, **271**
Differential Diagnoses for Laryngeal Signs in Dogs and Cats, **272**
Differential Diagnoses for Pharyngeal Signs in Dogs and Cats, **272**
17 Diagnostic Tests for the Larynx and Pharynx, 273
Radiography, **273**
Ultrasonography, **273**
Fluoroscopy, **273**
Computed Tomography and Magnetic Resonance Imaging, **273**
Laryngoscopy and Pharyngoscopy, **273**
18 Disorders of the Larynx and Pharynx, 277
Laryngeal Paralysis, **277**
Brachycephalic Airway Syndrome, **279**
Obstructive Laryngitis, **280**
Laryngeal Neoplasia, **281**
19 Clinical Manifestations of Lower Respiratory Tract Disorders, 282
Clinical Signs, **282**
Diagnostic Approach to Dogs and Cats With Lower Respiratory Tract Disease, **284**
20 Diagnostic Tests for the Lower Respiratory Tract, 287
Thoracic Radiography, **287**
Ultrasonography, **295**
Computed Tomography and Magnetic Resonance Imaging, **295**
Nuclear Imaging, **296**
Parasitology, **296**
Serology, **298**
Urine Antigen Tests, **298**
Polymerase Chain Reaction Tests, **298**
Tracheal Wash, **298**
Nonbronchoscopic Bronchoalveolar Lavage, **305**
Transthoracic Lung Aspiration and Biopsy, **310**
Bronchoscopy, **312**
Thoracotomy or Thoracoscopy With Lung Biopsy, **312**
Blood Gas Analysis, **313**
Pulse Oximetry, **318**
21 Disorders of the Trachea and Bronchi, 321
General Considerations, **321**
Canine Infectious Respiratory Disease Complex, Including Canine Influenza, **321**
Canine Chronic Bronchitis, **324**
Feline Bronchitis (Idiopathic), **328**
Tracheobronchomalacia (Collapsing Trachea), **333**
Allergic Bronchitis, **337**
Oslerus Osleri, **337**
22 Disorders of the Pulmonary Parenchyma and Vasculature, 340
Viral Pneumonias, **340**
Toxoplasmosis, **343**
Fungal Pneumonia, **344**
Pulmonary Parasites, **344**
Aspiration Pneumonia, **346**
Eosinophilic Lung Disease (Eosinophilic Bronchopneumopathy), **348**
Idiopathic Interstitial Pneumonias, **349**
Pulmonary Neoplasia, **352**
Pulmonary Hypertension, **353**
Pulmonary Thromboembolism (PTE), **354**
Pulmonary Edema, **356**
23 Clinical Manifestations and Diagnostic Tests of Pleural Cavity and Mediastinal Disease, 360
Clinical Signs, **360**
General Diagnostic Approach, **360**
Diagnostic Approach for Pleural Effusions Based on Fluid Cytology, **361**
Diagnostic Tests for the Pleural Cavity and Mediastinum, **364**
Chest Tubes: Indications and Placement, **367**
24 Disorders of the Pleural Cavity and Mediastinum, 371
Pyothorax, **371**
Chylothorax, **374**
Neoplastic Effusion, **375**
Pneumothorax, **376**
Mediastinal Masses, **377**
Pneumomediastinum, **378**
25 Emergency Management of Respiratory Distress, 379
General Considerations, **379**
Emergency Management Based on Localization, **379**
Oxygen Supplementation and Ventilation, **383**

PART THREE DIGESTIVE SYSTEM DISORDERS, 389
Michael D. Willard

26 Clinical Manifestations of Gastrointestinal Disorders, 389
Dysphagia, Halitosis, and Drooling, **389**
Distinguishing Regurgitation From Vomiting From Expectoration, **391**
Regurgitation, **392**
Vomiting, **394**
Hematemesis, **397**
Diarrhea, **398**
Hematochezia, **402**

Melena, 402
Tenesmus, 403
Constipation, 404
Fecal Incontinence, 405
Weight Loss, 405
Anorexia/Hyporexia, 407
Abdominal Effusion, 407
Acute Abdomen, 407
Abdominal Pain, 408
Abdominal Distention or Enlargement, 408

27 Diagnostic Tests for the Alimentary Tract, 412
Physical Examination, 412
Routine Laboratory Evaluation, 412
Fecal Parasitic Evaluation, 413
Fecal Digestion Tests, 413
Bacterial Fecal Culture, 414
ELISA, IFA, and PCR Fecal Analyses, 414
Cytologic Evaluation of Feces, 415
Electron Microscopy, 415
Radiography of the Alimentary Tract, 415
Ultrasonography of the Alimentary Tract, 415
Imaging of the Oral Cavity, Pharynx, and Esophagus, 416
Imaging of the Stomach and Small Intestine, 419
Peritoneal Fluid Analysis, 423
Digestion and Absorption Tests, 423
Serum Concentrations of Vitamins, 423
Endoscopy, 424
Biopsy Techniques and Submission, 429

28 General Therapeutic Principles, 432
Fluid Therapy, 432
Dietary Management, 434
Antiemetics, 437
Antacid Drugs, 438
Gastric and Cytoprotective Drugs, 439
Intestinal "Protectants", 440
Digestive Enzyme Supplementation, 440
Motility Modifiers, 440
Antiinflammatory and Antisecretory Drugs, 441
Antibacterial Drugs, 442
Probiotics/Prebiotics, 443
Fecal Transplantation, 443
Anthelmintic Drugs, 443
Enemas, Laxatives, and Cathartics, 443

29 Disorders of the Oral Cavity, Pharynx, and Esophagus, 447
Masses, Proliferations, and Inflammation of the Oropharynx, 447
Dysphagias, 451
Esophageal Weakness/Megaesophagus, 452
Esophageal Obstruction, 456

30 Disorders of the Stomach, 462
Gastritis, 462
Gastric Outflow Obstruction/Gastric Stasis, 465
Gastrointestinal Ulceration/Erosion, 470
Infiltrative Gastric Diseases, 471

31 Disorders of the Intestinal Tract, 474
Acute Diarrhea, 474
Infectious Diarrhea, 476
Bacterial Diseases: Common Themes, 480
Alimentary Tract Parasites, 485
Maldigestive Disease, 491
Non–Protein-Losing Malabsorptive Diseases, 491
Relation of Small Intestinal Dietary-Responsive Diarrhea and Antibiotic-Responsive Enteropathy, 492
Small Intestinal "Inflammatory Bowel Disease" (Chronic Enteropathy), 493
Protein-Losing Enteropathy, 495
Intestinal Obstruction, 498
Miscellaneous Intestinal Diseases, 502
Neoplasms of the Small Intestine, 502
Neoplasms of the Large Intestine, 503
Diseases of the Perineal Area and Anus, 504
Perianal Neoplasms, 506
Constipation, 506

32 Disorders of the Peritoneum, 510
Inflammatory Diseases, 510
Hemoabdomen, 513
Miscellaneous Peritoneal Disorders, 513

PART FOUR HEPATOBILIARY AND EXOCRINE PANCREATIC DISORDERS, 518

Penny J. Watson

33 Clinical Manifestations of Hepatobiliary and Pancreatic Disease, 518
General Considerations, 518
Gastrointestinal Signs, 518
Abdominal Pain, 519
Polyuria and Polydipsia, 519
Hepatic Encephalopathy, 522
Change in Liver Size, 524
Jaundice, Bilirubinuria, and Change in Fecal Color, 525
Coagulopathies, 527
Protein-Calorie Malnutrition, 529

34 Diagnostic Tests for the Hepatobiliary and Pancreatic System, 531
Diagnostic Approach, 531
Diagnostic Imaging, 545
Biopsy and Cytology, 553

35 Hepatobiliary Diseases in the Cat, 561
General Considerations, 561
Hepatic Lipidosis, 561
Biliary Tract Disease, 567
Extrahepatic Bile Duct Obstruction, 573
Ductal Plate Abnormalities, 574
Hepatic Amyloidosis, 575
Feline Copper Storage Disease, 576
Neoplasia, 576
Congenital Portosystemic Shunts, 577

Hepatobiliary Infections, 579
Toxic Hepatopathy, 580
Hepatobiliary Manifestations of Systemic Disease, 582
36 Hepatobiliary Diseases in the Dog, 584
General Considerations, 584
Chronic Hepatitis, 584
Acute Hepatitis, 598
Biliary Tract Disorders, 599
Congenital Vascular Disorders, 603
Focal Hepatic Lesions, 612
Hepatocutaneous Syndrome and Superficial Necrolytic Dermatitis, 615
Secondary Hepatopathies, 616
37 The Exocrine Pancreas, 620
General Considerations, 620
Pancreatitis, 620
Exocrine Pancreatic Insufficiency, 636
Exocrine Pancreatic Neoplasia, 641
Pancreatic Abscesses, Cysts, and Pseudocysts, 641

PART FIVE URINARY TRACT DISORDERS, 649

Stephen P. DiBartola and Jodi L. Westropp

38 Clinical Manifestations of Urinary Disorders, 649
Clinical Approach, 649
Presenting Problems, 650
39 Diagnostic Tests for the Urinary System, 658
Glomerular Function, 658
Tubular Function, 662
Urinalysis, 664
Microbiology, 670
Diagnostic Imaging, 671
Urodynamic Testing, 672
Urethrocystoscopy, 672
Renal Biopsy, 672
40 Glomerular Disease, 675
Normal Structure, 675
Pathogenesis, 676
Mechanisms of Immune Injury, 677
Progression, 677
Histopathologic Lesions of Glomerulonephritis, 678
Amyloidosis, 679
Clinical Findings, 680
Management of Patients With Glomerular Disease, 681
Complications, 684
41 Acute Kidney Injury and Chronic Kidney Disease, 686
Acute Kidney Injury, 686
Chronic Kidney Disease, 692
42 Bacterial Cystitis, Pyelonephritis, and Prostatitis in the Dog and Cat, 704
Introduction, 704
Classification of Bacterial Cystitis, 704
Bacterial Prostatitis, 710
43 Canine and Feline Urolithiasis, 712
Introduction, 712
Calcium Oxalate Calculi, 714
Ureterolithiasis in Dogs and Cats, 714
Conclusions, 722
44 Obstructive and Nonobstructive Feline Idiopathic Cystitis, 724
Introduction, 724
Pathophysiology, 724
Diagnostic Tests for Cats With Lower Urinary Tract Signs, 725
Treatment Options, 726
Conclusions, 729
45 Disorders of Micturition, 730
Anatomy and Physiology, 730
Definitions and Types of Urinary Incontinence, 730

PART SIX ENDOCRINE DISORDERS, 740

Richard W. Nelson and Ann-Marie Della Maggiore

46 Disorders of the Hypothalamus and Pituitary Gland, 740
Polyuria and Polydipsia, 740
Diabetes Insipidus, 741
Primary (Psychogenic) Polydipsia, 746
Endocrine Alopecia, 747
Feline Acromegaly, 749
Pituitary Dwarfism, 753
47 Disorders of the Parathyroid Gland, 758
Classification of Hyperparathyroidism, 758
Primary Hyperparathyroidism, 758
Primary Hypoparathyroidism, 763
48 Disorders of the Thyroid Gland, 767
Hypothyroidism in Dogs, 767
Hypothyroidism in Cats, 785
Hyperthyroidism in Cats, 788
Canine Thyroid Neoplasia, 800
49 Disorders of the Endocrine Pancreas, 806
Hyperglycemia, 806
Hypoglycemia, 806
Diabetes Mellitus in Dogs, 809
Diabetes Mellitus in Cats, 830
Diabetic Ketoacidosis, 840
Insulin-Secreting β-Cell Neoplasia, 847
Gastrin-Secreting Neoplasia, 853
50 Disorders of the Adrenal Gland, 857
Hyperadrenocorticism in Dogs, 857
Occult (Atypical) Hyperadrenocorticism in Dogs, 878
Hyperadrenocorticism in Cats, 878
Hypoadrenocorticism, 883
Atypical Hypoadrenocorticism, 889
Pheochromocytoma, 889
Incidental Adrenal Mass, 892

PART SEVEN METABOLIC AND ELECTROLYTE DISORDERS, 898

Jennifer A. Larsen and Ann-Marie Della Maggiore

51 Weight Loss and Obesity, 898
Polyphagia With Weight Loss, **898**
Obesity, **899**
52 Hyperlipidemia, 908
Hyperlipidemia, **908**
53 Electrolyte Imbalances, 915
Hypernatremia, **915**
Hyponatremia, **917**
Hyperkalemia, **919**
Hypokalemia, **921**
Hypercalcemia, **923**
Hypocalcemia, **927**
Hyperphosphatemia, **929**
Hypophosphatemia, **930**
Hypomagnesemia, **931**
Hypermagnesemia, **933**

PART EIGHT REPRODUCTIVE SYSTEM DISORDERS, 935

Autumn P. Davidson

54 The Practice of Theriogenology, 935
The Prebreeding Consultation, **935**
Estrous Cycle of the Bitch, **937**
Canine Ovulation Timing: Evaluation of the Estrous Cycle to Identify the Optimal Time to Breed, **940**
The Dog and Tom, **945**
Fresh, Fresh Chilled, and Frozen Artificial Inseminations (AI), **947**
Estrous Cycle of the Queen, **948**
Obstetrics, **949**
55 Clinical Conditions of the Bitch and Queen, 953
Normal Variations of the Estrous Cycle, **953**
Abnormalities of the Canine Estrous Cycle, **954**
Manipulation of the Estrous Cycle, **958**
Prepartum Disorders, **960**
Pregnancy Loss Associated With Infectious Disease, **963**
Abortion Associated With Other Bacteria, **965**
Metabolic Disorders, **966**
Parturition and Parturient Disorders, **968**
Postpartum Disorders, **974**
Disorders of the Reproductive Tract in Ovariohysterectomized Bitches and Queens, **979**
Infertility/Subfertility in the Bitch and Queen, **984**
Microbiology and Female Fertility, **984**
Cystic Endometrial Hyperplasia/Pyometra Complex, **985**
56 Clinical Conditions of the Dog and Tom, 990
Cryptorchidism, **990**
Testicular Torsion, **991**
Persistent Penile Frenulum, **992**
Urethral Prolapse, **992**
Scrotal Dermatitis, **992**
Balanoposthitis, **992**
Priapism, Paraphimosis, and Phimosis, **993**
Testicular Neoplasia in Stud Dogs, **996**
Microbiology and Male Fertility, **997**
Prostatic Disorders in the Valuable Stud Dog, **1001**
Congenital Infertility, **1005**
Disorders of Sexual Differentiation, **1005**
57 Neonatology and Pediatrics, 1007
Neonatal Resuscitation, **1007**
Anomalies Apparent at the Neonatal Exam, **1013**

PART NINE NERVOUS SYSTEM AND NEUROMUSCULAR DISORDERS, 1037

Susan M. Taylor

58 Lesion Localization and the Neurologic Examination, 1037
Functional Anatomy of the Nervous System and Lesion Localization, **1037**
Screening Neurologic Examination, **1043**
Diagnostic Approach, **1061**
59 Diagnostic Tests for Nervous System and Neuromuscular Disorders, 1063
Neurologic Examination, **1063**
Routine Laboratory Evaluation, **1063**
Immunology, Serology, and Microbiology, **1064**
Routine Systemic Diagnostic Imaging, **1064**
Diagnostic Imaging of the Nervous System, **1064**
Cerebrospinal Fluid Collection and Analysis, **1067**
Electrodiagnostic Testing, **1071**
Biopsy of Muscle and Nerve, **1073**
60 Intracranial Disorders, 1074
General Considerations, **1074**
Abnormal Mentation, **1074**
Hypermetria, **1074**
Diagnostic Approach to Animals With Intracranial Disease, **1075**
Intracranial Disorders, **1075**
61 Loss of Vision and Pupillary Abnormalities, 1084
General Considerations, **1084**
Neuroophthalmologic Evaluation, **1084**
Loss of Vision, **1087**
Horner Syndrome, **1089**
Protrusion of the Third Eyelid, **1091**
62 Seizures and Other Paroxysmal Events, 1093
Seizures, **1093**
Nonepileptic Paroxysmal Events, **1093**
Seizure Descriptions, **1093**
Seizure Classification and Localization, **1094**
Differential Diagnosis, **1095**
Diagnostic Evaluation, **1098**
Antiepileptic Drug Therapy, **1100**

Antiepileptic Drugs, 1101
Alternative Therapies, 1104
Emergency Therapy for Dogs and Cats in Status Epilepticus, 1104
Paroxysmal Events That Are Not Seizures, 1105
63 Head Tilt, 1109
General Considerations, 1109
Localization of Lesions, 1109
Disorders Causing Peripheral Vestibular Disease, 1111
Disorders Causing Central Vestibular Disease, 1115
64 Encephalitis, Myelitis, and Meningitis, 1117
General Considerations, 1117
Neck Pain, 1117
Noninfectious Inflammatory Disorders, 1119
Infectious Inflammatory Disorders, 1123
65 Disorders of the Spinal Cord, 1130
General Considerations, 1130
Localizing Spinal Cord Lesions, 1130
Peracute or Acute Spinal Cord Dysfunction, 1133
Progressive Spinal Cord Dysfunction, 1142
66 Disorders of Peripheral Nerves and the Neuromuscular Junction, 1157
General Considerations, 1157
Focal Neuropathies, 1157
Polyneuropathies, 1163
Disorders of the Neuromuscular Junction, 1168
Dysautonomia, 1172
67 Disorders of Muscle, 1174
General Considerations, 1174
Inflammatory Myopathies, 1174
Acquired Metabolic Myopathies, 1178
Noninflammatory Inherited Myopathies, 1179
Involuntary Alterations in Muscle Tone and Movement, 1181
Dyskinesias, 1183
Disorders Causing Exercise Intolerance or Collapse, 1183

PART TEN JOINT DISORDERS, 1187
Susan M. Taylor

68 Clinical Manifestations of and Diagnostic Tests for Joint Disorders, 1187
General Considerations, 1187
Clinical Manifestations, 1187
Diagnostic Approach, 1187
Diagnostic Tests, 1189
69 Disorders of the Joints, 1195
General Considerations, 1195
Noninflammatory Joint Disease, 1195
Infectious Inflammatory Joint Diseases, 1197
Noninfectious Polyarthritis: Nonerosive, 1201
Noninfectious Polyarthritis: Erosive, 1206

PART ELEVEN IMMUNE-MEDIATED DISORDERS, 1211
Andrew Woolcock and J. Catharine R. Scott-Moncrieff

70 Pathogenesis of Immune-Mediated Disorders, 1211
General Considerations and Definition, 1211
Immunopathologic Mechanisms, 1211
Pathogenesis of Immune-Mediated Disorders, 1212
Organ Systems Involved in Autoimmune Disorders, 1214
71 Diagnostic Testing for Immune-Mediated Disease, 1215
Clinical Diagnostic Approach, 1215
Specific Diagnostic Tests, 1215
Antiplatelet Antibodies, 1216
72 Treatment of Primary Immune-Mediated Diseases, 1220
Principles of Treatment of Immune-Mediated Diseases, 1220
Overview of Immunosuppressive Therapy, 1220
Glucocorticoids, 1221
Azathioprine, 1223
Chlorambucil, 1224
Cyclosporine (Ciclosporin), 1224
Leflunomide, 1226
Mycophenolate Mofetil, 1227
Splenectomy, 1228
Human Intravenous Immunoglobulin, 1228
Pentoxifylline, 1228
Vincristine, 1229
73 Common Immune-Mediated Diseases, 1231
Immune-Mediated Hemolytic Anemia, 1231
Feline Immune-Mediated Hemolytic Anemia, 1238
Pure Red Cell Aplasia, 1238
Idiopathic Aplastic Anemia, 1240
Immune-Mediated Thrombocytopenia, 1240
Immune-Mediated Neutropenia, 1244
Polyarthritis, 1245
Systemic Lupus Erythematosus, 1247
Glomerulonephritis, 1249
Acquired Myasthenia Gravis, 1250
Perianal Fistula, 1251
Immune-Mediated Myositis, 1252

PART TWELVE ONCOLOGY, 1257
C. Guillermo Couto

74 Cytology, 1257
General Considerations, 1257
Fine-Needle Aspiration, 1257
Impression Smears, 1258
Staining of Cytologic Specimens, 1258
Interpretation of Cytologic Specimens, 1258
75 Principles of Cancer Treatment, 1265
General Considerations, 1265

Patient-Related Factors, 1265
Family-Related Factors, 1265
Treatment-Related Factors, 1266
76 Practical Chemotherapy, 1269
Cell and Tumor Kinetics, 1269
Basic Principles of Chemotherapy, 1270
Indications and Contraindications of Chemotherapy, 1272
Mechanism of Action of Anticancer Drugs, 1272
Types of Anticancer Drugs, 1272
Metronomic Chemotherapy, 1273
Safe Handling of Anticancer Drugs, 1274
77 Complications of Cancer Chemotherapy, 1276
General Considerations, 1276
Hematologic Toxicity, 1276
Gastrointestinal Toxicity, 1280
Hypersensitivity Reactions, 1281
Dermatologic Toxicity, 1282
Pancreatitis, 1283
Cardiotoxicity, 1283
Urotoxicity, 1284
Hepatotoxicity, 1285
Neurotoxicity, 1285
Pulmonary Toxicity, 1285
Acute Tumor Lysis Syndrome, 1286
78 Approach to the Patient With a Mass, 1288
Approach to the Cat or Dog With a Solitary Mass, 1288
Approach to the Patient With Metastatic Lesions, 1289
Approach to the Patient With a Mediastinal Mass, 1290
79 Lymphoma, 1294
80 Leukemias, 1311
Definitions and Classification, 1311
Leukemias in Dogs, 1313
Leukemias in Cats, 1319
81 Selected Neoplasms in Dogs and Cats, 1322
Hemangiosarcoma in Dogs, 1322
Osteosarcoma, 1325
Mast Cell Tumors in Dogs and Cats, 1328
Injection Site Sarcomas in Cats, 1334

PART THIRTEEN HEMATOLOGY, 1340

C. Guillermo Couto

82 Anemia, 1340
Definition, 1340
Clinical and Clinicopathologic Evaluation, 1340
Management of the Anemic Patient, 1345
Transfusion Therapy, 1355
83 Clinical Pathology in Greyhounds and Other Sighthounds, 1360
Hematology, 1360
Hemostasis, 1361
Clinical Chemistry, 1361
Clinical Pathology in Greyhounds: The Author's Experience, 1364
Conclusions, 1366
84 Erythrocytosis, 1368
Definition and Classification, 1368
85 Leukopenia and Leukocytosis, 1371
General Considerations, 1371
Normal Leukocyte Morphology and Physiology, 1371
Leukocyte Changes in Disease, 1372
86 Combined Cytopenias and Leukoerythroblastosis, 1381
Definitions and Classification, 1381
Clinicopathologic Features, 1381
87 Disorders of Hemostasis, 1387
General Considerations, 1387
Physiology of Hemostasis, 1387
Clinical Manifestations of Spontaneous Bleeding Disorders, 1388
Clinicopathologic Evaluation of the Bleeding Patient, 1389
Management of the Bleeding Patient, 1393
Primary Hemostatic Defects, 1394
Secondary Hemostatic Defects, 1399
Mixed (Combined) Hemostatic Defects, 1400
Thrombosis, 1405
88 Lymphadenopathy and Splenomegaly, 1407
Applied Anatomy and Histology, 1407
Function, 1407
Lymphadenopathy, 1407
Splenomegaly, 1411
Approach to Patients With Lymphadenopathy or Splenomegaly, 1414
Management of Lymphadenopathy or Splenomegaly, 1418
89 Hyperproteinemia, 1420
90 Fever of Undetermined Origin, 1423
Fever and Fever of Undetermined Origin, 1423
Disorders Associated With Fever of Undetermined Origin, 1423
Diagnostic Approach to the Patient With Fever of Undetermined Origin, 1424

PART FOURTEEN INFECTIOUS DISEASES, 1427

Michael R. Lappin

91 Laboratory Diagnosis of Infectious Diseases, 1427
Demonstration of the Organism, 1427
Antibody Detection, 1433
Antemortem Diagnosis of Infectious Diseases, 1435
92 Practical Antimicrobial Chemotherapy, 1436
Anaerobic Infections, 1438
Bacteremia and Bacterial Endocarditis, 1440
Central Nervous System Infections, 1442
Gastrointestinal Tract and Hepatic Infections, 1442
Musculoskeletal Infections, 1443

Respiratory Tract Infections, **1444**
Skin and Soft Tissue Infections, **1445**
Urogenital Tract Infections, **1445**
93 Prevention of Infectious Diseases, 1448
Biosecurity Procedures for Small Animal Hospitals, **1448**
Biosecurity Procedures for Clients, **1450**
Vaccination Protocols, **1451**
94 Polysystemic Bacterial Diseases, 1457
Canine Bartonellosis, **1457**
Feline Bartonellosis, **1458**
Feline Plague, **1460**
Leptospirosis, **1462**

PART ONE ▪ Cardiovascular System Disorders

Wendy A. Ware and Jessica L. Ward

CHAPTER 1

Clinical Manifestations of Cardiac Disease

SIGNS OF HEART DISEASE

Several signs can indicate the presence of heart disease, even if the animal is not clinically in "heart failure." So-called objective signs of heart disease are, for the most part, cardiac specific. These are cardiac murmurs, rhythm disturbances, jugular pulsations, and cardiac enlargement. Notable exceptions to this generalization include murmurs that are functional (nonpathologic) in nature and the normal rhythm irregularity of sinus arrhythmia. Other clinical signs may indicate heart disease but can occur with noncardiac diseases as well. These include syncope, excessively weak or strong arterial pulses, cough or respiratory difficulty, exercise intolerance, abdominal distention, and cyanosis. Further evaluation using thoracic radiography, cardiac biomarker tests, echocardiography, electrocardiography (ECG), and sometimes other tests usually is indicated when signs consistent with cardiovascular (CV) disease are present.

SIGNS OF HEART FAILURE

Heart failure generally is considered to occur when the heart cannot adequately meet the body's circulatory needs or can do so only with high filling (venous) pressures. Not all animals with heart disease will develop heart failure. Of those that do, the majority show clinical signs (Box 1.1) related to high venous pressure behind one or both ventricles (congestive signs), and some also manifest signs of inadequate blood ejection from the heart (low output signs). Congestive signs associated with right-sided heart failure stem from systemic venous hypertension and the resulting increase in systemic capillary hydrostatic pressure. High left-heart filling pressure causes pulmonary venous engorgement and edema. Signs of biventricular failure develop in some animals. Chronic left-sided congestive heart failure (CHF) can promote the development of right-sided congestive signs when pulmonary venous hypertension markedly raises pulmonary arterial pressure. Signs of low cardiac output are similar regardless of which ventricle is affected, because output from the left heart is coupled to that from the right heart. Heart failure is discussed further in Chapter 3 and within the context of specific diseases.

WEAKNESS AND EXERCISE INTOLERANCE

Animals with heart failure often cannot adequately raise cardiac output to sustain increased levels of activity. Furthermore, vascular and metabolic changes that occur over time impair skeletal muscle perfusion during exercise and contribute to reduced exercise tolerance. Increased pulmonary vascular pressure and edema also lead to poor exercise ability. Episodes of exertional weakness or collapse can relate to these changes or to an acute decrease in cardiac output caused by arrhythmias (Box 1.2).

SYNCOPE

Syncope is characterized by transient unconsciousness, with loss of postural tone (collapse), from insufficient oxygen or glucose delivery to the brain. Various cardiac and noncardiac abnormalities can cause syncope and intermittent weakness (see Box 1.2). Syncope can be confused with seizure episodes. A careful description of the animal's behavior or activity before the collapse event, during the event itself, and following the collapse, as well as a drug history, can help the clinician differentiate among syncopal attacks, episodic weakness, and true seizures. Syncope often is associated with exertion or excitement. The actual event can include rear limb weakness or sudden collapse, lateral recumbency, stiffening of the forelimbs with opisthotonos, and micturition (Fig. 1.1). Vocalization is common; however tonic/clonic motion, facial fits, and defecation are not. An aura (which often occurs before seizure activity), postictal dementia, and neurologic deficits are not expected in dogs and cats with CV syncope. Sometimes profound hypotension or asystole causes hypoxic "convulsive syncope," with seizure-like

BOX 1.1

Clinical Signs of Heart Failure

Congestive Signs—Left (↑ Left Heart Filling Pressure)

Pulmonary venous congestion
Pulmonary edema (causes tachypnea, ↑ respiratory effort, cough, orthopnea, pulmonary crackles, tiring, cyanosis, hemoptysis)
Postcapillary pulmonary hypertension
Secondary right-sided heart failure
Cardiac arrhythmias

Congestive Signs—Right (↑ Right Heart Filling Pressure)

Systemic venous congestion (causes ↑ central venous pressure, jugular vein distention)
Hepatic ± splenic congestion
Pleural effusion (causes ↑ respiratory effort, orthopnea, cyanosis)
Ascites
Small pericardial effusion
Subcutaneous edema
Cardiac arrhythmias

Low Cardiac Output Signs

Tiring
Exertional weakness
Syncope
Prerenal azotemia
Cyanosis (from poor peripheral circulation)
Cardiac arrhythmias

FIG 1.1
Syncope in a Doberman Pinscher with paroxysmal ventricular tachycardia. Note the extended head and neck with stiffened forelimbs. Involuntary micturition also occurred, followed shortly by return of consciousness and normal activity.

activity or twitching; however, these convulsive syncopal episodes are preceded by loss of muscle tone. Presyncope, where reduced brain perfusion (or substrate delivery) is not severe enough to cause unconsciousness, may appear as transient "wobbliness" or weakness, especially in the rear limbs.

BOX 1.2

Causes of Syncope or Intermittent Weakness

Cardiovascular Causes

Bradyarrhythmias (second- or third-degree AV block, sinus arrest, sick sinus syndrome, atrial standstill)
Tachyarrhythmias (paroxysmal atrial or ventricular tachycardia, reentrant supraventricular tachycardia, atrial fibrillation)
Congenital ventricular outflow obstruction (pulmonic stenosis, subaortic stenosis)
Acquired ventricular outflow obstruction (heartworm disease and other causes of pulmonary hypertension, hypertrophic obstructive cardiomyopathy, intracardiac tumor, thrombus)
Cyanotic heart disease (tetralogy of Fallot, pulmonary hypertension, and "reversed" shunt)
Impaired forward cardiac output (severe valvular insufficiency, dilated cardiomyopathy, myocardial infarction or inflammation)
Impaired cardiac filling (e.g., cardiac tamponade, constrictive pericarditis, hypertrophic or restrictive cardiomyopathy, intracardiac tumor, thrombus)
Cardiovascular drugs (diuretics, vasodilators)
Neurocardiogenic reflexes (vasovagal, cough-syncope, other situational syncope)

Pulmonary Causes

Diseases causing hypoxemia
Pulmonary hypertension
Pulmonary thromboembolism

Metabolic and Hematologic Causes

Hypoglycemia
Hypoadrenocorticism
Electrolyte imbalance (especially potassium, calcium)
Anemia
Sudden hemorrhage

Neurologic Causes

Cerebrovascular accident
Brain tumor
(Seizures)

Neuromuscular Disease

(Narcolepsy, cataplexy)

AV, Atrioventricular.

Tests to explore the cause of intermittent weakness or syncope usually include ECG recordings (during rest, exercise, and/or after exercise or a vagal maneuver), complete blood count (CBC), serum biochemical analysis (including electrolytes and glucose), heartworm testing, neurologic examination, thoracic radiographs, and echocardiography. Other studies for neuromuscular or neurologic disease also may be valuable. Intermittent cardiac arrhythmias that are not apparent on resting ECG may be uncovered by ambulatory ECG monitoring, using a 24-hour Holter, event, or

implantable loop recording device. In-hospital continuous ECG monitoring for a period of time sometimes reveals a culprit arrhythmia also.

Cardiovascular Causes of Syncope

Various arrhythmias, obstruction to ventricular outflow, cyanotic congenital heart defects, and acquired diseases that impair cardiac output are the usual causes of CV syncope. Activation of vasodepressor reflexes and excessive dosages of CV drugs also can induce syncope. Arrhythmias that provoke syncope usually are associated with either very fast or very slow heart rates and can occur with or without identifiable underlying organic heart disease. Ventricular outflow obstruction can provoke syncope or sudden weakness if cardiac output becomes inadequate during exercise or if high systolic pressure activates ventricular mechanoreceptors, causing inappropriate reflex bradycardia and hypotension. Both dilated cardiomyopathy and severe mitral insufficiency can impair forward cardiac output, especially during exertion. Vasodilator and diuretic drugs can induce syncope if given in excess.

Syncope caused by abnormal peripheral vascular and/or neurologic reflex responses is not well defined in animals, but is thought to occur in some patients. Syncope associated with sudden bradycardia after a burst of sinus tachycardia has been documented, especially in small breed dogs with advanced atrioventricular (AV) valve disease; excitement often precipitates such an episode. Doberman Pinschers and Boxers similarly may experience syncope after sudden bradycardia. Postural hypotension and hypersensitivity of carotid sinus receptors infrequently can provoke syncope by inappropriate peripheral vasodilation and bradycardia.

Fainting associated with a coughing fit (cough syncope or "cough-drop") occurs in some dogs with marked left atrial (LA) enlargement and bronchial compression, as well as in dogs with primary respiratory disease. Several mechanisms have been proposed, including an acute decrease in cardiac filling and output during the cough, peripheral vasodilation after the cough, and increased cerebrospinal fluid pressure with intracranial venous compression. Severe pulmonary disease, anemia, certain metabolic abnormalities, and primary neurologic diseases also can cause collapse that resembles CV syncope.

COUGH AND OTHER RESPIRATORY SIGNS

CHF in dogs produces tachypnea, respiratory distress, and sometimes coughing. These signs also can occur with the pulmonary vascular pathology and pneumonitis of heartworm disease in both dogs and cats. Noncardiac conditions, including diseases of the upper and lower airways, pulmonary parenchyma (including noncardiogenic pulmonary edema), pulmonary vasculature, and pleural space, as well as certain nonrespiratory conditions, also should be considered in patients with cough, tachypnea, or dyspnea (see Chapter 19).

The cough associated with cardiogenic pulmonary edema in dogs often is soft and moist; it sometimes sounds like gagging. Cats, in contrast, rarely cough from pulmonary edema. Tachypnea progressing to dyspnea occurs in both species. Pleural and pericardial effusions occasionally are associated with coughing as well. Mainstem bronchus collapse or compression associated with severe LA enlargement can stimulate a dry or hacking cough in dogs with chronic mitral valve disease, even when pulmonary edema or congestion is absent. Concurrent bronchomalacia is likely to be a contributing factor in these cases. A heart base tumor, enlarged hilar lymph nodes, or other masses that impinge on an airway also can stimulate this type of cough.

When respiratory signs have a cardiac cause, other evidence of heart disease usually is evident, such as generalized cardiomegaly, LA enlargement, pulmonary venous congestion, lung infiltrates that resolve with diuretic therapy, or a positive heartworm test. Findings on physical examination, thoracic radiographs, cardiac biomarker assays, echocardiogram, and sometimes an ECG, help in differentiating cardiac from noncardiac causes.

CARDIOVASCULAR EXAMINATION

The medical history (Box 1.3) is an important part of the CV evaluation and can help guide the choice of diagnostic tests because it may suggest various cardiac or noncardiac diseases. The patient's signalment is useful because some

BOX 1.3

Important Historic Information

- Signalment (age, breed, gender)?
- Vaccination status?
- What is the diet? Have there been any recent changes in food or water consumption?
- Where was the animal obtained?
- Is the pet housed indoors or outdoors?
- How much time is spent outdoors? Supervised?
- What activity level is normal? Does the animal tire easily now?
- Has there been any coughing? When? Describe episodes.
- Has there been any excessive or unexpected panting or heavy breathing?
- Has there been any vomiting or gagging? Diarrhea?
- Have there been any recent changes in urinary habits?
- Have there been any episodes of fainting or weakness?
- Do the tongue/mucous membranes always look pink, especially during exercise?
- Have there been any recent changes in attitude or activity level?
- Are medications being given for this problem? What? How much? How often? Do they help?
- Have medications been used in the past for this problem? What? How much? Were they effective?

congenital and acquired abnormalities are more prevalent in certain breeds or life stages, or because specific findings are common in individuals of a given breed (such as a soft left basilar ejection murmur in normal Greyhounds and other sighthounds).

Physical evaluation of the patient with suspected heart disease includes observation (for example, of attitude, posture, body condition, level of anxiety, respiratory pattern) and a general physical examination. The CV examination itself consists of evaluating the peripheral circulation (mucous membranes), systemic veins (especially the jugular veins), systemic arterial pulses (usually the femoral arteries), and the precordium (left and right chest wall over the heart), as well as auscultation of the heart and lungs, and palpating or percussing for abnormal fluid accumulation (e.g., ascites, subcutaneous edema, pleural effusion). Proficiency in all aspects of the CV examination requires practice but is important for accurate patient assessment and monitoring.

RESPIRATORY PATTERNS

Respiratory difficulty (dyspnea) usually causes the animal to appear anxious. Increased respiratory effort, flared nostrils, and often a rapid rate of breathing are evident (Fig. 1.2). Increased depth of respiration (hyperpnea) can result from hypoxemia, hypercarbia, or acidosis. Pulmonary edema (or other pulmonary infiltrates) increases lung stiffness; the rapid and shallow breathing (tachypnea) that results helps minimize the work of breathing. In the absence of primary lung disease, an increase in resting respiratory rate often is an early indicator of pulmonary edema. Lung stiffness also increases with pleural fluid or air accumulation and can produce tachypnea, too. However, with large-volume pleural effusion or pneumothorax, respiratory motions become increasingly labored and exaggerated as the animal struggles to expand the collapsed lungs; the respiratory rate often is not elevated in these cases.

It is important to note whether the respiratory difficulty is more intense during a particular phase of respiration. Prolonged, labored inspiration usually is associated with upper airway obstructive disorders, whereas prolonged expiration occurs with lower airway obstruction as well as pulmonary infiltrative disease (including edema). Animals with severely compromised ventilation may refuse to lie down; rather, they stand or sit with elbows abducted to allow maximal rib expansion, and they resist being positioned in lateral or dorsal recumbency (orthopnea). Cats with dyspnea often crouch in a sternal position with elbows abducted. Open-mouth breathing usually is a sign of severe respiratory distress in cats (Fig. 1.3). The increased respiratory rate associated with excitement, fever, fear, or pain generally can be differentiated from dyspnea by careful observation and physical examination.

MUCOUS MEMBRANES

Mucous membrane color and capillary refill time (CRT) are used to evaluate peripheral perfusion. The oral mucosa usually is assessed, although caudal mucous membranes (prepuce or vagina) also can be evaluated. The CRT is determined by applying digital pressure to blanch the membrane; color should return within 2 seconds. Slower refill times occur as a result of dehydration and other causes of decreased cardiac output because of high peripheral sympathetic tone and vasoconstriction. Pale mucous membranes occur with either anemia or peripheral vasoconstriction. The CRT is normal in anemic animals unless hypoperfusion also is present. However, the CRT can be difficult to assess in severely anemic animals because of the lack of color contrast. In animals with polycythemia (erythrocytosis) or exercise-induced rear limb weakness, the color of the caudal membranes should be compared with that of the oral membranes for evidence of differential cyanosis (see p. 115 in Chapter 5). If oral membranes are heavily pigmented, the ocular

FIG 1.2
Dyspnea in an older male Golden Retriever with dilated cardiomyopathy and fulminant pulmonary edema. The dog appeared highly anxious, with rapid labored respirations and hypersalivation. Respiratory arrest occurred within minutes of this photograph being taken, but the dog was resuscitated.

FIG 1.3
Severe dyspnea is manifested in this cat by open-mouth breathing, infrequent swallowing (drooling saliva), and reluctance to lie down. Note also the dilated pupils associated with heightened sympathetic tone.

BOX 1.4

Abnormal Mucous Membrane Color

Pale Mucous Membranes

Anemia
Poor cardiac output/high sympathetic tone

Injected, Brick-Red Membranes

Polycythemia (erythrocytosis)
Sepsis
Excitement
Other causes of peripheral vasodilation

Cyanotic Mucous Membranes*

Pulmonary parenchymal disease
Airway obstruction
Pleural space disease
Pulmonary edema
Right-to-left shunting congenital cardiac defect
Hypoventilation
Shock
Cold exposure
Methemoglobinemia

Differential Cyanosis

Reversed patent ductus arteriosus (head and forelimbs receive normally oxygenated blood, but caudal part of body receives desaturated blood via the ductus, which arises from the descending aorta)

Icteric Mucous Membranes

Hemolysis
Hepatobiliary disease
Biliary obstruction

*Anemic animals might not appear cyanotic even with marked hypoxemia because 5 g/dL of desaturated hemoglobin is necessary for visible cyanosis.

conjunctiva can be evaluated. Box 1.4 outlines causes for abnormal mucous membrane color. Petechiae in the mucous membranes might be evident in animals with platelet disorders (see Chapter 87). In addition, oral and ocular membranes often are areas where icterus (jaundice) is first detected; a yellowish cast to these membranes should prompt further evaluation for hemolysis (see Chapter 82) or hepatobiliary disease (see Chapter 33).

JUGULAR VEINS

Systemic venous and right heart filling pressures are reflected at the jugular veins. These veins should not be distended when the animal is standing with its head in a normal position (jaw parallel to the floor). Persistent jugular vein distention occurs in patients with right-sided CHF (because of high right heart filling pressure), external compression of the cranial vena cava (as from a cranial mediastinal mass), and jugular vein or cranial vena cava thrombosis (Fig. 1.4).

Jugular pulsations that extend higher than one third of the way up the neck from the thoracic inlet also are

FIG 1.4
Prominent jugular vein distention in a cat with signs of right-sided congestive heart failure from dilated cardiomyopathy.

abnormal. Sometimes the carotid pulse wave is transmitted through adjacent soft tissues, mimicking a jugular pulse in thin or excited animals. To differentiate a true jugular pulse from carotid transmission, lightly occlude the jugular vein below the area of visible pulsation. If the pulse disappears, it is a true jugular pulsation; if the pulse continues, it is being transmitted from the carotid artery. Jugular pulse waves are related to atrial contraction and filling. Visible pulsations occur in animals with tricuspid insufficiency (after the first heart sound, during ventricular contraction), conditions causing a stiff and hypertrophied right ventricle (just before the first heart sound, during atrial contraction), or arrhythmias that cause the atria to contract against closed AV valves (so-called cannon "a" waves). Specific causes of jugular vein distention and pulsations are listed in Box 1.5. Impaired right ventricular (RV) filling, reduced pulmonary blood flow, or tricuspid regurgitation can cause a positive *hepatojugular* (*abdominojugular*) *reflux* test even in the absence of jugular distention or pulsations at rest. To test for this reflux, apply firm pressure to the cranial abdomen while the animal stands quietly with head and neck in normal position. This transiently increases venous return. Jugular distention that persists while abdominal pressure is applied constitutes a positive (abnormal) test. Normal animals have little to no change in the jugular vein with this maneuver.

ARTERIAL PULSES

The strength and regularity of the peripheral arterial pressure waves and the pulse rate are assessed by palpating the femoral or other peripheral arteries (Box 1.6). Subjective evaluation of pulse strength is based on the difference between the systolic and diastolic arterial pressures (that is,

BOX 1.5

Causes of Jugular Vein Distention/Pulsation

Distention Alone

Pericardial effusion/tamponade
Right atrial mass/inflow obstruction
Dilated cardiomyopathy
Cranial mediastinal mass
Jugular vein/cranial vena cava thrombosis

Pulsation ± Distention

Tricuspid regurgitation of any cause (degenerative, cardiomyopathy, congenital, secondary to diseases causing right ventricular pressure overload)
Pulmonic stenosis
Heartworm disease
Pulmonary hypertension
Ventricular premature contractions
Complete (third-degree) heart block
Constrictive pericarditis
Hypervolemia

BOX 1.6

Abnormal Arterial Pulses

Weak Pulses

Dilated cardiomyopathy
(Sub) aortic stenosis
Pulmonic stenosis
Shock
Dehydration

Strong Pulses

Excitement
Hyperthyroidism
Fever
Hypertrophic cardiomyopathy

Very Strong, Bounding Pulses

Patent ductus arteriosus
Fever/sepsis
Severe aortic regurgitation

the pulse pressure). When the difference is wide, the pulse feels strong on palpation; abnormally strong pulses are termed *hyperkinetic.* When the pressure difference is small, the pulse feels weak *(hypokinetic).* If the rise to maximum systolic arterial pressure is prolonged, as with severe subaortic stenosis, the pulse also tends to feel weak *(pulsus parvus et tardus).* Both femoral pulses should be palpated and compared; absence of pulse or a weaker pulse on one side could be caused by thromboembolic disease. Femoral pulses can be difficult to palpate in cats, even when normal. Often an elusive pulse can be found by gently working a fingertip between the dorsomedial thigh muscles toward the femur, in the area of the femoral triangle, where the femoral artery enters the leg.

The femoral arterial pulse rate should be evaluated simultaneously with the direct heart rate, which is obtained by auscultation or chest wall palpation. Fewer femoral pulses than heartbeats constitute a pulse deficit. Various cardiac arrhythmias induce pulse deficits by causing the heart to beat before adequate ventricular filling has occurred. Consequently, minimal or even no blood is ejected for those beats, and a palpable pulse is absent. Other arterial pulse variations also occur occasionally. Alternately weak then strong pulsations can result from severe myocardial failure *(pulsus alternans)* or from a normal heartbeat alternating with a premature beat *(bigeminy),* which causes reduced ventricular filling and ejection. An exaggerated decrease in systolic arterial pressure during inspiration occurs from cardiac tamponade *(pulsus paradoxus)*; a weak arterial pulse strength may be detectable during inspiration in those patients.

PRECORDIUM

The term "precordium" refers to the area of the chest wall that overlies the heart on both sides of the thorax. To palpate the precordium, place the palm and fingers of each hand on the corresponding side of the animal's chest wall over the heart (e.g., right hand over the right precordial area and left hand over the left precordial area). Normally the strongest systolic impulse is felt over the area of the left cardiac apex (located at approximately the fifth intercostal space near the costochondral junction). Cardiomegaly or a space-occupying mass within the chest can shift the precordial impulse to an abnormal location. Decreased intensity of the precordial impulse can be caused by obesity, weak cardiac contractions, pericardial effusion, intrathoracic masses, pleural effusion, or pneumothorax. The precordial impulse should be stronger on the left chest wall than on the right. A stronger right precordial impulse can result from RV hypertrophy or displacement of the heart into the right hemithorax by a mass lesion, lung atelectasis, or chest deformity. Very loud cardiac murmurs cause palpable vibrations on the chest wall known as a *precordial thrill.* This feels like a "buzzing" sensation to the hand. A precordial thrill usually is localized to the area of maximum murmur intensity.

EVALUATION FOR FLUID ACCUMULATION

Right-sided CHF promotes abnormal fluid accumulation within body cavities (Fig. 1.5; see also Fig. 9.3) and occasionally in the subcutis of dependent areas. Palpation and ballottement of the abdomen, percussion of the chest in the standing animal, and palpation of dependent areas are used to detect effusions and subcutaneous edema. Fluid accumulation secondary to right-sided heart failure usually is accompanied by abnormal jugular vein distention with or without pulsations, unless the animal's circulating blood volume is diminished from diuretic administration or other cause. Hepatomegaly and splenomegaly also may be noted in cats and dogs with right-sided CHF.

FIG 1.5
Abdominal distention caused by ascites from right heart failure in a 7-year-old Golden Retriever.

FIG 1.6
During cardiac auscultation, respiratory noise and purring often can be decreased or eliminated by gently placing a finger over one or both nostrils for brief periods of time.

AUSCULTATION

Thoracic auscultation is used to assess heart rate and rhythm, identify normal heart sounds, determine the presence or absence of abnormal sounds, and evaluate pulmonary sounds. Heart sounds are created by turbulent blood flow and associated vibrations in adjacent tissue during the cardiac cycle. Although many of these sounds are too low in frequency or intensity to be audible, others can be heard with the stethoscope or even palpated. Heart sounds are classified as transient sounds (those of short duration) and cardiac murmurs (longer sounds occurring during a normally silent part of the cardiac cycle). Cardiac murmurs and transient sounds are described by their timing within the cardiac cycle and by general characteristics of sound: frequency (pitch), amplitude of vibrations (intensity/loudness), duration, and quality (timbre). Sound quality is affected by the physical characteristics of the vibrating structures.

Because many heart sounds can be difficult to hear, a cooperative animal and a quiet room are important during auscultation. The animal should be standing, if possible, so that the heart is in its normal position. Panting in dogs is discouraged by holding the animal's mouth shut. Respiratory noise can be decreased further by placing a finger over one or both nostrils for a short time. Purring in cats often can be stopped by briefly holding a finger over one or both nostrils (Fig. 1.6), gently pressing the cricothyroid ligament region with a fingertip, waving an alcohol-soaked cotton ball near the cat's nose, or turning on a water faucet near the animal. Various other artifacts can interfere with auscultation, including respiratory clicks, air movement sounds, shivering, muscle twitching, hair rubbing against the stethoscope, gastrointestinal sounds, and extraneous room noises.

The traditional stethoscope has both a stiff, flat diaphragm and a bell on the chestpiece. The diaphragm, when applied firmly to the chest wall, allows better auscultation of higher-frequency heart sounds than those of low frequency. The bell, applied lightly to the chest wall, facilitates auscultation of lower-frequency sounds such as S_3 and S_4 (see the section on Gallop Sounds). Stethoscopes with a single-sided chestpiece are designed to function as a diaphragm when used with firm pressure against the skin and as a bell when used with light pressure. Ideally the stethoscope should have short double tubing and comfortable eartips. The binaural eartubes should be angled rostrally to align with the examiner's ear canals (Fig. 1.7).

FIG 1.7
Note the angulation of the stethoscope binaurals for optimal alignment with the clinician's ear canals (top of picture is rostral). The flat diaphragm of the chestpiece faces left, and the concave bell faces right.

Both sides of the chest should be carefully auscultated, with special attention to the valve areas (Fig. 1.8). The stethoscope is moved gradually to all areas of the chest. The examiner should concentrate on the various heart sounds, correlating them to the events of the cardiac cycle, and listen for any abnormal sounds in systole and diastole successively. The normal heart sounds (S_1 and S_2) are used as a framework for timing abnormal sounds. The point of maximal intensity (PMI) of any abnormal sounds should be located. The examiner should focus on cardiac auscultation separately from

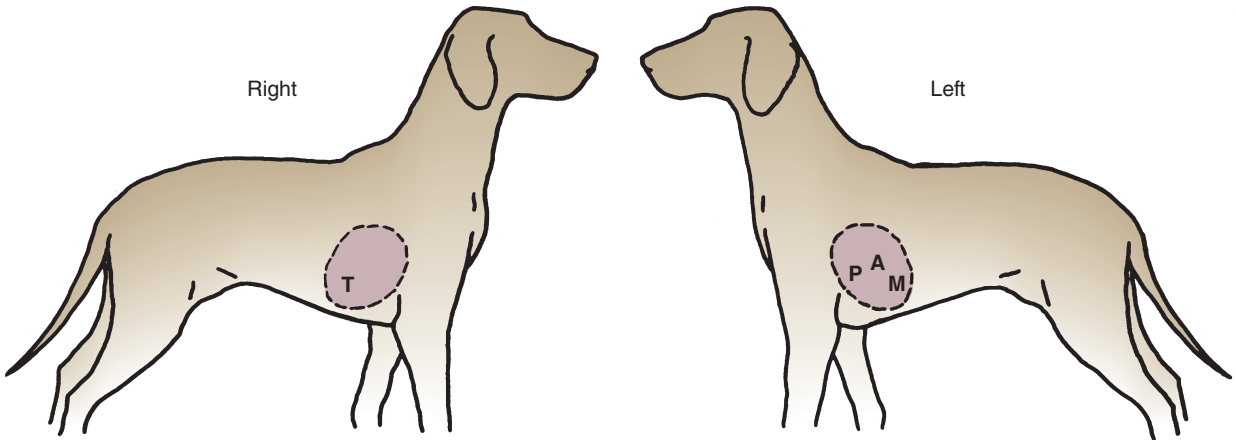

FIG 1.8

pulmonary auscultation because full assimilation of sounds from both systems simultaneously is unlikely. Pulmonary auscultation is described further in Chapter 20.

Transient Heart Sounds

The heart sounds heard normally in dogs and cats are S_1 (associated with closure and tensing of the AV valves and associated structures at the onset of systole) and S_2 (associated with closure of the aortic and pulmonic valves following ejection). The diastolic sounds (S_3 and S_4) are not audible in normal dogs and cats. Fig. 1.9 correlates the hemodynamic events of the cardiac cycle with the ECG and timing of the heart sounds. It is important to understand these events and identify the timing (from a clinical perspective) of systole (between S_1 and S_2) and diastole (after S_2 until the next S_1) in the animal. The precordial impulse occurs just after S_1 (systole), and the arterial pulse occurs between S_1 and S_2.

Sometimes the first (S_1) and second (S_2) heart sounds are altered in intensity. The normal heart sounds may be louder in dogs and cats with a thin chest wall, high sympathetic tone, tachycardia, or systemic arterial hypertension. Shortened PR intervals increase the intensity of S_1. Muffled sounds can result from obesity, pericardial effusion, diaphragmatic hernia, dilated cardiomyopathy, hypovolemia/poor ventricular filling, or pleural effusion. A split or sloppy-sounding S_1 may be normal, especially in large dogs, or it may result from ventricular premature contractions or an intraventricular conduction delay. The intensity of S_2 can be increased by pulmonary hypertension of any cause (see Chapter 10). Cardiac arrhythmias often cause variation in the intensity (or even absence) of heart sounds.

Normal physiologic splitting of S_2 occasionally is heard in some (larger) dogs because of variation in stroke volume during the respiratory cycle. During inspiration, increased venous return to the right ventricle tends to delay closure of the pulmonic valve, whereas reduced filling of the left

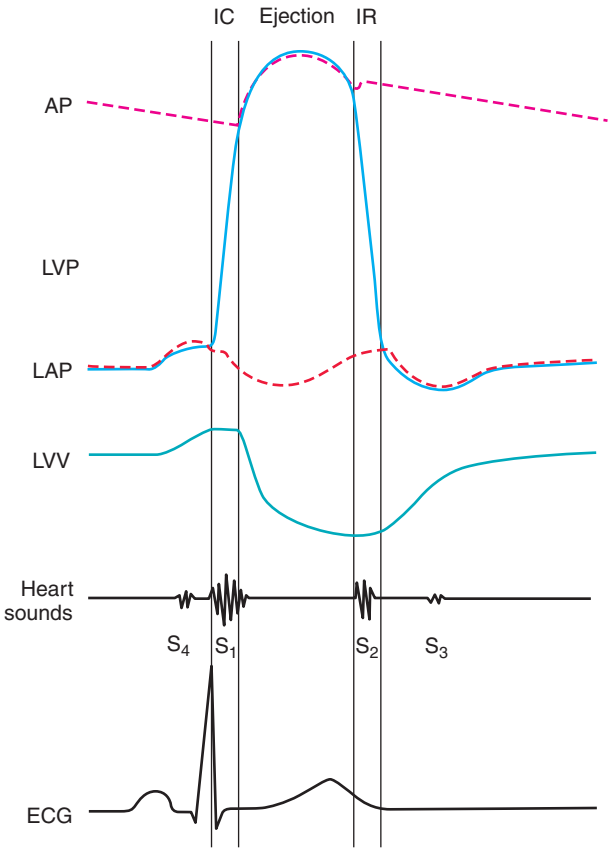

FIG 1.9

ventricle accelerates aortic closure. Pathologic splitting of S_2 can result from delayed ventricular activation or prolonged RV ejection secondary to ventricular premature beats, right bundle branch block, a ventricular or atrial septal defect, or pulmonary hypertension.

Gallop Sounds

The third (S_3) and fourth (S_4) heart sounds occur during diastole (see Fig. 1.9) and are not normally audible in dogs and cats. When an S_3 or S_4 sound is heard, the heart can sound like a galloping horse, hence the term *gallop rhythm.* This term can be confusing because the presence or absence of an audible S_3 or S_4 has nothing to do with the heart's rhythm (that is, the origin of cardiac electrical activation and the intracardiac conduction process). Gallop sounds usually are heard best with the bell of the stethoscope (or by light pressure applied to a single-sided chestpiece) because they are of lower frequency than S_1 and S_2. At very fast heart rates, differentiation of S_3 from S_4 may be impossible. If both sounds are present, they may be superimposed, which is called a *summation gallop.*

The S_3 gallop, also known as an *S_3 gallop* or *ventricular gallop,* is associated with low-frequency vibrations at the end of the rapid ventricular filling phase. An audible S_3 in the dog or cat usually indicates ventricular dilation with myocardial failure. The extra sound often is very subtle although sometimes it can be fairly loud and easily detected; it is heard best over the cardiac apex. This sound may be the only auscultable abnormality in an animal with dilated cardiomyopathy. An S_3 gallop also may be audible in dogs with advanced mitral valve disease and CHF.

The S_4 gallop, also called an *atrial* or *presystolic gallop,* is associated with low-frequency vibrations triggered by blood flow into the ventricles during atrial contraction (just after the P wave of the ECG). An audible S_4 in the dog or cat usually is associated with increased ventricular stiffness and hypertrophy, such as with hypertrophic cardiomyopathy or hyperthyroidism in cats. A transient S_4 gallop of unclear significance sometimes is heard in stressed or anemic cats.

Other Transient Sounds

Other brief abnormal sounds are audible in some cases. Systolic clicks are mid-to-late systolic sounds that usually are heard best over the mitral valve area. These sounds have been associated with degenerative valvular disease (endocardiosis), mitral valve prolapse, and congenital mitral dysplasia; a concurrent mitral insufficiency murmur can be present. In dogs with degenerative valvular disease, a mitral click might be the first abnormal sound noted, with a murmur developing over time. An early systolic, high-pitched ejection sound at the left base can occur in animals with valvular pulmonic stenosis or other diseases that cause dilation of a great artery. The sound is thought to arise from either the sudden checking of a fused pulmonic valve or the rapid filling of a dilated vessel during ejection. Rarely, constrictive pericardial disease causes an audible pericardial knock. This diastolic sound arises from sudden checking of ventricular filling by the constrictive pericardium; its timing is similar to the S_3.

Cardiac Murmurs

There are many causes for cardiac murmurs. Most involve a structural cardiac abnormality and are considered pathologic murmurs. However, some murmurs do not and are considered nonpathologic. Nonpathologic murmurs are systolic in timing. They can occur for physiologic reasons, for example, when blood viscosity is reduced by anemia, or when cardiac output is increased from fever, hyperthyroidism, etc.; these are known as *functional* murmurs. Sometimes a soft murmur is heard in an animal without evidence for structural cardiac disease or physiologic alteration. These are considered *innocent* murmurs and often are found in young puppies. Many animals with a pathologic murmur also have other clinical signs consistent with heart disease. However, pathologic as well as nonpathologic murmurs often are discovered as incidental findings on physical examination. In these cases, it is important to determine if a clinically important cardiac disease or physiologic abnormality is the cause or not. Careful physical examination and auscultation can help the clinician decide how aggressively (or whether) to immediately pursue additional diagnostic testing.

Cardiac murmurs are described by their timing within the cardiac cycle (systolic or diastolic, or portions thereof), intensity, PMI on the precordium, radiation over the chest wall, quality, and pitch. Systolic murmurs can occur in early (protosystolic), middle (mesosystolic), or late (telesystolic) systole or throughout systole (holosystolic). Diastolic murmurs generally occur in early diastole (protodiastolic) or throughout diastole (holodiastolic). Murmurs at the end of diastole are termed *presystolic.* Continuous murmurs begin in systole and extend through S_2 into all or part of diastole. Murmur intensity generally is graded on a scale of 1 to 6 (sometimes written I to VI) (Table 1.1). The PMI usually is indicated by the hemithorax (right or left) and valve area or intercostal space where it is located, or by the terms *apex* or *base.* Because murmurs can radiate extensively, the entire thorax, thoracic inlet, and carotid artery areas should be auscultated. The pitch and quality of a murmur relate to its frequency and subjective assessment. "Noisy" or "harsh" murmurs contain mixed frequencies. "Musical" murmurs are of essentially one frequency with its overtones; these can sound like a "whoop" or "honk."

Murmurs also can be described by their phonocardiographic configuration (Fig. 1.10). A plateau-shaped or "regurgitant" murmur begins at the time of S_1 and remains of fairly uniform intensity throughout systole. Sometimes this murmur configuration also is called *holosystolic*, because it generally is consistent throughout systole. Loud regurgitant/holosystolic murmurs can mask the S_1 and S_2 sounds. AV valve insufficiency and interventricular septal defects commonly cause this type of murmur because turbulent blood flow begins at the time of AV valve closing and continues throughout ventricular systole. A crescendo-decrescendo or diamond-shaped murmur starts softly, builds intensity in

midsystole, and then diminishes; the S_1 and S_2 sounds usually can be heard before and after the murmur, respectively. This type is also called an *ejection murmur* because it occurs during ventricular ejection, usually because of a ventricular outflow obstruction. A decrescendo murmur tapers from its initial intensity over time; it may occur in systole or diastole. Continuous (machinery) murmurs occur throughout systole and (well into or) throughout diastole.

TABLE 1.1

Grading of Heart Murmurs

GRADE	MURMUR
1	Very soft murmur; heard only over its site of origin, after prolonged listening in quiet surroundings
2	Soft murmur but easily heard over its site of origin (usually a particular valve area)
3	Moderate-intensity murmur; usually radiates to other precordial/valve areas too
4	Loud murmur but without a precordial thrill; radiates widely and usually can be heard over most precordial regions
5	Loud murmur with a palpable precordial thrill; radiates widely and usually can be heard clearly over all precordial regions
6	Very loud murmur with a precordial thrill; radiates widely, generally is heard clearly over all precordial areas, and also can be heard with the stethoscope chestpiece lifted slightly (~1 cm) from the chest wall (at the murmur PMI)

Systolic murmurs

Systolic murmurs can be decrescendo, holosystolic (plateau-shaped), or ejection (crescendo-decrescendo) in configuration. It can be difficult to differentiate these by auscultation alone. However, the most important steps toward diagnosis include establishing that the murmur occurs in systole (rather than diastole), determining its PMI, and grading its intensity. Fig. 1.11 depicts the typical PMI of various murmurs over the chest wall.

Functional, nonpathologic murmurs usually are heard best over the left heart base. They are soft to moderate in intensity and of decrescendo or crescendo-decrescendo configuration. Functional murmurs have no apparent CV structural cause and can accompany physiologic

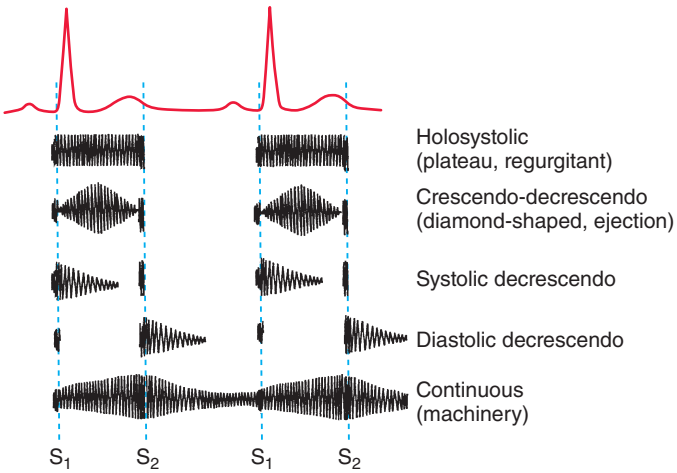

FIG 1.10
The phonocardiographic shape (configuration) and the timing of different murmurs are illustrated in this diagram.

(From Ware WA: *Cardiovascular disease in small animal medicine,* London, 2011, Manson Publishing.)

abnormalities (and also are called *physiologic murmurs*). Physiologic murmurs have been associated with anemia, fever, high sympathetic tone, hyperthyroidism, marked bradycardia, peripheral arteriovenous fistulae, hypoproteinemia, and athletic hearts. Aortic dilation (for example, from hypertension) and dynamic RV outflow obstruction are other conditions associated with systolic murmurs in cats. Innocent puppy murmurs also are nonpathologic and generally disappear by the time the animal is about 6 months old.

The murmur of mitral insufficiency (regurgitation) most often is heard best at the left apex, in the area of the mitral valve. It radiates well dorsally and often to the left base and right chest wall. Mitral insufficiency characteristically causes a plateau-shaped murmur (holosystolic timing), but in its early stages the murmur may be protosystolic, tapering to a decrescendo configuration. Occasionally this murmur has a musical or "whoop-like" quality. With degenerative mitral valve disease, murmur intensity usually relates to disease severity.

Systolic ejection murmurs most often are heard at the left base. Ventricular outflow obstruction, usually from a fixed narrowing (e.g., subaortic or pulmonic valve stenosis) or dynamic muscular obstruction, is the typical cause. Ejection murmurs become louder as cardiac output or contractile strength increases. The subaortic stenosis murmur is heard well at the low left base and also at the right base, because the murmur radiates up the aortic arch, which curves toward the right. This murmur also radiates up the carotid arteries and, when loud, occasionally can be heard on the calvarium. Soft (grade 1-2/6), nonpathologic (functional) systolic ejection murmurs are common in sighthounds, Boxers, and certain other large breeds; these can be related to a large stroke volume, as well as breed-related left ventricular (LV) outflow tract characteristics. The murmur of pulmonic stenosis is best heard at the cranial left base. Relative pulmonic stenosis occurs when flow volume through a structurally normal valve is abnormally increased (as with a large left-to-right shunting atrial or ventricular septal defect).

Most murmurs heard on the right chest wall are holosystolic, plateau-shaped murmurs, except for the subaortic stenosis murmur (discussed earlier). The tricuspid insufficiency murmur is loudest at the right apex over the tricuspid valve. Its pitch or quality may be noticeably different from a concurrent mitral insufficiency murmur. Moderate to severe tricuspid insufficiency often is accompanied by jugular pulsations. Ventricular septal defects also cause holosystolic murmurs. The PMI usually is at the right sternal border, reflecting the direction of the intracardiac shunt. A large ventricular septal defect can also cause the murmur of relative pulmonic stenosis.

In the general population of apparently healthy cats, the prevalence of systolic murmurs is estimated at up to 40%, and is even higher in older cats. Although a systolic murmur can accompany subclinical structural cardiac disease, especially in older cats where the prevalence of cardiomyopathy can be almost 30%, the presence of a murmur alone is not a highly sensitive predictor of cardiomyopathy. This is especially true in young cats. The PMI of most feline murmurs is near the sternal border. Many of these murmurs are associated with dynamic left (or right) ventricular outflow obstruction. Congenital cardiac malformations are another potential cause of murmurs in cats. NT-proBNP measurement can help with screening for structural disease in cats. However, an echocardiogram performed by a veterinary cardiologist or other person with advanced echocardiography training is the most sensitive tool for detecting structural disease in cats with a murmur.

Diastolic murmurs

Diastolic murmurs are uncommon in dogs and cats. They are always pathologic. Aortic valve insufficiency from infective endocarditis is the most common cause, although congenital malformation or degenerative aortic valve disease occasionally occurs. Clinically relevant pulmonic valve insufficiency is rare, but an audible pulmonic insufficiency murmur would be more likely in the face of pulmonary hypertension. These diastolic murmurs begin at the time of S_2 and are heard best at the left base. They are decrescendo in configuration and extend a variable time into diastole, depending on the pressure difference between the associated great vessel and ventricle. Some aortic insufficiency murmurs have a musical quality.

Continuous murmurs

As implied by the name, continuous ("machinery") murmurs occur throughout the cardiac cycle. They indicate that a substantial pressure gradient exists continuously between two connecting vessels. The murmur is not interrupted at the time of S_2; rather, its intensity often is greater at that time. The murmur becomes softer toward the end of diastole, and at slow heart rates it may even become inaudible by mid- or late-diastole. Patent ductus arteriosus (PDA) is by far the most common cause of a continuous murmur. The PDA murmur is loudest high at the left base, dorsal to the pulmonic valve area; it tends to radiate cranially, ventrally, and to the right. The systolic component usually is louder and heard well all over the chest. The diastolic component often is more localized to the left base. The diastolic component (and the correct diagnosis) may be missed if only the cardiac apical area is auscultated.

Continuous murmurs can be confused with concurrent systolic ejection and diastolic decrescendo murmurs (the so-called *to-and-fro* murmur). However, with to-and-fro murmurs, the ejection (systolic) component tapers in late systole, and the S_2 usually can be heard as a distinct sound. The most common cause of a to-and-fro murmur is the combination of subaortic stenosis and aortic valve insufficiency (usually as a result of aortic valve endocarditis). Rarely, stenosis and insufficiency of the pulmonic valve cause this type of murmur. Likewise, both a holosystolic and a diastolic decrescendo murmur can occur together occasionally (such as with a ventricular septal defect and aortic insufficiency from loss of aortic root support); this also is not considered a true *continuous* murmur.

CHAPTER 2

Diagnostic Tests for the Cardiovascular System

CARDIAC BIOCHEMICAL MARKERS

Certain cardiac biomarkers have potential diagnostic and prognostic utility in dogs and cats, especially the cardiac troponins and natriuretic peptides. Cardiac troponins are regulatory proteins attached to the cardiac actin (thin) contractile filaments. Circulating concentrations of cardiac troponin proteins normally are very low; however, myocyte injury allows their leakage into the cytoplasm and extracellular fluid. Cardiac troponin I (cTnI) is the protein usually measured clinically. It is more sensitive for detecting myocardial injury than other biochemical markers of muscle damage (such as cardiac-specific creatine kinase), although it usually does not differentiate the underlying cause. Serum cTnI increases relatively rapidly with severe injury. Because the half-life of this biomarker is short, it can decrease rapidly; the half-life in dogs has been estimated at about 6 hours. Persistently increased cTnI indicates ongoing myocardial damage. Moderate elevations in cTnI can occur in chronic heart disease, although levels often are normal with mild disease. This is thought to reflect myocardial remodeling. Myocardial inflammation, trauma, various acquired and congenital cardiac diseases, and congestive heart failure (CHF) are associated with increased cTnI concentrations, although there can be overlap with clinically normal animals. Strenuous exercise and some noncardiac disease, such as gastric dilatation/volvulus, can be associated with minimal cTnI increases. Renal dysfunction can falsely elevate cTnI, and older animals may have mildly elevated cTnI. Normal Greyhounds appear to have slightly higher cTnI concentration than other breeds. Human assays for cTnI can be used in dogs and cats. Standard (older) cTnI tests have a lower limit of detection of about 0.02 ng/mL with an upper detection limit of about 40 ng/mL. Some labs consider a cTnI concentration of 0.09 ng/mL as the upper limit of normal. Others indicate that cTnI concentrations <0.2 ng/mL are to be considered normal (Troponin I Canine/Feline, IDEXX). A high-sensitivity cTnI test (with a detection range of 0.006-50 ng/mL) has been validated in dogs and cats; this can detect milder cTnI elevation in early to moderate cardiac disease (such as with canine chronic mitral valve disease), although clinical utility remains to be defined.

The natriuretic peptides (or their precursors) can be useful biomarkers for identifying the presence and possibly prognosis of heart disease and CHF. Increased circulating concentrations occur with vascular volume expansion, decreased renal clearance, and when their production is stimulated (as with atrial stretch, ventricular strain and hypertrophy, hypoxia, tachyarrhythmias, and occasionally from ectopic noncardiac production). The natriuretic peptides (atrial [ANP] and brain [BNP]) help regulate blood volume and pressure and antagonize the renin-angiotensin-aldosterone axis, among other effects. They are synthesized as preprohormones, then cleaved to a prohormone, and finally to their inactive amino terminal (NT-pro-) and active carboxyterminal (C-) fragments. The N-terminal fragments remain in circulation longer and reach higher plasma concentrations than the active hormone molecules.

NT-proBNP is measured most often, and the degree of its elevation generally correlates with cardiac disease severity. In animals with dyspnea, NT-proBNP measurement can help the clinician decide whether it is more likely due to CHF or a noncardiac cause. Similar to cTnI, natriuretic peptides are better used as functional markers of cardiac disease rather than of specific pathology. However, circulating (NT-pro)BNP concentrations also can rise with certain noncardiac abnormalities, including renal dysfunction, pulmonary hypertension, and hyperthyroidism (in cats). Species-specific assays are required. Canine and feline NT-proBNP measurement is commercially available (Cardiopet proBNP, Canine and Feline; IDEXX). Plasma concentrations of less than (800-) 900 pmol/L (dogs) and less than 100 pmol/L (cats) are associated with a low risk of clinically significant heart disease. However, some Doberman Pinschers with occult cardiomyopathy have had NT-proBNP concentrations below this cut-off. Dogs with respiratory signs, especially with a murmur, and a plasma NT-proBNP concentration >(1400-)1800 pmol/L are more likely to have

CHF as the underlying cause. Plasma NT-proBNP between 901-1800 pmol/L in dogs represents a "gray" zone, where increased stress on the heart is likely but CHF cannot be reliably differentiated. When NT-proBNP is elevated, additional diagnostic tests (such as thoracic radiography and echocardiography) are recommended. Small breed dogs with chronic mitral valve disease that have a NT-proBNP >1500 pmol/L are at high risk for developing CHF within the next 12 months. An assay for canine plasma C-BNP (Cardio-BNP; ANTECH) is also available; the manufacturer reports a cut-off value of 6 pg/mL as being highly sensitive and specific for CHF in dyspneic dogs.

In cats, a NT-proBNP >100 pmol/L is likely to indicate increased stress or stretch on the myocardium, and follow-up testing with echocardiography, and blood pressure and T4 (in older cats) measurement, is recommended. Hypertension, hyperthyroidism, and renal dysfunction can elevate NT-proBNP levels. Cats with respiratory signs and a NT-proBNP >270 pmol/L are likely to have CHF. For cats with NT-proBNP between 100 and 269 pmol/L, respiratory signs are less likely to be caused by CHF; however, additional testing, as previously noted, is advised to screen for preclinical cardiovascular disease. A point of care (POC), SNAP Feline proBNP test (IDEXX), can be helpful for differentiating CHF from noncardiac causes of dyspnea, although caution with interpretation is advised. For example, a negative POC proBNP SNAP test in a cat with pleural effusion strongly suggests a noncardiac cause; however, a positive test can be less specific. This POC test is better at identifying the absence of moderate to severe cardiac disease (high negative predictive value) in cats, whether symptomatic or not.

CARDIAC RADIOGRAPHY

Thoracic radiographs are important for assessing overall heart size and shape, pulmonary vessels, and lung parenchyma, as well as surrounding structures. Both lateral and dorsoventral (DV) or ventrodorsal (VD) views should be obtained; a three-view study, with both left and right lateral images, usually is preferred. On lateral views, the ribs should be aligned with each other dorsally. On DV or VD views, the sternum, vertebral bodies, and dorsal spinous processes should be superimposed. Consistency in views chosen is important because slight changes in cardiac shadow appearance occur with different positions. For example, the heart tends to look more elongated on VD view in comparison to its appearance on DV view. In general, the DV view yields better definition of the hilar area and caudal pulmonary arteries. Careful (not obliquely tilted) patient positioning is important. Exposure should be made at the time of peak inspiration. On expiration, the lungs appear denser, the heart is relatively larger, the diaphragm may overlap the caudal heart border, and pulmonary vessels are poorly delineated.

Chest conformation must be considered when evaluating cardiac size and shape in dogs because normal cardiac appearance may vary from breed to breed. The cardiac shadow in dogs with a round or barrel-shaped chest has greater sternal contact on lateral view and an oval shape on DV or VD view. In contrast, the heart has an upright, elongated appearance on lateral view and a small, almost circular shape on DV or VD view in narrow- and deep-chested dogs. Because of variations in chest conformation and the influences of respiration, cardiac cycle, and positioning on the apparent size of the cardiac shadow, mild cardiomegaly may be difficult to identify. Also, excess pericardial fat may mimic the appearance of cardiomegaly. The cardiac shadow in puppies normally appears slightly large relative to thoracic size compared with that of adult dogs. Radiographic suggestion of abnormal cardiac size or shape should be considered within the context of the physical examination and other test findings in all cases.

The vertebral heart score (VHS) is one widely used means of assessing cardiomegaly in dogs and cats because there is good correlation between body length and heart size, although chest conformation may have some influence. Measurements for the VHS are obtained using the lateral view (Fig. 2.1) in adult dogs and puppies. The cardiac long axis is measured from the ventral border of the left mainstem bronchus to the most ventral aspect of the cardiac apex. This same distance is compared with the thoracic spine beginning at the cranial edge of T4; length is estimated to the nearest 0.1

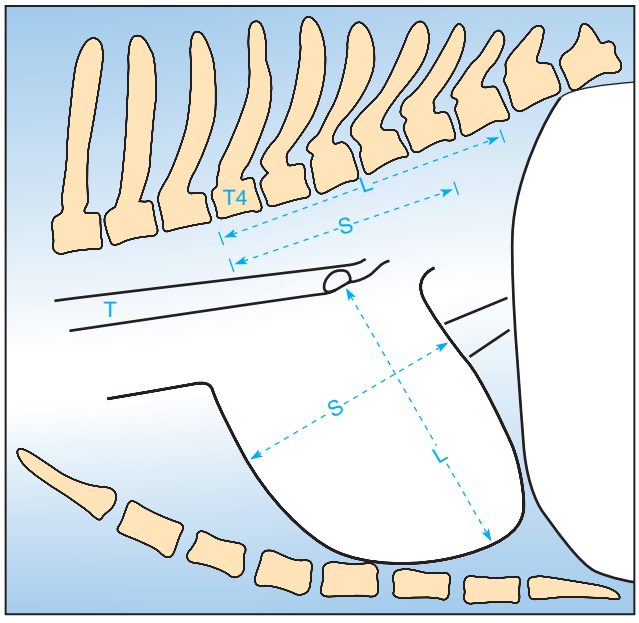

FIG 2.1
Diagram illustrating the vertebral heart score (VHS) measurement method using the lateral chest radiograph. The long-axis (L) and short-axis (S) heart dimensions are transposed onto the vertebral column and recorded as the number of vertebrae beginning with the cranial edge of T4. These values are added to obtain the VHS. In this example, L = 5.8 v, S = 4.6 v; therefore VHS = 10.4 v. *T,* Trachea. (Modified from Buchanan JW, Bücheler J: Vertebral scale system to measure canine heart size in radiographs, *J Am Vet Med Assoc* 206:194, 1995.)

vertebra. The maximum perpendicular short axis is measured in the central third of the heart shadow; the short axis is also measured in number of vertebrae (to the nearest 0.1) beginning with T4. Both measurements are added to yield the VHS. A VHS between 8.5 and 10.5 vertebrae (v) is considered normal for most breeds. However, some variation exists among breeds. In dogs with a short thorax (e.g., Miniature Schnauzer), an upper limit of 11 v may be normal. The VHS in normal Greyhounds, Whippets, and some other breeds such as the Labrador Retriever may normally exceed 11 v, and the VHS range in normal Boxers is thought to extend to 12.6 v. In contrast, an upper limit of 9.5 v may be normal in dogs with a long thorax (e.g., Dachshund).

In cats, the cardiac silhouette on lateral view is aligned more parallel to the sternum than in dogs; this often is accentuated in older cats. Radiographic positioning can influence the relative size, shape, and position of the heart because the feline thorax is so flexible. On lateral view, the normal cat heart is less than or equal to two intercostal spaces (ICSs) in width and less than 70% of the height of the thorax. On DV view the heart is normally no more than one half the width of the thorax. Measurement of VHS is useful in cats as well. From lateral radiographs in cats, mean VHS in normal cats is 7.3 to 7.5 vertebrae (range 6.7-8.1 v). A VHS over 9 v strongly suggests heart disease in cats. In normal cats, the mean short-axis cardiac dimension taken from DV or VD view, compared with the thoracic spine beginning at T4 on lateral view, is 3.4 to 3.5 v, with 4 v identified as the upper limit of normal. In kittens, as in puppies, the relative size of the heart compared with that of the thorax is larger than in adults because of smaller lung volume.

An abnormally small heart shadow (microcardia) usually is caused by markedly reduced venous return from severe hypovolemia. The cardiac apex appears more pointed and may be elevated from the sternum.

CARDIOMEGALY

Generalized enlargement of the cardiac silhouette on plain thoracic radiographs may indicate true cardiomegaly or pericardial distention. With cardiac enlargement, the contours of different chambers usually are still evident, although massive right ventricular (RV) and right atrial (RA) dilation can cause a rounded cardiac silhouette. Fluid, fat, or viscera within the pericardium tends to obliterate these contours and can create a globoid heart shadow (see Fig. 9.1, p. 175 and Fig. 9.4, p. 179). Common differential diagnoses for cardiac enlargement patterns are listed in Box 2.1. A clock-face analogy is often used to identify regions on cardiac silhouette where specific chamber or vascular enlargement typically are seen, especially on DV/VD view.

CARDIAC CHAMBER ENLARGEMENT PATTERNS

Most diseases that cause cardiac dilation or hypertrophy affect two or more chambers. For example, mitral insufficiency leads to left ventricular (LV) and left atrial (LA) enlargement; pulmonic stenosis causes RV enlargement, a main pulmonary artery bulge, and often RA dilation. Even when only one side of the heart is affected, the cardiac silhouette may appear generally enlarged because of chamber superimposition. For descriptive purposes, however, specific chamber enlargement patterns are presented in the following sections. Fig. 2.2 illustrates various patterns of chamber enlargement.

BOX 2.1

Common Differential Diagnoses for Radiographic Signs of Cardiomegaly

Generalized Enlargement of the Cardiac Shadow

Dilated cardiomyopathy
Chronic mitral and tricuspid insufficiency
Pericardial effusion
Peritoneopericardial diaphragmatic hernia
Tricuspid dysplasia
Ventricular or atrial septal defect
Patent ductus arteriosus

Pulmonic stenosis
Tetralogy of Fallot
Atrial septal defect
Pulmonary hypertension
Mass lesion within the right heart

Left Atrium

The left atrium (LA) is the most dorsocaudal chamber of the heart, although its auricular appendage extends to the left and craniad. On lateral view, an enlarged LA bulges dorsally and caudally, elevating the left and sometimes right mainstem bronchus. Severe LA enlargement may be associated with collapse or compression of the left mainstem bronchus.

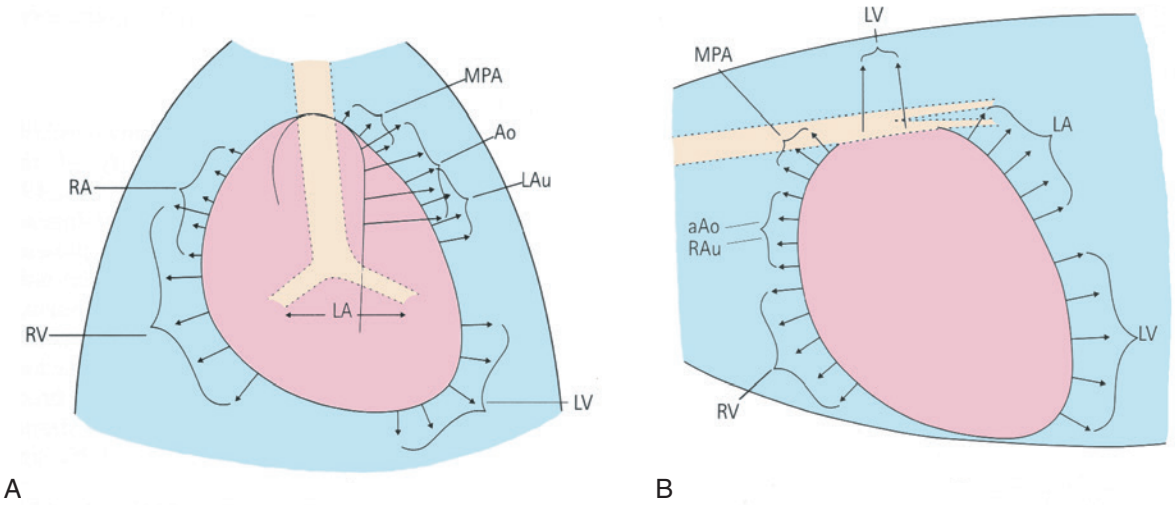

FIG 2.2
Common radiographic enlargement patterns. Diagrams indicating direction of enlargement of cardiac chambers and great vessels in the dorsoventral **(A)** and lateral **(B)** views. *Ao,* Aorta (descending); *LA,* left atrium; *LAu,* left auricle; *LV,* left ventricle; *MPA,* main pulmonary artery; *RA,* right atrium; *RAu,* right auricle; *RV,* right ventricle. (Modified from Ware WA: *Cardiovascular disease in small animal medicine*, London, 2011, Manson Publishing.)

In cats, the caudal heart border is normally quite straight on lateral view; LA enlargement causes subtle to marked convexity of the dorsocaudal heart border with elevation of the mainstem bronchi.

On DV or VD view, the mainstem bronchi tend to be displaced laterally and may curve slightly around a markedly enlarged LA (sometimes referred to as the "bowed-legged cowboy sign"). Concurrent left auricular enlargement causes a bulge in the 2- to 3-o'clock area of the cardiac silhouette. Massive LA enlargement sometimes appears as a large, rounded soft tissue opacity superimposed over the LV apical area on DV (VD) view (Fig. 2.3). In some cats, marked LA enlargement creates a "valentine"-shaped cardiac silhouette (see Fig. 8.7, p. 169) because it causes widening of the cranial aspect of the heart. LA size is influenced by the pressure or volume load imposed, as well as by its duration. For example, mitral regurgitation of gradually increasing severity can cause massive LA enlargement without pulmonary edema, if chamber dilation occurs slowly at relatively low pressure. Conversely, chordae tendineae rupture can acutely cause severe valvular regurgitation with rapid and marked LA pressure increase, leading to pulmonary edema with relatively normal LA size.

Left Ventricle

LV enlargement is manifested on lateral view by a taller cardiac silhouette with elevation of the carina and caudal vena cava (CaVC). The caudal heart border becomes convex, but cardiac apical sternal contact is maintained. On DV/VD view, rounding and enlargement occur in the 2- to 5-o'clock position. Some cats with hypertrophic cardiomyopathy maintain a pointed LV apical appearance.

Right Atrium

RA enlargement expands the cranial heart border and widens the cardiac silhouette on lateral view. Tracheal elevation may occur over the cranial portion of the heart shadow. Bulging of the cardiac shadow on DV/VD view occurs in the 9- to 11-o'clock position. The right atrium (RA) is largely superimposed over the right ventricle (RV), so differentiation from RV enlargement is difficult; however, concurrent enlargement of both chambers is common.

Right Ventricle

RV enlargement (dilation or hypertrophy) usually causes increased convexity of the cranioventral heart border and elevation of the trachea over the cranial heart border on lateral view. With severe RV enlargement and relatively normal left heart size, the apex is elevated from the sternum (see Fig. 10.1, p. 191); the carina and CaVC are also elevated. The degree of sternal contact of the heart shadow is not, by itself, a reliable sign of RV enlargement because of breed variation in chest conformation. On DV/VD view, the heart tends to take on a reverse-D configuration, especially without concurrent left-sided enlargement. The apex may be shifted leftward, and the right heart border bulges to the right.

INTRATHORACIC BLOOD VESSELS

Great Vessels

The aorta and main pulmonary artery dilate in response to chronic arterial hypertension or increased turbulence (poststenotic dilation). Subaortic stenosis causes dilation of the ascending aorta. Because of its location within the mediastinum, dilation here is not easily detected, although widening and increased opacity of the dorsocranial heart

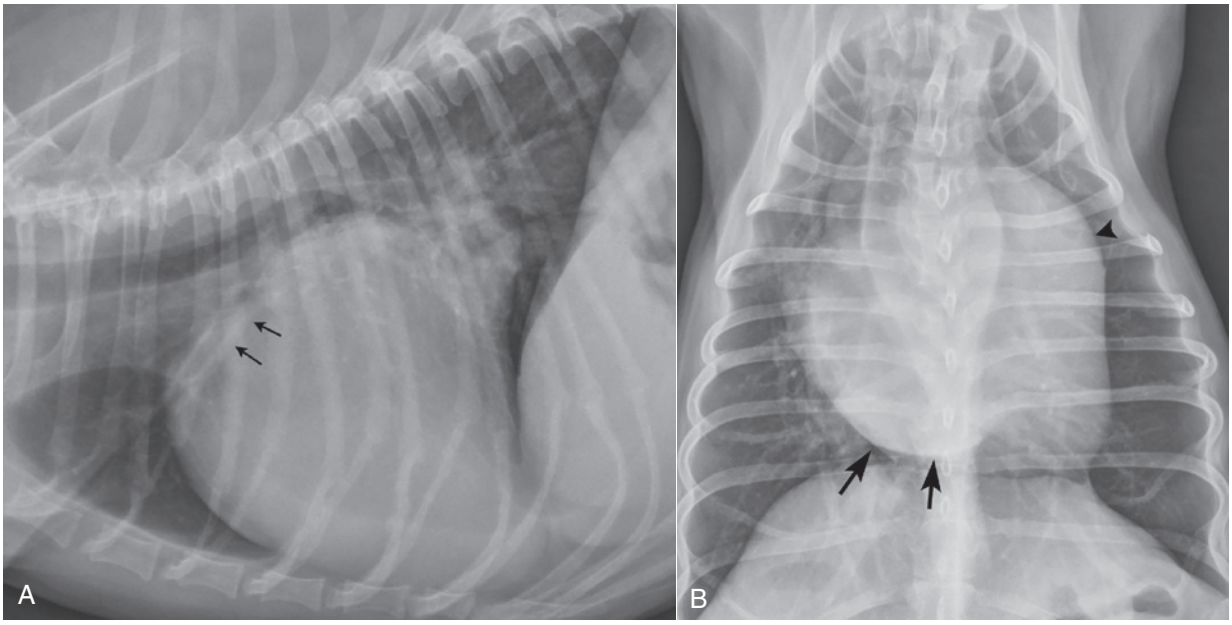

FIG 2.3
Lateral **(A)** and dorsoventral **(B)** views from a dog with chronic mitral regurgitation. Marked left ventricular and atrial enlargement are evident. Dorsal displacement of the carina and pulmonary venous distension *(arrows)* are seen in **A;** the caudal edge of the left atrium *(arrows),* superimposed over the ventricular shadow, and a prominent left auricular bulge *(arrowhead)* are seen in **B.**

shadow may be observed. Patent ductus arteriosus causes a localized dilation in the descending aorta just caudal to the arch where the ductus exits; this "ductus bump" is seen on DV or VD view in the 2- to 3-o'clock position. A prominent aortic arch is more common in cats than dogs. The thoracic aorta of older cats also may have an undulating appearance. Systemic hypertension should be a consideration in these cases.

Severe dilation of the main pulmonary trunk (usually associated with pulmonic stenosis or pulmonary hypertension) can appear as a bulge superimposed over the trachea on lateral radiograph. On DV view in the dog, main pulmonary trunk enlargement causes a bulge in the 1- to 2-o'clock position. In the cat, the main pulmonary trunk is slightly more medial and is usually obscured within the mediastinum.

The CaVC normally angles cranioventrally from the diaphragm to the heart. The width of the CaVC is approximately that of the descending thoracic aorta, although its size changes with respiration. The CaVC-cardiac junction is pushed dorsally with enlargement of either ventricle. Persistent widening of the CaVC could indicate RV failure, cardiac tamponade, pericardial constriction, or other obstruction to right heart inflow. The following comparative findings suggest CaVC distention: CaVC/aortic diameter (at same ICS) greater than 1.5; CaVC/length of the thoracic vertebra directly above the tracheal bifurcation greater than 1.3; and CaVC/width of right fourth rib (just ventral to the spine) greater than 3.5. A thin CaVC can indicate hypovolemia, poor venous return, or pulmonary overinflation.

Lobar Pulmonary Vessels

Pulmonary arteries are located dorsal and lateral to their accompanying veins and bronchi. In other words, pulmonary veins are "ventral and central." On lateral view, the cranial lobar vessels in the nondependent ("up-side") lung are more ventral and larger than those in the dependent lung. The width of the cranial lobar vessels is measured where they cross the fourth rib in dogs or at the cranial heart border (fourth to fifth rib) in cats. These vessels are normally 0.5 to 1 times the diameter of the proximal one third of the fourth rib. The DV view is best for evaluating the caudal pulmonary vessels. The caudal lobar vessels that are 0.5 to 1 times the width of the ninth (dogs) or tenth (cats) rib at the point of intersection are normal. However, in many normal dogs, the right caudal pulmonary vessels are slightly wider than the ninth rib. This may be true in cats as well. Four pulmonary vascular patterns are usually described: overcirculation, undercirculation, prominent pulmonary arteries, and prominent pulmonary veins.

An overcirculation pattern occurs when the lungs are hyperperfused, as occurs with left-to-right shunts, overhydration, and other hyperdynamic states. Pulmonary arteries and veins are both prominent. The increased perfusion also generally increases lung opacity.

Pulmonary undercirculation is characterized by thin pulmonary arteries and veins, along with increased pulmonary lucency. Severe dehydration, hypovolemia, obstruction to RV inflow, right-sided CHF, and tetralogy of Fallot can cause this pattern. Some animals with pulmonic stenosis appear to

have pulmonary undercirculation. Overinflation of the lungs or overexposure of radiographs also minimizes the appearance of pulmonary vessels.

Pulmonary arteries that are larger than their accompanying veins indicate pulmonary arterial hypertension. The pulmonary arteries become dilated, tortuous, and blunted, and visualization of the terminal portions is lost. Heartworm disease often causes this pulmonary vascular pattern, in addition to patchy to diffuse interstitial pulmonary infiltrates.

Prominent pulmonary veins are a sign of pulmonary venous congestion, usually from left-sided CHF. On lateral view, the cranial lobar veins are larger and denser than their accompanying arteries and may sag ventrally. Dilated, tortuous pulmonary veins may be seen entering the dorsocaudal aspect of the enlarged LA in dogs and cats with chronic pulmonary venous hypertension. However pulmonary venous dilation is not always visualized in patients with left-sided heart failure. In cats with acute cardiogenic pulmonary edema, enlargement of both pulmonary veins and arteries is common.

PATTERNS OF PULMONARY EDEMA

Pulmonary interstitial fluid accumulation increases pulmonary opacity. Pulmonary vessels appear ill-defined, and bronchial walls look thick as interstitial fluid accumulates around vessels and bronchi. As pulmonary edema worsens, areas of fluffy or mottled fluid opacity progressively become more confluent. Alveolar edema causes greater opacity in the lung fields and obscures vessels and outer bronchial walls. The air-filled bronchi appear as lucent, branching lines surrounded by fluid density (air bronchograms). Interstitial and alveolar patterns of pulmonary infiltration can be caused by many pulmonary diseases, as well as by cardiogenic edema. The distribution of these pulmonary infiltrates is important, especially in dogs. Cardiogenic pulmonary edema in dogs classically is located in dorsal and perihilar areas and is often bilaterally symmetric. Nevertheless, some dogs develop an asymmetric or concurrent ventral distribution of cardiogenic edema. The distribution of cardiogenic edema in cats is usually uneven and patchy, although some cats have a diffuse, uniform pattern. The infiltrates can be distributed throughout the lung fields or concentrated in ventral, middle, or caudal zones. Both the radiographic technique and the phase of respiration influence the apparent severity of interstitial infiltrates. Other abnormalities on thoracic radiographs are discussed in Chapter 20.

OTHER IMAGING TECHNIQUES

Cardiac Computed Tomography and Magnetic Resonance Imaging

Cardiac computed tomography (CT) and magnetic resonance imaging (MRI) are now more widely available in veterinary practice and provide greater anatomic detail than plain radiographs. Their requirements for greater technical expertise, study duration, and expense, as well as the need for heavy sedation or general anesthesia, may be limitations in some cases. CT combines multiple radiographic image slices to produce detailed cross-sectional images from reconstructed three-dimensional (3-D) orientations. MRI uses radio waves and a magnetic field, rather than ionizing radiation, to create detailed tissue images. These techniques can allow greater differentiation among cardiovascular structures, varying tissue types, and the blood pool. Identification of pathologic morphology, such as from cardiac congenital malformations or mass lesions, is a major application. These modalities also are more sensitive than plain radiographs for detecting pulmonary nodules. Because cardiac movement during the imaging sequence reduces image quality, physiologic (electrocardiographic) gating is used for optimal cardiac imaging. Evaluation of cardiac volumes, myocardial function, perfusion, or valve function also may be performed. Different cardiac MRI imaging sequences are used depending on the application or type of information desired. For example, "black blood" MRI scans allow better assessment of anatomical details and abnormalities, whereas "bright blood" sequences are used to evaluate cardiac function.

Nuclear Cardiology

Radionuclide, or nuclear, methods of evaluating cardiopulmonary function are available at some veterinary referral centers. These techniques can provide noninvasive assessment of cardiac output, ejection fraction, and other measures of cardiac performance, as well as myocardial blood flow and metabolism.

ECHOCARDIOGRAPHY

Echocardiography (cardiac ultrasonography) is an important noninvasive tool for imaging the heart and surrounding structures. Anatomic relationships and cardiac function can be assessed by evaluating cardiac chamber size, wall thickness, wall motion, valve configuration and motion, and proximal great vessels and other parameters. Pericardial and pleural fluid are easily detected, and mass lesions within and adjacent to the heart can be identified. This section provides an overview of the basic echocardiographic examination, and an introduction to Doppler echocardiography and other modalities. Readers looking for more detail are referred to the excellent, in-depth Echocardiography chapter by Bonagura and Luis-Fuentes (see Suggested Readings list).

Like other diagnostic modalities, echocardiography is best used within the context of a thorough history, cardiovascular examination, and other appropriate tests. Technical expertise is essential to adequately perform and interpret a complete echocardiographic examination. The importance of the echocardiographer's skill and understanding of normal and abnormal cardiovascular anatomy and physiology cannot be overemphasized. Yet often, some important information is attainable with even rudimentary echocardiographic or "thoracic focused assessment with sonography for trauma" (TFAST) training and experience. For example, a large pericardial effusion, marked LA enlargement, and severe LV dilation with poor versus vigorous ventricular wall

motion are readily detectable and can guide initial management. Nevertheless, follow-up evaluation by a veterinary cardiologist or other individual with advanced echocardiographic training usually is advisable. In addition, a lung ultrasound examination (see p. 33) could rapidly narrow the differential diagnosis list and help guide initial therapy in patients with respiratory signs.

BASIC PRINCIPLES

Echocardiography uses pulsed, high-frequency sound waves that are reflected, refracted, and absorbed by body tissue interfaces. Only the reflected portion can be received and processed for display. Transducer frequency, power output, and various processing controls influence the intensity and clarity of the displayed echo images. Individual patient characteristics also affect the quality of images obtained. Sound waves do not travel well through bone (ribs) and air (lungs); these structures may preclude good visualization of the entire heart. Several echo modalities commonly are used for clinical examinations: two-dimensional (2-D, real-time), M-mode, and Doppler modalities. Each has important applications (described later).

Sound waves are propagated through soft tissue at a characteristic speed (≈1540 m/sec), which allows the location and size of various structures to be determined in relation to the origin of the ultrasound beam at any point in time. With 2-D and M-mode echocardiography, stronger echoes are returned when the ultrasound beam is oriented perpendicular to the imaged structure. Stronger echoes also result when there is greater mismatch in acoustic impedance (related to tissue density) between two adjacent tissues, because this produces a more reflective boundary. Very reflective interfaces such as bone/tissue or air/tissue interfere with imaging of weaker echoes from deeper tissue interfaces. The ultrasound beam decreases in intensity as it penetrates through the body's tissues (because of beam divergence, absorption, scatter, and reflection of wave energy at tissue interfaces); echoes returning from deeper structures tend to be weaker.

In general, higher frequency ultrasound energy permits better resolution of small structures because of the beam's characteristics (longer near field and lesser far field divergence). However, higher frequencies have less penetrating ability as more energy is absorbed and scattered by the soft tissues. Conversely, a transducer that produces lower frequencies provides greater penetration depth but less well-defined images. Frequencies generally used for small animal echocardiography range from about 3.5 megahertz (MHz) for large dogs to greater than 10 MHz for cats and small dogs. However, image optimization also involves many other technical factors and settings that can vary among manufacturers and are beyond the scope of this chapter.

Strongly reflective tissues are referred to as being *hyperechoic* or *of increased echogenicity.* Poorly reflecting tissues are *hypoechoic*; fluid, which does not reflect sound, is *anechoic* or sonolucent. Tissue behind an area of sonolucency appears hyperechoic because of acoustic enhancement. On the other hand, through-transmission of the ultrasound beam is blocked by a strongly hyperechoic object (such as a rib), and an acoustic shadow (where no image appears) is cast behind the object.

For most echocardiographic examinations, the animal is gently restrained in lateral recumbency; better-quality images usually are obtained when the heart is imaged from the recumbent side. For this the animal is placed on a table or platform with an edge cut out, which allows the echocardiographer to position and manipulate the transducer from the animal's dependent side. Some animals can be adequately imaged while standing; however, patient movement often is challenging. Shaving a small area of hair over the transducer placement site improves skin contact and usually image clarity. Coupling gel is applied to produce air-free contact between skin and transducer. The transducer is placed over the area of the precordial impulse (or other appropriate site), and its position is adjusted to find a good "acoustic window" that allows clear visualization of the heart. The right and left parasternal transducer positions are used most often. Minor adjustment of the animal's forelimb or torso position may be required to obtain a good acoustic window. Once the heart is located, the transducer is angled or rotated to obtain the desired views. Controls for factors such as beam strength, focus, and postprocessing parameters are adjusted as needed to optimize the image. For 2-D and M-mode studies, better image definition is achieved when the ultrasound beam is oriented perpendicular to the cardiac structures. Image artifacts are common and can mimic a cardiac abnormality. Sometimes a lesion is suspected that is not truly present; other times an actual abnormality is obscured. If a suspected lesion can be visualized in more than one imaging plane, this provides greater assurance that it is real.

A basic echocardiographic examination is obtained from the right parasternal position and includes standard 2-D imaging planes and carefully obtained M-mode views. A more complete examination includes standard left parasternal views as well as any other modified views needed to further evaluate specific lesions. Doppler evaluation provides important additional information. A complete examination may be quite time consuming in some patients.

Echocardiography usually can be performed with minimal or no chemical restraint. For animals that will not lie quietly with gentle manual restraint, light sedation is helpful. Sedation protocols for dogs include either butorphanol (0.2-0.3 mg/kg, IV or IM), or butorphanol (same dose) mixed with acepromazine (0.02-0.03 mg/kg, IV or IM), or buprenorphine (0.005-0.01 mg/kg, IV or IM) combined with acepromazine (0.02-0.03 mg/kg, IV or IM). For cats, butorphanol (0.2-0.25 mg/kg IM) mixed with acepromazine (0.05-0.1 mg/kg IM) or midazolam (0.2 mg/kg IM) often is adequate after a 20 to 30 minute rest period in a quiet room. However, some cats require more intense sedation. A combination of butorphanol (0.2-0.4 mg/kg IM) and alfaxalone (1-2 mg/kg IM) can be effective and does not raise heart rate like ketamine does. Predictably fractious cats also can be pretreated at home (~2-3 hours before the echo appointment) with gabapentin at 50 mg (for small cats) to 150 mg

(for very large cats); have the owner mix the contents of the appropriately sized capsule with a tiny amount of wet food and administer on an empty stomach. If additional sedation is required to perform the echo, a light dose of butorphanol can be effective. Other strategies have included acepromazine (0.1 mg/kg IM) followed in 15 minutes by ketamine (2 mg/kg [or 5-10 mg/cat] IV), although this can undesirably increase heart rate.

TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Two-dimensional echocardiography displays a plane of tissue (depth and width). Anatomic structure and motion, including changes caused by various acquired or congenital abnormalities, are evident; actual blood flow is not visualized with 2-D or M-mode imaging alone.

Common Two-Dimensional Echocardiographic Views

A variety of planes can be imaged from several chest wall locations. Most standard views are obtained from either the right or left parasternal positions (directly over the heart and close to the sternum). Images sometimes are obtained from the subxiphoid (subcostal) position. Long-axis views are obtained with the imaging plane parallel to the long axis of the heart; short-axis views are perpendicular to this plane (Figs. 2.4 to 2.9). Images are described by the location of the transducer and the imaging plane used (for example, right

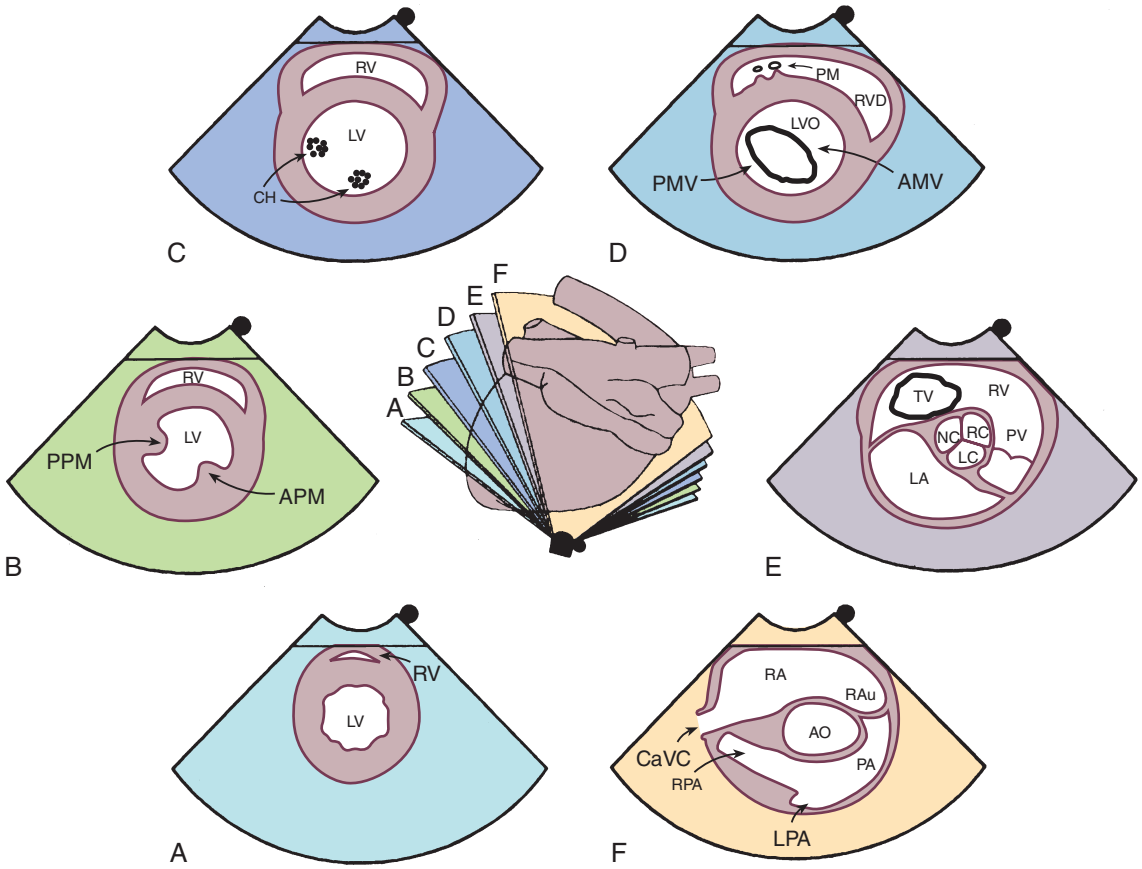

FIG 2.4
Two-dimensional short-axis echocardiographic views from the right parasternal position. The center diagram indicates the orientation of the ultrasound beam used to image cardiac structures at the six levels shown. Several of these positions guide M-mode beam placement, and occasionally can be used for Doppler evaluation of tricuspid and pulmonary flows. Corresponding echo images are shown clockwise from the bottom. **(A)** Apex. **(B)** Papillary muscle. **(C)** Chordae tendineae. **(D)** Mitral valve. **(E)** Aortic valve. **(F)** Pulmonary artery. *AMV,* Anterior (septal) mitral valve cusp; *AO,* aorta; *APM,* anterior papillary muscle; *CaVC,* caudal vena cava; *CH,* chordae tendineae; *LA,* left atrium; *LPA,* left pulmonary artery; *LV,* left ventricle; *LVO,* left ventricular outflow tract; *PA,* pulmonary artery; *PM,* papillary muscle; *PMV,* posterior mitral valve cusp; *PPM,* posterior papillary muscle; *PV,* pulmonary valve; *RA,* right atrium; *RAu,* right auricle; *RC, LC, NC,* right, left, and noncoronary cusps of aortic valve; *RPA,* right pulmonary artery; *RV,* right ventricle; *RVO,* right ventricular outflow tract; *TV,* tricuspid valve. (Modified from Thomas WP et al.: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, *J Vet Intern Med* 7:247, 1993.)

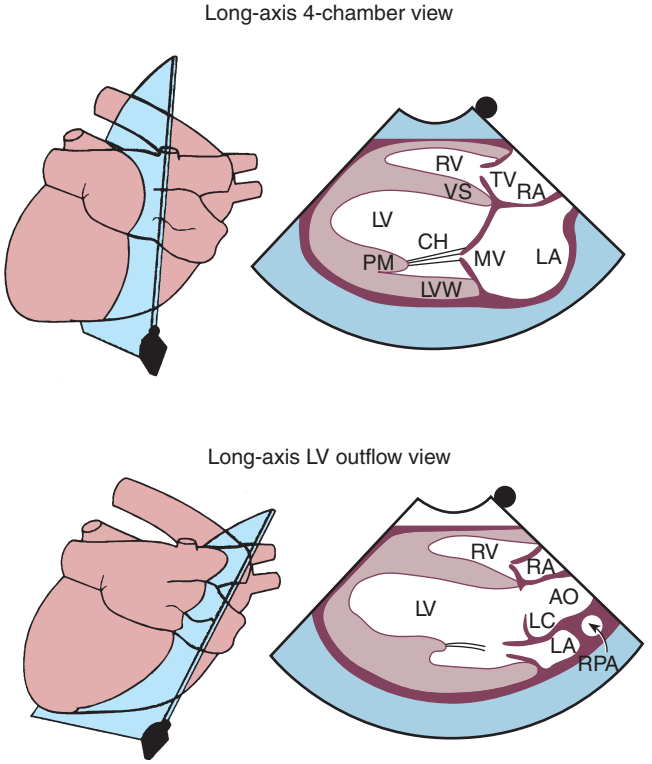

FIG 2.5
Two-dimensional long-axis echocardiographic views from right parasternal position. Each diagram on the left indicates the location of the ultrasound beam as it transects the heart from the right side, resulting in the corresponding echo image on the right. Long-axis four-chamber (left ventricular inflow) view is above. Long-axis view of the left ventricular outflow region is below. *AO,* Aorta; *CH,* chordae tendinae; *LA,* left atrium; *LC,* left coronary cusp of aortic valve; *LV,* left ventricle; *LVW,* left ventricular wall; *MV,* mitral valve; *PM,* papillary muscle; *RA,* right atrium; *RPA,* right pulmonary artery; *RV,* right ventricle; *TV,* tricuspid valve; *VS,* interventricular septum. (Modified from Thomas WP et al.: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, *J Vet Intern Med* 7:247, 1993.)

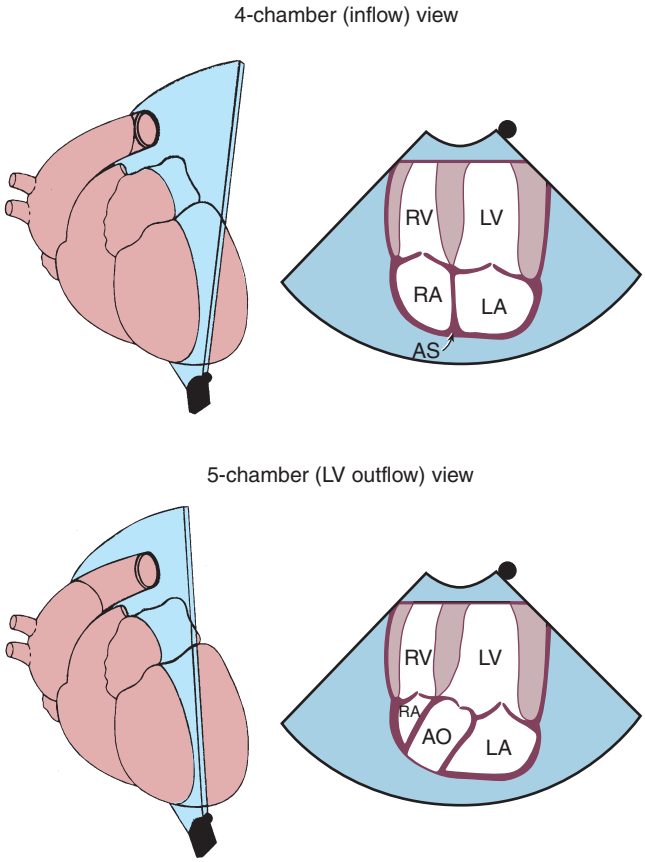

FIG 2.6
Left caudal (apical) parasternal position. Four-chamber view optimized for ventricular inflow is above. Five-chamber view optimized for left ventricular outflow is below. These views provide good Doppler velocity signals from the mitral and sometimes the aortic valve regions. *AO,* Aorta; *AS,* interatrial septum; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Modified from Thomas WP et al.: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, *J Vet Intern Med* 7:247, 1993.)

parasternal short-axis view, left cranial parasternal long-axis view). Two-dimensional imaging allows an overall assessment of cardiac chamber orientation, size, and wall thickness. The RV wall normally is about one third the thickness of the LV free wall and should be no greater than half its thickness. The size of the RA and RV chambers is compared with that of the LA and LV; the right parasternal long axis and left apical four-chamber views are most useful for this. All valves and related structures, as well as the great vessels, also are systematically examined. Any suspected abnormality should be scanned using multiple planes to further verify and delineate it.

End diastolic and peak systolic LV internal dimensions and wall thicknesses usually are obtained using M-mode, but appropriately timed 2-D frames also can be used. Several methods can be used to estimate LV volume and wall mass. LA size should be assessed from 2-D rather than M-mode images. Several methods for measuring LA size have been described, and they are not interchangeable. The method used should be specified, to minimize variability in results, especially for comparative and repeated studies.

One method is to measure the end-systolic LA (LAs) internal cranial-caudal diameter (top-to-bottom on screen), just before mitral valve opening, using a right parasternal long-axis four-chamber view optimized for the mitral valve/LV inflow tract and excludes the aortic root. The measurement line should be positioned mid-atrium and aligned parallel to the mitral annulus. In cats, this LAs dimension normally is less than 16 mm, although adjustment of this cut-off up or down is appropriate in very small or very large cats, respectively. A LAs diameter in cats greater than ~22 mm is considered severe LA enlargement and indicates greater risk for thromboembolism. Because dogs have greater

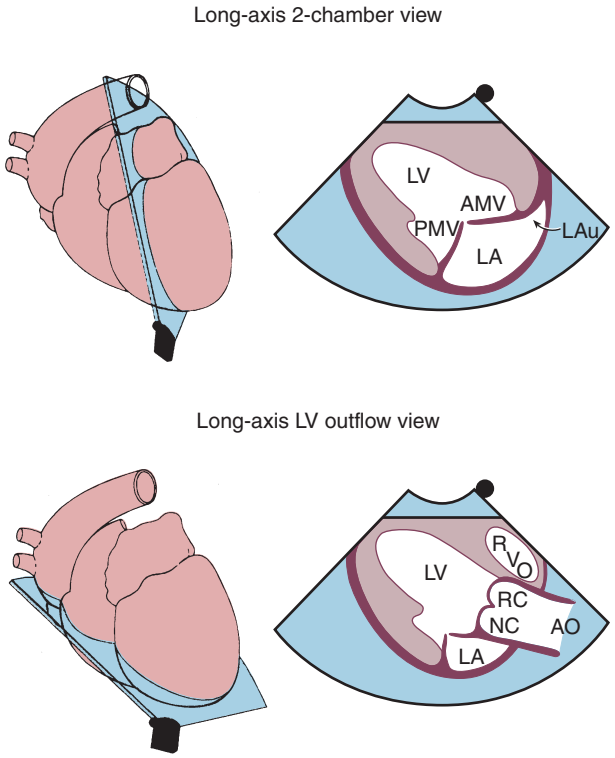

FIG 2.7
Left caudal (apical) parasternal two-dimensional views optimized for left ventricular inflow and left auricle (2-chamber view; above) and left ventricular outflow (3-chamber view; below); the outflow view sometimes is obtained with the aorta pointing to the lower left of the image. The 3-chamber view can provide good alignment with left ventricular outflow velocity (although the subcostal position [not illustrated here] is often better). *AMV,* Anterior (septal) mitral valve cusp; *AO,* aorta; *LA,* left atrium; *LAu,* left auricle; *LV,* left ventricle; *PMV,* posterior mitral valve cusp; *RC, NC,* right and noncoronary cusps of aortic valve; *RVO,* right ventricular outflow tract. (Modified from Thomas WP et al.: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, *J Vet Intern Med* 7:247, 1993.)

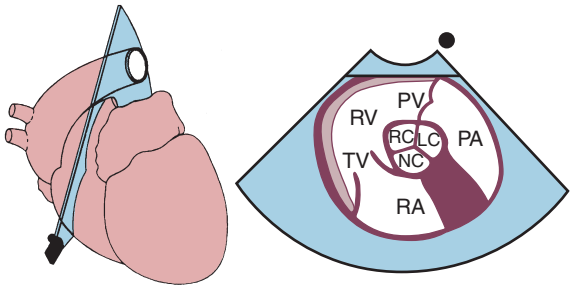

FIG 2.8
Left cranial parasternal short-axis view optimized for right ventricular inflow and outflow. This view is useful for Doppler interrogation of tricuspid and pulmonary artery flows. *PA,* Pulmonary artery; *PV,* pulmonary valve; *RA,* right atrium; *RC, LC, NC,* right, left, and noncoronary cusps of aortic valve; *RV,* right ventricle; *TV,* tricuspid valve. (Modified from Thomas WP et al.: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, *J Vet Intern Med* 7:247, 1993.)

body size variation, the LA dimension usually is compared with an aortic measurement, both for the long-axis, systolic dimension as well as for the short-axis, diastolic dimension (see next paragraph). Regarding the long axis, LAs comparison, some clinicians advocate using the distance between the open aortic leaflets (at the valve hinge points) during midsystole (AoVs), measured from a right long-axis view optimized for the LV outflow tract and aortic valve. The ratio of Las:AoVs in normal dogs is thought to be <2.6. However, if the 2-D aortic root diameter is measured across the sinuses of Valsalva, the ratio of LAs:aortic root in normal dogs usually is ≤1.9.

Another LA size assessment method, often used in dogs, employs the right parasternal short-axis view and compares the LA dimension in diastole (LAd) to the aortic diameter. This sometimes is called the "Scandinavian" method. The 2-D image is optimized to include the LA and auricle, as well as the aortic valve. The internal LA dimension is measured in early diastole, along a line extending from and parallel to the commissure formed by the closed left and noncoronary aortic valve cusps. The aortic dimension measurement, from the same frozen 2-D frame, also aligns with the same valve commissure and includes only one sinus of Valsalva. The LAd:aortic root ratio using this short-axis method in normal dogs usually is between 1.3 to 1.4. Ratios over 1.5 to 1.6 indicate LA enlargement. However, LA size evaluation using this short-axis method can be confounded by the fact that maximal LA size is not measured, by variability in the imaging plane used among echocardiographers, and by inconsistent measurement timing, especially when the aortic valve leaflets are not clearly imaged.

M-MODE ECHOCARDIOGRAPHY

This modality provides a one-dimensional (depth) view into the heart. M-mode images represent echoes from various tissue interfaces along the axis of the beam (displayed vertically on the screen). These echoes, which move during the cardiac cycle, are displayed against time (on the horizontal axis). Thus the "wavy" lines seen on these recordings correspond to the positions of specific structures in relation to the transducer, as well as to each other at any point in time. Accurate M-mode beam placement, using a moveable cursor line superimposed on an appropriate 2-D (real-time) image, is essential for measurement purposes. M-mode images usually provide cleaner resolution of cardiac borders than 2-D images because of their higher sampling rate. Measurements of cardiac dimensions and motion throughout the cardiac cycle often are more accurately obtained from M-mode tracings, especially when coupled with a simultaneously recorded ECG (or phonocardiogram). Difficulty in achieving consistent and accurate

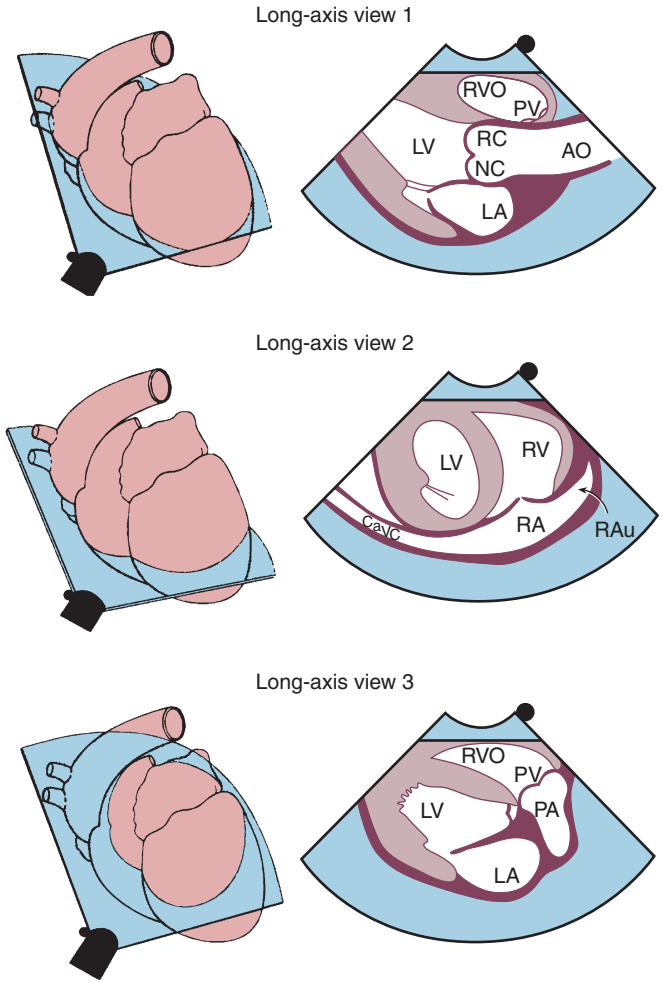

FIG 2.9
Left cranial parasternal long-axis views optimized for aortic root (above), right atrium and auricle (middle), and right ventricular outflow and main pulmonary artery (below). These views are used to evaluate the heart base and can provide good Doppler signals for tricuspid and pulmonary flows. *AO,* Aorta; *CaVC,* caudal vena cava; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *PV,* pulmonary valve; *RA,* right atrium; *RAu,* right auricle; *RC, NC,* right and noncoronary cusps of aortic valve; *RV,* right ventricle; *RVO,* right ventricular outflow tract. (Modified from Thomas WP et al.: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, *J Vet Intern Med* 7:247, 1993.)

beam placement for standard measurements and calculations can be a limitation.

M-Mode Views

Standard M-mode views are obtained from the right parasternal transducer position. The M-mode cursor is positioned with 2-D guidance using the right parasternal short-axis view; angling the transducer so that the LV appears as round as possible helps ensure the ultrasound beam is oriented perpendicular to the axis of the LV. Some clinicians prefer using the long-axis view to obtain images for ventricular measurements; however, it may be more difficult to verify that the beam is transecting the LV at its maximum dimension. Precise positioning of the ultrasound beam within the heart (perpendicular to the structures to be measured) and clear endocardial images are essential for accurate M-mode measurements and calculations. For example, papillary muscles within the LV must be avoided when measuring free-wall thickness. Fig. 2.10 illustrates standard M-mode views. In cases where the M-mode cursor cannot be optimally aligned (e.g., in animals with focal or asymmetric hypertrophy), wall thickness measurements from 2-D images are preferred, although in animals with a high heart rate, obtaining true end-diastolic frames can be uncertain.

Common Measurements and Normal Values

The standard dimensions measured with M-mode and their timing also are indicated in Fig. 2.10. The "leading edge" technique is used when possible (i.e., from the edge closest to the transducer [leading edge] of one side of the dimension to the leading edge of the other). In this way, only one endocardial thickness is included in the measurement. LV wall and interventricular septal thicknesses, as well as LV chamber dimensions, should be determined at the level of the chordae tendineae rather than the apex or mitral valve level. Measurements also may be taken from 2-D images if they are of high resolution, and frames from the appropriate times in the cardiac cycle are used. Body size greatly influences echocardiographic measurements, especially in dogs. However, the relationship between body weight or surface area and cardiac dimensions is not linear. Rather, cardiac linear dimensions are more closely related to body length, which is proportional to body weight to the ⅓ power ($BW^{⅓}$). Allometric scaling has been used to generate guidelines for common cardiac dimension measurements in normal dogs (see Table 2.1). Mean values are listed for selected weights along with 95% prediction intervals. However, these prediction intervals are quite wide, especially for larger dogs, and may encompass some degree of LV enlargement. Somatotype and breed may have additional influence on normal echo values in some dogs. For example, healthy Boxers can have increased LV wall thickness and smaller aortic dimensions relative to nonBoxer dogs, although chamber dimensions are comparable. Slightly higher LV wall thickness and chamber dimensions have been observed in Greyhounds compared with other dogs of comparable weight. Endurance training also affects measured parameters, reflecting the increased cardiac mass and volume associated with frequent and sustained strenuous exercise. Normal measurements in cats are more uniform but also are influenced by body size (Table 2.2). Chamber volume and ejection fraction are better estimated from optimized 2-D frames using the modified Simpsons' method rather than M-mode images because of the greater potential for inaccurate geometric assumptions from one-dimensional measurements (see Suggested Readings for further information). The right parasternal four-chamber

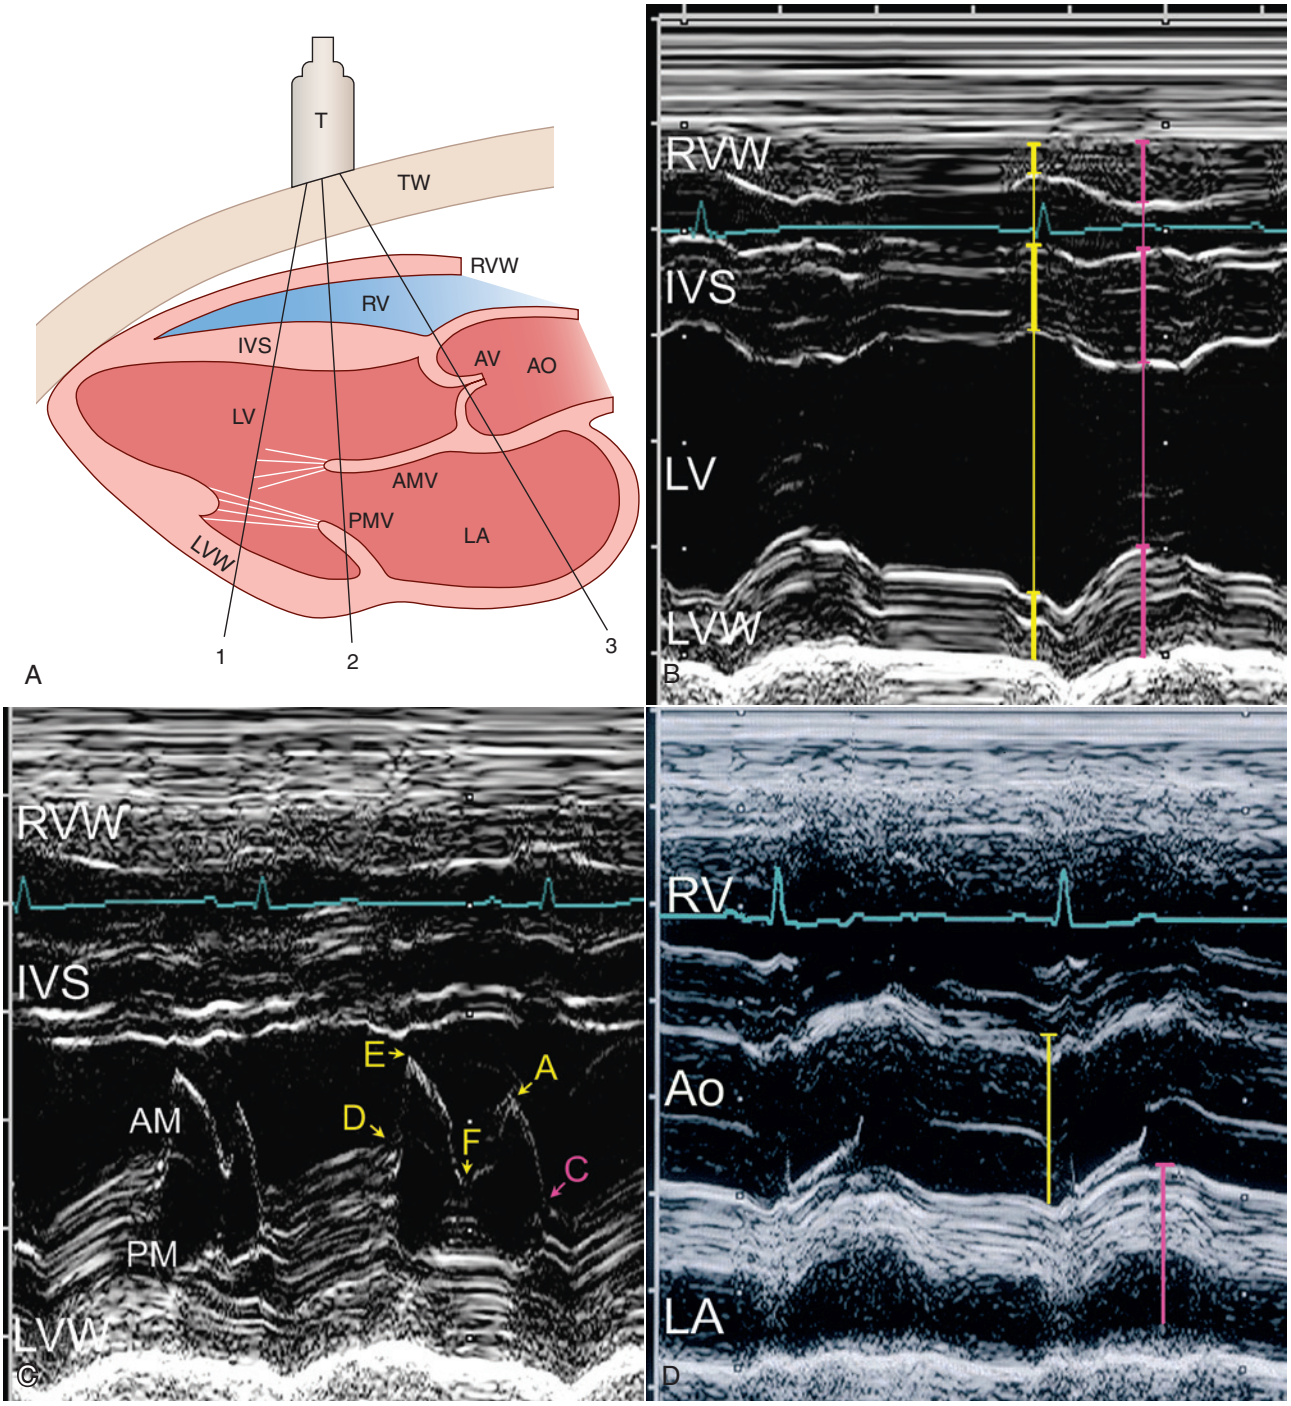

FIG 2.10
Common M-mode views. **(A)** Diagram indicates the approximate orientation of the one-dimensional ultrasound beam through the heart to achieve the corresponding M-mode images. **(B)** Image at the level of the chordae tendineae within the left ventricular lumen (LV), corresponding to cursor line "1" in **A.** A lead II ECG is recorded with the echo images for timing within the cardiac cycle. End diastole occurs at the onset of the QRS complex (yellow time/measure line); end systole (pink time/measure line) is the time when the dimension between the interventricular septum (IVS) and left ventricular free wall (LVW) is smallest. Internal dimensions of the LV are measured from the leading (anterior) edge of the left endocardial wall of the IVS to the leading edge (luminal surface) of the posterior LVW. The thickness of the IVS is measured from the right endocardial surface of the IVS to the leading edge of the left endocardial septal wall at end diastole and end systole; the posterior LVW is measured at the same times from the endocardial surface to (but not including) the leading edge of the epicardial echoes. **(C)** Image at the mitral valve level, cursor line "2" in **A.** The motion of the anterior (AM) and posterior (PM) mitral leaflets is described by the letters shown. Diastolic opening of the valve occurs at point D, and systolic closing occurs at point C (see text for more information). **(D)** Image at the aortic root (Ao) level "3" (where valve cusps are seen). Diameter is measured at end diastole from the leading (anterior) edge of the anterior aortic wall to the leading edge of the posterior wall. The left atrium (LA; usually the auricular region) is below the aorta (pink measure line, in systole); however, the M-mode dimension underestimates LA size in most animals (see text). *RV,* Right ventricular lumen; *RVW,* right ventricular wall.

FS (25-) 27% to 40 (-47)%.
EPSS ≤ 6 mm.
Guidelines for approximate normal canine M-mode measurements based on allometric scaling to body weight (kg) to the ⅓ power ($BW^{⅓}$). Values may not be accurate for dogs that are extremely obese or thin, old or young, or athletic. Upper end of $LVID_D$ prediction interval also may encompass mild LV dilation.
AO, Aortic root; *BW,* body weight; *EPSS,* mitral E-point septal separation; *FS,* fractional shortening; IVS_D, interventricular septal thickness in diastole; IVS_S, interventricular septal thickness in systole; *LA,* left atrium; $LVID_D$, left ventricular diameter in diastole; $LVID_S$, left ventricular diameter in systole; LVW_D, left ventricular free wall thickness in diastole; LVW_S, left ventricular free wall thickness in systole.
*M-mode average measurement values and 95% prediction intervals for normal dogs.
†Note that M-mode LA measurement does not reflect maximum LA diameter (see text, p. 26). LA size should be assessed from appropriate 2-D images (see p. 21).
(From Cornell CC et al.: Allometric scaling of M-mode cardiac measurements in normal adult dogs, *J Vet Intern Med* 18:311, 2004.)

long-axis view, optimized for greatest LV size, often is better for assessing LV volume than the left apical view.

Diastolic measurements are made at the onset of the QRS complex of a simultaneously recorded ECG. Systolic measurements of the LV are made from the point of peak downward motion of the septum to the leading edge of the LV free-wall endocardium at the same instant. The septum and LV wall normally move toward each other in systole, although their peak movement may not coincide if electrical activation is not simultaneous. Paradoxic septal motion, in which the septum seems to move away from the LV wall and toward the transducer in systole, occurs in some cases of RV volume and/or pressure overload. This abnormal septal motion also can be visualized on 2-D images; it precludes accurate assessment of LV function using fractional shortening (FS; also called % delta D).

EPSS ≤ 4 mm.
AO, Aortic root; *EPSS,* mitral E-point septal separation; *FS,* fractional shortening; IVS_D, interventricular septum at end diastole; IVS_S, interventricular septum at end systole; *LA,* left atrium (systole); $LVID_D$, left ventricular internal diameter at end diastole; $LVID_S$, left ventricular internal diameter at end systole; LVW_D, left ventricular wall at end diastole; LVW_S, left ventricular wall at end systole.
*These values are based on the author's experience and compilation of published studies. Measurements can be higher in large cats. Ketamine increases heart rate and decreases $LVID_d$. See Suggested Readings for additional references.
†Orientation of M-mode cursor across the LA is variable among animals; maximum LA dimension is best assessed by two-dimensional imaging.

The FS commonly is used to estimate LV systolic function in dogs and cats. FS is the percent change in LV dimension from diastole to systole ([LVIDd − LVIDs]/LVIDd × 100). Most normal dogs have an FS between (25%-) 27% and 40 (-47)%; FS in most cats is between 35% and 65%, although there is some variability. It is important to remember that this index, like others taken during the cardiac ejection phase, has the important limitation of being dependent on ventricular loading conditions. For example, reduced LV afterload (as occurs with mitral insufficiency, ventricular septal defect, or peripheral vasodilation) facilitates blood flow out of the LV during systole, and therefore produces a smaller end-systolic dimension and greater FS. This "enhancement" of FS occurs even though intrinsic myocardial contractility is not increased. The exaggerated FS common in patients with severe mitral regurgitation creates the appearance of increased contractility in those with normal myocardial function and can mask deteriorating contractile function. Regional wall motion abnormalities and arrhythmias also can affect the FS.

The use of the calculated end-systolic volume index (ESVI) has been suggested as a more accurate way to assess myocardial contractility in the presence of mitral regurgitation in dogs. This index (ESV/m^2 body surface area) compares ventricular size after ejection with body size rather than with the dilated end-diastolic ventricular size. LV volumes should be estimated from 2-D rather than M-mode images. Extrapolation from human studies to dogs suggests an ESVI less than 30 mL/m^2 is normal, 30 to 60 mL/m^2 indicates mild LV systolic dysfunction, 60 to 90 mL/m^2 represents moderate LV dysfunction, and greater than 90 mL/m^2 indicates severe LV dysfunction. Other methods also can be used to assess LV function.

Mitral valve motion is evaluated with M-mode also. The anterior (septal) leaflet is most prominent; its motion has an "M" configuration. The posterior (parietal) leaflet is smaller; its motion mirrors the anterior leaflet, appearing as a "W." Tricuspid valve motion is similar. The mitral valve motion pattern is identified by letters (Fig. 2.10C). Point E occurs at maximal opening of the valve during the rapid ventricular filling phase. The valve drifts into a more closed position (point F) at the end of rapid ventricular filling. Atrial contraction causes the valve to open again (point A). At rapid heart rates, the E and A points often merge. The mitral valve closes (point C) at the onset of ventricular contraction. In normal animals, the mitral E point is close to the interventricular septum. Increased E point-to-septal separation usually is associated with reduced myocardial contractility, although aortic insufficiency also can cause this. In animals with dynamic LV outflow obstruction, hemodynamic forces during ejection pull the anterior mitral leaflet toward the septum, causing so-called *systolic anterior motion* (SAM). With SAM, some of the normally straight mitral echoes (between points C and D) bend toward the septum during systole (see Fig. 8.5, p. 164). Diastolic flutter of the anterior mitral leaflet sometimes can be seen when an aortic insufficiency jet causes the leaflet to vibrate (Figs. 2.11 and 2.12).

The diameter of the aortic root and sometimes its motion are measured with M-mode. The parallel walls of the aortic root shift rightward (upward on the screen) in systole. During diastole, one or two aortic valve cusps may be visualized as a straight line parallel to and centered between the aortic wall echoes. At the onset of ejection, the cusps separate toward the walls of the aortic root and then quickly come together again at the end of ejection. The shape of these echoes (two cusps) has been described as a train of boxcars or little rectangular boxes attached together by a string. Aortic diameter is measured at the level of the valve annulus in end diastole. The amplitude of posterior-to-anterior motion of the aortic root is often decreased in animals with poor cardiac output. The LA dimension (caudal to the aortic root) is measured at maximal systolic excursion. In normal cats and dogs, the (M-mode) ratio of LA to aortic root diameters is about 1 : 1. However, LA size is underestimated with this M-mode view because (especially in dogs) the M-mode cursor usually transects the LA close to the left auricle, not at its maximal dimension. In cats, the M-mode beam is more likely to cross the body of the LA, but its orientation can be inconsistent. Echo beam placement may be difficult in some animals, and the pulmonary artery can be inadvertently imaged instead. Therefore LA size assessment is best done from 2-D images.

Systolic time intervals (STIs) have been used sporadically to estimate cardiac function, but they also are influenced by cardiac filling and afterload. These intervals can be calculated if the opening and closing of the aortic valve are clearly seen on M-mode and a simultaneous ECG is recorded for timing. The common STIs are: LV ejection time (duration of time the aortic valve is open), preejection period (time from the onset of the QRS to aortic valve opening), and total electromechanical systole (LV ejection time plus preejection period). STIs also can be derived using Doppler echocardiography.

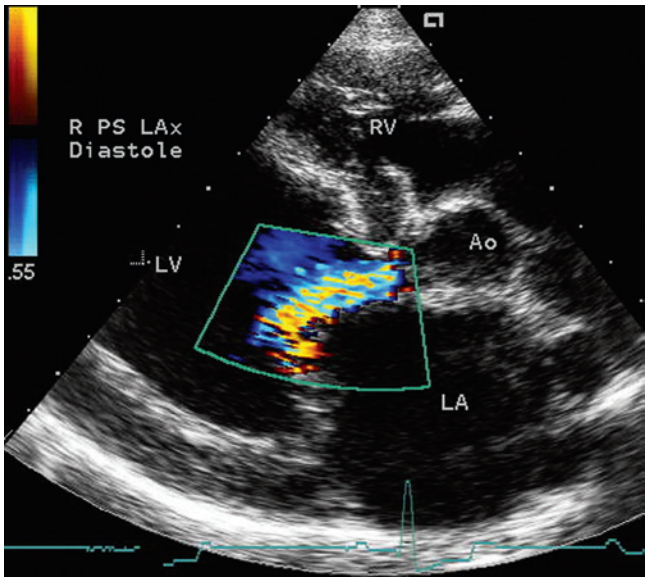

FIG 2.11
Color flow Doppler image of an aortic regurgitation jet angled toward and along the anterior leaflet of the mitral valve in a 2-year-old Rottweiler with aortic valve endocarditis. The regurgitant jet causes the mitral leaflet to flutter in diastole as seen in Fig. 2.12. Imaged from the right parasternal long-axis position. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RV,* right ventricle.

CONTRAST ECHOCARDIOGRAPHY

This technique, often called a "bubble study," uses rapid injection of a substance containing "microbubbles" either into a peripheral vein or selectively into the heart. These microbubbles generate tiny pinpoint echoes that temporarily "opacify" the blood pool being imaged (Fig. 2.13). The microbubbles appear as bright sparkles moving with the blood flow. Agitated sterile saline solution, a mixture of saline and the patient's blood, and commercial echo-contrast agents can be used as echo-contrast material. After injection into a peripheral vein, bubbles appear in the right heart chambers. Bubbles seen in the left heart or aorta indicate a right-to-left shunt. Saline microbubbles do not pass through the pulmonary capillaries (although some commercially available echo-contrast agents do), so agitated saline-contrast injection via selective left-sided heart catheterization is required to visualize intracardiac left-to-right shunts or mitral regurgitation. Doppler echocardiography has largely replaced echo-contrast studies, but they are still a useful tool in some cases.

DOPPLER ECHOCARDIOGRAPHY

Blood flow direction and velocity are imaged with Doppler echocardiography. Several types of Doppler echocardiography are used clinically, including pulsed wave (PW),

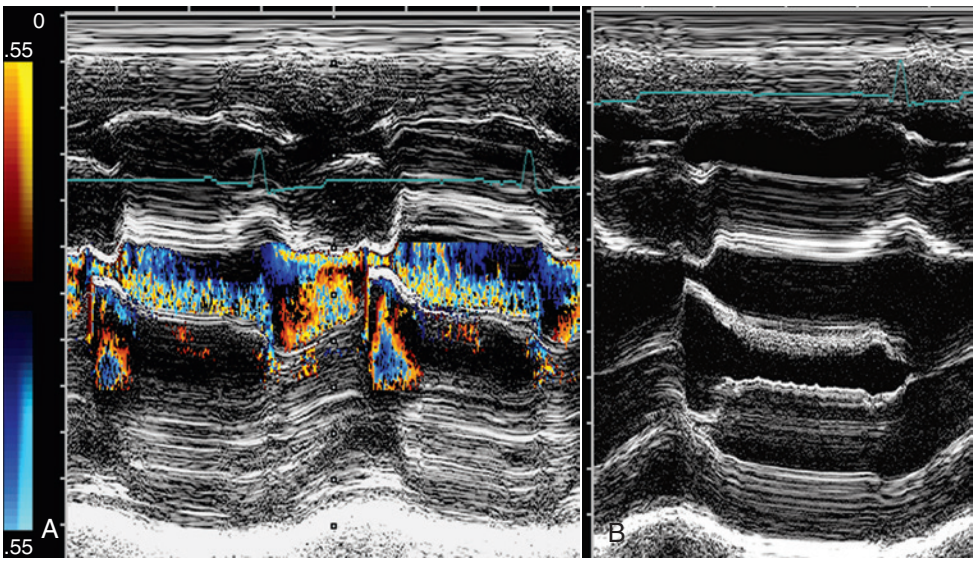

FIG 2.12
Color M-mode **(A)** and standard M-mode **(B)** images of the mitral valve from the dog in Fig. 2.11. The disturbed flow from aortic regurgitation is represented by the colors along the anterior leaflet in the left ventricular outflow region. Fine oscillations (fluttering) of the anterior mitral leaflet are seen in **B;** the leaflet appears wide and "fuzzy" compared with the thin, discrete posterior leaflet.

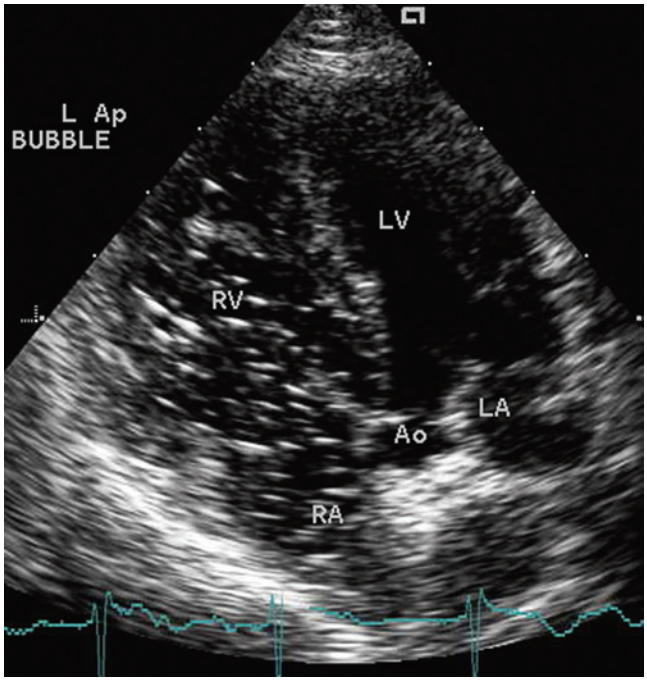

FIG 2.13
Echo "bubble" study in a dog with pulmonary hypertension. Bright speckles fill the right atrial and right ventricular chambers after an injection of agitated saline into a peripheral vein. Because there was no intracardiac shunt in this dog, no "bubbles" are seen in the left heart chambers, despite abnormally high right heart pressures. View from left apical position; *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

continuous wave (CW), and color flow (CF) mapping. Important clinical applications relate to identification of abnormal flow direction or turbulence and increased flow velocity. This allows detection and quantification of valvular insufficiency, obstructive lesions, and cardiac shunts. Cardiac output and other indicators of systolic function, as well as Doppler-derived indices of diastolic function, can be assessed. Adequate Doppler examinations are technically demanding and require a good understanding of hemodynamic principles and cardiac anatomy.

The Doppler modality is based on detection of frequency shifts between the emitted ultrasound energy and echoes reflected from moving blood cells (the Doppler shift*). Echoes returning from cells moving away from the transducer are of lower frequency, and those from cells moving toward the transducer are of higher frequency than the emitted signal. The higher the velocity of the cells, the greater the frequency shift. Optimal blood flow profiles and calculation of maximal blood flow velocity are possible when the ultrasound beam is aligned parallel to the flow. This contrasts with the perpendicular beam orientation needed for optimal M-mode and 2-D imaging. Calculated blood flow velocity diminishes as the angle of incidence between the Doppler ultrasound beam and direction of blood flow diverges from 0 degrees. This is because the calculated flow velocity is inversely related to the cosine of this angle (cosine 0 degrees = 1). As long as the angle between the ultrasound beam and path of blood flow is less than 20 degrees, maximal flow velocity can be estimated with reasonable accuracy. As the angle of incidence increases, the calculated velocity decreases. At an angle of 90 degrees, the calculated velocity is 0 (cosine 90 degrees = 0); therefore no flow signal is recorded when the ultrasound beam is perpendicular to blood flow. Flow signals usually are displayed with time on the x axis and velocity (scaled in m/sec or cm/sec) on the y axis. A zero baseline demarcates flow direction away from (below baseline) or toward (above baseline) the transducer. Higher velocities are displayed farther from baseline. Other flow characteristics (such as turbulence) also affect the Doppler spectral display.

Pulsed Wave Doppler

PW Doppler uses short bursts of ultrasound to analyze echoes returned from a specified area (designated the sample volume) along the Doppler cursor line. The advantage of PW Doppler is that blood flow velocity, direction, and spectral characteristics can be calculated from a specific location within the heart or blood vessel. The main disadvantage is that the maximum measurable velocity is limited. The pulse repetition frequency (time required to send, receive, and process returning echoes), as well as the transmitted frequency and the distance of the sample volume from the transducer, determine the maximum measurable velocity (called the *Nyquist limit*). The Nyquist limit is defined as two times the pulse repetition frequency. Lower frequency transducers and closer sample volume placement increase the Nyquist limit. When blood flow velocity is higher than the Nyquist limit, *aliasing* or velocity ambiguity occurs. This is displayed as a band of velocity signals extending above and below ("wrapped around") the baseline, so neither velocity nor direction is measurable (Fig. 2.14). When blood cells in a sample volume are moving in the same direction and at the same velocity, the velocity spectrum displayed with PW Doppler is relatively thin (tight). Variation in flow velocity within the sample volume causes spectral broadening (widening).

Characteristic blood flow patterns are obtained from the different valve areas. Flow across both AV valves has a similar pattern; likewise, flow patterns across the semilunar valve areas are similar. Normal diastolic flow across the mitral valve (Fig. 2.15) and tricuspid valve consists of an initial higher velocity signal during the rapid ventricular filling phase (E wave), which is followed by a smaller velocity signal associated with atrial contraction (A wave). Breed, age, and body weight have little influence on normal Doppler measurements. Peak velocities normally are higher across the mitral (peak E usually ≤ 0.9-1.0 m/sec; peak A usually ≤ 0.6-0.7 m/sec) compared with the tricuspid valve (peak E usually ≤ 0.8-0.9 m/sec; peak A usually ≤ 0.5-0.6 m/sec). The

*$V = C(\pm\Delta f/2f_0\cos\theta)$
V, Calculated blood flow velocity (m/sec); *C,* speed of sound in soft tissue (1540 m/sec); *±Δf,* Doppler frequency shift; f_0, transmitted frequency; *θ,* intercept angle (between ultrasound beam and blood flow direction).

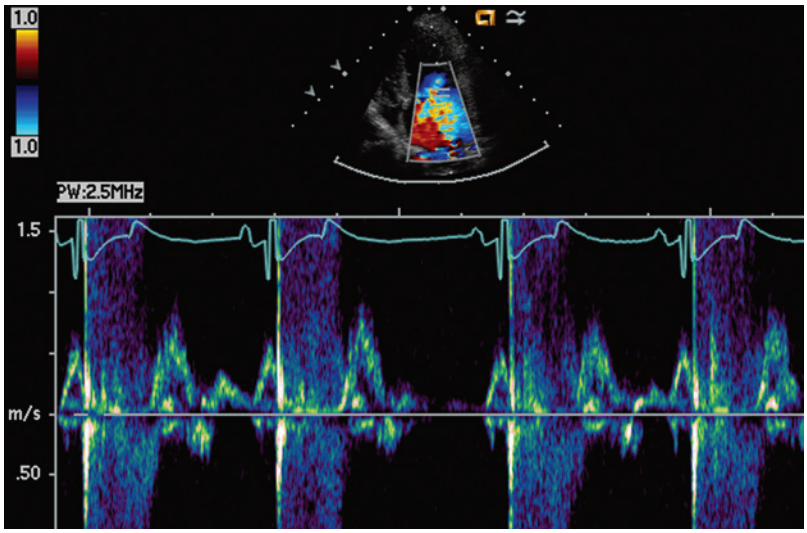

FIG 2.14
Mitral diastolic inflow and systolic regurgitant flow in a dog with degenerative mitral valve disease recorded with PW Doppler from left caudal parasternal position. The direction of mitral regurgitant flow is away from the transducer (below baseline). However, this direction cannot be discerned with PW because the flow velocity is too high, and the signal is *aliased* ("wrapped around the baseline").

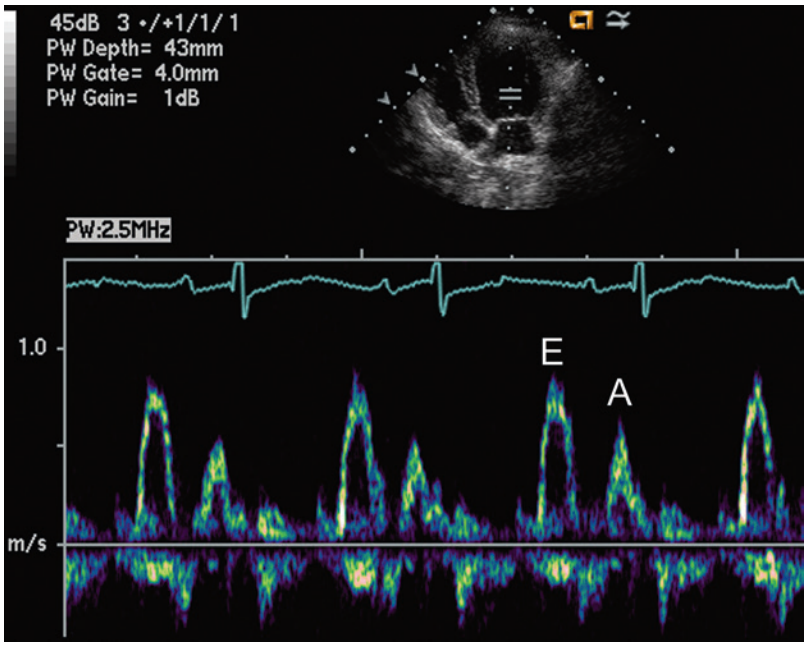

FIG 2.15
Normal mitral valve inflow recorded with PW Doppler from the left caudal (apical) parasternal position in a dog. The flow signal (above baseline) following the QRS-T of the ECG represents early diastolic flow into the ventricle *(E);* the second, smaller peak after the P wave represents inflow from atrial contraction *(A)*. Velocity scale in meters/second is on the left.

left apical four-chamber view usually provides optimal alignment for assessing mitral inflow velocities; the left cranial short-axis view is usually best for tricuspid inflow, although other imaging planes may provide adequate alignment in some cases. Multiple pulsed Doppler-derived and other indices have been used to assess diastolic function; however, no single index provides full insight to the complex process of ventricular filling. Some of these include the mitral valve inflow pattern (E/A ratio), tissue Doppler imaging of LV wall motion, isovolumic relaxation time (IVRT), mitral E:IVRT,

pulmonary venous flow patterns, and others (see Suggested Readings for more information).

Flow across the pulmonary and aortic valves (Fig. 2.16) accelerates rapidly during ejection with more gradual deceleration. Sample volume placement is at or just distal to the valve. Peak systolic pulmonary velocity is ≤ 1.4 to 1.5 m/sec in most normal dogs; the left cranial views usually provide better flow alignment. Peak aortic velocity is usually ≤ 1.6 to 1.7 m/sec, although some normal dogs (especially when unsedated) have peak aortic velocities slightly above 2 m/sec because of increased stroke volume, high sympathetic tone, or breed-related outflow tract structural characteristics. Ventricular outflow obstruction causes more rapid flow acceleration, increased peak velocity, and turbulence. In general, aortic velocities over 2.2 (-2.4) m/sec are consistent with outflow obstruction. Between 1.7 and approximately 2.2 m/sec lies a "gray zone" where mild LV outflow obstruction (e.g., some cases of subaortic stenosis) cannot be differentiated with certainty from normal but vigorous LV ejection. Maximal aortic/LV outflow velocities are obtained from the subcostal (subxiphoid) position in most dogs; however, in some dogs, the left apical view provides higher velocity recordings. The LV outflow region should be interrogated from both views and the greater maximal velocity value used.

Continuous Wave Doppler

CW Doppler employs continuous and simultaneous ultrasound transmission and reception along the line of interrogation. Theoretically, there is no maximum velocity limit with CW Doppler, so high-velocity flows can be measured (Fig. 2.17). The disadvantage of CW Doppler is that sampling of blood flow velocity and direction occurs all along the ultrasound beam, not in a specified area (so-called range ambiguity).

Pressure Gradient Estimation

In combination with M-mode and 2-D imaging, Doppler estimation of pressure gradients is used to assess the severity of congenital or acquired flow obstructions. In addition, the peak velocity of a valvular insufficiency jet can be used to estimate the pressure gradient across a regurgitant valve. The instantaneous pressure gradient across a stenotic or regurgitant valve is estimated using the maximum measured velocity of the flow jet. CF Doppler is useful to depict the flow jet's orientation and aid cursor alignment. Careful Doppler beam alignment is essential to record maximum velocity. CW Doppler is employed if aliasing occurs with PW Doppler. A modification of the Bernoulli equation is used to estimate pressure gradient (other factors in this relationship generally are of minimal clinical importance and are ignored):

$$\textbf{Pressure Gradient} = 4 \times (\textbf{maximum velocity})^2$$

Pulmonary artery systolic pressure can be estimated from maximal tricuspid regurgitation jet velocity (TRmax), if there is no RV outflow obstruction or pulmonic valve stenosis. The calculated systolic pressure gradient plus RA pressure (estimated as about 5 to 10 mm Hg, or the measured central venous pressure [CVP]) equals the peak RV systolic pressure, which approximates pulmonary artery systolic pressure. Pulmonary hypertension (PH) is associated with TRmax values over 2.8 m/sec. The severity of PH generally

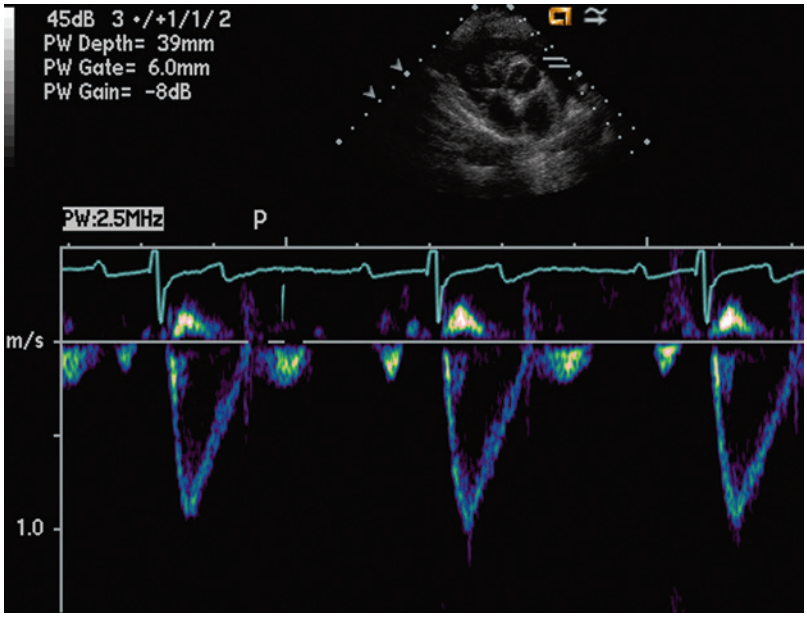

FIG 2.16
Normal pulmonary flow recorded with PW Doppler from the left cranial short-axis position in a dog. There is rapid blood flow acceleration (below baseline) into the pulmonary artery, with a peak velocity of about 1.0 m/sec. Velocity scale in meters per second is on the left.

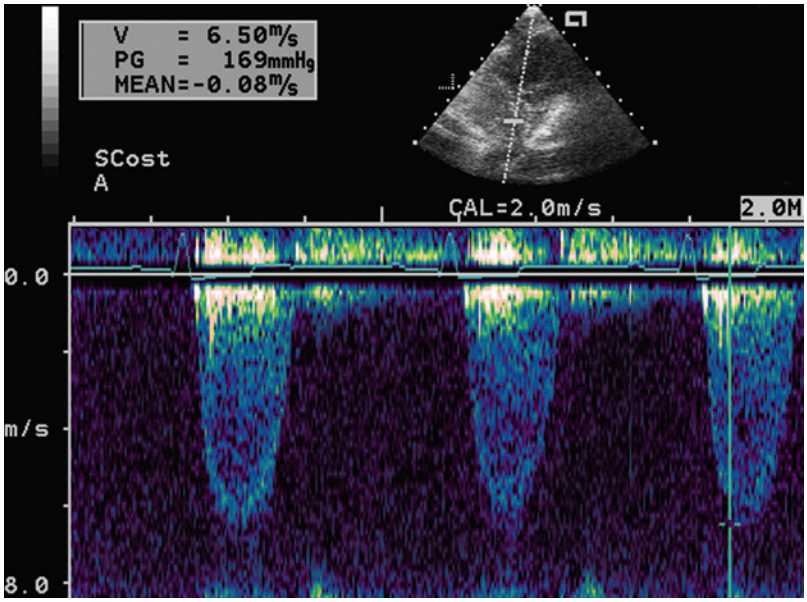

FIG 2.17
Continuous wave Doppler recording of high-velocity aortic outflow in a dog with severe subaortic stenosis, imaged from the subcostal position. Estimated systolic pressure gradient across the outflow region is 169 mm Hg, based on a peak velocity of 6.5 m/sec. Velocity scale in meters/second is on the left.

is categorized as mild (estimated systolic pulmonary artery pressure ≈35-50 mm Hg; TRmax 2.9-3.5 m/sec), moderate (≈51-75 mm Hg; TRmax 3.6-4.3 m/sec), or severe (>75 mm Hg; TRmax > 4.3 m/sec). Likewise, pulmonary diastolic pressure can be estimated from a pulmonary regurgitant (PR) jet velocity at end-diastole. The calculated end-diastolic pressure gradient between the pulmonary artery and the RV, plus the estimated RV diastolic pressure, represents pulmonary arterial diastolic pressure. The peak (early diastolic) PR provides an approximation of mean pulmonary artery pressure; peak PR velocities over 2.2 m/sec suggest PH.

Color Flow Mapping

CF mapping is a form of PW Doppler that combines the M-mode or 2-D modality with blood flow imaging. However, instead of one sample volume along one scan line, many sample volumes are analyzed along multiple scan lines. The mean frequency shifts obtained from multiple sample volumes are color coded for direction (in relation to the transducer) and velocity. Most systems code blood flow toward the transducer as red and blood flow away from the transducer as blue. Zero velocity is indicated by black, meaning either no flow or flow perpendicular to the angle of incidence. Differences in relative velocity of flow can be accentuated, and the presence of multiple velocities and directions of flow (turbulence) can be indicated by different display maps that use variations in brightness and color. Aliasing occurs often, even with normal blood flows, because of low Nyquist limits. Signal aliasing is displayed as a reversal of color (e.g., red shifting to blue; Fig. 2.18). Turbulence

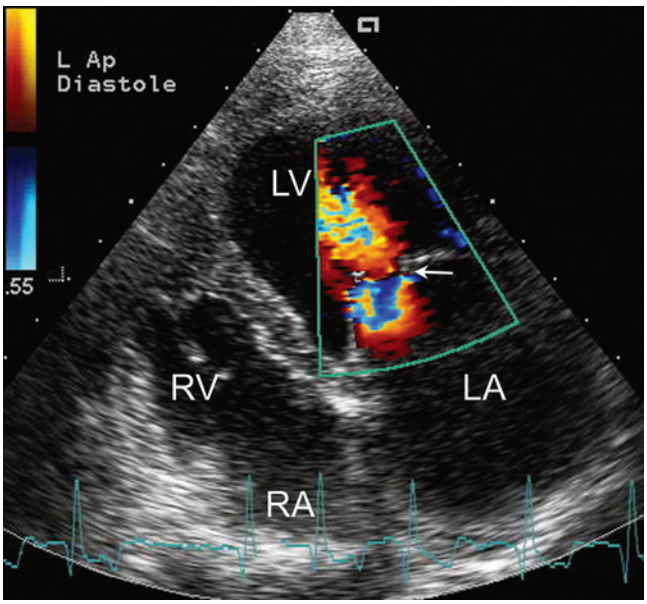

FIG 2.18
Example of color flow aliasing in a dog with mitral valve stenosis and atrial fibrillation. Diastolic flow toward the narrowed mitral orifice *(arrow)* accelerates beyond the Nyquist limit, causing red-coded flow (blood moving toward transducer) to alias to blue, then again to red, and once more to blue. Turbulent flow is seen within the left ventricle at the top of the two-dimensional image.

produces multiple velocities and directions of flow in an area resulting in a mixing of color; this display can be enhanced using a variance map, which adds shades of yellow or green to the red/blue display (Fig. 2.19).

The severity of valve regurgitation is estimated subjectively by the size and shape of the regurgitant jet during CF imaging. Although technical and hemodynamic factors confound the accuracy of such assessment, wide and long regurgitant jets generally are associated with more severe regurgitation than jets that are narrow at their point of origin. Other methods for quantifying valve regurgitation have been described as well. Maximum regurgitant jet velocity is not a good indicator of severity, especially with mitral regurgitation. Changes in chamber size (i.e., eccentric hypertrophy and remodeling) provide a better indication of severity with chronic regurgitation.

OTHER ECHOCARDIOGRAPHIC MODALITIES

Doppler Tissue Imaging and 2-D Speckle Tracking

Doppler tissue imaging (DTI) is a modality used to assess the motion of tissue, rather than blood cells, by altering the signal processing and filtering of returning echoes. Myocardial velocity patterns can be assessed with CF and PW spectral DTI techniques. Spectral DTI provides greater temporal resolution and quantifies velocity of myocardial motion at specific locations, such as the lateral or septal aspects of the mitral annulus (Fig. 2.20). Color DTI methods display mean myocardial velocities from different regions. Other techniques used to assess regional myocardial function and synchrony can be derived from DTI methods, including myocardial velocity gradients, myocardial strain, and strain rate.

Myocardial strain and strain rate indices can be helpful in assessing subclinical myocardial wall motion abnormalities and ventricular dyssynchrony. Strain is a measure of myocardial deformation or percent change from its original dimension. Strain rate describes the temporal rate of deformation. A significant limitation of Doppler-based techniques is their angle dependence, complicated by cardiac translational motion. A "speckle tracking" modality, based on 2-D echocardiography rather than DTI, is often used now as a potentially more accurate way to assess regional myocardial motion, strain, and strain rate. This modality relies on tracking the motion of gray scale "speckles" within the myocardium as they move throughout the cardiac cycle. More information can be found in the Suggested Readings.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) employs transducers mounted on a flexible, steerable endoscope tip to image cardiac structures through the esophageal wall. TEE can provide clearer images of some cardiac structures (especially those at or above the AV junction) compared with transthoracic echocardiography because chest wall and lung interference is avoided. This technique can be particularly useful for defining some congenital cardiac defects and identifying

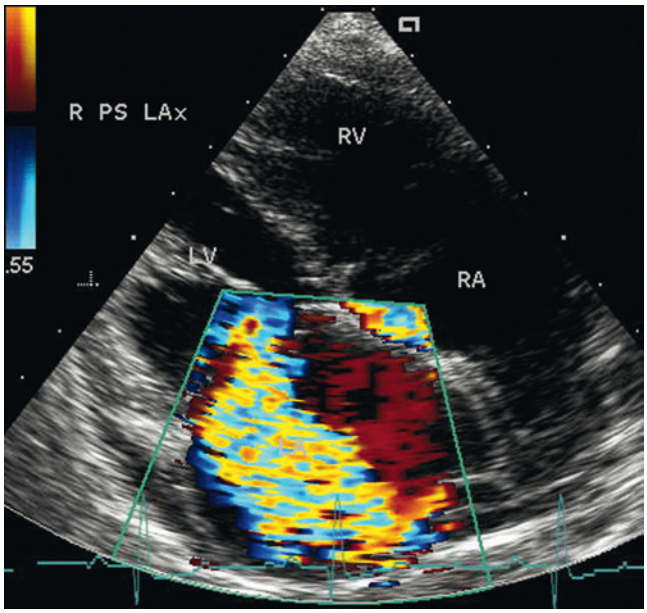

FIG 2.19
Systolic frame showing turbulent regurgitant flow into the enlarged LA of a dog with chronic mitral valve disease. The regurgitant jet curves around the dorsal aspect of the LA. Imaged from the right parasternal long-axis, four-chamber view. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

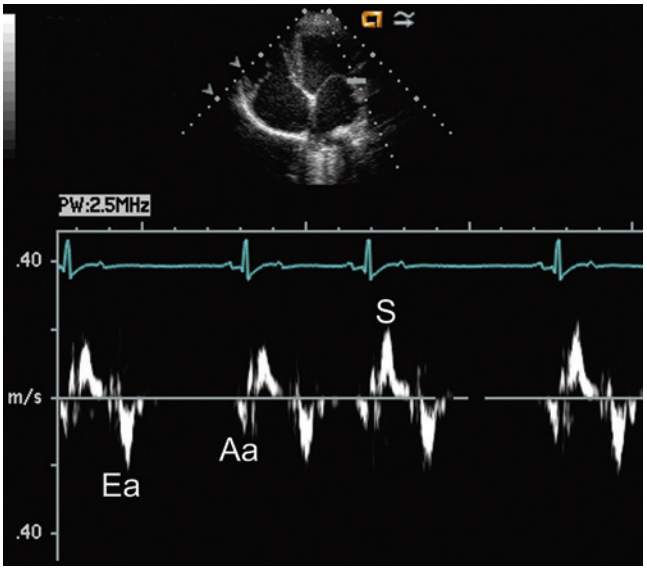

FIG 2.20
PW Doppler tissue image from a cat. The mitral annulus moves toward the left apex (and transducer) in systole *(S).* Early diastolic filling *(Ea)* shifts the annulus away from the apex as the LV expands. Additional motion occurs with late diastolic filling from atrial contraction *(Aa).*

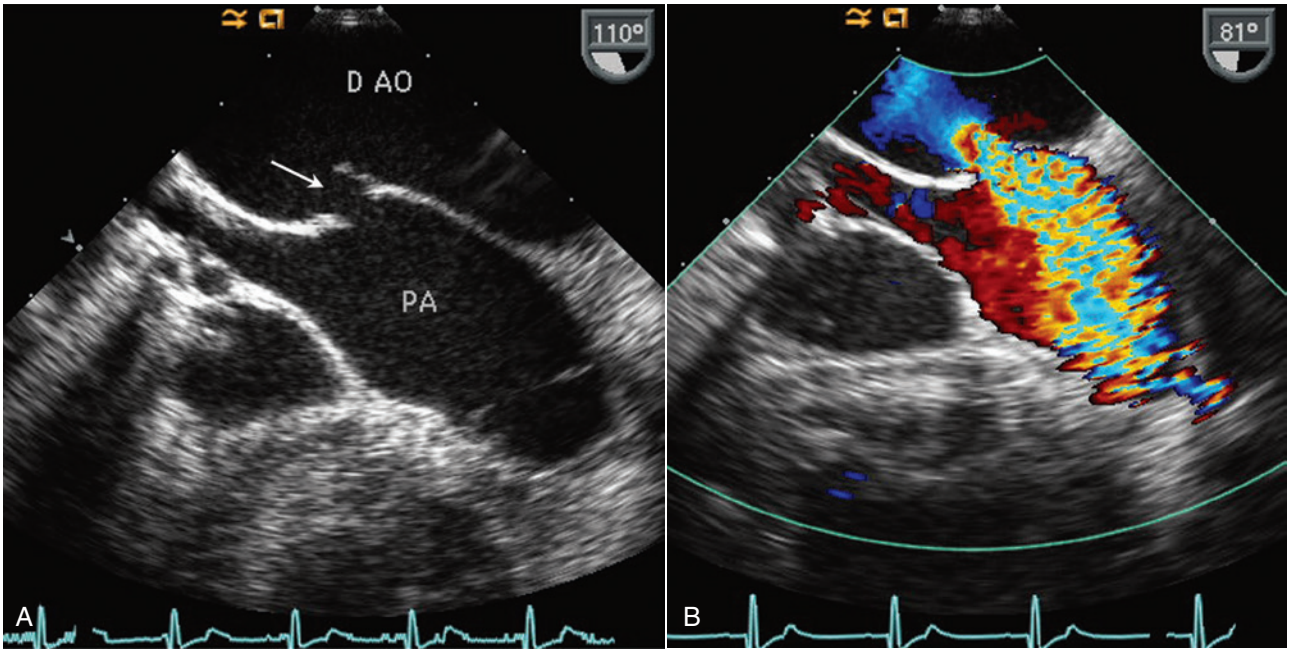

FIG 2.21

thrombi, tumors, or endocarditis lesions, as well as guiding cardiac interventional procedures (Fig. 2.21). The need for general anesthesia and the expense of the endoscopic transducers are the main disadvantages of TEE. Complications related to the endoscopy procedure are uncommon.

Three-Dimensional Echocardiography

The ability to generate and manipulate 3-D ultrasound images of the heart and other structures is becoming more widely available as a means to further evaluate cardiac structure and function. Anatomic and blood flow abnormalities can be viewed from any angle by rotating or bisecting the 3-D images. Three-dimensional capability is incorporated into some multimodality transthoracic and transesophageal transducers. Data acquisition for 3-D reconstruction of the entire heart generally requires several cardiac cycles.

LUNG ULTRASOUND

POC lung ultrasound (Vet BLUE protocol; Lisciandro, 2014) provides a means to detect pulmonary infiltrates and certain other abnormalities by the artifact or tissue interface patterns they cause. For patients presented in respiratory distress, a rapid lung ultrasound can help the clinician decide whether CHF or noncardiac disease is most likely. The exam can be done quickly with the patient in sternal or standing position and without shaving to minimize patient stress. Although not a replacement for thoracic radiographs, the technique can help direct acute therapy until the patient is stable enough for radiography. Lung ultrasound detects pulmonary edema, and other infiltrates, by the presence of artifacts known as "B" lines (also called lung rockets, comet tails, ring-down artifact). B lines are created because of the marked acoustic mismatch between small fluid-filled lung spaces and surrounding air. B lines appear as hyperechoic vertical artifacts stretching from the pleural-pulmonary interface to the furthest depth seen on the ultrasound image (Fig. 2.22); these B lines are narrowest at their origin and move with respiration. Cardiogenic pulmonary edema is strongly associated with the presence of three or more B lines in at least two of four standard positions on both sides of the chest; these occur most frequently in the middle lung zones. Pulmonary infiltrates other than cardiogenic edema can produce B lines too, although often not as extensively; such causes could include interstitial or alveolar infiltrates associated with acute respiratory distress syndrome, neoplasia, pneumonia, heartworm pneumonitis, pulmonary thromboembolism, noncardiogenic edema (as from electrocution or drowning), and pulmonary hemorrhage. An increased LA:Ao ratio, seen on concurrent focused echocardiogram, provides additional evidence for cardiac disease. The clinical history and initial physical exam findings also may suggest a cardiac versus noncardiac cause. The presence of pleural and pericardial effusions can be seen with ultrasound as well. See the Suggested Readings list for additional information about POC ultrasound.

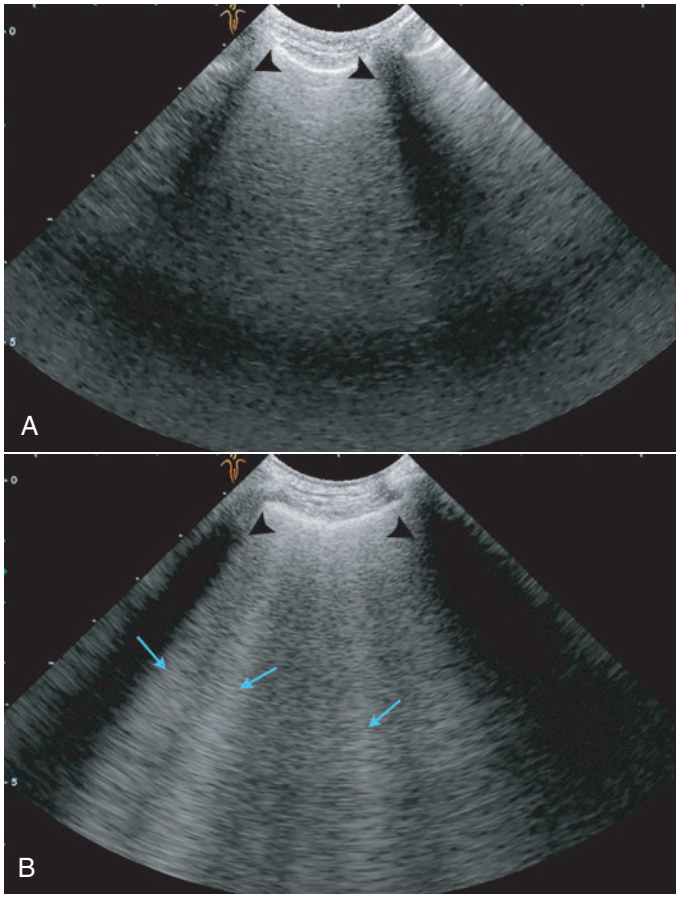

FIG 2.22
(A) Lung ultrasound image from a normal dog shows the typical appearance of well aerated lung, with its fine horizontal "A line" pattern, between two rib shadows (*arrowheads*). **(B)** Lung ultrasound image from a dog with pulmonary edema. Hyperechoic, vertical "B lines" (*small arrows*), which extend from the pleural-pulmonary interface (at top) to the bottom of the image, represent artifacts caused by the juxtaposition of intrapulmonary fluid/infiltrate and air-filled alveoli (creating a high acoustic impedance gradient).

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) graphically represents the electrical depolarization and repolarization of cardiac muscle. The ECG provides information on heart rate, rhythm, and intracardiac conduction; it may also suggest specific chamber enlargement, myocardial disease, ischemia, pericardial disease, certain electrolyte imbalances, and some drug toxicities. However, the ECG alone cannot be used to identify the presence of CHF, assess the strength (or even presence) of cardiac contractions, or predict whether the animal will survive an anesthetic or surgical procedure.

NORMAL ECG WAVEFORMS

The normal cardiac rhythm originates in the sinoatrial (SA) node. Specialized conduction pathways facilitate activation of the atria and ventricles (Fig. 2.23). The ECG waveforms, P-QRS-T, are generated as heart muscle is depolarized and then repolarized (Fig. 2.24 and Table 2.3). The QRS

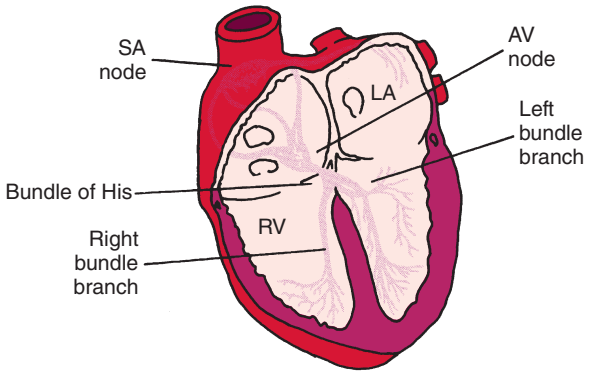

FIG 2.23

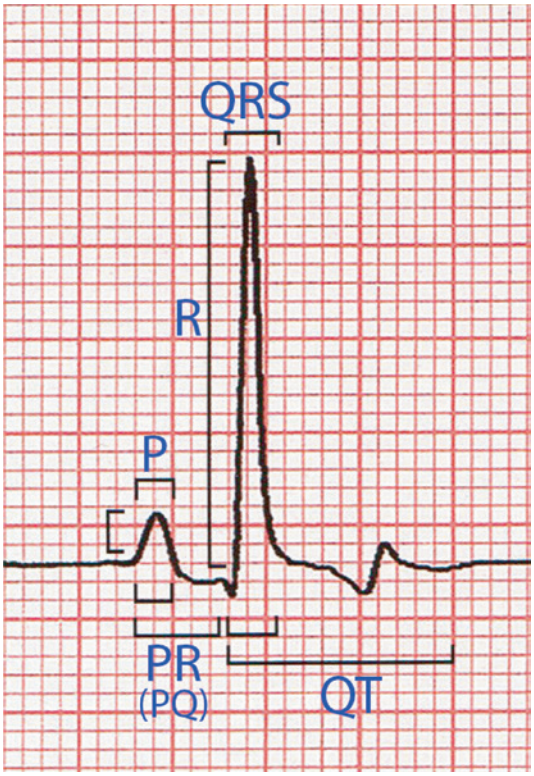

FIG 2.24
Normal canine P-QRS-T complex in lead II. Paper speed is 50 mm/sec (0.02 sec per each small box); calibration is standard (1 cm = 1 mV, 0.1 mV per each small box). Time intervals (seconds) are measured from left to right; waveform amplitudes (millivolts) are measured as positive (upward) or negative (downward) motion from baseline.

TABLE 2.3
Normal Cardiac Waveforms

WAVEFORM	EVENT
P	Depolarization (activation) of atrial muscle; normally is positive in leads II and aV_F
PR interval	Time from onset of atrial muscle activation, through conduction over the AV node, bundle of His, and Purkinje fibers; also called *PQ interval*
QRS complex	Depolarization of ventricular muscle; by definition, Q is the first negative deflection (if present), R the first positive deflection, and S is the negative deflection after the R wave
J point	End of the QRS complex (and ventricular muscle activation); junction of QRS and ST segment
ST segment	Represents the period between ventricular depolarization and repolarization (correlates with phase 2 of the action potential)
T wave	Ventricular muscle repolarization
QT interval	Total time of ventricular depolarization and repolarization

AV, Atrioventricular.

complex, as a representation of ventricular muscle electrical activation, does not necessarily have individual Q, R, and S wave components (or variations thereof). The configuration of the QRS complex depends on the lead being recorded, as well as the animal's intraventricular conduction characteristics.

LEAD SYSTEMS

Various leads are used to evaluate the cardiac activation process. The orientation of a lead with respect to the heart is called the *lead axis.* Each lead has direction and polarity. If the myocardial depolarization or repolarization wave travels parallel to the lead axis, a relatively large deflection will be recorded in that lead. As the angle between the lead axis and the orientation of the activation wave increases toward 90 degrees, the ECG deflection for that lead becomes smaller; it becomes isoelectric when the activation wave is perpendicular to the lead axis. Each lead has a positive and a negative pole or direction. A positive deflection will be recorded in a lead if the cardiac activation wave travels toward the positive pole (electrode) of that lead. If the wave of depolarization travels away from the positive pole, a negative deflection will be recorded in that ECG lead. Both bipolar and unipolar ECG leads are used clinically. A bipolar lead records electrical potential differences between two electrodes on the body surface; the lead axis is oriented between these two points. Unipolar leads have a recording (positive) electrode on the body surface. The negative pole of unipolar leads is formed by "Wilson's central terminal" (V), which is an average of all other electrodes and is analogous to zero.

The standard limb lead system records cardiac electrical activity in the frontal plane (as depicted by a DV/VD radiograph). In this plane, left-to-right and cranial-to-caudal currents are recorded. Fig. 2.25 depicts the six standard frontal leads (hexaxial lead system) overlying the cardiac ventricles. Unipolar limb leads are "augmented" (aVF, etc.) because their voltage is so low. Unipolar chest (precordial) leads "view" the heart from the transverse plane (Fig. 2.26). Box 2.2 lists common ECG lead systems.

APPROACH TO ECG INTERPRETATION

Routine ECG recording usually is done with the animal placed in right lateral recumbency on a nonconducting surface. The proximal limbs are parallel to each other and perpendicular to the torso. Other body positions may change the various waveform amplitudes and affect the calculated mean electrical axis (MEA). However, if only heart rate and rhythm are desired, any recording position can be used.

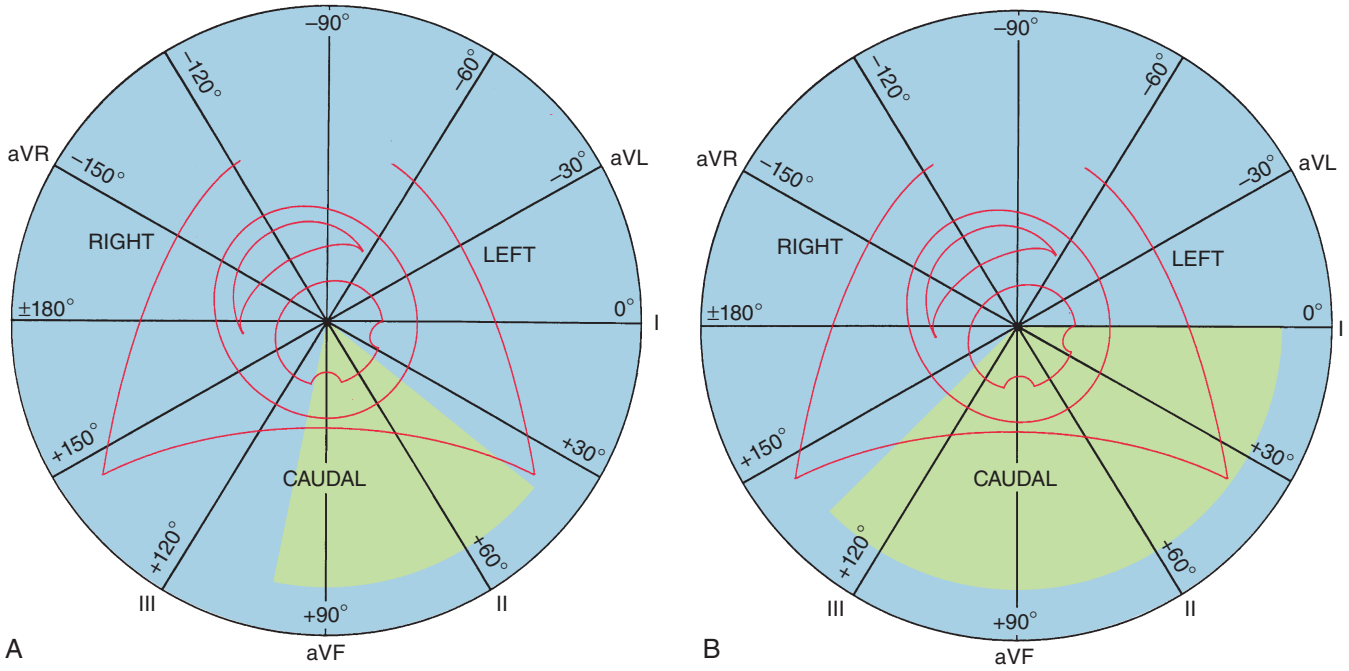

FIG 2.25
Frontal lead system: diagrams of six frontal leads over schematic of left and right ventricles within the thorax. Circular field is used for determining direction and magnitude of cardiac electrical activation. Each lead is labeled at its positive pole. Shaded area represents normal range for mean electrical axis. **(A)** Dog. **(B)** Cat.

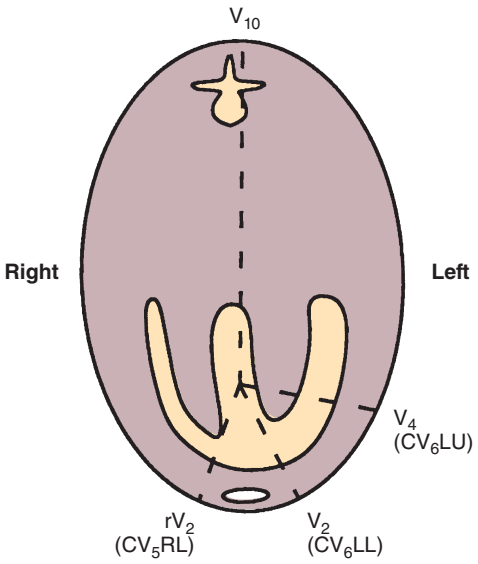

FIG 2.26
Commonly used chest leads seen from cross-sectional view. CV_5RL is located at right edge of the sternum in fifth intercostal space (ICS), CV_6LL is near sternum at sixth ICS, CV_6LU is at costochondral junction at sixth ICS, and V_{10} is located near seventh dorsal spinous process.

BOX 2.2

Small Animal Electrocardiographic Lead Systems

Standard Bipolar Limb Leads

I	RA (–) compared with LA (+)
II	RA (–) compared with LL (+)
III	LA (–) compared with LL (+)

Augmented Unipolar Limb Leads

Orthogonal Leads

X	Lead I (right to left) in the frontal plane
Y	Lead aV_F (cranial to caudal) in the midsagittal plane
Z	Lead V_{10} (ventral to dorsal) in the transverse plane

ICS, Intercostal space; *LA,* left arm (forelimb); *LL,* left leg (hindlimb); *RA,* right arm (forelimb).

Front limb electrodes are placed at the elbows or slightly below, not touching the chest wall or each other. Rear limb electrodes are placed at the stifles or hocks. With alligator clip or button/plate electrodes, copious ECG paste or (less ideally) alcohol is used to ensure good contact. Communication between two electrodes via a bridge of paste or alcohol or by physical contact should be avoided. The animal is gently restrained in position to minimize movement artifacts. A relaxed and quiet patient produces a better quality tracing. Holding the mouth shut to discourage panting or placing a hand on the chest of a trembling animal may be helpful.

A good ECG recording produces minimal artifact from patient movement, no electrical interference, and a clean baseline. The ECG complexes should be centered and totally contained within the background gridwork so that neither the top nor bottom of the QRS complex is clipped off. If the complexes are too large to fit entirely within the grid, the calibration should be adjusted (e.g., from standard [1 cm = 1 mV] to ½ standard [0.5 cm = 1 mV]). The calibration used during the recording must be known to accurately measure waveform amplitude. A calibration square wave (1 mV amplitude) can be inscribed manually during recording if this is not done automatically. The paper or digital recording speed and lead(s) used also must be evident for interpretation.

A consistent approach to ECG interpretation is recommended. First the recording speed, lead(s) used, and calibration are identified. Then the heart rate, heart rhythm, and MEA are determined. Finally, individual waveforms are measured. The heart rate is the number of complexes (or beats) per minute. Unless otherwise specified, this means QRS complexes (rather than P waves) are counted to provide the heart (ventricular) rate. Heart rate can be calculated by counting the number of complexes in 3 or 6 seconds and then multiplying by 20 or 10, respectively. If the heart rhythm is regular, 3000 divided by the number of small boxes (at paper/trace speed 50 mm/sec) between successive RR intervals equals the instantaneous heart rate. Because variations in heart rate are so common (in dogs especially), determining an average heart rate over several seconds is usually more accurate and practical than calculating an instantaneous heart rate.

Heart rhythm is assessed by scanning the entire ECG recording for irregularities and identifying individual waveforms. The presence and pattern of P waves and QRS-T complexes are determined. The relationship between the P waves and QRS-Ts is then evaluated. Calipers are often useful for evaluating the regularity and interrelationships of the waveforms. Estimation of MEA is described on p. 45.

Individual waveforms and intervals are, by convention, measured using lead II. Complex amplitude is recorded in millivolts and duration in seconds (or msec). Only one thickness of the inscribed pen/trace line should be included for each measurement. At 25 mm/sec recording speed, each small (1 mm) box on the ECG gridwork is 0.04 second in duration (from left to right). At 50 mm/sec recording speed, each small box equals 0.02 second. A deflection from baseline (up or down) of 10 small boxes (1 cm) equals 1 mV at standard calibration (0.1 mV per small box). ECG reference ranges for cats and dogs (Table 2.4) are representative of most normal animals, although complex measurements for some subpopulations can fall outside these ranges. For example, endurance-trained dogs can have ECG measurements that exceed the "normal" range, probably reflecting the training effects on heart size. Such changes in nontrained dogs suggest pathologic cardiac enlargement. Manual frequency filters, available on many ECG machines, can markedly attenuate the recorded voltages of some waveforms when activated, although baseline artifact is reduced. The effects of filtering on QRS amplitude may complicate the assessment for ECG chamber enlargement criteria.

SINUS RHYTHMS

The normal cardiac rhythm originates in the sinus node and produces the P-QRS-T waveforms previously described. The P waves are positive in caudal leads (II and aVF), and the PR (also called PQ) intervals are consistent. Regular sinus rhythm is characterized by less than 10% variation in the timing of the QRS to QRS (or R to R) intervals. Normally the QRS complexes are narrow and upright in leads II and aVF. However, an intraventricular conduction disturbance or ventricular enlargement pattern may cause them to be wide or abnormally shaped.

Sinus arrhythmia is characterized by cyclic slowing and speeding of the sinus rate. This usually is associated with respiration; the sinus rate tends to increase on inspiration and decrease with expiration as a result of fluctuations in vagal tone. There also may be a cyclic change in P-wave configuration ("wandering pacemaker") with the P waves becoming taller and spiked during inspiration and flatter in expiration. Sinus arrhythmia is a common and normal rhythm variation in dogs. It occurs in resting cats but rarely is seen in the clinical setting. Pronounced sinus arrhythmia can be associated with chronic pulmonary disease, especially in dogs.

"Brady-" and "tachy-" are modifying terms that describe abnormally slow or fast rhythms, respectively, without identifying intracardiac origin. Both sinus bradycardia and sinus tachycardia are rhythms that originate in the sinus node and are conducted normally; however, the heart rate of sinus bradycardia is slower than normal for the species, whereas that of sinus tachycardia is faster than normal. Some causes of sinus bradycardia and tachycardia are listed in Box 2.3.

Sinus arrest is the absence of sinus activity lasting at least twice as long as the animal's longest expected QRS to QRS interval. An escape complex usually interrupts the resulting pause if sinus activity does not resume soon enough. Long pauses can cause fainting or weakness. Sinus arrest cannot be differentiated with certainty from SA block on the surface ECG. Fig. 2.27 illustrates various sinus rhythms.

TABLE 2.4

Normal Electrocardiographic Reference Ranges for Dogs and Cats

DOGS	CATS
Heart Rate	
60-160 beats/min (adults) to 220 beats/min (puppies)	(120-)140-240 beats/min
Mean Electrical Axis (Frontal Plane)	
+40 to +100 degrees	0 to +160 degrees
Measurements (Lead II)	
P-wave duration (maximum)	
0.04 sec (0.05 sec, giant breeds)	0.035-0.04 sec
P-wave height (maximum)	
0.4 mV	0.2 mV
PR interval	
0.06-0.13 sec	0.05-0.09 sec
QRS complex duration (maximum)	
0.05 sec (small breeds) 0.06 sec (large breeds)	0.04 sec
R-wave height (maximum)	
2.5 mV (small breeds) 3 mV (large breeds)*	0.9 mV in any lead; QRS total in any lead <1.2 mV
ST segment deviation	
<0.2 mV depression <0.15 mV elevation	<0.1 mV deviation
T wave	
Usually < 25% of R wave height; can be positive, negative, or biphasic	Maximum 0.3 mV; can be positive (most common), negative, or biphasic
QT interval duration	
0.15-0.25 (to 0.27) sec; varies inversely with heart rate	0.12-0.18 (range 0.07-0.2) sec; varies inversely with heart rate
Chest Leads	
V_1; rV_2: positive T wave V_{2-3}: S wave 0.8 mV maximum; R wave 2.5 mV maximum* V_{4-6}: S wave 0.7 mV maximum; R wave 3 mV maximum* V_{10}: negative QRS; negative T wave	R wave 1.0 mV maximum in chest leads R/Q < 1.0; negative T wave

Each small box on the ECG paper grid is 0.02 second wide at 50 mm/sec paper speed, 0.04 second wide at 25 mm/sec, and 0.1 mV high at a calibration of 1 cm = 1 mV.
*May be greater in thin, deep-chested dogs younger than 2 years old.

ECTOPIC RHYTHMS

Impulses originating from outside the sinus node (known as *ectopic* impulses) are abnormal and create an arrhythmia (dysrhythmia). Ectopic impulses are described on the basis of their general site of origin (atrial, junctional, supraventricular, ventricular) and their timing (Fig. 2.28). *Timing* refers to whether the impulse occurs earlier than the next expected sinus impulse (and therefore is *premature*) or after a longer pause (considered late or *escape*). Escape complexes represent activation of a subsidiary pacemaker and function as a rescue mechanism for the heart. Premature ectopic impulses (complexes) occur singly or in multiples; groups of three or more constitute an episode of tachycardia. Episodes of tachycardia can consist of a brief run of ventricular premature complexes (VPCs; *paroxysmal* tachycardia) or can be quite prolonged (*sustained* tachycardia).

BOX 2.3

Causes of Sinus Bradycardia and Sinus Tachycardia

Sinus Bradycardia

Hypothermia
Hypothyroidism
Drugs (e.g., some tranquilizers, anesthetics, β-blockers, calcium entry blockers, digoxin)
Increased intracranial pressure
Brainstem lesions
Ocular pressure
Carotid sinus pressure
Other causes of high vagal tone (e.g., airway obstruction)
Sinus node disease
Severe metabolic disease (e.g., hyperkalemia, uremia)
Normal variation (athletic dog)
Cardiac arrest (before or after)

Sinus Tachycardia

Hyperthermia/fever
Hyperthyroidism
Anemia/hypoxia
Heart failure
Hypotension
Shock
Sepsis
Anxiety/fear
Excitement
Exercise
Pain
Drugs (e.g., anticholinergics, sympathomimetics)
Toxicities (e.g., chocolate, amphetamines, theophylline)
Electric shock
Other causes of high sympathetic tone

When a premature complex follows each normal sinus QRS, this creates a bigeminal pattern; the origin of the premature complexes determines whether the rhythm is described as atrial or ventricular *bigeminy*. Fig. 2.29 contains examples of ectopic supraventricular and ventricular complexes and rhythms.

Supraventricular Premature Complexes

Supraventricular premature complexes are impulses that originate above the atrioventricular (AV) node, either in the atria or the AV junctional area. Because they are conducted into and through the ventricles via the normal conduction pathway, their QRS configuration is normal (unless an intraventricular conduction disturbance also is present). Premature ectopic complexes arising within the atria (APCs, or PACs) usually are preceded by an abnormal P wave (of either positive, negative, or biphasic configuration) called a *P′ wave*. If an ectopic P′ wave occurs before the AV node has completely repolarized, the impulse may not be conducted into the ventricles (an example of physiologic AV block). In some cases, the premature impulse is conducted slowly (prolonged P′Q interval) or with a bundle branch block pattern. Although P′ waves usually do not precede junctional complexes, retrograde conduction into the atria sometimes causes a negative P′ wave to follow, be superimposed on, or even precede the associated QRS complex. If the specific origin of the ectopic complex(es) is unclear, the more general term *supraventricular premature complex* (or *supraventricular tachycardia*) is used. Clinically it often is more important to determine whether an arrhythmia originates from above the AV node (supraventricular) or below it (ventricular) rather than the more specific localization. Supraventricular premature complexes that also depolarize the sinus node reset the sinus rhythm and create a *noncompensatory pause* (i.e., the interval between the sinus complexes that precede and follow the premature complex is less than that of three consecutive sinus complexes).

Supraventricular Tachycardias

Tachycardias of supraventricular origin often involve a reentrant pathway using the AV node (either within the AV node or using an accessory pathway); a premature supraventricular or ventricular impulse can initiate reentrant supraventricular tachycardia (SVT). During episodes of reentrant SVT in animals with ventricular preexcitation (see p. 44), the PR interval usually normalizes (or becomes prolonged) and retrograde P′ waves may be evident. The QRS complexes are of normal configuration unless a simultaneous intraventricular conduction disturbance is present.

Atrial tachycardia is caused by rapid discharge of an abnormal atrial focus or by atrial reentry (repetitive activation caused by conduction of the electrical impulse around an abnormal circuit within the atria). In dogs, the atrial activation rate usually is between 260 and 380/minute. The P′ waves are often hidden in the QRS-T complexes. Atrial tachycardia can be paroxysmal or sustained. It generally is a regular rhythm unless the rate is too fast for the AV node to conduct every impulse, in which case physiologic AV block causes irregular ventricular activation. A consistent ratio of atrial impulses to ventricular activation (e.g., 2:1 or 3:1 AV conduction) preserves the regularity of this arrhythmia. Sometimes the impulses traverse the AV node but are delayed within the ventricular conduction system, causing a bundle branch block pattern on the ECG. Differentiation from ventricular tachycardia can be challenging in these cases.

Atrial Flutter

Atrial flutter is produced by rapid (usually > 400 impulses/min) waves of electrical activation regularly cycling through the atria. The ventricular response may be irregular or regular, depending on the pattern of AV conduction. The ECG baseline shows "saw tooth" flutter waves that represent the fast, recurrent atrial activation. Atrial flutter is not a stable rhythm; it often degenerates into atrial fibrillation (AF), or may convert back to sinus rhythm.

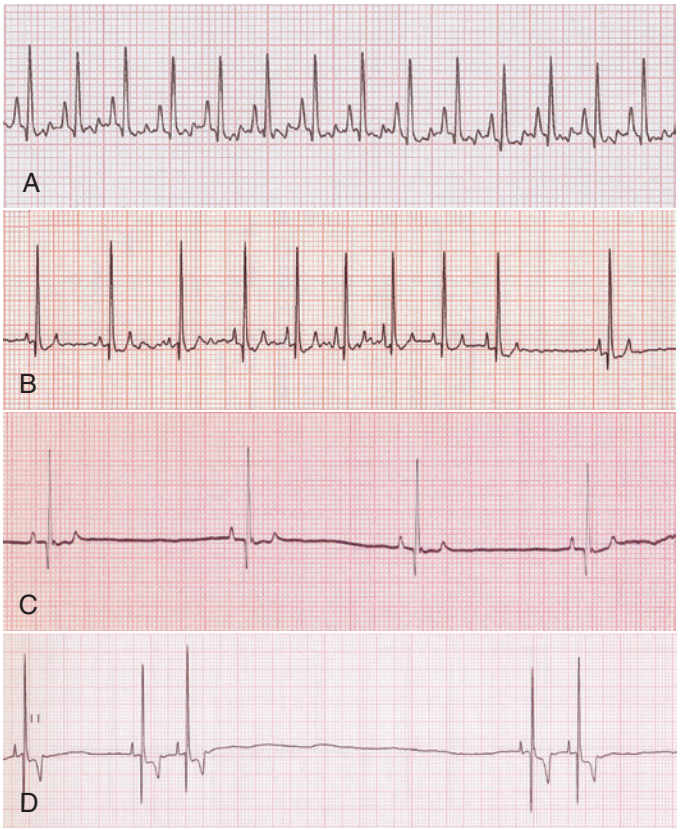

FIG 2.27
Sinus rhythms. **(A)** Sinus tachycardia in an older Shih Tzu; heart rate ~ 200 beats/min. **(B)** Sinus arrhythmia with wandering pacemaker in a dog. Note gradual variation in P-wave height associated with respiratory changes in heart rate; this variation is normal in the dog. Some baseline muscle tremor artifact is evident. **(C)** Sinus bradycardia (heart rate 40 beats/min) in a dog with brain disease. **(D)** Intermittent periods of sinus arrest in a 13-year-old Cocker Spaniel. All ECGs are lead II, 25 mm/sec, 1 cm = 1 mV.

Atrial Fibrillation

This common arrhythmia is characterized by rapid and chaotic electrical activation within the atria. There are no P waves on the ECG because there is no uniform atrial depolarization wave. Rather, the baseline usually shows small, irregular undulations (fibrillation waves). Lack of organized electrical activity also prevents effective atrial contraction. The AV node, being bombarded by these chaotic electrical impulses, conducts as many and as quickly as possible to the ventricles. Ultimately the (ventricular) heart rate is determined by AV conduction velocity and recovery time, which are influenced by prevailing autonomic tone. AF causes an irregular heart rhythm that is quite rapid when sympathetic tone is high (Fig. 2.30). The QRS complexes usually are normal in configuration because intraventricular conduction usually is normal. Minor variation in QRS complex amplitude is common, however, and intermittent or sustained bundle branch blocks can occur. AF tends to be a consequence of marked atrial enlargement in dogs and especially in cats; it often is preceded by intermittent atrial tachyarrhythmias and perhaps atrial flutter. AF sometimes occurs spontaneously in giant breed dogs without evidence of underlying heart disease; this is known as *lone AF*. The heart rate often is normal in dogs with lone AF.

Ventricular Premature Complexes

VPCs, or PVCs, originate below the AV node. Therefore ventricular muscle activation does not occur via the normal ventricular conduction pathway, and the QRS configuration of VPCs differs from the animal's normal sinus QRS complexes. Ventricular ectopic complexes usually are wider than sinus-origin complexes because of the slower intramuscular conduction. Because VPCs usually are not conducted backward through the AV node into the atria, the sinus rate continues undisturbed and the VPC is followed by a so-called *compensatory pause* in the sinus rhythm. When the configuration of multiple VPCs or ventricular tachycardia is consistent, the complexes are described as *uniform* or *monomorphic*. When VPCs in an individual animal have differing configurations, they are said to be *multiform* or *polymorphic*. Increased electrical instability may accompany multiform VPCs or ventricular tachycardia.

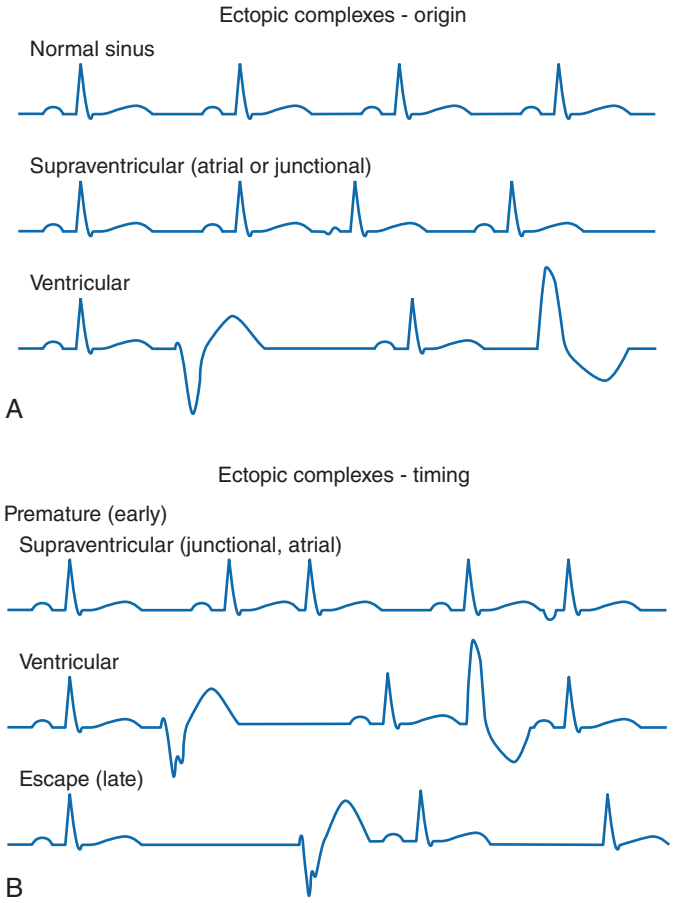

FIG 2.28
Diagrams illustrating the appearance of ectopic complexes. Abnormal impulses can originate **(A)** above the AV node (supraventricular) or from within the ventricles (ventricular). Supraventricular ectopic complexes have a normal-appearing QRS. An abnormal P wave usually precedes a complex originating in atrial tissue; no P wave (or a retrograde P wave in the ST segment—not shown) is common with an impulse originating from the AV junction. Ventricular-origin QRS complexes have a different configuration from the normal sinus QRS. The timing **(B)** of ectopic complexes refers to whether they appear before the next expected sinus complex (premature or early) or after a longer than expected pause (escape or late).

Ventricular Tachycardia

Ventricular tachycardia consists of a series of VPCs (usually at a rate > 100 beats/min). The QRS to QRS (RR) interval most often is regular, although some variation can occur. Nonconducted sinus P waves may be superimposed on or between the ventricular complexes, although they are unrelated to the VPCs because the AV node and/or ventricles are in the refractory period (physiologic AV dissociation). The term *capture beat* refers to the successful conduction of a sinus P wave into the ventricles uninterrupted by another VPC (i.e., the sinus node has "recaptured" the ventricles). If the normal ventricular activation sequence is interrupted by a VPC, a *fusion* complex can result. A fusion complex represents a melding of the normal QRS configuration and that of the VPC (see Fig. 2.29, *F*). Fusion complexes often are observed at the onset or end of a paroxysm (run) of ventricular tachycardia; they are preceded by a P wave and shortened PR interval. Identification of P waves (whether conducted or not) or fusion complexes helps in differentiating ventricular tachycardia from SVT with abnormal (aberrant) intraventricular conduction.

Polymorphic ventricular tachycardia is characterized by QRS complexes that vary in size, polarity, and often rate; sometimes the QRS configuration appears as if it were rotating around the isoelectric baseline. *Torsades de pointes* is a specific form of polymorphic ventricular tachycardia associated with Q-T interval prolongation.

Accelerated Idioventricular Rhythm

Also called *accelerated ventricular rhythm* or *idioventricular tachycardia,* an accelerated idioventricular rhythm originates within the ventricles and has a rate of about 60 to 100 beats/min in the dog (perhaps somewhat faster in the cat). Because the rate is slower than true ventricular tachycardia, it usually is a less serious rhythm disturbance. An accelerated ventricular rhythm can appear intermittently during sinus arrhythmia, as the sinus rate decreases; then the idioventricular rhythm usually is suppressed as the sinus rate increases. This rhythm is common in dogs recovering from motor vehicle trauma; it also occurs in many dogs with severe intra-abdominal or systemic disease. Often this rhythm disturbance has no deleterious effects, although it could progress to ventricular tachycardia, especially in clinically unstable patients.

Ventricular Fibrillation

Ventricular fibrillation (VF) is a lethal rhythm characterized by multiple reentrant circuits causing chaotic electrical activity within the ventricles. The ECG shows an irregularly undulating baseline with no recognizable waveforms (Fig. 2.31). The chaotic electrical activation causes only weak, uncoordinated mechanical activation, so there is no effective ventricular pumping function. Ventricular flutter, which appears as rapid sine-wave activity on the ECG, may precede fibrillation. "Course" VF has slightly larger ECG oscillations than "fine" VF and may precede it before death.

Escape Complexes

Ventricular asystole is the absence of ventricular electrical (and mechanical) activity. Escape complexes originate from automatic (*subsidiary pacemaker*) cells within the atria, the AV junction, or the ventricles (see Fig. 2.32, *B*) and constitute a protective mechanism. An escape complex occurs only after a pause in the dominant (usually sinus) rhythm. If the dominant rhythm does not resume, the escape focus continues to discharge at its own intrinsic rate, producing an *escape rhythm* (Fig. 2.32, *C*). Escape rhythms usually are regular. Ventricular escape rhythms (idioventricular rhythms) usually have an intrinsic rate of less than 40 to 50 beats/min in the dog and 100 beats/min in the cat, although

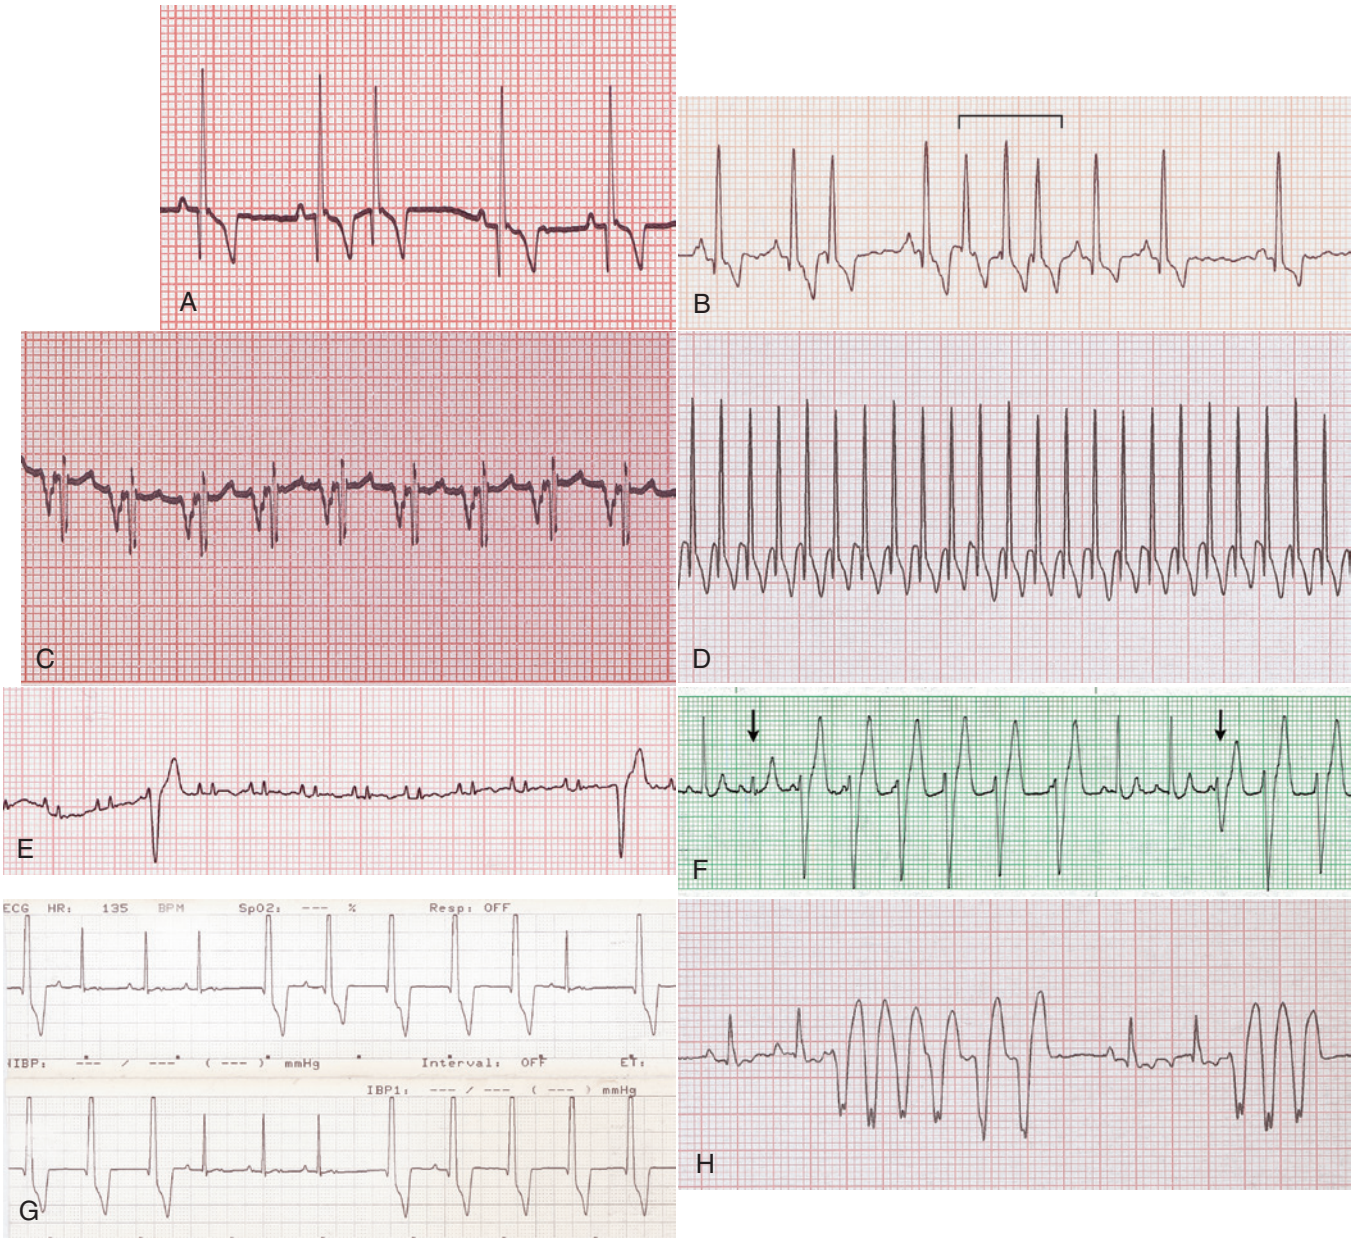

FIG 2.29
Ectopic complexes and rhythms. **(A)** Supraventricular premature complex in an old Doberman Pinscher. **(B)** Short paroxysm of supraventricular tachycardia *(bracket)* with 1 single premature complex in a mixed-breed dog with mitral regurgitation (lead II, 25 mm/sec). **(C)** Sustained atrial tachycardia in Irish Setter with mitral stenosis. Note negative, abnormal P waves. **(D)** Rapid supraventricular tachycardia in a Labrador Retriever puppy (heart rate ~360 beats/min). **(E)** Sinus rhythm with two isolated ventricular premature complexes in a cat with hypertrophic cardiomyopathy. **(F)** Intermittent paroxysms of ventricular tachycardia demonstrating fusion complexes *(arrows)* in a dog. **(G)** Accelerated idioventricular rhythm interspersed with a background of sinus arrhythmia in a dog. **(H)** Paroxysmal, rapid ventricular tachycardia in a dog with dilated cardiomyopathy. All ECGs are lead II, 25 mm/sec.

higher ventricular escape rates can occur. Junctional escape rhythms usually range from 40 to 60 beats/min in the dog, with a faster rate expected in the cat. It is important to differentiate escape from premature complexes. Escape activity should never be suppressed with antiarrhythmic drugs.

CONDUCTION DISTURBANCES

Abnormal impulse conduction within the atria can occur at several sites. SA block prevents impulse transmission from the SA node to adjacent atrial muscle. Although this cannot reliably be differentiated from sinus arrest on the ECG, with

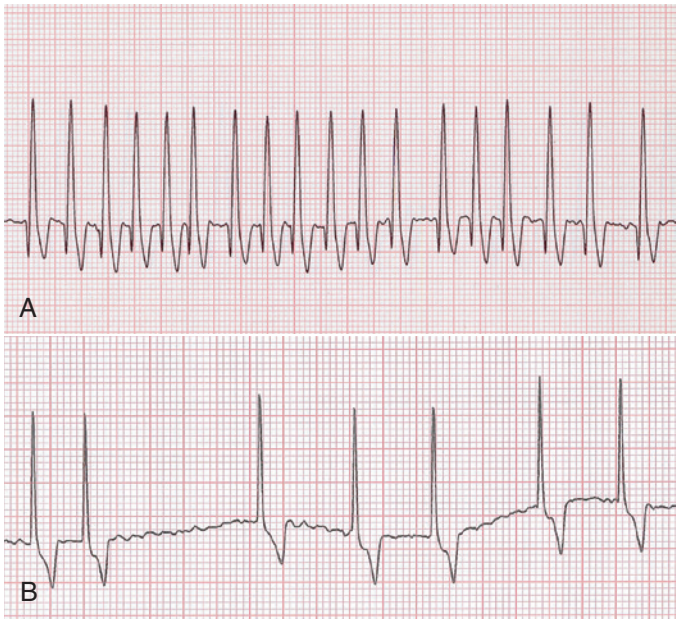

FIG 2.30
Atrial fibrillation. **(A)** Uncontrolled atrial fibrillation (heart rate 240 beats/min) in a Labrador Retriever with dilated cardiomyopathy (lead II, 25 mm/sec). **(B)** Well-controlled ventricular response rate after therapy in a different dog (heart rate ~100 beats/min). Note baseline fibrillation waves, lack of identifiable P waves, and irregular RR intervals. Lead II, 25 mm/sec.

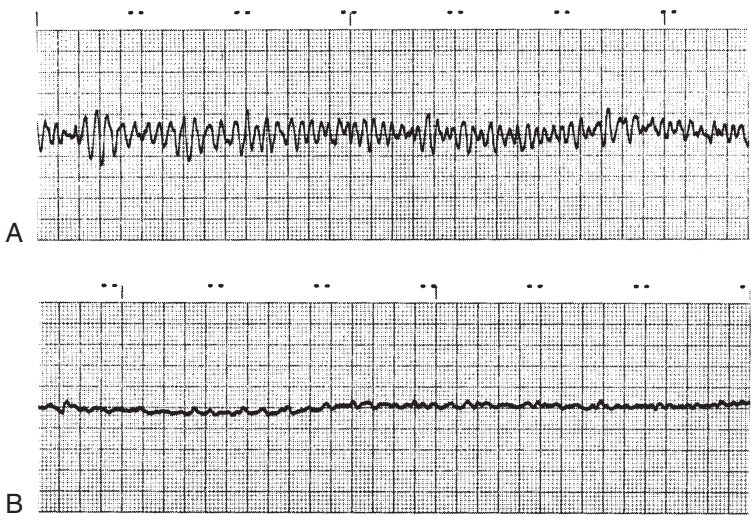

FIG 2.31
Ventricular fibrillation. Note chaotic baseline motion and absence of organized waveforms. **(A)** Coarse fibrillation; **(B)** fine fibrillation. Lead II, 25 mm/sec, dog.

SA block the interval between P waves is a multiple of the normal P–P interval. An (atrial, junctional, or ventricular) escape rhythm should take over the cardiac rhythm if there is prolonged sinus arrest or block. Atrial standstill occurs when diseased atrial muscle prevents normal electrical and mechanical function, regardless of sinus node activity; consequently, a junctional or ventricular escape rhythm results. P waves are not seen with atrial standstill. Because hyperkalemia interferes with normal atrial function, it can mimic atrial standstill.

Conduction Disturbances Within the Atrioventricular Node

Abnormalities of AV conduction can occur from excessive vagal tone; drugs (e.g., digoxin, xylazine, medetomidine, verapamil, anesthetic agents); and organic disease of the AV

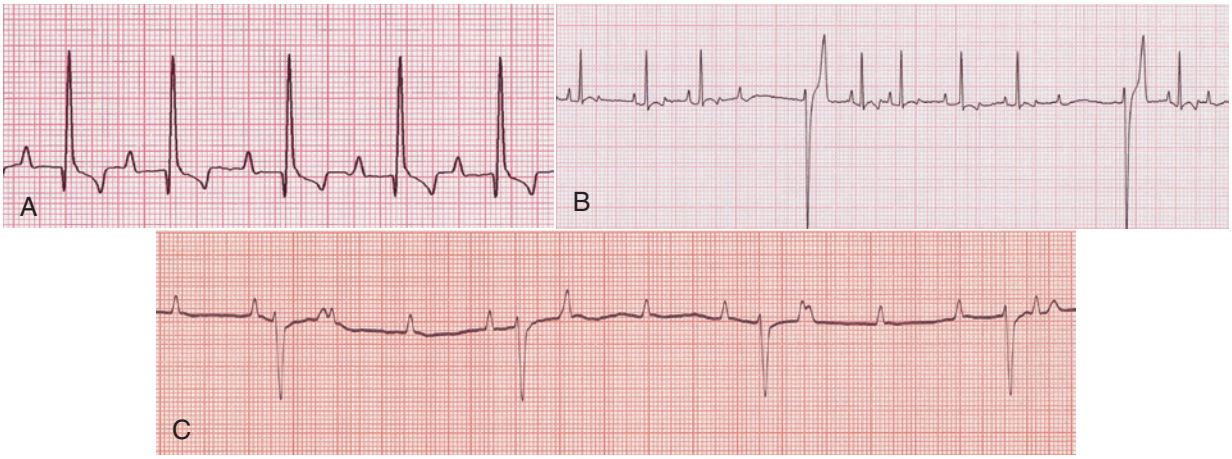

FIG 2.32
Atrioventricular (AV) conduction abnormalities. **(A)** First-degree AV block in an older Cocker Spaniel (lead II, 50 mm/sec). **(B)** Second-degree AV block (Wenckebach) with two ventricular escape complexes in an older West Highland White Terrier. The differentiation between escape and premature complexes is crucial (lead II, 25 mm/sec). **(C)** Complete (third-degree) heart block in a 19-year-old Lhasa Apso. There is underlying sinus rhythm, but no P waves are conducted; a slow ventricular escape rhythm has resulted (lead II, 25 mm/sec).

node and/or intraventricular conduction system. Three major types of AV conduction disturbance are described (Fig. 2.32). First-degree (1°) AV block, the mildest AV conduction disturbance, occurs when the atrial to ventricular conduction time is prolonged. All impulses are conducted with 1° AV block, but the PR interval is longer than normal. Second-degree (2°) AV block is characterized by intermittent AV conduction; some P waves are not followed by a QRS complex. When many P waves are not conducted, the patient is described as having high-grade 2° AV block. There are two subtypes of 2° AV block. Mobitz type I (Wenckebach) is characterized by progressive PR interval prolongation until conduction fails, resulting in a nonconducted P wave; it frequently is associated with high vagal tone or disorders of the AV node itself. Mobitz type II 2° AV block is characterized by uniform PR intervals preceding the blocked impulse; it is more likely to be associated with disease lower in the AV conduction system (e.g., bundle of His or major bundle branches). An alternative classification of 2° AV block based on QRS configuration has been described. Patients with type A 2° block have a normal, narrow QRS configuration; those with type B 2° block have a wide or abnormal QRS configuration, which suggests diffuse disease lower in the ventricular conduction system. Mobitz type I AV block usually is type A, whereas Mobitz type II frequently is type B. Escape complexes commonly appear during long pauses in ventricular activation. Third-degree (3°) or complete AV block means complete failure of AV conduction; no sinus (or supraventricular) impulses are conducted into the ventricles. Although a regular sinus rhythm or sinus arrhythmia often is evident, the P waves are completely dissociated from the QRS complexes, which result from a (usually) regular ventricular escape rhythm.

Intraventricular Conduction Disturbances

Abnormal (aberrant) ventricular conduction occurs in association with slowed or blocked impulse transmission within a major bundle branch or ventricular region. The right bundle branch, or the left anterior or posterior fascicles of the left bundle branch, can be affected singly or in combination. A block in all three major branches results in 3° (complete) heart block. Electrical activation of the myocardium served by the blocked pathway occurs relatively slowly, from myocyte to myocyte. Therefore the QRS complexes appear wide and abnormal, similar to a ventricular-origin QRS complex (Fig. 2.33). Right bundle branch block (RBBB) is sometimes identified in otherwise normal dogs and cats, although it can occur from disease or distention of the RV. Left bundle branch block (LBBB) usually is related to clinically relevant underlying LV disease. The left anterior fascicular block (LAFB) pattern is common with concentric LV hypertrophy and in cats with hypertrophic cardiomyopathy.

Ventricular Preexcitation

Early activation (preexcitation) of part of the ventricular myocardium can occur when there is an accessory conduction pathway that bypasses the normal, more slowly conducting AV nodal pathway. Several types of preexcitation and accessory pathways have been described. Most cause a shortened PR interval. Wolff-Parkinson-White (WPW) preexcitation also is characterized by early widening and slurring of the QRS by a so-called *delta* wave (Fig. 2.34). This pattern occurs because the accessory pathway (Kent bundle) lies outside the AV node (is extranodal) and allows early depolarization (represented by the delta wave) of part of the ventricle away from where normal ventricular activation begins. Other accessory pathways may connect the atria or

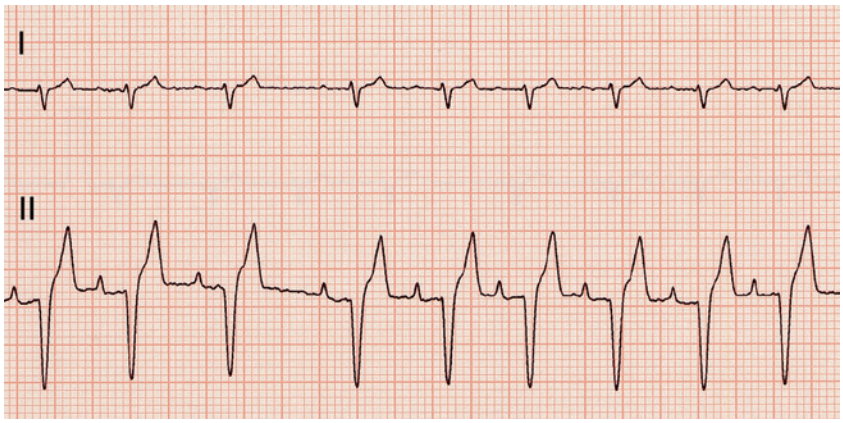

FIG 2.33
Electrocardiogram from a dog that developed right bundle branch block and first-degree AV block after doxorubicin therapy. Sinus arrhythmia, leads I and II, 25 mm/sec, 1 cm = 1 mV.

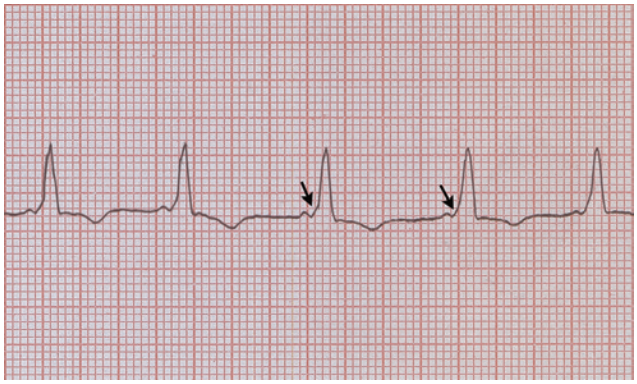

FIG 2.34
Ventricular preexcitation in a cat. Note slowed QRS upstroke (delta wave; *arrows*) immediately following each P wave. Lead II, 50 mm/sec, 1 cm = 1 mV.

dorsal areas of the AV node directly to the bundle of His. These cause a short PR interval without early QRS widening. Preexcitation can occur consistently, or be intermittent or concealed (not evident on ECG). The danger with preexcitation is that a reentrant SVT can occur using the accessory pathway and AV node (also called *AV reciprocating tachycardia*). In the most common pattern, the tachycardia impulses travel down into the ventricles via the AV node (antegrade or orthodromic conduction), then back up to the atria via the accessory pathway; however sometimes the direction is reversed. Rapid AV reciprocating tachycardia can cause weakness, syncope, CHF, and death. The presence of the WPW pattern on ECG in conjunction with AV reciprocating tachycardia that causes clinical signs is known as the *WPW syndrome*.

MEAN ELECTRICAL AXIS

The MEA describes the average direction of the ventricular depolarization process in the frontal plane. It represents the summation of the various instantaneous vectors that occur from beginning until completion of ventricular muscle depolarization. Major intraventricular conduction disturbances and/or ventricular enlargement can shift the average direction of ventricular activation and therefore the MEA. By convention, only the six frontal plane leads are used to determine MEA. Either of the following methods can be used:

1. Find the lead (I, II, III, aVR, aVL, or aVF) with the largest R wave (*Note:* the R wave, by definition, is a positive deflection). The positive electrode of this lead is the approximate orientation of the MEA.
2. Find the lead (I, II, III, aVR, aVL, or aVF) where the QRS complex is most isoelectric (i.e., the positive and negative QRS deflections are of about equal amplitude). Then identify the lead oriented perpendicular to this "isoelectric" lead on the hexaxial lead diagram (see Fig. 2.25). If the QRS complex in this perpendicular lead is mostly positive, the MEA is oriented toward the positive pole (electrode) of this lead. If the QRS in the perpendicular lead is mostly negative, the MEA is oriented toward that lead's negative pole. If all frontal plane leads appear isoelectric, the MEA is indeterminate. Fig. 2.25 shows the normal MEA range for dogs and cats.

CHAMBER ENLARGEMENT AND BUNDLE BRANCH BLOCK PATTERNS

Changes in the ECG waveforms can suggest enlargement or abnormal conduction within a particular cardiac chamber, although enlargement does not always produce these changes. A widened P wave is the classic pattern of LA enlargement (so-called *p mitrale*); sometimes the P wave is notched as well as wide. Tall, spiked P waves (so-called *p pulmonale*) suggest RA enlargement. With atrial enlargement, the usually obscure atrial repolarization (T_a) wave may be evident as a baseline shift in the opposite direction of the P wave.

A right-axis deviation and an S wave in lead I are strong criteria for RV enlargement (or RBBB). Other ECG changes usually can be found as well. Three or more of the criteria listed in Box 2.4 generally are present when RV enlargement exists. RV enlargement (dilation or hypertrophy) is likely to be pronounced if it is evident on the ECG because LV activation forces are normally so dominant. LV dilation and eccentric hypertrophy typically increase R-wave amplitude in the caudal leads (II and aVF) and sometimes widen the QRS. LV concentric hypertrophy inconsistently produces a left-axis deviation.

Conduction block in any of the major ventricular conduction pathways disturbs the normal activation process and alters QRS configuration. Electrical activation in regions of ventricular muscle served by the affected bundle branch occurs late and progresses slowly. This widens the QRS complex (especially the terminal portion of it) and shifts the QRS (and MEA) orientation toward the area of delayed activation. Box 2.4 and Fig. 2.35 summarize ECG patterns associated with ventricular enlargement or conduction delay. Box 2.5 lists common clinical associations.

BOX 2.4

Ventricular Chamber Enlargement and Conduction Abnormality Patterns

Normal

Normal mean electrical axis
No S wave in lead I
R wave taller in lead II than in lead I
Lead V_2 R wave larger than S wave

Right Ventricular Enlargement

Right-axis deviation
S wave present in lead I
S wave in V_{2-3} larger than R wave or > 0.8 mV
Q-S ("W" shape) in V_{10}
Positive T wave in lead V_{10}
Deep S wave in leads II, III, and aV_F

Right Bundle Branch Block (RBBB)

Same as right ventricular enlargement, with prolonged terminal (latter) portion of the QRS (wide, sloppy S wave)

Left Ventricular Dilation (Eccentric Hypertrophy)

Normal frontal axis
Taller than normal R wave in leads II, aV_F, V_{2-3}
Possibly widened QRS; slurring and displacement of ST segment and T-wave enlargement may also occur

Left Ventricular (Concentric) Hypertrophy

Left-axis deviation
R wave in lead I taller than R wave in leads II or aV_F
No S wave in lead I

Left Anterior Fascicular Block (LAFB)

Same as left ventricular hypertrophy, possibly with wider QRS

Left Bundle Branch Block (LBBB)

Normal frontal axis
Very wide and sloppy QRS; R waves may be taller than normal in leads II, aV_F, V_{2-3}
Small Q wave may be present in leads II, III, and aV_F (incomplete LBBB)

Other QRS Abnormalities

Small-voltage QRS complexes sometimes occur. Causes of reduced QRS amplitude include pleural or pericardial effusions, obesity, intrathoracic mass lesions, hypovolemia, and hypothyroidism. Small complexes occasionally are seen in dogs with dilated cardiomyopathy or without identifiable abnormalities.

Electrical alternans is an every-other-beat recurring alteration in QRS complex size or configuration. This most often is seen with large-volume pericardial effusions (see Chapter 9).

ST-T ABNORMALITIES

The ST segment extends from the end of the QRS complex (also called the *J-point*) to the onset of the T wave. In dogs

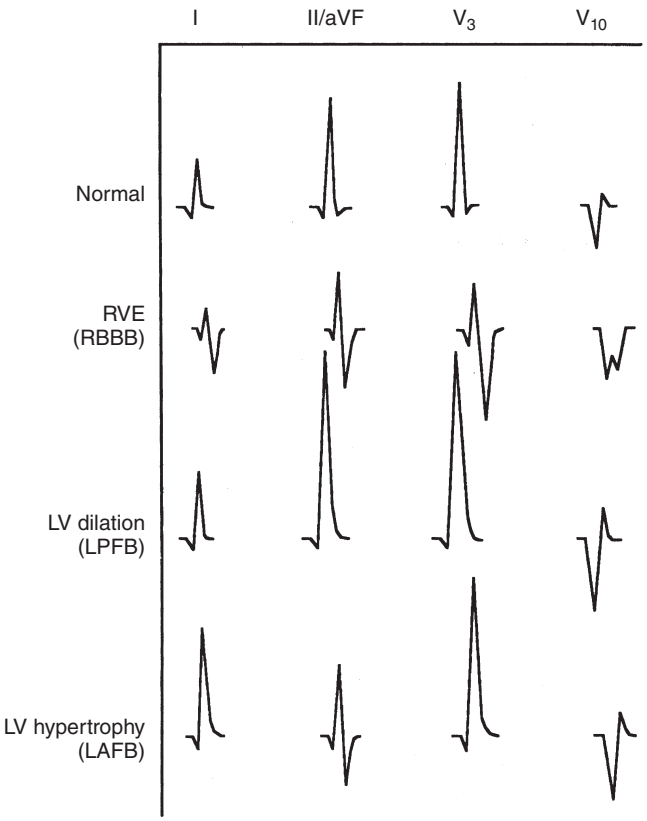

FIG 2.35
Schematic of common ventricular enlargement patterns and conduction abnormalities. Electrocardiogram leads are listed across top. *LAFB,* Left anterior fascicular block; *LPFB,* left posterior fascicular block; *LV,* left ventricular; *RBBB,* right bundle branch block; *RVE,* right ventricular enlargement.

BOX 2.5

Clinical Associations of Electrocardiographic Enlargement Patterns

Left Atrial Enlargement

Mitral insufficiency (acquired or congenital)
Cardiomyopathies
Patent ductus arteriosus
Subaortic stenosis
Ventricular septal defect
Mitral stenosis (rare)

Right Atrial Enlargement

Tricuspid insufficiency (acquired or congenital)
Chronic respiratory disease
Interatrial septal defect
Pulmonic stenosis

Left Ventricular Enlargement (Dilation)

Mitral insufficiency
Dilated cardiomyopathy
Aortic insufficiency
Patent ductus arteriosus
Ventricular septal defect
Subaortic stenosis

Left Ventricular Enlargement (Hypertrophy)

Hypertrophic cardiomyopathy
Subaortic stenosis

Right Ventricular Enlargement

Pulmonic stenosis
Tetralogy of Fallot
Tricuspid insufficiency (acquired or congenital)
Severe heartworm disease
Severe pulmonary hypertension (of other cause)

and cats this segment tends to slope into the T wave that follows without clear demarcation. Abnormal J-point and ST segment elevation (>0.15 mV in dogs or >0.1 mV in cats) or depression (>0.2 mV in dogs or >0.1 mV in cats) from baseline in leads I, II, or aVF often is clinically significant. Myocardial ischemia and other types of myocardial injuries are possible causes.

Atrial enlargement or tachycardia can cause pseudodepression of the ST segment because of prominent T_a waves. Other secondary causes of ST segment deviation include ventricular hypertrophy, slowed conduction, and some drugs (e.g., digoxin).

The T wave represents ventricular muscle repolarization; it may be positive, negative, or biphasic in normal cats and dogs. Changes in T wave size, shape, or polarity from previous recordings in a particular animal are probably clinically important. Abnormalities of the T wave can be primary (i.e., not related to the depolarization process) or secondary (i.e., related to abnormalities of ventricular depolarization). Secondary ST-T changes tend to be in the opposite direction of the main QRS deflection. Box 2.6 lists some causes of ST-T abnormalities.

QT Interval

The QT interval represents the total time of ventricular activation and repolarization. This interval varies inversely with average heart rate; for example, faster rates are associated with a shorter QT interval. Autonomic nervous tone, various drugs, and electrolyte disorders influence the duration of the QT interval (see Box 2.6). Inappropriate prolongation of the QT interval can facilitate development of serious reentrant arrhythmias when underlying nonuniformity in ventricular repolarization exists. Prediction equations for expected QT duration have been published for normal dogs and cats.

ELECTROCARDIOGRAPHIC MANIFESTATIONS OF DRUG TOXICITY AND ELECTROLYTE IMBALANCE

Antiarrhythmic agents, digoxin, anesthetic, and other drugs often alter heart rhythm and/or conduction either by their direct electrophysiologic effects or by affecting autonomic tone (Box 2.7).

Potassium has marked and complex influences on cardiac electrophysiology. Hypokalemia can increase spontaneous automaticity of cardiac cells, as well as nonuniformly slow repolarization and conduction; these effects predispose to both supraventricular and ventricular arrhythmias. Hypokalemia can cause progressive ST segment depression, reduced T wave amplitude, and QT interval prolongation. Severe hypokalemia also can increase QRS and P wave amplitudes and durations. In addition, hypokalemia exacerbates digoxin toxicity and reduces the effectiveness of class I antiarrhythmic agents (see Chapter 4). Hypernatremia and alkalosis worsen the effects of hypokalemia on the heart.

Moderate hyperkalemia actually has an antiarrhythmic effect by reducing automaticity and enhancing uniformity and speed of repolarization. However, rapid or severe increases in serum potassium concentration are arrhythmogenic, primarily because they slow conduction velocity and shorten the refractory period. A number of ECG changes may occur as serum potassium (K^+) concentration rises; however, these may be observed only inconsistently in clinical cases, perhaps because of additional concurrent metabolic abnormalities. Observations from experimental studies indicate an early change, as serum rises to and above 6 mEq/L, is a peaked ("tented") T wave as the QT interval shortens. However, the characteristic symmetric "tented" T wave may be evident in only some leads and may be of small amplitude. In addition, progressive slowing of intraventricular conduction leads to widening of the QRS complexes. Experimentally, conduction through the atria slows as serum K^+ nears 7 mEq/L, and P waves flatten. P waves disappear as atrial conduction fails at about 8 mEq/L. The sinus node is relatively resistant to the effects of hyperkalemia and continues to function, although the sinus rate may slow. Despite progressive atrial muscle unresponsiveness, specialized

BOX 2.6

Causes of ST Segment, T Wave, and QT Abnormalities

Depression of J Point/ST Segment

Myocardial ischemia
Myocardial infarction/injury (LV subendocardial)
Hyperkalemia or hypokalemia
Cardiac trauma
Secondary change (ventricular hypertrophy, conduction disturbance, VPCs)
Digitalis ("sagging" appearance)
Pseudodepression (prominent T_a wave)

Elevation of J Point/ST Segment

Pericarditis
Left ventricular epicardial injury
Myocardial infarction (transmural)
Myocardial hypoxia
Secondary change (ventricular hypertrophy, conduction disturbance, VPCs)
Digoxin toxicity

Prolongation of QT Interval

Hypocalcemia
Hypokalemia
Secondary to prolonged QRS
Hypothermia
Central nervous system abnormalities
Ethylene glycol poisoning
Quinidine toxicity

Shortening of QT Interval

Hypercalcemia
Hyperkalemia
Digitalis toxicity

Large T Waves

Myocardial hypoxia
Ventricular enlargement
Intraventricular conduction abnormalities
Hyperkalemia
Metabolic or respiratory diseases
Normal variation

Tented T Waves

Hyperkalemia

VPC, Ventricular premature complex.

fibers transmit sinus impulses to the ventricles, producing a *sinoventricular* rhythm. Hyperkalemia should be a differential diagnosis for patients with a wide-QRS complex rhythm without P waves, even if the heart rate is not slow. At extremely high serum K^+ concentrations (>10 mEq/L), an irregular ectopic ventricular rhythm, fibrillation, or asystole develops. Fig. 2.36 illustrates the electrocardiographic effects of severe hyperkalemia and the response to therapy in a dog with Addison disease. Hypocalcemia, hyponatremia, and acidosis accentuate the electrocardiographic changes caused by hyperkalemia, whereas hypercalcemia and hypernatremia tend to counteract them.

Marked ECG changes caused by other electrolyte disturbances are uncommon. Severe hypercalcemia or hypocalcemia could have noticeable effects (see Box 2.6), but this rarely is seen clinically. Severe hypomagnesemia can predispose to ventricular tachyarrhythmias and could cause U waves to appear on the ECG; in addition, it can exaggerate the effects of hypocalcemia as well as predispose to digoxin toxicity.

Heart Rate Variability

Phasic fluctuations in vagal and sympathetic tone during the respiratory cycle, as well as during slower periodic oscillations of arterial blood pressure, influence the variation in time between consecutive heartbeats. *Heart rate variability* (HRV) refers to the fluctuation of beat-to-beat time intervals around their mean value. HRV is influenced by baroreceptor function, the respiratory cycle, and sympathetic/parasympathetic balance. The degree of HRV decreases with severe myocardial dysfunction and heart failure, as well as other causes of increased sympathetic tone. The variation in instantaneous heart rate (R-to-R intervals) can be evaluated as a function of time (time-domain analysis) and in terms of the frequency and amplitude of its summed oscillatory components (frequency-domain or power spectral analysis). Frequency-domain analysis allows assessment of the balance between sympathetic and vagal modulation of the cardiovascular system. HRV assessment can provide an indicator of autonomic function, and possibly prognosis, although its clinical potential in veterinary patients has not been fully explored.

COMMON ARTIFACTS

Fig. 2.37 illustrates some common ECG artifacts. Electrical (60 Hz) interference can be minimized or eliminated by properly grounding the ECG machine. Turning off other electrical equipment or lights on the same circuit or having a different person restrain the animal may also help. Other artifacts sometimes are confused with arrhythmias; however, artifacts do not disturb the underlying cardiac rhythm. Conversely, ectopic complexes often disrupt the underlying rhythm; they also are followed by a T wave. Careful examination for these characteristics usually allows differentiation between intermittent artifacts and arrhythmias. When multiple leads can be recorded simultaneously, it is helpful to compare the cardiac rhythm and complex configurations in all leads available.

BOX 2.7

Electrocardiographic Changes Associated With Electrolyte Imbalance and Selected Drug Adverse Effects/Toxicity

Hyperkalemia (See Fig. 2.36)

Peaked (tented) T waves (can be large or small)
Short QT interval
Flat or absent P waves
Widened QRS
ST segment depression

Hypokalemia

Prolonged QT interval
ST segment depression
Small, biphasic T waves
Tachyarrhythmias

Hypercalcemia

Few effects
Short QT interval
Prolonged conduction
Tachyarrhythmias

Hypocalcemia

Prolonged QT interval
Tachyarrhythmias

Digoxin

PR prolongation
Second-degree (2°) or third-degree (3°) AV block
Sinus bradycardia or arrest
Accelerated junctional rhythm
Ventricular premature complexes
Ventricular tachycardia
Paroxysmal atrial tachycardia with block
Atrial fibrillation with slow ventricular rate

Lidocaine

AV block
Ventricular tachycardia
Sinus arrest

β-Blockers

Sinus bradycardia
Prolonged PR interval
AV block

Quinidine/Procainamide

Atropine-like effects
Prolonged QT interval
AV block
Ventricular tachyarrhythmias
Widened QRS complex
Sinus arrest

Medetomidine/Xylazine

Sinus bradycardia
Sinus arrest/sinoatrial block
AV block
Ventricular tachyarrhythmias (especially with halothane, epinephrine)

Barbiturates/Thiobarbiturates

Ventricular bigeminy

Halothane/Methoxyflurane

Sinus bradycardia
Ventricular arrhythmias (increased sensitivity to catecholamines, especially halothane)

AV, Atrioventricular.

AMBULATORY ELECTROCARDIOGRAPHY

Holter Monitoring

Continuous recording of cardiac electrical activity during normal daily activities (except swimming), strenuous exercise, and sleep is provided by Holter monitoring. This can be useful for detecting and quantifying intermittent cardiac arrhythmias and therefore helps identify cardiac causes of syncope and episodic weakness, if these occur during the monitoring period. Holter monitoring also is used to assess efficacy of antiarrhythmic drug therapy and to screen for arrhythmias associated with cardiomyopathy or other diseases. The Holter monitor is a small battery-powered digital (or analog) recorder worn by the patient, typically for 24 hours. Two or three ECG channels are recorded from modified chest leads using adhesive patch electrodes. During the recording period, the animal's activities are noted in a patient diary for later correlation with simultaneous ECG events. An event button on the Holter recorder can be activated to mark the time a syncopal or other episode is witnessed.

The recording is analyzed using computer algorithms that classify the recorded complexes, ideally with oversight and editing by a trained Holter technician experienced with veterinary recordings. This is important because a fully automated computer analysis can result in misclassification of some QRS complexes and artifacts from dog and cat recordings. A summary of the entire recording period and selected segments of the ECG are included in the Holter report. Evaluation of a full disclosure display of the entire recording also is helpful for comparison with the technician-selected ECG strips and the times of clinical events and patient activities noted in the patient diary (see Suggested Readings for more information). A Holter monitor, hook-up supplies, and analysis can be obtained from some commercial human Holter scanning services, as well as many veterinary teaching hospitals and cardiology referral centers.

Wide variation in heart rate can occur throughout the day in normal animals. In dogs, maximum heart rates of up to

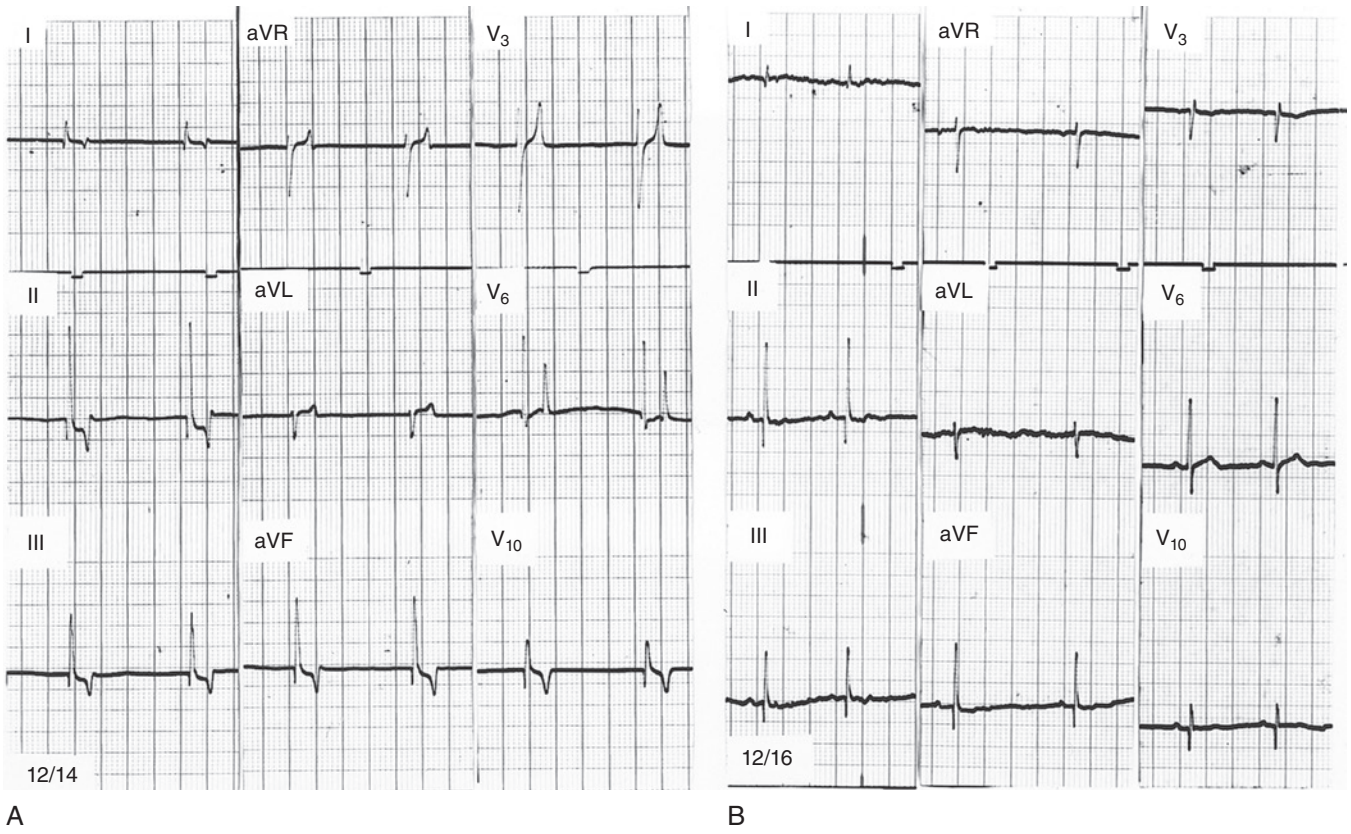

FIG 2.36
ECGs recorded in a female Poodle with hypoadrenocorticism at presentation **(A)** (K^+ = 10.2; Na^+ = 132 mEq/L), and 2 days later after treatment **(B)** (K^+ = 3.5; Na^+ = 144 mEq/L). Note absence of P waves, accentuated and tented T waves (especially in chest leads), shortened QT interval, and slightly widened QRS complexes in **A** compared with **B.** Leads as marked, 25 mm/sec, 1 cm = 1 mV.

300 beats/min have been recorded with excitement or activity. Episodes of bradycardia (<50 beats/min) are common, especially during quiet periods and sleep. Sinus arrhythmia, sinus pauses (sometimes for more than 5 seconds), and occasional 2° AV block appear to be common in dogs, especially at times when mean heart rate is lower. Heart rates in normal cats also vary widely over 24 hours, sometimes ranging from about 70 to 290 beats/min. Regular sinus rhythm predominates in normal cats, although sinus arrhythmia is evident at slower heart rates. Ventricular premature complexes occur only sporadically in normal dogs and cats; VPC prevalence appears to increase only slightly with age.

Intermittent Event Recording

Cardiac event recorders are small loop recorders. When activated, brief periods of a single modified chest lead ECG are stored within their microprocessor's memory. Event recorders are used most often to determine whether episodic weakness or syncope is caused by a cardiac arrhythmia. The event recorder typically is worn for periods of a week or longer. This is helpful in patients with intermittent weakness or collapse that may not recur often enough to be captured during a single 24-hour continuous ECG recording. However, because it cannot store prolonged, continuous ECG activity, the recorder must be manually activated when an episode is observed. The recorder then stores the ECG from a predetermined time frame (e.g., from 30-45 seconds before activation to 15-30 seconds after) for later retrieval and analysis.

Implantable (subcutaneous) ECG loop recorders also can be used in veterinary patients and allow intermittent ECG monitoring over a period of months. The ECG is recorded from two electrodes on the device's casing and held in a temporary memory buffer, similar to external event recorders, until manual or automatic activation triggers storage of a brief segment into more permanent memory. A compatible pacemaker programmer is used to set parameters for activation and recording, and to download the recorded ECG segments. Automatic activation is triggered by preset determinants for "bradycardia," "tachycardia," and "asystole."

Intermittent ECG acquisition using a handheld recording device (Kardia Mobile, AliveCor.com; Veterinary iPhone

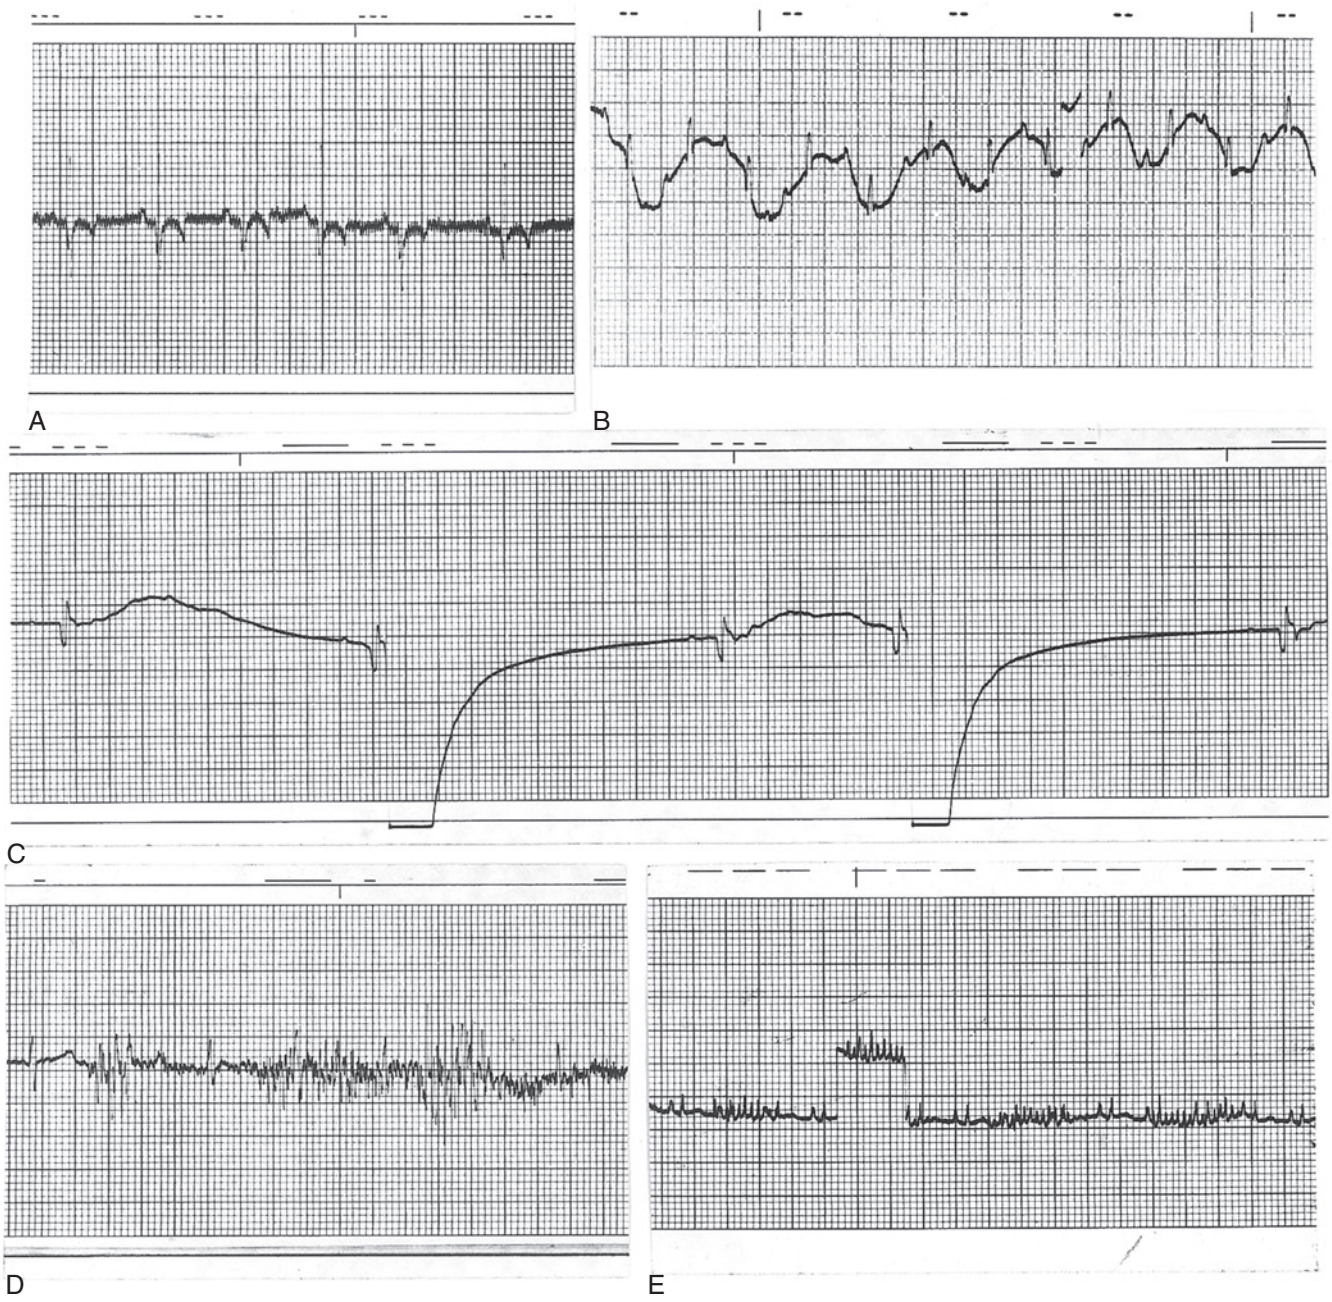

FIG 2.37
Common electrocardiogram artifacts. **(A)** 60 Hz electrical interference; lead III, 25 mm/sec, dog. **(B)** Baseline movement caused by panting; lead II, 25 mm/sec, dog. **(C)** Respiratory motion artifact; lead V_3, 50 mm/sec, dog. **(D)** Severe muscle tremor artifact; lead V_3, 50 mm/sec, cat. **(E)** Intermittent, rapid baseline spikes caused by purring in cat; a calibration mark is seen just left of the center of the strip. Lead aVF, 25 mm/sec.

ECG monitor, AliveCorVet.com) with smart phone interface is another means of assessing heart rate and rhythm that can be used anywhere. The patient is placed in right lateral recumbency, alcohol is applied to improve skin contact with electrodes on the back of the recorder, the device (with linked smart phone) is positioned on the chest wall over the heart, and the recording function is activated. After the ECG has been recorded, it is sent via email to the veterinarian for evaluation. This method can be useful for periodically assessing heart rhythm at home in cases with suspected arrhythmias and also for spot checks of heart rate control in animals with AF. Artifacts can hinder interpretation in some cases, especially in those patients that are not quiet and relaxed during recording.

OTHER TECHNIQUES

CENTRAL VENOUS PRESSURE MEASUREMENT

CVP is the fluid pressure within the RA and, by extension, the intrathoracic cranial vena cava. It is influenced by intravascular volume, venous compliance, and cardiac function. CVP measurement helps in differentiating high right heart-filling pressure (as from right heart failure or pericardial disease) from other causes of pleural or peritoneal effusion. However, it is important to note that pleural effusion itself can increase intrapleural pressure and raise CVP even in the absence of cardiac disease. Therefore CVP should be measured after thoracocentesis in patients with moderate- to large-volume pleural effusion. CVP sometimes is used to monitor critical patients receiving large intravenous fluid infusions. However, CVP is not an accurate reflection of left heart-filling pressure and thus is not a reliable way to monitor for cardiogenic pulmonary edema. The CVP in normal dogs and cats usually ranges from 0 to 8 (up to 10) cm H_2O. Fluctuations in CVP that parallel those of intrapleural pressure occur during respiration.

CVP is measured via a large-bore jugular catheter that extends into or close to the RA. The catheter is placed aseptically and connected by extension tubing and a three-way stopcock to a fluid administration set and container of crystalloid fluid. Free flow of fluid through this catheter system into the patient should be verified (stopcock side-port turned off). A water manometer is attached to the stopcock and positioned vertically with the stopcock (representing 0 cm H_2O) placed at the same horizontal level as the patient's RA. Usually the patient is placed in lateral or sternal recumbency for CVP measurement. The stopcock is turned off to the animal, allowing the manometer to fill with fluid; then the stopcock is turned off to the fluid reservoir so that the fluid column in the manometer equilibrates with the patient's CVP. Repeated measurements are more consistent when taken with the animal and manometer in the same position and during the expiratory phase of respiration. Small fluctuations in the manometer's fluid meniscus occur with the heartbeat, and slightly larger movement is associated with respiration. Marked change in the height of the fluid column associated with the heartbeat suggests either severe tricuspid insufficiency or that the catheter tip is within the RV.

ANGIOCARDIOGRAPHY

Nonselective angiocardiography can be used to define several acquired and congenital diseases, including cardiomyopathy and heartworm disease in cats, severe pulmonic or (sub) aortic stenosis, patent ductus arteriosus, and tetralogy of Fallot. Intracardiac septal defects and valvular regurgitation cannot reliably be identified. The quality of such studies is higher with a rapid injection of radiopaque contrast agent via a large-bore catheter and with smaller patient size. In most cases, echocardiography more safely provides similar or more information. However, evaluation of the pulmonary vasculature is better accomplished using nonselective angiocardiography.

Selective angiocardiography is performed by advancing cardiac catheters into specific areas of the heart or great vessels. Intracardiac and vascular pressure measurements, and blood sample acquisition for oxygen content assessment (oximetry), generally are done before making radiopaque contrast injections. Selective angiocardiography allows identification of abnormalities in anatomy and the path of blood flow. Doppler echocardiography often can provide comparable diagnostic information noninvasively. However, selective angiography is a necessary component of many cardiac interventional procedures.

CARDIAC CATHETERIZATION

Cardiac catheterization allows measurement of pressure, cardiac output, and blood oxygen concentrations from specific intracardiac locations. Specialized catheters are selectively placed into different areas of the heart and vasculature via the jugular vein, carotid artery, or femoral vessels. Congenital and acquired cardiac or vascular abnormalities can be identified with these procedures in combination with selective angiocardiography. The advantages of Doppler echocardiography often outweigh those of cardiac catheterization, especially in view of the good correlation between certain Doppler- and catheterization-derived measurements. However, cardiac catheterization is necessary for balloon valvuloplasty, ductal occlusion, and other interventional procedures.

Pulmonary capillary wedge pressure (PCWP) monitoring is done rarely to measure left heart-filling pressure in dogs with heart failure. A Swan-Ganz (end-hole, balloon-tipped) monitoring catheter is passed into the main pulmonary artery. When the balloon is inflated, the catheter tip becomes wedged in a smaller pulmonary artery, occluding flow in that vessel. The pressure measured at the catheter tip reflects pulmonary capillary pressure, which is essentially equivalent to LA pressure. This invasive technique allows differentiation of cardiogenic from noncardiogenic pulmonary edema and provides a means of monitoring cardiac output as well as the effectiveness of heart failure therapy. However, its use requires meticulous, aseptic catheter placement and continuous patient monitoring.

Endomyocardial Biopsy

Small samples of endocardium and adjacent myocardium can be obtained using a special bioptome passed into the RV via a jugular vein. Routine histopathology and other techniques to evaluate myocardial metabolic abnormalities can be performed on the samples. Endomyocardial biopsy sometimes is used for myocardial disease research but is rarely used in clinical veterinary practice.

CHAPTER 3

Management of Heart Failure

OVERVIEW OF HEART FAILURE

Heart failure entails abnormalities of cardiac systolic or diastolic function, or both. These can occur without evidence of abnormal fluid accumulation (congestion), especially in the initial stages of disease. *Congestive heart failure* (CHF) is characterized by high cardiac filling pressure, which leads to venous congestion and tissue fluid accumulation. It is considered a clinical syndrome rather than a specific etiologic diagnosis. The pathophysiology of heart failure is complex. It involves structural and functional changes within the heart and vasculature, as well as other organs. The process of progressive cardiac remodeling inherent to heart failure can develop secondary to cardiac injury or stress from valvular disease, genetic mutations, acute inflammation, ischemia, increased systolic pressure load, and other causes.

CARDIAC RESPONSES

Cardiac remodeling refers to the changes in myocardial size, shape, and stiffness that occur in response to various mechanical, biochemical, and molecular signals induced by the underlying injury or stress. These changes include myocardial cell hypertrophy, cardiac cell drop-out or self-destruction (apoptosis), excessive interstitial matrix formation, fibrosis, and destruction of normal collagen binding between individual myocytes. The latter, resulting from effects of myocardial collagenases or matrix metalloproteinases, can lead to cardiac chamber dilation or distortion from myocyte slippage. Stimuli for remodeling include mechanical forces (for example, increased wall stress from volume or pressure overload) and the effects of various neurohormones (such as angiotensin II, norepinephrine, endothelin, and aldosterone) and proinflammatory cytokines (including tumor necrosis factor [TNF]-α), as well as other cytokines (such as osteopontin and cardiotrophin-1). Contributing biochemical abnormalities, related to cellular energy production, calcium fluxes, protein synthesis, and catecholamine metabolism, have been variably identified in different models of heart failure and in clinical patients. Myocyte hypertrophy and reactive fibrosis increase total cardiac mass by eccentric and, in some cases, concentric patterns of hypertrophy. Ventricular hypertrophy can increase chamber stiffness, impair relaxation, and increase filling pressures. These abnormalities of diastolic function also can have a negative effect on systolic function. Ventricular remodeling also can promote the development of arrhythmias. The initiating stimulus underlying chronic cardiac remodeling might occur years before clinical evidence of heart failure appears.

Acute increases in ventricular filling (preload) induce greater contraction force and blood ejection. This response, known as the *Frank-Starling mechanism,* allows beat-to-beat adjustments that balance the output of the two ventricles and increase overall cardiac output in response to acute increases in hemodynamic load. In the short term, the Frank-Starling effect helps normalize cardiac output under conditions of increased volume or pressure loading, but these conditions also increase ventricular wall stress and oxygen consumption.

Ventricular wall stress is directly related to ventricular pressure and internal dimensions, and inversely related to wall thickness (Laplace's law). Increased wall stress induces myocardial hypertrophy. The hypertrophy pattern that develops depends on underlying disease conditions. A ventricular systolic pressure load induces *concentric* hypertrophy; myocardial fibers and ventricular walls thicken as contractile units (sarcomeres) are added in parallel. With severe hypertrophy, capillary density and myocardial perfusion may become inadequate, especially in subendocardial areas. Chronic myocardial hypoxia and ischemia stimulate further fibrosis and dysfunction. Chronic volume loading increases diastolic wall stress and leads to *eccentric* hypertrophy; myocardial fiber elongation and chamber dilation occur as new sarcomeres are laid down in series. Reductions in the extracellular collagen matrix and intercellular support structure have been documented in dogs with chronic volume overload from mitral insufficiency. Compensatory hypertrophy lessens the importance of the Frank-Starling mechanism in stable, chronic heart failure. Although volume loads are better tolerated because myocardial oxygen demand is not as severe, both abnormal pressure and volume loading impair cardiac performance over time.

Eventually, decompensation and myocardial failure develop. In patients with primary myocardial diseases, initial cardiac pressure and volume loads are normal; however, intrinsic defects of the heart muscle lead to observed hypertrophy or secondary dilation.

Cardiac hypertrophy and other remodeling changes begin long before heart failure becomes manifest. Biochemical abnormalities involving cell energy production, calcium fluxes, and contractile protein function can contribute to this process. Eventually, ventricular function progressively deteriorates as contractility and relaxation become more deranged. Clinical heart failure can be considered a state of decompensated hypertrophy.

SYSTEMIC RESPONSES

Neurohormonal Mechanisms

Neurohormonal (NH) responses contribute to cardiac remodeling and also have more far-reaching effects. Over time, excessive activation of NH "compensatory" mechanisms leads to the clinical syndrome of CHF. Although these mechanisms support circulation in the face of acute hypotension and hypovolemia, their chronic activation accelerates the deterioration of cardiac function. Major NH changes in heart failure include increased sympathetic nervous tone, attenuated vagal tone, renin-angiotensin-aldosterone system activation, and increased release of vasopressin (antidiuretic hormone, ADH-) and endothelin. These NH systems work independently and also interact together to increase vascular volume (by enhancing sodium and water retention and thirst) as well as vascular tone (Fig. 3.1). The expanded vascular volume increases ventricular filling (preload), which then enhances cardiac output. However, this comes at the cost of increased venous and capillary pressure, which promotes interstitial fluid accumulation. Although increased lymphatic flow helps moderate the effects of rising venous pressure, continued volume retention eventually leads to edema and effusions. Prolonged systemic vasoconstriction increases the workload on the heart, can reduce forward cardiac output, and may exacerbate valvular regurgitation. The extent to which these mechanisms are activated varies with the severity and etiology of heart failure. In general, as failure worsens, NH activation increases. Increased production of endothelins and proinflammatory cytokines, as well as altered expression of vasodilatory and natriuretic factors, also contributes to the complex interplay among these NH mechanisms and their consequences.

The effects of sympathetic stimulation (such as increased contractility, heart rate, and venous return) can initially increase cardiac output. However, over time, these effects become detrimental by increasing afterload stress and myocardial oxygen requirements, contributing to cellular damage and myocardial fibrosis, and enhancing the potential for cardiac arrhythmias. Persistent sympathetic stimulation reduces cardiac sensitivity to catecholamines. Downregulation (reduced number) of myocardial β_1-receptors and other changes in cellular signaling can help protect the myocardium against the cardiotoxic and arrhythmogenic effects of catecholamines. β-blocking agents can reverse β_1-receptor downregulation but may worsen heart failure. Cardiac β_2- and α_1-receptors also are present but are not downregulated; these are thought to contribute to myocardial remodeling and arrhythmogenesis. Another cardiac receptor subtype (β_3-receptors) may promote further myocardial function deterioration through a negative inotropic effect.

Normal feedback regulation of sympathetic nervous and hormonal systems depends on arterial and atrial baroreceptor function. Baroreceptor responsiveness becomes attenuated in chronic heart failure, which contributes to sustained sympathetic and hormonal activation and reduced inhibitory vagal effects. Baroreceptor function can improve with reversal of heart failure, increased myocardial contractility, decreased cardiac loading conditions, or inhibition of angiotensin II and aldosterone (which directly attenuate baroreceptor sensitivity). Digoxin has a positive effect on baroreceptor sensitivity.

The renin-angiotensin system (RAAS) has far-reaching effects. Whether systemic renin-angiotensin-aldosterone activation always occurs before overt congestive failure is unclear and may depend on the underlying etiology. Renin release from the renal juxtaglomerular apparatus occurs secondary to low renal artery perfusion pressure, renal β-adrenergic receptor stimulation, and reduced Na^+ delivery to the macula densa of the distal renal tubule. Stringent dietary salt restriction and diuretic or vasodilator therapy can promote renin release. Renin facilitates conversion of the precursor peptide angiotensinogen to angiotensin I (an inactive form). Angiotensin-converting enzyme (ACE), found in the lung and elsewhere, converts angiotensin I to the active angiotensin II and is involved in the degradation of certain vasodilator kinins. There are also alternative pathways for angiotensin II generation.

Angiotensin II has several important effects, including potent vasoconstriction and stimulation of aldosterone release from the adrenal cortex. Additional effects of angiotensin II include increased thirst and salt appetite, facilitation of neuronal norepinephrine synthesis and release, blockade of neuronal norepinephrine reuptake, stimulation of vasopressin (ADH) release, and increased adrenal epinephrine secretion. Inhibition of ACE can reduce NH activation and promote vasodilation and diuresis. Local production of angiotensin II also occurs in the heart, vasculature, adrenal glands, and other tissues in dogs and cats. Local activity affects cardiovascular structure and function by enhancing sympathetic effects and promoting tissue remodeling that can include hypertrophy, inflammation, and fibrosis. Tissue chymase is thought to be more important in the conversion to active angiotensin II than ACE in the myocardium and extracellular matrix.

Aldosterone promotes sodium and chloride reabsorption, as well as potassium and hydrogen ion secretion in the renal collecting tubules; the concurrent water reabsorption augments vascular volume. Increased aldosterone concentration can promote hypokalemia, hypomagnesemia, and impaired baroreceptor function. It can potentiate the effects of

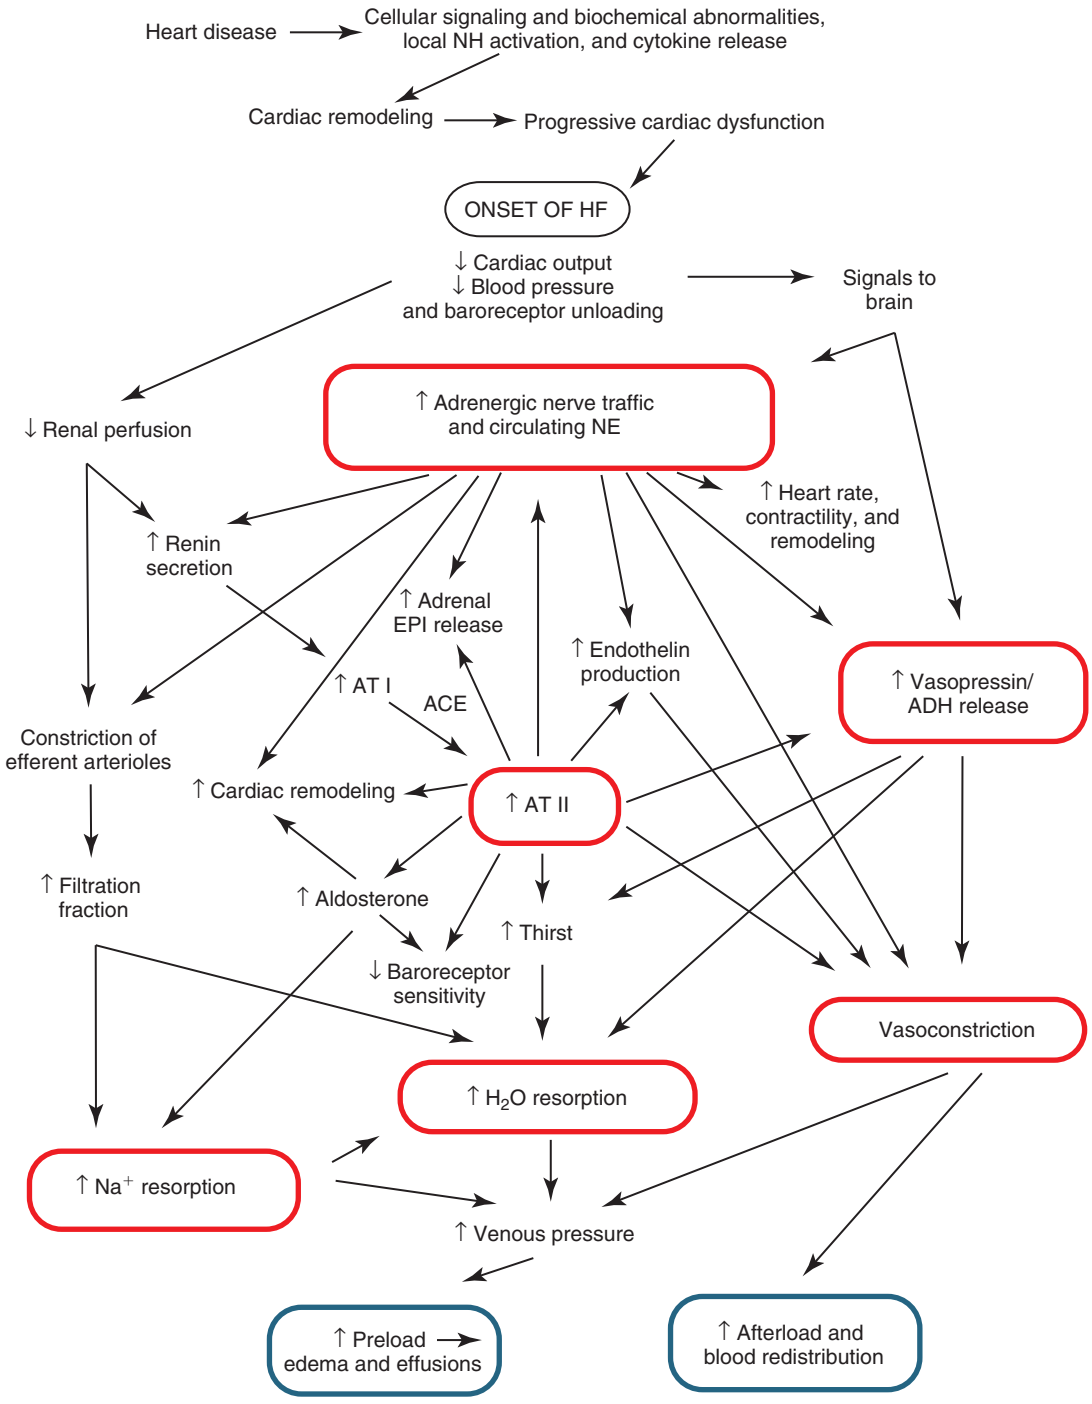

FIG 3.1
Important neurohormonal mechanisms leading to volume retention and increased afterload in congestive heart failure (CHF). *Note:* Additional mechanisms and interactions also contribute. Endogenous vasodilatory and natriuretic mechanisms also become activated during the evolution of CHF. *ACE,* Angiotensin-converting enzyme; *ADH,* antidiuretic hormone (vasopressin); *AT,* angiotensin; *EPI,* epinephrine; *HF,* heart failure; *NE,* norepinephrine.

catecholamines by blocking NE reuptake. Aldosterone receptors also are found in the heart and vasculature; aldosterone produced locally in the cardiovascular system mediates inflammation and fibrosis. Chronic exposure contributes to pathologic remodeling and myocardial fibrosis.

Arginine vasopressin (ADH) is released from the posterior pituitary gland. This hormone directly causes vasoconstriction and promotes free water reabsorption in the distal nephrons. Although increased plasma osmolality or reduced blood volume are the normal stimuli for ADH release,

reduced effective circulating volume and other nonosmotic stimuli (including sympathetic stimulation and angiotensin II) cause continued release of ADH in patients with heart failure. The continued release of ADH contributes to the dilutional hyponatremia sometimes found in patients with heart failure.

Increased circulating concentrations of other substances with a role in abnormal cardiovascular hypertrophy and/or fibrosis, including cytokines (e.g., TNF_{α}) and endothelins, also have been detected in animals with severe heart failure. Endothelin is a potent vasoconstrictor whose precursor peptide is produced by vascular endothelium. Endothelin production is stimulated by hypoxia and vascular mechanical factors and also by angiotensin II, ADH, norepinephrine, cytokines (including TNF_{α} and interleukin-I), and other factors.

Endogenous mechanisms that oppose the vasoconstrictor responses also are activated. These include natriuretic peptides, adrenomedullin, nitric oxide (NO), and vasodilator prostaglandins. Normally, a balance between vasodilator and vasoconstrictor effects maintains circulatory homeostasis, as well as renal solute excretion. As heart failure progresses, the influence of the vasoconstrictor mechanisms predominates despite increased activation of vasodilator mechanisms.

Natriuretic peptides are synthesized in the heart and play an important role in regulating blood volume and pressure. Atrial natriuretic peptide (ANP) is synthesized by atrial myocytes as a prohormone, which is then cleaved to the active peptide after its release. Mechanical stretch of the atrial wall stimulates ANP release. Brain natriuretic peptide (BNP) also is synthesized in the heart, mainly by the ventricles in response to myocardial dysfunction or ischemia. Natriuretic peptides promote diuresis, natriuresis, and peripheral vasodilation. They act to antagonize the effects of the RAAS, and also can alter vascular permeability and inhibit growth of smooth muscle cells. Natriuretic peptides are degraded by neutral endopeptidases. Circulating concentrations of ANP, BNP, and their precursor peptides (such as NT-proBNP) increase in patients with heart failure. This increase has been correlated with pulmonary capillary wedge pressure and severity of heart failure in both dogs and people. Adrenomedullin is another natriuretic and vasodilatory peptide produced in the adrenal medulla, heart, lung, and other tissues thought to play a role in heart failure.

NO, produced by the vascular endothelium in response to endothelial-nitric oxide synthetase (NOS), is a functional antagonist of endothelin and angiotensin II. This response is impaired in patients with heart failure. At the same time, myocardial inducible–NOS expression is enhanced; myocardial NO release has negative effects on myocyte function. Intrarenal vasodilator prostaglandins oppose the action of angiotensin II on the renal vasculature. The use of prostaglandin synthesis inhibitors in dogs or cats with severe heart failure could potentially reduce glomerular filtration (by increasing afferent arteriolar resistance) and enhance sodium retention.

Renal Effects

Renal efferent glomerular arteriolar constriction, mediated by sympathetic stimulation and angiotensin II, helps maintain glomerular filtration in the face of reduced cardiac output and renal blood flow. Higher oncotic and lower hydrostatic pressures develop in the peritubular capillaries, enhancing the reabsorption of tubular fluid and sodium. Angiotensin II–mediated aldosterone release further promotes sodium and water retention. Continued activation of these mechanisms leads to clinical edema and effusions.

Afferent arteriolar vasodilation mediated by endogenous prostaglandins and natriuretic peptides can partially offset the effects of efferent vasoconstriction, but progressive impairment of renal blood flow leads to renal insufficiency. Diuretics not only can magnify azotemia and electrolyte loss but also further reduce cardiac output and activate NH mechanisms.

Other Effects of Heart Failure

Reduced exercise capacity occurs in patients with heart failure. Although cardiac output may be fairly normal at rest, the ability to increase cardiac output in response to exercise is impaired. Inadequate forward output, poor diastolic filling, and pulmonary edema or pleural effusion can interfere with exercise ability. Furthermore, impaired peripheral vasodilation during exercise contributes to inadequate skeletal muscle perfusion and fatigue. Excessive peripheral sympathetic tone, angiotensin II (both circulating and locally produced), and vasopressin can contribute to impaired skeletal muscle vasodilatory capacity in patients with CHF. Increased vascular wall sodium content and interstitial fluid pressure stiffen and compress vessels. Other mechanisms can include impaired endothelium-dependent relaxation, increased endothelin concentration, and vascular wall changes induced by the growth factor effects of various NH vasoconstrictors. ACE inhibitor (ACEI) therapy, with or without spironolactone, may improve endothelial vasomotor function and exercise capacity. Pulmonary endothelial function is improved by ACEIs in dogs with CHF.

GENERAL CAUSES OF HEART FAILURE

The causes of heart failure are quite diverse. It can be useful to think of them in terms of underlying pathophysiology. In most cases of heart failure, the major initiating abnormality entails myocardial (systolic pump) failure, systolic pressure overload, volume overload, or reduced ventricular compliance (impaired filling). Nevertheless, several pathophysiologic abnormalities often coexist. Both systolic and diastolic function abnormalities are common in patients with advanced failure.

Myocardial failure is characterized by poor ventricular contractile function. It most commonly occurs from idiopathic dilated cardiomyopathy (DCM) but also from known causes of impaired myocardial contractility. Valvular insufficiency may or may not be present initially but usually develops as the affected ventricle dilates. Persistent tachyarrhythmias, some nutritional deficiencies, and other cardiac

insults also can lead to myocardial failure (see Chapters 7 and 8). Diseases that impose a volume or flow overload on the heart usually involve a primary "plumbing" problem (e.g., a leaky valve or abnormal systemic-to-pulmonary connection). Cardiac pump function often is maintained at a near-normal level for a prolonged time, although myocardial contractility does eventually deteriorate (see Chapters 5 and 6). Pressure overload results when the ventricle must generate higher-than-normal systolic pressure to eject blood. The concentric hypertrophy that develops as a compensatory mechanism increases ventricular wall thickness and stiffness, and can predispose to myocardial ischemia. Excessive pressure loads also eventually lead to declining myocardial contractility. Myocardial pressure overload is caused by ventricular outflow obstructions (congenital or acquired) and systemic or pulmonary hypertension (see Chapters 5, 10, and 11). Diseases that restrict ventricular filling impair diastolic function. These include hypertrophic and restrictive cardiomyopathies and pericardial diseases (see Chapters 8 and 9). Contractile ability usually is well maintained initially; however, elevated ventricular filling pressure leads to congestion behind the affected ventricle(s) and may diminish cardiac output. Other, less common causes of impaired filling include intracardiac mass lesions, congenital atrioventricular (AV) valve stenosis, and cor triatriatum. Table 3.1 lists common diseases according to their major initiating pathophysiology and typical clinical CHF manifestations.

TABLE 3.1

Common Causes of Congestive Heart Failure (CHF)

MAJOR PATHOPHYSIOLOGY	TYPICAL CHF MANIFESTATION*
Myocardial Failure	
Idiopathic dilated cardiomyopathy	Either L- or R-CHF
Infective myocarditis	Either L- or R-CHF
Drug toxicities (e.g., doxorubicin)	L-CHF
Myocardial ischemia/infarction (rare)	L-CHF
Volume-Flow Overload	
Mitral valve regurgitation (degenerative, congenital, infective)	L-CHF
Aortic regurgitation (infective endocarditis, congenital)	L-CHF
Ventricular septal defect	L-CHF
Patent ductus arteriosus	L-CHF
Tricuspid valve regurgitation (degenerative, congenital, infective)	R-CHF
Tricuspid endocarditis (rare)	R-CHF
Chronic anemia	Either L- or R-CHF
Thyrotoxicosis	Either L- or R-CHF
Pressure Overload	
(Sub)aortic stenosis	L-CHF
Systemic hypertension	L-CHF (rare)
Pulmonic stenosis	R-CHF
Heartworm disease	R-CHF
Pulmonary hypertension	R-CHF
Impaired Ventricular Filling	
Hypertrophic cardiomyopathy	L-(±R-) CHF
Restrictive cardiomyopathy	L-(±R-) CHF
Cardiac tamponade	R-CHF
Constrictive pericardial disease	R-CHF

**L-CHF*, Left-sided congestive heart failure signs (pulmonary edema as main congestive sign); *R-CHF*, right-sided congestive heart failure signs (pleural effusion and/or ascites as main congestive signs). Weakness and other low-output signs can occur with any of these diseases, especially those associated with arrhythmias.

APPROACH TO TREATING HEART FAILURE

Current perspectives on CHF management are based not only on mitigating the results of excessive NH activation (especially sodium and water retention) but also on modifying or blocking the activation process itself, with the aim of minimizing the progression of myocardial remodeling and dysfunction. Diuretics, dietary salt restriction, and some vasodilators help control signs of congestion. ACEIs, aldosterone, and sympathetic antagonists help modulate NH responses. Treatment strategies center on controlling edema and effusions, improving cardiac output, reducing cardiac workload, supporting myocardial function, and managing concurrent arrhythmias. The approach to these goals varies somewhat with different diseases, most notably those causing restriction to ventricular filling.

Classification of Severity

Guidelines for clinical staging of heart failure (based on the American Heart Association and American College of Cardiology [AHA/ACC] system) also are applied to veterinary patients (Table 3.2). These describe disease progression through four stages over time. This system emphasizes the importance of patient screening and early diagnosis. It is recommended as a guide in coordinating appropriate (and ideally, evidence-based) treatment to the severity of the clinical signs at each stage of disease. It also deemphasizes the term "congestive" in CHF because clinical signs of edema or effusions are not necessarily present all the time during the later stages (i.e., when CHF is "compensated" through appropriate medical therapy). Nevertheless, attention to the patient's fluid status is highly important.

The clinical severity of heart failure also is sometimes described according to the modified New York Heart Association (NYHA) classification scheme or the International

TABLE 3.2

Classification Systems for Heart Failure Severity

CLASSIFICATION	DEGREE OF SEVERITY
Modified AHA/ACC Heart Failure Staging System	
A	No apparent structural disease, yet considered "at risk" for developing heart disease (for example, breed-associated risk for DCM in Doberman Pinschers, and CMVD in Cavalier King Charles Spaniels)
B	Structural cardiac abnormality is evident (such as a murmur), but no clinical signs of heart failure have occurred
B1	Asymptomatic disease, with no/minimal radiographic or echo evidence of cardiac chamber enlargement/remodeling
B2	Asymptomatic disease, but cardiac chamber enlargement is evident
C	Structural cardiac abnormality evident, with clinical signs of heart failure either in the past (resolved with therapy) or currently present *Note:* Some clinicians subdivide stage C based on current signs of CHF into C1 – No current signs; C2 – mild congestive signs (low/medium grade); C3 – overt/severe CHF (high grade)
D	Persistent or end-stage heart failure signs, refractory to standard therapy (e.g., require ≥ 8-12 mg/kg/day of furosemide)
Modified NYHA Functional Classification	
I	Heart disease is present but no evidence of heart failure or exercise intolerance; cardiomegaly is minimal to absent
II	Heart disease present but clinical signs of failure only with strenuous exercise; radiographic cardiomegaly is usually present
III	Signs of heart failure with normal activity or mild exercise (e.g., cough, orthopnea); radiographic signs of cardiomegaly and pulmonary edema or pleural/abdominal effusion
IV	Severe clinical signs of heart failure at rest or with minimal activity; marked radiographic signs of CHF and cardiomegaly
International Small Animal Cardiac Health Council Functional Classification	
I	Asymptomatic patient
Ia	Signs of heart disease without cardiomegaly
Ib	Signs of heart disease and evidence of compensation (cardiomegaly)
II	Mild to moderate heart failure; clinical signs of failure evident at rest or with mild exercise and adversely affect quality of life
III	Advanced heart failure; clinical signs of CHF are immediately obvious
IIIa	Home care is possible
IIIb	Hospitalization recommended (cardiogenic shock, life-threatening edema, large pleural effusion, refractory ascites)

AHA/ACC, American Heart Association and American College of Cardiology; *CHF,* congestive heart failure.

Small Animal Cardiac Health Council (ISACHC) criteria. These systems group patients into functional categories on the basis of clinical observations rather than underlying cardiac disease or myocardial function. Such classification still can be helpful conceptually and for categorizing study patients, as well as complement the previously described staging system. Regardless of the clinical classification scheme, identification of the underlying etiology and contributing pathophysiologies, as well as the clinical severity, is important for individualized therapy.

PRECLINICAL CARDIAC DISEASE

Indications for cardiovascular medications in animals with preclinical (stage B) cardiac disease are not always clear-cut. Dogs and cats with systemic hypertension should receive appropriate antihypertensive therapy to help avoid target organ injury (see Chapter 11). For dogs with stage B2 chronic mitral valve disease, pimobendan has been shown to delay onset of CHF; pimobendan therapy is recommended for those dogs with clear evidence for cardiac enlargement that

have not yet developed signs of CHF (see Chapter 6). However, evidence is lacking regarding the use of pimobendan in dogs with early (stage B1) mitral valve disease, and it is not currently recommended at this stage. An ACEI generally is not advocated for dogs with preclinical mitral valve disease, unless it is used to reduce elevated blood pressure. However, some controversy remains, and although ACEIs do not appear to delay onset of CHF in most dogs with mitral valve disease, some dogs with advanced stage B2 disease might benefit from them. Doberman Pinschers, Irish Wolfhounds, and probably other dogs with occult DCM also benefit from the introduction of pimobendan and an ACEI before overt CHF develops (see Chapter 7). For cats with preclinical (stage B) hypertrophic cardiomyopathy (HCM), optimal strategy is not clear and consensus is lacking (see Chapter 8).

MANAGEMENT OF MILD OR EARLY CHF SIGNS

Mild pulmonary edema can produce subtle and variable clinical signs, including modest but persistent increases in resting respiratory rate (RRR; see later in this chapter), reduced exercise tolerance, excessive panting (in dogs), or occasional cough. Detecting mild changes in RRR is easier when owners know the animal's baseline rate and periodically have been monitoring the RRR. Thoracic radiographs are indicated when signs suggestive of decompensating CHF appear, especially if this is the first episode. When radiographic findings are consistent with mild cardiogenic pulmonary edema, initial therapy for CHF (furosemide, an ACEI, and pimobendan, if indicated), along with exercise restriction, often can be instituted on an outpatient basis. If the radiographs are nondiagnostic, but CHF is suspected, a furosemide trial (such as 2 mg/kg/day) with or without an ACEI can be given for a week or so, with RRR monitoring. If the clinical signs are caused by CHF, they usually resolve or substantially improve fairly quickly; in these cases additional CHF therapy, as indicated for the underlying disease, is added. An NT-proBNP test also can help in unclear cases, in that if the result is not elevated, the patient is unlikely to have CHF.

TREATMENT FOR ACUTE CONGESTIVE HEART FAILURE

GENERAL CONSIDERATIONS

Fulminant CHF is characterized by severe cardiogenic pulmonary edema, with or without pleural and/or abdominal effusions or poor cardiac output. It can occur in stage C or D patients. Therapy is aimed at rapidly clearing pulmonary edema, improving oxygenation, and optimizing cardiac output (Box 3.1). Thoracocentesis should be performed expediently if marked pleural effusion exists. Likewise, large-volume ascites should be drained, at least partially, to improve ventilation. Animals with severe CHF are greatly stressed. Physical activity must be maximally restricted to reduce total oxygen consumption; cage confinement is preferred. Environmental stresses such as excess heat and humidity or extreme cold should be avoided. When transported, the animal should be placed on a cart or carried. Unnecessary patient handling and use of oral medications should be avoided, when possible.

SUPPLEMENTAL OXYGEN

Oxygen administered by face mask or improvised hood, nasal catheter, endotracheal tube, or oxygen cage is beneficial as long as the method chosen does not increase the patient's distress. An oxygen cage with temperature and humidity controls is preferred; a setting of 65° F is recommended for normothermic animals. Oxygen flow of 6 to 10 L/min is usually adequate. Concentrations of 50% to 100% oxygen may be necessary initially, but this should be reduced within a few hours to 40% to avoid lung injury. When a nasal tube is used, humidified O_2 is delivered at a rate of 50 to 100 mL/kg/min. Extremely severe pulmonary edema with respiratory failure may respond to endotracheal or tracheotomy tube placement, airway suctioning, and mechanical ventilation. Positive end-expiratory pressure helps clear small airways and expands alveoli. Positive airway pressures can adversely affect hemodynamics, however, and extended use of high oxygen concentrations (>70%) can injure lung tissue (see Suggested Readings for more information). Continuous monitoring is essential for intubated animals.

DRUG THERAPY

Diuresis

Rapid diuresis can be achieved with intravenous (IV) furosemide; effects begin within 5 minutes, peak by 30 minutes, and last about 2 hours. This route also provides a mild venodilating effect. Some patients require aggressive initial doses or cumulative doses administered at frequent intervals (see Box 3.1). Furosemide can be given by constant rate infusion (CRI), which may provide greater diuresis than bolus injection. The veterinary formulation (50 mg/mL) can be diluted to 10 mg/mL for CRI using 5% dextrose in water (D_5W), lactated Ringer's solution (LRS), or sterile water. Dilution to 5 mg/mL in D_5W or sterile water also is described. The patient's respiratory rate, as well as other parameters (discussed in more detail later), guides the intensity of continued furosemide therapy. Once diuresis has begun and respiration improves, the dosage is reduced to prevent excessive volume contraction or electrolyte depletion.

Vasodilation

Vasodilator drugs can reduce pulmonary edema by increasing systemic venous capacitance, lowering pulmonary venous pressure, and reducing systemic arterial resistance. Although ACE inhibitors are a mainstay of chronic CHF management, more immediate afterload reduction usually is desirable for animals with acute pulmonary edema. The initial dose of an arteriolar vasodilator should be low, with subsequent titration upward as needed on the basis of blood pressure and clinical response. Arteriolar vasodilation is not

BOX 3.1

Acute Treatment of Decompensated Congestive Heart Failure

Minimize patient stress and excitement!
- Cage rest; transport on gurney (no activity allowed)
- Avoid excessive heat and humidity

Improve oxygenation:
- Ensure airway patency
- Give supplemental O_2 (avoid > 50% for > 24 hours)
- Postural support if needed (help maintain sternal recumbency, head elevation)
- If frothing evident, suction airways
- Intubate and mechanically ventilate if necessary
- Thoracocentesis, if moderate or severe pleural effusion suspected/documented

Diuresis
- Furosemide (dogs: 2-3[-5] mg/kg initial bolus, IV (or IM or SC), then 1-4 mg/kg q1-4h until respiratory rate decreases, then 1-4 mg/kg q6-12h; or use 0.6-1 mg/kg/h CRI over next 6 hours if inadequate response to boluses [see text]; cats: 1-2[-4] mg/kg initial bolus, IV (or IM or SC), then 1-2 mg/kg q1-4h until respiratory rate decreases, then 1-2 mg/kg q6-12h)
- (Provide access to water after diuresis is evident)

Support cardiac pump function (inodilator)
- Pimobendan (dogs: 0.2-0.3 mg/kg PO q12h, begin as soon as possible; cats: for CHF associated with advanced or end-stage cardiomyopathies or reduced contractility, dose as for dogs [controversial for first-onset CHF from HCM; not advised for HOCM])

Reduce anxiety:
- Butorphanol (dogs: 0.2-0.3 mg/kg IM [or IV, SC], can repeat in 30-60 min if needed; cats: 0.1-0.3 mg/kg IM [or IV, SC]); *or*
- Morphine (dogs: 0.025-0.1 mg/kg IV boluses q2-3 min to effect, or 0.1-0.5 mg/kg single IM or SC dose; do not use in cats); *or*
- Buprenorphine (cats: 0.005-0.02 mg/kg IV, IM, SC)

±Additional vasodilators:
- 2% Nitroglycerin ointment: dogs: 0.25-1.5 inch (0.6-3.8 cm) cutaneously q6h for 24-48 hours (can combine with hydralazine in dogs); cats: 0.25-0.5 inch (0.6-1.3 cm) cutaneously q6-8h for 24-48 hours; *or*
- Sodium nitroprusside (if able to monitor blood pressure closely): 0.5-1 µg/kg/min (initial) CRI in D_5W (for cats, dilute to 100-300 µg/mL). Titrate upward as needed; dogs: to 5(-15) µg/kg/min; cats: to 2(-5) µg/kg/min; until systolic blood pressure ~90-100 mm Hg (or mean of 70 mm Hg). Protect from light, and do not give for more than 24 hours; *or*
- Hydralazine (for further afterload reduction in dogs with MR, if not using nitroprusside); dogs: initial 0.5-1.0 mg/kg PO, repeat in 2-3 hours (until systolic arterial pressure is 90-110 mm Hg), then q12h; *or* cautious IV bolus at 0.05-0.1 mg/kg, repeat q1-2h if needed; *or*
- (Less useful as acute therapy [and avoid concurrent nitroprusside]: ACE inhibitor; *or* amlodipine [dogs: 0.05-0.1 mg/kg initially, to 0.3 mg/kg PO q12-24h]; see text)

±Additional inotropic support (if myocardial failure or persistent hypotension):
- Dobutamine* (1 µg/kg/minute initial CRI; titrate upward to effect q15-30 min, as needed; dogs: up to 20 µg/kg/min; cats: up to 10 µg/kg/min) for 24-48 hours then wean down. Alternatively, can use dopamine** (dogs: 1-10 µg/kg/min CRI; cats: 1-5 µg/kg/min CRI; start low, titrate to effect q15-30 min) for 24-48 hours then wean down; *and/or*
- Amrinone (1-3 mg/kg IV; 10-100 µg/kg/min CRI), or milrinone (50 µg/kg IV over 10 minutes initially; 0.375-0.75 µg/kg/min CRI [human dose])
- Digoxin (not generally used unless as adjunct for atrial fibrillation in dogs) PO (see Table 3.3); (digoxin loading dose [see text for indications]: PO—1 or 2 doses at twice calculated maintenance; dog IV [NOT advised unless other therapy not effective/available]: 0.0025 mg/kg slow IV bolus, repeat hourly over 4-hour period to effect (or total of 0.01 mg/kg)

±Reduce bronchoconstriction:
- Aminophylline (dogs: 4-8 mg/kg slow IV, IM, SC, or 6-10 mg/kg PO q6-8h; cats: 4-8 mg/kg IM, SC, PO q8-12h) or similar drug

Monitor and address abnormalities as possible:
- Respiratory rate, heart rate and rhythm, arterial pressure, O_2 saturation, body weight, urine output, hydration, attitude, appetite, serum biochemistry and blood gas analyses.

For acute CHF from diastolic dysfunction (e.g., cats with hypertrophic cardiomyopathy):
- General recommendations, O_2 therapy, furosemide, and sedation, as in the previous text.
- Thoracocentesis, if needed.
- ±Nitroglycerin
- If severe LV outflow obstruction or persistent and rapid sinus tachycardia, consider IV esmolol (200-500 µg/kg IV over 1 minute, followed by 25-200 µg/kg CRI) or diltiazem (0.15-0.25 mg/kg over 2-3 minutes IV)
- ±Pimobendan (see previous text)
- Monitor and manage abnormalities as possible (see previous text)
- ACE inhibitor (institute after appetite returns)

ACE, Angiotensin-converting enzyme; *CRI*, constant rate infusion; *D_5W*, 5% dextrose in water.
*Dilution of 250 mg dobutamine into 500 mL of D_5W or lactated Ringer's solution yields a solution of 500 µg/mL; CRI of 0.6 mL/kg/h provides 5 µg dobutamine/kg/min.
**Dilution of 40 mg dopamine into 500 mL of D_5W or lactated Ringer's solution provides a solution of 80 µg/mL; infusion at 0.75 mL/kg/h provides 1 µg dopamine/kg/min.

recommended for heart failure caused by diastolic dysfunction or ventricular outflow obstruction.

Sodium nitroprusside is a potent arteriolar and venous dilator with direct action on vascular smooth muscle; unfortunately, it has become prohibitively expensive in the United States. Nitroprusside is given by IV infusion because of its short duration of action. Blood pressure must be closely monitored when using this drug. The dose is titrated to maintain mean arterial pressure at about 80 mm Hg (at least > 70 mm Hg) or systolic blood pressure between 90 and 110 mm Hg. Nitroprusside CRI usually is continued for 12 to 24 hours. Dosage adjustments may be necessary because drug tolerance develops rapidly. Profound hypotension is the major adverse effect. Cyanide toxicity can result from excessive or prolonged use (e.g., longer than 48 hours). Nitroprusside should not be infused with other drugs and should be protected from light.

Hydralazine is an alternative to nitroprusside. It is a pure arteriolar dilator. Hydralazine is useful for refractory pulmonary edema caused by mitral regurgitation (MR) because it can reduce regurgitant flow and lower left atrial (LA) pressure. It should be used only cautiously in patients with DCM. An initial oral dose of 0.5 to 1 mg/kg (or 0.05 to 0.1 mg/kg IV or IM) can be repeated every 2 to 3 hours until the systolic blood pressure is between 90 and 110 mm Hg or clinical improvement is obvious. If blood pressure cannot be monitored, an initial PO dose of 1 mg/kg can be repeated in 2 to 4 hours if sufficient clinical improvement has not been observed. The addition of 2% nitroglycerin ointment may provide beneficial venodilating effects.

An ACEI or amlodipine, with or without nitroglycerin ointment, is an alternative to hydralazine/nitroglycerin. However, their onset of action is slower and effects are less pronounced, but this regimen can still be helpful. Usually an ACEI is introduced after the patient has been stabilized and appetite is returning. Amlodipine generally is reserved for dogs with refractory CHF caused by MR, or for patients with hypertension.

Nitroglycerin (and other orally or transcutaneously administered nitrates) acts mainly on venous smooth muscle to increase venous capacitance and reduce cardiac filling pressure. The major indication for nitroglycerin is acute cardiogenic pulmonary edema. Nitroglycerin ointment (2%) is applied to the skin, usually of the groin, axillary area, or ear pinna; however, the efficacy of this in heart failure is unclear. An application paper or glove is used to avoid contact with the skin of the person applying the drug.

Inotropic Support

The inodilator pimobendan is used for CHF caused by chronic MR and DCM, as well as a number of other causes of CHF. Its onset of action is fairly rapid, even with oral administration. The initial dose is usually given as soon as practicable, with subsequent doses continued as part of long-term HF management (see p. 69 and Table 3.3). The IV form of pimobendan is not yet available in the United States.

Other positive inotropic therapy might also be indicated for acute CHF caused by poor myocardial contractility or when there is persistent hypotension. Treatment for 1 to 3 days with an IV sympathomimetic (catecholamine) or phosphodiesterase (PDE) inhibitor drug can help support arterial pressure, forward cardiac output, and organ perfusion when myocardial failure or hypotension is severe.

Catecholamines enhance contractility via a cyclic adenosine monophosphate (cAMP)-mediated increase in intracellular Ca^{++}. They can provoke arrhythmias and increase pulmonary and systemic vascular resistance (potentially exacerbating edema formation). Their short half-life (<2 minutes) and extensive hepatic metabolism necessitate constant IV infusion. β-receptor downregulation and uncoupling limit their effectiveness within a few days of administration. Concurrent use of a β-blocker also blunts the effect of the catecholamines. Dobutamine (a synthetic analog of dopamine) has lesser effect on heart rate and afterload and is preferred over dopamine. Dobutamine stimulates β_1-receptors, with only weak action on β_2- and α-receptors. Lower doses (e.g., 3-7 μg/kg/min) have minimal effects on heart rate and blood pressure. The initial infusion rate should be low; this can be gradually increased over hours to achieve greater inotropic effect and maintain systolic arterial pressure between 90 and 120 mm Hg. Heart rate, rhythm, and blood pressure must be monitored closely. Although dobutamine is less arrhythmogenic than other catecholamines, higher infusion rates (e.g., 10-20 μg/kg/min) can precipitate supraventricular and ventricular arrhythmias. Adverse effects are more likely in cats; these include nausea and seizures at relatively low doses.

Dopamine at low doses (<2-5 μg/kg/min) also stimulates vasodilator dopaminergic receptors in some regional circulations. Low to moderate doses enhance contractility and cardiac output, but high doses (10-15 μg/kg/min) cause peripheral vasoconstriction and increase heart rate, O_2 consumption, and the risk of ventricular arrhythmias. An initial IV infusion of 1 μg/kg/min can be titrated upward to desired clinical effect. The infusion rate should be decreased if sinus tachycardia or other tachyarrhythmias develop.

Other acute IV inotropic therapy could include the bipyridine PDE inhibitors such as amrinone and milrinone increase intracellular Ca^{++} by inhibiting PDE III, an intracellular enzyme that degrades cAMP. However, they are unlikely to offer a substantive advantage over pimobendan. These drugs also cause vasodilation because increased cAMP promotes vascular smooth muscle relaxation. Hypotension, tachycardia, and gastrointestinal (GI) signs can occur when giving high doses. These drugs can exacerbate ventricular arrhythmias. The effects of amrinone are shortlived (<30 minutes) after IV injection in normal dogs, so CRI is required for sustained effect. Peak effects occur after 45 minutes of CRI in dogs. Amrinone is sometimes used as an initial slow IV bolus followed by CRI; half the original bolus dose can be repeated after 20 or 30 minutes. Milrinone has a much greater potency than amrinone, but there is scant information on the IV form in small animals. These agents could be

TABLE 3.3

Drugs for Managing Chronic Heart Failure

DRUG	DOGS	CATS
Diuretics		
Furosemide	1-3 (or more) mg/kg PO q8-24h (long term); use smallest effective dose. In refractory CHF, several intermittent 2 mg/kg SC doses/week, in place of PO doses, may be helpful (or use torsemide; see text [p. 66]). See Box 3.1 for acute CHF recommendations	1-2 (or more) mg/kg PO q8-24h; use smallest effective dose. See Box 3.1 for acute CHF recommendations
Torsemide	Dose at 1/12 to 1/8 of patient's total daily furosemide dose; administer in two divided doses	Same
Spironolactone	(0.5-)2 mg/kg PO q24h (or divided q12h)	0.5-1 mg/kg PO q24h (or divided q12h)
Chlorothiazide	10-40 mg/kg PO q12-48h (start qod with low dose)	10-40 mg/kg PO q12-48h (start qod with low dose)
Hydrochlorothiazide	0.5-4 mg/kg PO q12-48h (start qod with low dose)	0.5-2 mg/kg PO q12-48h (start qod with low dose)
ACE Inhibitors		
Enalapril	0.5 mg/kg PO q12-24h	0.25-0.5 mg/kg PO q(12-)24h
Benazepril	0.25-0.5 mg/kg PO q(12-)24h	0.25-0.5 mg/kg PO q(12-)24h
Captopril	0.5-2 mg/kg PO q8-12h	0.5-1.25 mg/kg PO q(8-)24h
Lisinopril	0.25-0.5 mg/kg PO q(12-)24h	0.25-0.5 mg/kg PO q24h
Ramipril	0.125-0.25 mg/kg PO q24h	0.125 mg/kg PO q24h
Imidapril	0.25 mg/kg PO q24h	—
Other Vasodilators		
Hydralazine	0.5-2 (to 3) mg/kg PO q12h (to 1 mg/kg initial). See Box 3.1 for acute CHF recommendations	2.5 (up to 10) mg/cat PO q12h
Amlodipine	0.05 (initial) to 0.3(-0.5) mg/kg PO q(12-)24h	0.3125-0.625(-1.25) mg/cat (or 0.1-0.5 mg/kg) PO q24(-12)h
Prazosin	0.05-0.2 mg/kg PO q8-12h	0.25-0.5 mg/cat PO q12-24h
Nitroglycerin 2% ointment	1/4-1½ inch cutaneously q4-6h for 24-48 hours	1/4-½ inch cutaneously q4-6h for 24-48 hours
Isosorbide dinitrate	0.5-2 mg/kg PO q(8-)12h	—
Isosorbide mononitrate	0.25-2 mg/kg PO q12h	—
Positive Inotropes		
Pimobendan	0.2-0.3 mg/kg PO q12h; for refractory (stage D) CHF, could be increased up to 0.4-0.5 mg/kg q8h	As for dog, or 1.25 mg/cat PO q12(-8)h
Digoxin	PO: 0.003-0.005 mg/kg PO q12h. Decrease by 10% for elixir. Maximum: 0.5 mg/day or 0.375 mg/day for Doberman Pinschers. (See Box 3.1 for loading doses)	0.007 mg/kg (or 1/4 of 0.125 mg tab) PO q48h

used concurrently with digoxin and a catecholamine but would seem redundant with pimobendan.

If arrhythmias develop during IV inotropic therapy, the infusion rate is reduced or the drug is discontinued. Catecholamine infusion is likely to increase the ventricular response rate in animals with atrial fibrillation (AF), by enhancing AV conduction. If dobutamine or dopamine is deemed necessary for such a case, diltiazem (IV or oral) is used to reduce the heart rate (see Table 4.2). Oral digoxin with an initial loading dose is an alternative. Digoxin is not recommended intravenously; the only, and rare, exception might be for a sustained supraventricular tachyarrhythmia when other acute antiarrhythmic therapy is unavailable or ineffective (see Chapter 4, p. 80). Acidosis and hypoxemia associated with severe pulmonary edema can increase myocardial sensitivity to digitalis-induced arrhythmias.

Other Acute Therapy

Mild sedation (see Box 3.1) can reduce anxiety. Because morphine can induce vomiting, butorphanol is a better choice in dogs. Morphine is contraindicated in dogs with neurogenic edema because it can raise intracranial pressure. Morphine should not be used in cats.

Some dogs with severe pulmonary edema and bronchoconstriction benefit from short-term bronchodilator therapy. Aminophylline, given slowly IV or IM, has mild diuretic and positive inotropic actions as well as a bronchodilating effect; it also decreases fatigue of respiratory muscles. Adverse effects include increased sympathomimetic activity and arrhythmias. The oral route can be used when respiration improves because GI absorption is rapid.

HEART FAILURE CAUSED BY DIASTOLIC DYSFUNCTION

When acute CHF is caused by hypertrophic or restrictive cardiomyopathy, thoracocentesis (if needed), diuretics, and oxygen therapy are given as outlined previously. Cutaneous nitroglycerin can also be used. For cats with a rapid tachyarrhythmia, persistent sinus tachycardia, or marked LV outflow obstruction, a β_1-blocker such as atenolol or IV esmolol can reduce the frequency of ectopic beats, control heart rate, and reduce the LV outflow pressure gradient. However, propranolol (or another nonselective β-blocker) should be avoided in patients with fulminant pulmonary edema because β_2-blockade could induce bronchoconstriction. Pimobendan can be helpful in cats with reduced myocardial contractility, restrictive or end-stage cardiomyopathy, and recurrent or progressive CHF from HCM. Whether pimobendan therapy should be started at first-onset CHF in cats with HCM is controversial; prospective clinical evidence is awaited to support or refute this use. In cats with hypertrophic obstructive cardiomyopathy (HOCM), there is concern regarding use of pimobendan (as well as other positive inotropic or vasodilator agents). Because increased contractility and arterial vasodilation can worsen dynamic LV outflow obstruction and potentially cause hypotension, pimobendan is theoretically contraindicated.

Arteriolar vasodilators can be detrimental in the presence of LV outflow obstruction, because afterload reduction provokes greater systolic obstruction (see Chapter 8). However, ACEIs at standard doses do not appear to worsen the LV outflow gradient. Addition of an ACEI is recommended as soon as the animal begins eating again.

MONITORING AND FOLLOW-UP

Repeated assessment is important for monitoring the effectiveness of therapy and for early detection of hypotension or severe azotemia caused by excessive diuresis. Mild azotemia is common. Hypokalemia and metabolic alkalosis also can occur after aggressive diuresis. Maintaining serum potassium concentration within the mid- to high-normal range is especially important for animals with arrhythmias. Serum biochemical testing every 24 to 48 hours is advised until the patient is drinking well and beginning to eat.

Arterial blood pressure should be monitored, usually by indirect means because gaining arterial access can increase patient stress. Indirect measures of organ perfusion such as capillary refill time, mucous membrane color, pulse oximetry, urine output, toe-web temperature, and mentation also are useful. Body weight should be monitored, especially with aggressive diuretic therapy.

Central venous pressure (CVP) does not adequately reflect left heart filling pressures. It should not be used to guide diuretic or fluid therapy in patients with cardiogenic pulmonary edema. Although pulmonary capillary wedge pressure can reliably guide therapy, placement and care of an indwelling pulmonary artery catheter require meticulous attention to asepsis and close monitoring.

Pulse oximetry is helpful for monitoring oxygen saturation (SpO_2). Supplemental O_2 should be given if SpO_2 is less than 90%; mechanical ventilation is indicated if SpO_2 is less than 80% despite O_2 therapy. Arterial sampling for blood gas analysis is more accurate but is stressful for the patient. Resolution of radiographic evidence for pulmonary edema usually lags behind clinical improvement by a day or two.

After respiratory signs begin to abate and diuresis is evident, drinking water is offered. Fluid administration (either subcutaneously or intravenously) generally is NOT advised for patients with CHF. In most cases, gradual rehydration by free choice water intake is preferred even after aggressive diuresis. However, cautious fluid therapy may be necessary for heart failure patients with advanced renal dysfunction, marked hypokalemia, hypotension, persistent anorexia, digoxin toxicity, or other serious systemic disease. Some animals require relatively high cardiac filling pressure to maintain cardiac output, especially those with myocardial failure or markedly reduced ventricular compliance (as from HCM or pericardial disease). Diuresis and vasodilation in such cases can cause inadequate cardiac output and hypotension. For most patients with decompensated CHF that need a drug by CRI, the smallest fluid volume possible should be used. Careful monitoring and continued diuretic use are important to prevent recurrent pulmonary edema. When additional fluid therapy is necessary, D_5W or a reduced

sodium fluid (such as 0.45% NaCl with 2.5% dextrose) with added KCl is administered at a conservative rate (for example, 15 to 30 mL/kg/day IV). Alternatively, 0.45% NaCl with 2.5% dextrose or LRS can be administered subcutaneously.

Potassium supplementation at a maintenance rate is provided by 0.05 to 0.1 mEq/kg/h (or more conservatively, 0.5-2 mEq/kg/day). For animals with hypokalemia, higher rates are used: 0.15 to 0.2 mEq/kg/h for mild K^+ deficiency; 0.25 to 0.3 mEq/kg/h for moderate deficiency; and 0.4 to 0.5 mEq/kg/h for severe deficiency. Serum K^+ concentration measurement in 4 to 6 hours is advised when supplementing for moderate to severe deficiency. Hyponatremia and worsened fluid retention can develop after administering low-sodium IV solutions in some patients. These require a more balanced crystalloid solution. Other supportive therapies for CHF and any underlying disease(s) depend on individual patient needs. Parenteral fluid administration is discontinued as the animal is able to resume oral food and water intake.

MANAGEMENT OF CHRONIC HEART FAILURE

GENERAL CONSIDERATIONS

A general approach to chronic heart failure therapy is presented in this section. Additional information is found in the chapters describing different diseases. Long-term heart failure management in dogs with chronic mitral valve disease or DCM generally involves a combination of furosemide, pimobendan, an ACEI (usually enalapril or benazepril), and the addition of spironolactone. A diet moderately reduced in salt also is recommended for most heart failure patients. Therapy is tailored to the individual animal's needs by adjusting dosages, adding or substituting drugs, and modifying lifestyle or diet. Pleural effusion and large-volume ascites that accumulate despite medical therapy should be drained to facilitate respiration. Likewise, pericardial effusion that compromises cardiac filling must be drained (see Chapter 9). As heart disease progresses, more aggressive therapy usually is necessary.

Exercise restriction helps reduce cardiac workload regardless of heart failure etiology. For animals with active CHF, no exercise should be allowed until all signs of congestion have been well controlled. Strenuous exercise can provoke dyspnea and potentially serious cardiac arrhythmias even in animals with compensated CHF. However, regular mild to moderate activity (as tolerated) is thought to be beneficial for patients with no clinical signs of congestion (i.e., compensated heart failure). Chronic heart failure is associated with skeletal muscle changes that lead to fatigue and dyspnea. Physical training is known to improve cardiopulmonary function and quality of life in human patients with chronic heart failure. This is partly mediated by improvement in vascular endothelial function and restoration of flow-dependent vasodilation. Although it is difficult to know how much exercise is best, regular (not sporadic) mild to moderate activity is encouraged, as long as excessive respiratory effort or fatigue is not induced. Bursts of strenuous activity should be avoided.

DIURETICS

Diuretic therapy remains fundamental for the long-term management of CHF because of its ability to decrease cardiogenic pulmonary edema and effusions (see Table 3.3). Furosemide (and other loop diuretics) interferes with ion transport in the loop of Henle and has the potent ability to promote both salt and water loss. Diuretics of other classes, such as potassium-sparing agents and thiazides, are sometimes combined with furosemide for more intense diuresis in patients with advanced heart failure. Given to excess, diuretics promote excessive volume contraction and activate the renin-angiotensin-aldosterone cascade. Diuretics also can exacerbate preexisting dehydration or azotemia. Therefore the indication for their use in such animals should be clearly established, and the lowest effective dose should be used.

Furosemide

Furosemide is the loop diuretic used most widely for cats and dogs with heart failure (also see p. 61). It acts on the ascending limb of the loop of Henle to inhibit active Cl^-, K^+, and Na^+ cotransport, thereby promoting excretion of these electrolytes and H^+; Ca^{++} and Mg^{++} are also lost in the urine. Loop diuretics also can increase systemic venous capacitance, possibly by mediating renal prostaglandin release. In addition, furosemide may promote salt loss by increasing total renal blood flow and preferentially enhancing renal cortical flow. The loop diuretics are well absorbed when given orally. After oral administration, diuresis occurs within 1 hour, peaks between 1 and 2 hours, and may last for 6 hours. Furosemide is highly protein bound; about 80% is actively secreted unchanged in the proximal renal tubules, with the remainder excreted as glucuronide.

Although aggressive furosemide treatment is indicated for acute, fulminant pulmonary edema, the smallest effective doses should be used for chronic heart failure therapy. The dosage will vary depending on the clinical situation. Respiratory pattern, hydration, body weight, exercise tolerance, renal function, and serum electrolyte concentrations are used to monitor response to therapy. Furosemide (or other diuretic) alone is not recommended as the sole treatment for chronic heart failure because it can exacerbate NH activation and reduce renal function.

Adverse effects usually are related to excessive fluid and/or electrolyte losses. Lower doses are used in cats because they are more sensitive to the drug than dogs. Although hypokalemia is the most common electrolyte disturbance, it is unusual in dogs that are not anorexic. Excessive diuresis can result in hyponatremic, hypochloremic alkalosis.

Other Loop Diuretics

Other more potent loop diuretics are sometimes used instead of furosemide. Torsemide (dosed initially at one

tenth of the patient's prior furosemide dose) has been useful in dogs with refractory CHF and diuretic resistance. It produces greater Na^+ excretion, has a longer half-life, and also has some anti-aldosterone effect. Adverse effects are similar to those of furosemide but potentially more intense.

Spironolactone

Spironolactone is probably more useful for its anti-aldosterone effects in cardiac and other tissues than for its diuretic effect, although it may be a helpful adjunct in patients with chronic refractory heart failure. Spironolactone is a competitive antagonist of aldosterone. In the kidney, it promotes Na^+ loss and K^+ retention in the distal renal tubule and can reduce the renal potassium wasting of furosemide and other diuretics, especially when circulating aldosterone concentration is high. However, it has negligible diuretic effect in normal dogs.

Despite initial decline in aldosterone release with ACEI therapy, aldosterone levels can increase with time (so-called aldosterone escape). This may involve reduced hepatic clearance, increased release stimulated by K^+ elevation or Na^+ depletion, and local tissue aldosterone production. Spironolactone's anti-aldosterone effect is thought to mitigate aldosterone-induced cardiovascular remodeling and baroreceptor dysfunction. The drug has improved survival in people with moderate to severe CHF. This might relate to a reduction in susceptibility to ventricular tachyarrhythmias from lessened myocardial fibrosis and inflammatory cytokine expression. In dogs with DCM and chronic MR, spironolactone (at 2 mg/kg/day PO) was associated with improved morbidity and mortality, although not all reports note a survival benefit.

Spironolactone's onset of action is slow; peak effect occurs within 2 to 3 days. Administration with food increases its bioavailability. Because it is a potassium-sparing diuretic, it must be used cautiously in patients receiving an ACEI or potassium supplement, and it is absolutely contraindicated in hyperkalemic patients. Adverse effects usually relate to excess K^+ retention and GI disturbances. Spironolactone may decrease digoxin clearance. Ulcerative facial dermatitis has occurred in cats, especially at higher doses.

Eplerenone is another aldosterone antagonist with more selective action. In experimental heart failure, eplerenone significantly reduced ventricular remodeling and fibrosis. Clinical experience in dogs and cats is lacking, however, and it is unclear whether this drug is more advantageous than spironolactone.

Thiazide Diuretics

Thiazide diuretics decrease Na^+ and Cl^- absorption and increase Ca^{++} absorption in the distal convoluted tubules. Mild to moderate diuresis with excretion of Na^+, Cl^-, K^+, and Mg^{++} results, and alkalosis can occur. The thiazides decrease renal blood flow and should not be used in azotemic animals. Adverse effects are uncommon when used alone (not advised for CHF) in the absence of azotemia. However, marked hypokalemia or other electrolyte disturbance, severe azotemia, and dehydration can occur when used in combination with other diuretics, with excessive use, or in anorectic patients. Thiazides can cause hyperglycemia in diabetic or prediabetic animals by inhibiting conversion of proinsulin to insulin. Chlorothiazide's effects begin within 1 hour, peak at 4 hours, and last 6 to 12 hours. Hydrochlorothiazide produces diuresis within 2 hours, with peak effect at 4 hours, and duration of about 12 hours. Dosing every other day or even less frequently (instead of q12-24h) may be necessary to avoid serious azotemia and electrolyte abnormalities when used in the management of chronic refractory heart failure.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACEIs are indicated for most causes of chronic heart failure (see Table 3.3). Their use has led to clinical improvement and lowered mortality rates in people with heart failure. Similar benefits seem to occur in dogs with stages C and D heart failure from myocardial failure or volume overload. Cats with diastolic dysfunction are also thought to benefit from ACEIs. Although ACEI therapy does not delay CHF onset in most dogs with preclinical (stage B) chronic MR, it remains an integral part of standard therapy once CHF develops (stage C).

ACEIs moderate excess NH responses in several ways; therefore they have considerable advantages over hydralazine and other arteriolar dilators. ACEIs have only modest diuretic and vasodilatory effects; their main benefits arise from opposing the effects of NH activation and abnormal cardiovascular remodeling changes. By blocking the formation of angiotensin II, ACEIs allow arteriolar and venous vasodilation. The secondary inhibition of aldosterone release helps reduce Na^+ and water retention and therefore edema/effusions, as well as the adverse effects of aldosterone directly on the heart. ACEIs reduce ventricular arrhythmias and the rate of sudden death in people (and probably animals) with heart failure, likely because angiotensin II–induced facilitation of norepinephrine and epinephrine release is inhibited. Their vasodilating effects may be enhanced by vasodilator kinins normally degraded by ACE. A local vasodilating effect may occur through inhibition of ACE found within vascular walls, even in the absence of high circulating renin concentrations. Local ACE inhibition may be beneficial by modulating vascular smooth muscle and myocardial remodeling. However, it is unclear whether ACE inhibitors prevent ventricular remodeling and dilation in dogs with spontaneous heart disease. ACE inhibitors have been variably effective in treating dogs with hypertension.

Most ACEIs (except captopril and lisinopril) are prodrugs that are converted to their active form in the liver; therefore severe liver dysfunction can interfere with this conversion. Adverse effects of ACEIs include vomiting/diarrhea, deterioration of renal function, hypotension, and

hyperkalemia (especially when used with a potassium-sparing diuretic or potassium supplement). Angiotensin II is important in mediating renal efferent arteriolar constriction, which maintains glomerular filtration when renal blood flow decreases. As long as cardiac output and renal perfusion improve with therapy, renal function is usually maintained. Poor glomerular filtration is more likely to result with overdiuresis, excess vasodilation, or severe myocardial dysfunction. Measurement of serum creatinine and electrolytes is recommended within 1 week of initiating therapy and periodically thereafter. Azotemia is first addressed by decreasing the diuretic dosage. If necessary, the ACEI dosage is decreased or discontinued. Hypotension can usually be avoided by starting with low initial doses. Other adverse effects reported in people include rash, pruritus, impairment of taste, proteinuria, cough, and neutropenia. The mechanism of ACEI-induced cough in people is unclear but may involve inhibition of endogenous bradykinin degradation or may be associated with increased NO generation. NO has an inflammatory effect on bronchial epithelial cells.

Enalapril

Enalapril is about 20% to 40% bioavailable; administration with food does not reduce its bioavailability. It is hydrolyzed in the liver to enalaprilat, its most active form. Peak ACE-inhibiting activity occurs within 4 to 6 hours in dogs. Duration of action is 12 to 14 hours, and effects are minimal by 24 hours at the recommended once-daily dose. Enalapril often is given once daily initially but usually is increased to every 12 hours in dogs being treated for CHF. In cats, maximal activity occurs within 2 to 4 hours after an oral dose of either 0.25 or 0.5 mg/kg; some ACE inhibition (50% of control) persists for 2 to 3 days. Enalapril and its active metabolite are excreted in the urine. Renal failure and severe CHF prolong its half-life, so reduced doses or use of benazepril instead are recommended in such patients. Severe liver dysfunction will interfere with the conversion of the prodrug to the active enalaprilat. Injectable enalaprilat is also available, but sparse veterinary data exist on its use; this form is not well absorbed orally.

Benazepril

Benazepril is metabolized to its active form, benazeprilat. Only about 40% is absorbed when administered orally, but feeding does not affect absorption. After oral administration, peak ACE inhibition occurs within 2 hours in dogs and cats; its effect can last more than 24 hours. In cats doses of 0.25 to 0.5 mg/kg result in 100% inhibition of ACE, which is maintained at greater than 90% for 24 hours and tapers off to about 80% by 36 hours. Benazepril has an initial half-life of 2.4 hours and terminal half-life of about 29 hours in cats. Repeated doses produce moderate increases in drug plasma concentration. Benazepril is a preferred ACEI for animals with renal disease. This drug is eliminated equally in urine and bile in dogs. In cats about 85% of the drug is excreted in the feces and only 15% in urine. The drug is generally well tolerated. It may also slow renal function deterioration in cats with kidney disease.

Other Angiotensin-Converting Enzyme Inhibitors

Other ACEIs used in animals with heart failure have included ramipril, imidapril, lisinopril, and captopril. Ramipril is rapidly absorbed and converted to ramiprilat, although bioavailability is fairly low (similar to benazepril). Ramipril produces good ACE inhibition within 1-2 hours; with high affinity for ACE, its ACEI effect can last ~24 hours despite rapid clearance of free ramiprilat. Ramipril's pharmacokinetic properties are not significantly altered by moderate renal dysfunction. Imidapril also is comparable to enalapril and benazepril in efficacy. It appears to have a longer half-life, about 18-20 hours, in dogs. Elimination of both ramipril and imidapril is about 40% through the kidney and 60% by the liver. Captopril, the first ACEI used clinically, contains a sulfhydryl group, in contrast to enalapril and others. Although disulfide metabolites can act as free radical scavengers, the clinical significance of this for animals in heart failure is unclear. Captopril is rarely used as it requires more frequent dosing. Hemodynamic effects peak in 1 to 2 hours after oral administration and last less than 4 hours in dogs. Captopril is excreted in the urine. Lisinopril is a lysine analog of enalaprilat with direct ACE-inhibiting effects. Its bioavailability is between 25% and 50%, and absorption is not affected by feeding. The time to peak effect is 6 to 8 hours. The duration of ACE inhibition appears long, but more specific information in animals is lacking. Once-daily administration has been tried with apparent effectiveness.

Angiotensin Receptor Blockers

The angiotensin receptor blockers (ARBs) are drugs that directly block type I angiotensin II receptors rather than reduce the production of angiotensin II. The ARB agents sometimes are called "sartans" (valsartan, losartan, telmisartan, etc.). In experimental models of myocardial ischemia and heart failure, ARB treatment has reduced ventricular remodeling, fibrosis, and dysfunction, as does ACEI. Some experimental evidence suggests the combination of an ARB with an ACEI might reduce ventricular remodeling to a greater degree than with either agent alone. However, their combined use is not advocated in people with heart failure. Clinical experience with ARB use in dogs and cats with CHF is slim, although some studies are underway. Whether, or in what situations, an ARB instead of an ACEI (or possibly both together) would be most effective in the setting of CHF in dogs and cats is not clear.

A new combination drug for heart failure in people (Entresto, Novartis) incorporates the ARB valsartan with sacubitril, an inhibitor of neprilysin (the enzyme that degrades natriuretic peptides). In people with CHF and reduced myocardial contractility, this combination drug has reduced mortality and hospitalization, compared with enalapril. Clinical experience with this agent in dogs (and cats) with CHF is limited so far.

POSITIVE INOTROPIC AGENTS

Pimobendan

Pimobendan (Vetmedin) is called an *inodilator* because it increases contractility while also causing systemic and pulmonary vasodilation (see Table 3.3). Pimobendan has a calcium-sensitizing effect on the contractile proteins by increasing the affinity of the regulatory protein troponin C for Ca^{++}. This promotes increased contractility without an increase in free cellular Ca^{++} and therefore myocardial O_2 requirement. As a benzimidazole-derivative phosphodiesterase III inhibitor, pimobendan also slows cAMP breakdown and enhances adrenergic effects on Ca^{++} fluxes and myocardial contractility. The drug potentially has other beneficial effects by modulating NH and proinflammatory cytokine activation. It also has some antithrombotic properties but only at high doses. Peak plasma concentrations occur within an hour of oral dosing. Bioavailability is about 60% in dogs, but this decreases in the presence of food, so administration at least an hour before feeding sometimes is recommended. Pimobendan is highly proteinbound. Elimination is mainly via hepatic metabolism and biliary excretion. There is an active metabolite with phosphodiesterase III inhibitory effect that contributes to the drug's systemic and pulmonary vasodilatory effects. Concurrent Ca^{++} or β-blocker therapy may diminish the drug's positive inotropic effect. Adverse effects are uncommon but can include anorexia, vomiting, or diarrhea.

Pimobendan has been shown to improve clinical status and survival in dogs with CHF from DCM or chronic MR when added to standard therapy. Pimobendan is associated with longer survival times when compared with ACEI in dogs with CHF, although the combination of pimobendan with an ACEI usually is employed clinically. Pimobendan does not appear to increase the frequency of ventricular arrhythmias and sudden death in dogs with CHF. Pimobendan also is now recommended therapy for dogs with advanced preclinical chronic mitral valve disease (stage B2) because it can delay the onset of CHF, as shown in a large prospective multinational study (Epic trial). Likewise, pimobendan was shown to delay CHF onset and improve survival in Doberman Pinschers and Irish Wolfhounds with occult DCM. It presumably benefits other animals with progressive myocardial function deterioration as well. There is disagreement regarding pimobendan's use in cats with first-onset CHF caused by HCM, and it may be contraindicated for HOCM, as previously noted (p. 65). However, pimobendan is a recommended component of CHF therapy for cats with dilated, restrictive, and other end-stage cardiomyopathies.

Digoxin

As an oral positive inotropic drug, digoxin has been eclipsed by pimobendan. However, digoxin still is used in some cases of advanced DCM and end-stage MR as an adjunct to, and combined with, pimobendan to support myocardial function. Digoxin's ability to sensitize baroreceptors and thereby modulate NH activation probably is its most important attribute in patients with heart failure. Digoxin has only a modest positive inotropic effect and a narrow therapeutic window, so it must be dosed and monitored carefully. Digoxin is used most often for heart rate control in dogs with AF; it is moderately effective for slowing AV conduction. Digoxin also can suppress some other supraventricular arrhythmias (see Chapter 4). Digoxin generally is contraindicated when sinus or AV node disease is present. Other potential contraindications include azotemia, ventricular tachyarrhythmias (because it can exacerbate such arrhythmias), and concurrent use of a drug that can potentiate digoxin's effects. Digoxin usually is contraindicated in patients with HCM, especially those with ventricular outflow obstruction. It is almost never used in cats now. Digoxin is not helpful in patients with pericardial disease. Because of its potential toxicity, low doses are used and serum concentrations should be monitored. Serum concentrations in the low to mid therapeutic range are desired (see p. 70).

Digoxin increases contractility by competitively binding and inhibiting the Na^+, K^+-ATPase pump at the myocardial cell membrane. Intracellular Na^+ accumulation then promotes Ca^{++} entry via the sodium-calcium exchange. However, digoxin's inotropic effect may be minimal in diseased myocardial cells in which systolic Ca^{++} release and diastolic reuptake are impaired, and it can predispose to cellular Ca^{++} overload, delayed afterdepolarizations, and electrical instability.

The antiarrhythmic effects of digoxin are mediated primarily by increased parasympathetic tone to the sinus and AV nodes and atria. Some direct effects further prolong conduction time and refractory period of the AV node. Sinus rate slowing, reduced ventricular response rate to AF and atrial flutter, and suppression of atrial premature depolarizations are resulting effects. Although some ventricular arrhythmias might be suppressed (probably via enhanced vagal tone), digoxin has potential arrhythmogenic effects, especially in patients with heart failure.

Oral maintenance doses are used to initiate digoxin therapy. When a more rapid increase in serum concentration is important, the drug can be given at twice the oral maintenance dose for 1 to 2 doses. However, loading doses can result in toxic concentrations. IV digoxin loading is not recommended. Alternate IV drug therapy for supraventricular tachycardia usually is more effective (see Chapter 4), and other positive inotropic drugs (see p. 63 and Box 3.1) are safer and more effective than digoxin for immediate support of myocardial contractility.

Digoxin is well absorbed orally and undergoes minimal hepatic metabolism; absorption is approximately 60% for the tablet form and 75% for the elixir. Kaolin-pectin compounds, antacids, the presence of food, and malabsorption syndromes decrease bioavailability. About 27% of the drug in serum is proteinbound. The serum half-life in dogs ranges from less than 23 to more than 39 hours; therapeutic serum concentrations are achieved within 2 to 4.5 days with every 12-hour dosing. In cats, the reported serum half-life ranges widely from about 25 to more than 78 hours; chronic oral administration increases the drug's half-life. The alcohol-based

elixir produces approximately 50% higher serum concentrations than the tablet form of digoxin. For the rare feline case where digoxin might be helpful, dosing every 48 hours produces effective serum concentrations, with steady state achieved in about 10 days. Digoxin elimination is primarily by glomerular filtration and renal secretion in dogs, although approximately 15% is metabolized by the liver. Renal and hepatic elimination appear equally important in cats.

Serum digoxin concentration (and risk of toxicity) increases with renal failure because of reduced clearance and volume of distribution. However, there is no consistent correlation between the degree of azotemia and the serum digoxin concentration in dogs. Lower doses and close monitoring of serum digoxin concentration are recommended in animals with renal disease.

Digoxin dose and serum concentration are only weakly correlated in dogs with heart failure. Because much of the drug is bound to skeletal muscle, animals with reduced muscle mass or cachexia as well as those with compromised renal function easily can become toxic at usual calculated doses. Digoxin has poor lipid solubility. Initial dosing should be based on the patient's estimated lean body weight, especially in obese animals. Management of digoxin toxicity is outlined later. Conservative dosing and monitoring of serum digoxin concentrations are important to prevent toxicity.

Serum concentration measurement is recommended at 7 days (or 10 days for cats) after beginning digoxin therapy. Digoxin serum concentration also should be measured after a dosage change, or whenever potential signs of toxicity occur. Samples should be drawn 8 (to 10) hours post-dose. The target serum concentration range is 0.8 to 1.5 ng/mL. If the serum concentration is less than 0.8 ng/mL, the digoxin dose could be increased by 25% to 30%, and the serum concentration remeasured the following week. If serum concentrations cannot be measured and toxicity is suspected, the drug should be discontinued. If necessary, the drug can be reinstituted at half of the original dose after a couple days.

Digoxin Toxicity

Azotemia and hypokalemia both predispose to digoxin toxicity. Therefore it is important to monitor renal function and serum electrolyte concentrations during digoxin therapy. Hypokalemia predisposes the patient to myocardial toxicity by allowing increased digoxin binding to membrane Na^+, K^+-ATPase; conversely, hyperkalemia displaces digitalis from those binding sites. Hypercalcemia and hypernatremia potentiate both the inotropic and the toxic effects of the drug. Hyperthyroidism can potentiate the myocardial effects of the drug. Hypoxia sensitizes the myocardium to the toxic effects of digoxin. Certain drugs can affect serum digoxin concentrations when administered concurrently, including amiodarone, quinidine, and verapamil. Diltiazem, prazosin, spironolactone, and triamterene possibly increase serum digoxin concentration. Drugs affecting hepatic microsomal enzymes may also have effects on digoxin metabolism.

Digoxin toxicity causes GI, myocardial, and sometimes central nervous system (CNS) signs. GI toxicity can develop before signs of myocardial toxicity. Signs include anorexia, depression, vomiting, borborygmi, and diarrhea. Some of these GI signs result from the direct effects of digoxin on chemoreceptors in the area postrema of the medulla. CNS signs include depression and disorientation.

Myocardial toxicity can cause ventricular or supraventricular tachyarrhythmias, sinus arrest, Mobitz type I second-degree AV block, and junctional rhythms. Myocardial toxicity can occur before any other signs and can lead to collapse and death, especially in animals with myocardial failure. Therefore PR interval prolongation on the electrocardiogram (ECG) or signs of GI toxicity should not be used to guide progressive dosing of digoxin. Digoxin can stimulate spontaneous automaticity of myocardial cells by inducing and potentiating late afterdepolarizations; cellular stretch, calcium overloading, and hypokalemia enhance this effect. Toxic concentrations enhance automaticity by increasing sympathetic tone to the heart, whereas the parasympathetic effects of slowed conduction and altered refractory period facilitate development of reentrant arrhythmias. In patients taking digoxin, toxicity should be suspected when ventricular arrhythmias or tachyarrhythmias with impaired conduction appear.

Therapy for digoxin toxicity depends on its manifestations. GI signs usually respond to drug withdrawal and correction of fluid or electrolyte abnormalities. AV conduction disturbances resolve after drug withdrawal, although anticholinergic therapy may be necessary. Lidocaine is used to treat digoxin-induced ventricular tachyarrhythmias because it can suppress arrhythmias caused by re-entry and late afterdepolarizations, with little effect on sinus rate and AV conduction. A β-blocker might help control ventricular tachyarrhythmias not responsive to lidocaine alone, but this is not used if AV conduction block is present. Phenytoin (diphenylhydantoin) is a rarely used alternative antiarrhythmic agent for dogs with digoxin-induced ventricular tachyarrhythmias if lidocaine is ineffective (see Chapter 4, p. 82).

If the serum potassium concentration is less than 4 mEq/L, IV potassium supplementation is helpful (see p. 83). Magnesium supplementation also can help in suppressing arrhythmias; $MgSO_4$ has been used at 25 to 40 mg/kg via slow IV bolus, followed by infusion of the same dose over 12 to 24 hours. Fluid therapy to correct dehydration and maximize renal function should be used only with caution and at conservative volumes in patients with heart failure. Quinidine should not be used because it increases digoxin serum concentration. Oral administration of the steroid-binding resin cholestyramine is useful only soon after accidental digoxin overdose because this drug undergoes minimal enterohepatic circulation. A preparation of digoxin-specific antigen-binding fragments (digoxin-immune Fab) derived from ovine antidigoxin antibodies occasionally has been used for digoxin overdose; the Fab fragment–digoxin complex inactivates digoxin's effects and is subsequently excreted by the kidney.

OTHER VASODILATORS

Vasodilators can affect arterioles, venous capacitance vessels, or both ("balanced" vasodilators). Arteriolar dilators relax arteriolar smooth muscle and thereby decrease systemic vascular resistance and LV afterload. In patients with MR, arteriolar dilators decrease the systolic pressure gradient across the mitral valve, reduce regurgitant flow, and enhance forward flow into the aorta. Reduced regurgitant flow can diminish LA pressure, pulmonary congestion, and possibly LA size. Arteriolar vasodilators are used in advanced heart failure from MR and sometimes DCM, as an adjunct to ACEI and other therapy, to provide additional afterload reduction.

Arteriolar (or mixed) vasodilator therapy is initiated using low doses to avoid hypotension and reflex tachycardia. Reduction in concurrent diuretic dosage may be advisable. Monitoring for signs of hypotension is especially important. Ideally, arterial blood pressure is measured multiple times over several hours after starting therapy or dosage increase. Dosage titration to a mean arterial pressure between 70 to 80 mm Hg has been suggested as a therapeutic goal; however, systolic pressures of less than 90 to 100 mm Hg should be avoided. A venous pO_2 of greater than 30 mm Hg (from a free-flowing jugular vein), as a means to indicate reduced tissue oxygen extraction, also can help guide dosage titration. Clinical signs of drug-induced hypotension include weakness, lethargy, tachycardia, and poor peripheral perfusion. The vasodilator dose can be titrated upward, if necessary, while monitoring for hypotension with each increase in dose.

Venodilators relax systemic veins, increase venous capacitance, decrease cardiac filling pressures (preload), and reduce pulmonary congestion. They are most often used in the setting of acute CHF.

Hydralazine

Hydralazine directly relaxes arteriolar smooth muscle when the vascular endothelium is intact, but it has little effect on the venous system. The drug reduces arterial blood pressure, improves pulmonary edema, and increases jugular venous oxygen tension (presumably from increased cardiac output) in dogs with MR and heart failure. The most common indication for hydralazine is acute, severe CHF from MR when nitroprusside use is impractical. Hydralazine can cause marked reflex tachycardia. The dosage should be reduced if this occurs. Hydralazine can contribute to the enhanced NH response in patients with heart failure, which makes it less desirable than ACEIs for chronic use.

Hydralazine has a faster onset of action than amlodipine. Its effect peaks within 3 hours and lasts up to 12 hours. Administration of hydralazine with food decreases bioavailability by more than 60%. There also is extensive first-pass hepatic metabolism of this drug. However, increased doses saturate this mechanism and increase bioavailability in dogs. General precautions for initiating and titrating therapy are outlined in the preceding section.

Hypotension is the most common adverse effect of hydralazine therapy. GI upset also can occur, which may require drug discontinuation. High dosages have been associated with a lupus-like syndrome in people, although this has not been reported in animals.

Amlodipine

This dihydropyridine L-type Ca^{++} channel blocker causes peripheral vasodilation as its major action. Amlodipine has little effect on AV conduction. Besides being used to treat hypertension in cats, and sometimes in dogs (see Chapter 11), it is an adjunctive therapy for advanced stage C (and stage D) heart failure. In dogs that cannot tolerate ACEIs, amlodipine could be used in combination with a nitrate.

Amlodipine's oral bioavailability is good. It has a long duration of action (at least 24 hours in dogs). Plasma concentration peaks in 3 to 8 hours; half-life is about 30 hours. Plasma concentrations increase with long-term therapy. Maximal effect develops over 4 to 7 days after therapy is begun in dogs. The drug is metabolized in the liver. Elimination is through the urine and feces. Because of the delay in achieving maximum effect, low initial doses and weekly blood pressure monitoring during up-titration are recommended. An initial dose of 0.05 to 0.1 mg/kg PO q24(-12)h is suggested when used for additional afterload reduction in dogs receiving other heart failure therapy. Chronic administration of amlodipine (for ≥ 5 months) has been associated with development of gingival hyperplasia in a small number of dogs being treated for chronic degenerative valve disease; the hyperplasia appears to resolve after amlodipine discontinuation.

Prazosin

Prazosin selectively blocks α_1-receptors in both arterial and venous walls. It rarely is used for chronic CHF management because drug tolerance develops over time, and the capsule dose size is inconvenient in small animals. Controlled clinical studies in dogs are lacking. Hypotension, especially after the initial dose, is the most common adverse effect. Tachycardia is less likely to occur than with hydralazine because presynaptic α_2-receptors, important in the feedback control of norepinephrine release, are not blocked.

Nitrates

Nitrates act as venodilators (although IV nitroprusside has mixed vasodilator effects; see p. 63). They are metabolized in vascular smooth muscle to produce NO, which indirectly mediates vasodilation. Nitroglycerin ointment or isosorbide dinitrate has been used occasionally in the management of chronic CHF, either combined with standard therapy for refractory CHF or with hydralazine or amlodipine in animals that cannot tolerate ACEIs. Nitrates affect blood redistribution in people, but there are few studies involving dogs, especially using the oral route for CHF management. There is extensive first-pass hepatic metabolism, and the efficacy of oral nitrates is questionable. Nitroglycerin ointment (2%) is applied cutaneously (see p. 63). Self-adhesive,

sustained-release preparations may be useful, but they have not been systematically evaluated in small animals. Transdermal patches (0.2 mg/h [5 mg/24 h] nitroglycerin transdermal system), applied for 12 hours per day, have been used with anecdotal success in large dogs. Large doses, frequent application, or long-acting formulations are most likely to be associated with drug tolerance. Whether intermittent treatment (with drug-free intervals) prevents nitrate tolerance from developing in dogs and cats is unknown. Isosorbide dinitrate and mononitrate are orally administered nitrates. Their efficacy in dogs is unknown. They occasionally have been used in refractory (stage D) heart failure or in combination with an arteriolar dilator for patients unable to tolerate an ACEI.

DIETARY CONSIDERATIONS

A good-quality diet with adequate calories and protein, as well as moderate salt restriction, is recommended for most patients with chronic heart failure. Progressive weight loss can be problematic, especially as heart failure advances, so diet palatability and calorie content are important. Protein restriction is not recommended unless there is concurrent renal disease. Heart failure can interfere with the kidney's ability to excrete sodium and water loads. Therefore moderate dietary salt restriction is recommended to help control fluid accumulation. However, very low salt intake can increase RAAS activation. It is unclear whether reduced-salt intake is necessary before overt CHF develops; however, at minimum, refraining from feeding the patient high-salt table scraps or treats is prudent. High-salt foods include processed meats, canned fish, cheese, canned vegetables and soups, breads, salty processed snack foods, as well as many dog treats.

A moderate degree of salt restriction entails a sodium intake of about 30 mg/kg/day (about 0.06% sodium for canned food or 210-240 mg/100 g of dry food). Although diets for senior animals or those with renal disease usually provide this level of salt, their protein restriction is a drawback for many cases. Supplementing with additional protein (such as hard-boiled eggs or cooked chicken) is a strategy. Other commercial diets that provide reduced-salt, adequate protein, and omega-3 fatty acid (FA) supplementation are available (including Royal Canin Veterinary Diet Canine Early Cardiac, Hill's Prescription Diet j/d, Purina Veterinary Diets JM Joint Mobility, or Purina's CV Cardiovascular Feline Formula); a good source for additional information and updates can be found at www.tufts.edu/vet/heartsmart. Prescription cardiac diets (such as Hill's Prescription Diet h/d) usually have greater sodium restriction (e.g., 13 mg sodium/kg/day, or about 90-100 mg sodium/100 g of dry food, or 0.025% sodium in a canned food), but also can have more protein restriction. Although possibly helpful in managing refractory CHF, an additional protein source may be needed. Severe sodium restriction (e.g., 7 mg/kg/day) can exacerbate NH activation and contribute to hyponatremia. Recipes for homemade low-salt diets are available but providing balanced vitamin and mineral content may be difficult.

Dietary changes are best instituted gradually and when the patient is not in acute CHF; for example, mix the new with the old diet in a 1:3 or 1:4 ratio for several days, then gradually increase the proportion of new diet over a week or so until the new diet alone is being fed. Drinking water in some areas can contain high sodium concentrations. This might become important for animals with end-stage CHF that is difficult to control. Nonsoftened water or (where water from the public water supply contains > 150 ppm of sodium) distilled water can be recommended to further decrease salt intake. Supplementation of specific nutrients is important in some cases (discussed later).

Inappetence is a common problem with advanced heart failure, even though energy needs are increased. Fatigue, increased respiratory effort, azotemia, adverse medication effects (including digoxin toxicity), and low diet palatability all can contribute to poor appetite. At the same time, poor splanchnic perfusion, bowel and pancreatic edema, and secondary intestinal lymphangiectasia may reduce nutrient absorption and promote protein loss in advanced CHF. Hypoalbuminemia and reduced immune function may develop. Such factors, as well as renal or hepatic dysfunction, also can alter the pharmacokinetics of certain drugs.

Strategies that can help improve appetite include warming the food to enhance its flavor, adding small amounts of more palatable human foods (e.g., nonsalted meats or gravy, low-sodium soup) or canned reduced-sodium cat food. Sprinkling on a salt substitute (KCl) or garlic powder, handfeeding, and providing small quantities of the diet several times a day also can help. In some cases, a drug with appetite-stimulating properties (such as mirtazapine or capromorelin, or cyproheptadine for cats) might help, although their effects in patients with CHF are not well reported.

Cardiac cachexia is the syndrome of progressive muscle wasting as well as fat loss associated with advanced chronic CHF. Increased energy requirements, metabolic abnormalities, and reduced food intake are contributing factors. Cardiac cachexia usually is identified only after CHF develops and becomes most evident in cases with more chronic, refractory heart failure. It is seen in dogs more often than cats, especially those with right-sided CHF signs and/or DCM. Muscle loss over the spine and gluteal region usually is noted first. Weakness and fatigue occur with loss of lean body mass; cardiac mass also can be affected. Cardiac cachexia is thought to be a predictor of poor survival. It also is associated with reduced immune function in people. The pathogenesis of cardiac cachexia involves multiple factors, especially proinflammatory cytokines, TNF_{α}, and interleukin-1. These substances suppress appetite and promote hypercatabolism. Dietary supplementation with fish oils, which are high in omega-3 fatty acids (eicosapentaenoic [EPA] and docosahexaenoic [DHA] acids) can reduce cytokine production, may improve endothelial function, and appear to have antiarrhythmic effects, among other benefits. Oral doses of 40 mg/kg/day EPA and 25 mg/kg/day DHA have been suggested. Over-the-counter fish oil capsules containing 180 mg EPA and 120 mg DHA in each 1-g capsule can be used at a

dose of 1 capsule per 10 lb of body weight per day. Several veterinary fish oil supplements also are available. Cod liver oil and flax seed oil are not recommended for omega-3 FA supplementation.

Grossly obese pets with heart disease may benefit from a weight-reducing diet. Obesity increases metabolic demands on the heart and expands blood volume. Mechanical interference with respiration promotes hypoventilation, which could contribute to cor pulmonale and complicate preexisting heart disease. However, animals in heart failure that are mildly overweight, or that gain or maintain their weight, could have a survival advantage.

Taurine

Taurine is an essential nutrient for cats. Prolonged deficiency causes myocardial failure and other abnormalities (see Chapter 8, p. 169). Most commercial and prescription cat foods are well supplemented with taurine, which has markedly reduced the prevalence of taurine-responsive DCM in cats. But taurine concentrations should be measured in cats diagnosed with DCM, because the diet of some cats may still be deficient. Taurine-deficient cats are given oral supplements of taurine (250-500 mg) twice daily.

Some dogs with DCM appear deficient in taurine and/or L-carnitine, most notably American Cocker Spaniels but also others (see Chapter 7, p. 151). Dogs fed protein-restricted or vegetarian diets can become taurine-deficient, and some develop evidence of DCM. Taurine supplementation for dogs less than 25 kg is 500 to 1000 mg every 8 hours; for dogs 25 to 40 kg the dose is 1 to 2 g every 8 to 12 hours. Although not all taurine-deficient American Cocker Spaniels need both taurine and L-carnitine, most appear to.

L-Carnitine

Although L-carnitine deficiency has been identified in Boxers and Doberman Pinschers with DCM, its prevalence is thought to be low, and the number of affected dogs responsive to L-carnitine supplementation even lower. Nevertheless, a trial period of supplementation (at a higher dosage) may be worthwhile. After at least 4 months, reevaluation by echocardiogram is done to assess LV functional improvement. Dogs treated with carnitine supplementation may give off a peculiar odor.

The minimum effective dose of L-carnitine is not known; it may vary with the type of deficiency, if present at all. Several dose ranges have been suggested, including 50 to 100 mg/kg PO every 8 to 12 hours for systemic deficiency or 200 mg/kg every 8 hours for myopathic deficiency. Others use 1 g of oral L-carnitine every 8 hours for dogs less than 25 kg and a dose of 2 g every 12 hours for dogs between 25 and 40 kg. One half teaspoonful of pure L-carnitine powder is the equivalent of 1 g. Both taurine and L-carnitine can be mixed with food for easier administration.

Other Supplements

The role of other dietary supplements is unclear. Oxidative stress and free-radical damage probably play a role in the pathogenesis of myocardial dysfunction. Increased circulating cytokines in heart failure can promote oxidative stress. Although vitamin C supplementation has a beneficial effect on endothelial function, the role of supplemental antioxidant vitamins in animals with CHF is unclear. Coenzyme Q-10 is an antioxidant and co-factor involved in cellular energy production. Whether it provides any measurable benefit is controversial; doses of 30(-90) mg PO q12h have been used in dogs with uncertain effect.

β-Blockers in Patients With Heart Failure

β-blockers must be used cautiously, especially in animals with myocardial failure, because of their negative inotropic effect. Their main role is in the management of certain arrhythmias, such as AF and sometimes ventricular tachyarrhythmias (see Chapter 4). Although in people with heart failure, chronic use of some β-blockers can improve cardiac function and reduce pathologic ventricular remodeling and mortality, a similar clinical benefit of chronic low-dose β-blocker therapy has not been proven in dogs or cats. Currently, β-blockers are not recommended as part of routine combination therapy for chronic heart failure, unless indicated for cardiac rhythm or rate control. Careful monitoring is important because CHF decompensation, bradycardia, and hypotension can occur, necessitating β-blocker dosage reduction or discontinuation.

CHRONIC DIASTOLIC DYSFUNCTION

Furosemide is continued orally in patients with CHF from HCM and other causes of diastolic dysfunction. Gradual reduction to the lowest dosage and frequency effective for controlling edema is the aim. An ACEI is thought to be beneficial in most cases and is instituted during the transition to chronic therapy, if not before. Antiplatelet therapy is recommended for cats (see Chapter 12). Some cats appear to benefit from pimobendan, especially those with advanced disease or reduced systolic function (see previous discussion). Spironolactone also can be useful as adjunct therapy, especially for cases with recurrent pleural effusion. Diltiazem or a β-blocker is not recommended routinely for most cats with CHF from HCM, because efficacy has not been established and their long-term effect is questionable. However, one or the other of these agents may be indicated for antiarrhythmic therapy (see Chapter 4). The use of ivabradine (a "funny" current [I_f] inhibitor) for heart rate control could prove helpful in the future by improving diastolic filling time; clinical experience is needed to guide specific recommendations.

REEVALUATION AND MONITORING

Client education is important for the long-term management of chronic heart failure. A good understanding of the patient's underlying disease, the signs of heart failure, and the purpose and potential adverse effects of each medication make compliance and early identification of complications more likely. Home monitoring of the patient's resting (ideally, sleeping) respiratory rate is hugely helpful for monitoring control of

pulmonary edema in animals with chronic heart failure. Even before the initial onset of CHF, when the patient still has stage B disease, the authors recommend that clients assess the RRR to become comfortable with the technique and to establish the animal's baseline RRR (see Box 3.2). RRRs for normal animals in the home environment usually are 30 breaths/min or less. A persistent increase (of ≥ 20%) above the patient's normal baseline RRR often is the earliest sign of decompensating heart failure. RRRs above 40 breaths/min typically accompany clinical pulmonary edema. This is because pulmonary edema increases lung stiffness; faster, more shallow respirations reduce the work of ventilating stiffer lungs. It is more difficult to monitor heart rate without disturbing the animal's rest or sleep. However, in cases where this can be done, a persistent increase in resting heart rate usually accompanies the heightened sympathetic tone of decompensating CHF.

In addition to home monitoring, periodic recheck examinations are important because complications often develop. The time frame for recheck visits may vary from a few days to every 4 months or so, depending on heart disease severity and patient stability. All medications and their dosage schedules should be reviewed at each visit. Ask the owner about the patient's RRR, diet, appetite level, activity and stamina, whether there are any problems with administering the medications or if refills are needed, and any other concerns.

A thorough physical examination (see Chapter 1) is important at each evaluation. Depending on the patient's status, additional clinical tests might include blood pressure measurement, thoracic radiographs, serum biochemistry analyses, resting or ambulatory ECG recording, an echocardiogram, or other tests. Measurement of serum electrolyte and creatinine or blood urea nitrogen (BUN) concentrations is usually done at each recheck visit. Electrolyte imbalance (especially hypokalemia or hyperkalemia, hypomagnesemia, and sometimes hyponatremia) can occur from the use of diuretics, ACEIs, and salt restriction. Poor appetite as well as loop diuretics can promote hypokalemia; however, potassium supplements should not be used without documenting hypokalemia, especially when an ACEI and spironolactone are prescribed. Serum magnesium concentration does not accurately reflect total body stores; however, supplementation may be especially beneficial in animals that develop ventricular arrhythmias while receiving furosemide and digoxin. Hyponatremia in patients with severe CHF results from an inability to excrete free water (dilutional hyponatremia) rather than from a total body sodium deficit. It can be difficult to correct and is considered a poor prognostic sign. In some cases, reducing the furosemide and/or other diuretic dose, cautiously adding/increasing an arteriolar vasodilator (to improve renal perfusion), or increasing inotropic support (with higher pimobendan dose or addition of another inotrope) might improve serum Na^+ concentration. However, vigilant monitoring is necessary to avoid worsened congestion, hypotension, and other potential adverse effects.

Many factors can exacerbate the signs of heart failure, including physical exertion, infection, anemia, exogenous fluid administration (excess volume or sodium load), high-salt diet or dietary indiscretion, erratic administration of medication, inappropriate medication dosage for the level of disease, development of cardiac arrhythmias, environmental stress (such as heat, humidity, cold, smoke), development or worsening of concurrent extracardiac disease, and progression of underlying heart disease (including ruptured chordae tendineae, secondary pulmonary hypertension and right heart failure, and LA tear). Repeated episodes of acute, decompensated congestive failure that sometimes require hospitalization and intensive diuresis are relatively common in patients with chronic progressive heart failure.

BOX 3.2

Owner Instructions for Monitoring Resting Respiratory Rate

While your pet is quietly sleeping (or almost sleeping) and without touching or disturbing him/her, count the number of breaths taken during a period of 15 seconds. (You can usually determine this by watching the chest move in and out.)

Multiply this number by 4 to obtain the breaths per minute.

Keep track of this number by recording it in a calendar or logbook, or with a respiratory rate monitoring phone app.

Most dogs and cats with normal lungs have an RRR of <30 breaths/min; some are <20/min.

Once you have determined your pet's normal baseline RRR, continue to monitor the RRR periodically.

If this number becomes persistently increased by more than 20% above his/her normal baseline (and especially if the RRR increases >40 breaths/min), this may be an early indicator of congestion (fluid) in the lungs and you should contact your veterinarian.

STRATEGIES FOR RECURRENT OR REFRACTORY CONGESTIVE HEART FAILURE

It is important to confirm that the standard stage C heart failure therapies are being appropriately administered to patients that develop recurrent, decompensated CHF. For dogs, especially those with chronic MR or DCM, this involves furosemide (at approximately 2 mg/kg q12 or 8 h), combined with pimobendan (at 0.2-0.3 mg/kg q12h) and an ACEI (usually enalapril or benazepril, at 0.5 mg/kg q12h); spironolactone (2 mg/kg q24h) usually is included here as well. Recurrent episodes of CHF often respond initially to an increased dose of furosemide and/or pimobendan (to q8h ±increased dosage, see following text). Renal function and electrolytes should be assessed; ultimately, increases in furosemide dosage are limited mainly by kidney function. If the ACEI has been dosed only once daily, it is increased to every 12 hours, unless this is not tolerated. If spironolactone is not already being administered, it should be added. Arrhythmias commonly develop in animals with advanced heart failure

and can precipitate congestive signs. It is important to characterize the type and severity of the arrhythmia to guide treatment. Effective antiarrhythmic therapy can help control CHF signs. For AF, therapy is adjusted to maintain a heart rate of <140 or 150 beats/min in the hospital, or between 80 and 110 beats/min at home, (for example, by a gradual increase in diltiazem dosage, and using serum digoxin concentration measurement to optimize digoxin dose; see Chapter 4 for additional information). Referral to a veterinary cardiologist, or internist with extensive experience managing CHF, is encouraged and appropriate for patients with advanced cardiac disease and CHF. Specialty consultation can help further characterize the patient's cardiac status and any complicating factors, optimize therapy, and provide support with ongoing patient care.

Refractory, stage D, heart failure is considered to be present when the patient requires over 8-12 mg/kg/day of furosemide to control edema, despite other standard heart failure therapy previously outlined. Acute pulmonary edema requiring hospitalization is managed as outlined in Box 3.1. Additional strategies for chronic CHF management are described here; they usually are instituted one at a time (not necessarily in the order presented) so that effectiveness can be evaluated. As always, therapy must be tailored for the individual patient's needs. Additional afterload reduction (amlodipine or hydralazine) can be helpful for dogs with MR and sometimes DCM; start with low doses and gradually titrate the dose upward as needed, while monitoring blood pressure. An arteriolar vasodilator is not recommended for cats with HCM or dogs with fixed ventricular outflow obstruction (e.g., subaortic stenosis). Pimobendan dosing frequency can be increased to every 8 hours, or dosage raised up to 0.4 to 0.5 mg/dose. For most cats with refractory CHF, pimobendan can be added to therapy or its dosage increased. For dogs with severe pulmonary hypertension and collapse episodes or right-sided CHF signs, addition of sildenafil (1-2 mg/kg q12h PO) can reduce clinical signs. Modification of diuretic therapy can be helpful for dogs that require very high furosemide doses. Torsemide can be used instead of furosemide, beginning at a total daily dose (mg) that is $\frac{1}{12}$ to $\frac{1}{10}$ of the total furosemide dose being given per day. An alternate strategy, if torsemide is not used, is the addition of a third diuretic (thiazide) to furosemide and spironolactone; however, very conservative dosing and close attention to renal function and electrolytes are necessary because severe derangements can develop quickly. Digoxin, if not previously used and not contraindicated, might be useful for additional inotropic support and its baroreceptor sensitizing effect. More stringent dietary salt restriction can be tried; however, it is important to support the patient's appetite and food intake. Dogs without pulmonary edema that persistently have a dry cough associated with bronchomalacia and/or main bronchus compression from marked LA enlargement often benefit from a cough suppressant. For dogs with concurrent airway disease, a bronchodilator also might be helpful as long as it does not provoke tachyarrhythmias.

CHAPTER 4

Cardiac Arrhythmias and Antiarrhythmic Therapy

GENERAL CONSIDERATIONS

Cardiac arrhythmias occur for many reasons. Although some arrhythmias are of no clinical consequence, others cause serious hemodynamic compromise and sudden death, especially in animals with underlying heart disease. It is important to make an accurate electrocardiographic diagnosis, as well as to consider the arrhythmia's clinical context, before deciding whether to use antiarrhythmic therapy. For example, the risk of death associated with ventricular tachyarrhythmias is higher in people when myocardial function is impaired. Dogs with cardiomyopathy also are known to have increased risk for sudden death, especially Doberman Pinschers and Boxers. In addition, an inherited disorder predisposing to sudden death has been identified in young German Shepherds. On the other hand, the ventricular premature activity that occurs commonly after thoracic trauma or splenectomy in previously healthy animals (see p. 41) usually is benign and resolves without therapy.

Occasional ventricular premature complexes (VPCs) occur without consequence in many animals. However, arrhythmias that compromise cardiac output and coronary perfusion promote myocardial ischemia, hypotension, reduced cardiac pump function, and sometimes sudden death. These arrhythmias tend to be either quite rapid (such as sustained ventricular or supraventricular tachyarrhythmias) or slow (such as advanced atrioventricular [AV] block with a slow or unstable ventricular escape rhythm). Sometimes, however, a lethal arrhythmia such as ventricular fibrillation (VF) occurs without an antecedent sustained arrhythmia. Sustained tachycardia of either supraventricular or ventricular origin reduces cardiac output acutely, and eventually (within weeks) it leads to myocardial dysfunction and congestive heart failure (CHF).

DEVELOPMENT OF ARRHYTHMIAS

Multiple factors underlie cardiac rhythm disturbances. Abnormalities of conduction or automaticity caused by cardiac structural or pathophysiologic remodeling can predispose to arrhythmias, even in the absence of overt cardiac disease. Genetic factors and environmental stresses contribute to this. However, additional triggering (such as a premature stimulus or abrupt change in heart rate) and/or modulating factors (such as changes in autonomic tone, circulating catecholamines, ischemia, or electrolyte disturbances) are thought to be necessary to provoke and sustain a rhythm disturbance. For example, episodes of anger or aggressive behavior have been linked to increased susceptibility to ischemic arrhythmias and sudden arrhythmic death in both dogs and people. Various stresses that lead to abnormal cardiac remodeling also could play a role in arrhythmia development. Remodeling can involve myocyte hypertrophy, changes in the structure or function of ion channels, tissue fibrosis, and other changes related to neurohormonal activity, cytokines, and other signaling systems (see Chapter 3). Although some of these changes act as positive compensatory mechanisms in the short term, they can have harmful and arrhythmogenic long-term effects. It is thought that if such underlying arrhythmogenic modulators could be controlled or reduced, arrhythmias would be lessened. The higher survival in human heart failure patients treated with angiotensin-converting enzyme inhibitors (ACEI), spironolactone, and some β-blockers supports this concept. There is similar evidence for ACEIs in dogs with dilated cardiomyopathy (DCM) and reason to suspect that other therapies might be beneficial as well.

APPROACH TO ARRHYTHMIA MANAGEMENT

Specific antiarrhythmic drug therapy may or may not be warranted in an individual patient (see guidelines later). If antiarrhythmic therapy is pursued, it should be with defined goals in mind. For example, usually an immediate goal is to restore hemodynamic stability. Although ideal goals might include conversion to sinus rhythm, correction of underlying cause, and prevention of further arrhythmia and sudden death, suppression of all abnormal beats generally is not a realistic goal. Successful therapy could mean sufficient reduction in frequency (e.g., by ≥70%-80%) or repetitive rate of ectopic beats to eliminate clinical signs. It must be

recognized, however, that even with apparently complete conversion to sinus rhythm, the risk of sudden death from a lethal arrhythmia may remain. It is also important to remember that all antiarrhythmic drugs can have adverse effects, including provoking additional arrhythmias (proarrhythmic effect).

Various arrhythmias and their electrocardiographic characteristics are described in Chapter 2. This section provides a general approach to managing cardiac rhythm disturbances. Nevertheless, much remains to be learned about effective arrhythmia management and the prevention of sudden death.

1. Record and interpret an electrocardiogram (ECG) (Box 4.1); identify and define any arrhythmia. An extended ECG recording period may be necessary (e.g., Holter or event monitoring or extended in-hospital monitoring).
2. Evaluate the whole patient, including history, physical examination findings, and clinical/laboratory test results. Are signs of hemodynamic impairment evident (e.g., episodic weakness, syncope, signs of CHF)? Are other signs of cardiac disease present (e.g., heart murmur, cardiomegaly)? Are there additional abnormalities (e.g., fever, abnormal blood chemistry or hemogram values, respiratory compromise with hypoxia, other extracardiac disease, trauma, or pain)? Is the animal receiving any medications? Correct what can be corrected!
3. Decide whether to use antiarrhythmic drug therapy. Consider signalment, history, clinical signs, and underlying disease, as well as the potential benefits/risks of the drug(s) under consideration.
4. If an antiarrhythmic drug is to be used, define the goals of therapy for this patient.
5. Initiate treatment and determine drug effectiveness. Adjust dose or try alternate agents, if needed.
6. Monitor patient status. Assess arrhythmia control (consider repeated Holter monitoring), manage underlying disease(s), and watch for adverse drug effects and other complications.

BOX 4.1

ECG Interpretation Guide

1. Determine the heart rate. Is it too fast, too slow, or normal?
2. Is the rhythm regular or irregular?
3. Is sinus rhythm present (with or without other abnormalities), or are there no consistent P-QRS-T relationships?
4. Are all P waves followed by a QRS and all QRS complexes preceded by a P wave?
5. If premature (early) complexes are present, do they look the same as sinus QRS complexes (implying atrial or junctional [supraventricular] origin), or are they wide and of different configuration than sinus complexes (implying a ventricular origin [or possibly abnormal ventricular conduction of a supraventricular complex])?
6. Are premature QRS complexes preceded by an abnormal P wave (suggesting atrial origin)?
7. Are there baseline undulations instead of clear and consistent P waves, with a rapid, irregular QRS occurrence (compatible with atrial fibrillation)?
8. Are there long pauses in the underlying rhythm before an abnormal complex occurs (escape beat)?
9. Is an intermittent AV conduction disturbance present?
10. Is there a lack of consistent temporal relationship between P waves and QRS complexes, with a slow and regular QRS occurrence (implying complete AV block with escape rhythm)?
11. For sinus and supraventricular complexes, is the mean electrical axis normal?
12. Are all measurements and waveform durations within normal limits?

See Chapter 2 for more specific information.

DIAGNOSIS AND MANAGEMENT OF COMMON ARRHYTHMIAS

Cardiac arrhythmias in a given animal often occur inconsistently and are influenced by drug therapy, prevailing autonomic tone, baroreceptor reflexes, and variations in heart rate. Treatment decisions are based on consideration of the origin (supraventricular or ventricular), timing (premature or escape), and severity of the rhythm disturbance, as well as the clinical context. Accurate ECG interpretation is important. Although a routine (resting) ECG documents arrhythmias present during the recording period, it provides only a glimpse of the cardiac rhythm occurring over time. Because marked variation in frequency and severity of arrhythmias can occur over time, potentially critical arrhythmias are easy to miss. For this reason, Holter (or other ambulatory ECG) monitoring can be useful in assessing the severity and frequency of arrhythmias and monitoring treatment efficacy. Some rhythm abnormalities do not require therapy, whereas others demand immediate aggressive treatment. Close patient monitoring is especially important in patients with more serious arrhythmias.

Supraventricular tachyarrhythmias occur from various mechanisms, including reentry involving the AV node, accessory pathways, or sinoatrial (SA) node, as well as abnormal automaticity within atrial or junctional tissue. Many patients have atrial enlargement. Common underlying heart diseases include chronic mitral or tricuspid valve degeneration with regurgitation, DCM, congenital malformations, and cardiac neoplasia. Other factors also may predispose to atrial tachyarrhythmias (Box 4.2).

VPCs occur with disorders that affect cardiac tissue directly or indirectly through neurohormonal effects (see Box 4.2). For instance, disorders of the central nervous system (CNS) can produce abnormal autonomic neural effects in the heart, and provoke ventricular or supraventricular arrhythmias (brain-heart syndrome). When VPCs

Hypothermia
Fever
Sepsis/toxemia
Trauma (thoracic or abdominal)
Gastric dilation/volvulus
Splenic mass or splenectomy
Hemangiosarcoma
Pulmonary disease
Uremia
Pancreatitis
Pheochromocytoma
Other endocrine diseases (diabetes mellitus, Addison disease, hypothyroidism)
High sympathetic tone (pain, anxiety, fever)
Central nervous system disease (increases in sympathetic or vagal stimulation)
Electric shock
Drugs (digoxin, sympathomimetics, anesthetics, tranquilizers, anticholinergics, antiarrhythmics)

are infrequent or underlying cardiac function is normal, adverse hemodynamic effects may be negligible. However, hemodynamic impairment can be severe in dogs or cats with underlying heart disease, rapid ventricular rates, or myocardial depression stemming from a systemic disease.

Factors such as underlying hypoxia, electrolyte or acid-base imbalances, and abnormal hormone concentrations (e.g., hyperthyroidism) can exacerbate arrhythmias. Therefore, correcting these improves arrhythmia control. Because some drugs can provoke arrhythmias, reducing dosage or discontinuing the medication may be necessary.

CLINICAL PRESENTATION

Box 4.3 lists common arrhythmias according to a clinical description of the heartbeat.

TACHYARRHYTHMIAS

Rapid Irregular Rhythms

Irregular heart rhythms are common. The ECG is important for differentiating abnormal rhythms and sinus arrhythmia. Pulse deficits (see p. 6) and an irregular, weak pulse with heart sounds of varying intensity and regularity may be detected on physical examination. Premature contractions interrupt ventricular filling and reduce stroke volume, sometimes to the extent that there is no ejection at all for that cycle (Fig. 4.1). Rapid atrial fibrillation (AF) and premature contractions of any origin often cause such pulse deficits. VPCs can cause audible splitting of the heart sounds because of asynchronous ventricular activation. Ventricular and supraventricular tachycardias (SVTs) and AF cause more severe hemodynamic compromise than do isolated premature contractions, especially in patients with underlying heart disease.

Rapid Regular Rhythms

Rapid regular rhythms include sinus tachycardia, sustained SVT, and sustained ventricular tachycardia. Sinus tachycardia is caused by high sympathetic tone or drug-induced vagal blockade. Underlying factors include anxiety, pain, fever, thyrotoxicosis, heart failure, hypotension, shock, the

ingestion of stimulants or toxins (e.g., chocolate, caffeine), or drugs (e.g., catecholamines, anticholinergics, theophylline, and related agents). The heart rate in dogs and cats with sinus tachycardia usually is well under 300 beats/min, although it could be higher in those with thyrotoxicosis or in those (particularly cats) that have ingested exogenous stimulants or drugs. Alleviation of the underlying cause and intravenous (IV) fluid administration to reverse hypotension (in animals without edema) should cause sympathetic tone and sinus rate to decrease.

SVT of varying causes can be difficult to differentiate from sinus tachycardia. The heart rate with SVT may be greater than 300 beats/min, but it is uncommon for the sinus rate to be this rapid. Patients with SVTs usually have a normal QRS configuration (narrow and upright in lead II). However, if an intraventricular conduction disturbance is present, SVT may resemble ventricular tachycardia. A vagal maneuver (see p. 82) can be useful in differentiating among narrow QRS complex tachycardias.

Sustained, rapid arrhythmias lead to decreases in cardiac output, arterial blood pressure, and coronary perfusion. CHF eventually may result. Signs of poor cardiac output and hypotension include weakness, depression, pallor, prolonged capillary refill time, exercise intolerance, syncope, dyspnea, prerenal azotemia, worsening rhythm disturbances, and sometimes altered mentation, seizure activity, and sudden death.

Supraventricular Tachyarrhythmias

Occasional premature beats do not require specific therapy. Factors that predispose to these arrhythmias should be minimized as possible (e.g., discontinue or reduce dosage of predisposing drugs, manage heart failure if present, and treat metabolic or endocrine abnormalities).

Oral therapy for frequent supraventricular premature beats or paroxysmal tachycardia

Initial oral therapy for frequent atrial premature complexes (APCs) or paroxysmal SVT can involve either diltiazem, digoxin, a β-blocker, or a combination of these (Fig. 4.2). For patients with CHF, if the arrhythmia is not sufficiently controlled with diltiazem (or digoxin), along with other therapy indicated for heart failure, the combination of diltiazem with digoxin (or a β-blocker with digoxin) may be effective. Cats with hypertrophic cardiomyopathy (HCM) or hyperthyroidism usually are treated with a β-blocker such as atenolol, although diltiazem could be an alternative. Refractory, frequent supraventricular tachyarrhythmias may respond to amiodarone, sotalol, procainamide, or propafenone.

Acute therapy for supraventricular tachycardia

More aggressive therapy is warranted for rapid, sustained supraventricular tachyarrhythmias because of the hemodynamic impairment caused. A vagal maneuver can be tried initially (see p. 82). IV access is secured, and fluid administered to maintain blood pressure and enhance endogenous vagal tone. However, caution is necessary. Patients with known or suspected heart failure generally should not receive IV fluid or should receive only a small volume administered slowly. If a vagal maneuver does not terminate the arrhythmia, diltiazem IV (or oral loading) is a good first-choice agent. However, it has a negative inotropic effect, so low doses and slow administration are important when used IV, especially in patents with suspected DCM. A slowly administered IV β-blocker (such as esmolol or propranolol) is an alternative therapy but also has negative inotropic effects. Occasional cases of reentrant SVT or automatic atrial tachycardia respond to IV lidocaine, which may be worth trying given this drug's relative safety. Other strategies in refractory cases include IV amiodarone, oral sotalol, or a class IA or IC drug. Oral digoxin often is less effective than diltiazem but might be useful in some cases. Digoxin has a slower onset of action, and it increases vagal tone. IV digoxin is not recommended, as it also can increase central sympathetic output. Adenosine has been ineffective for terminating SVTs in dogs. Further cardiac diagnostic tests are indicated once conversion is achieved or the ventricular rate has decreased to fewer than 200 beats/min. Options for longer-term oral therapy to control recurrence include diltiazem, amiodarone, a β-blocker, digoxin, or propafenone; combination therapy may be necessary.

Paroxysmal AV reciprocating tachycardia (AVRT) is a reentrant tachycardia involving an accessory pathway and the AV node (see p. 44). It is interrupted by slowing conduction or prolonging the refractory period of either or both tissues. A vagal maneuver may slow AV conduction enough to terminate the rhythm. Diltiazem and β-blockers slow AV

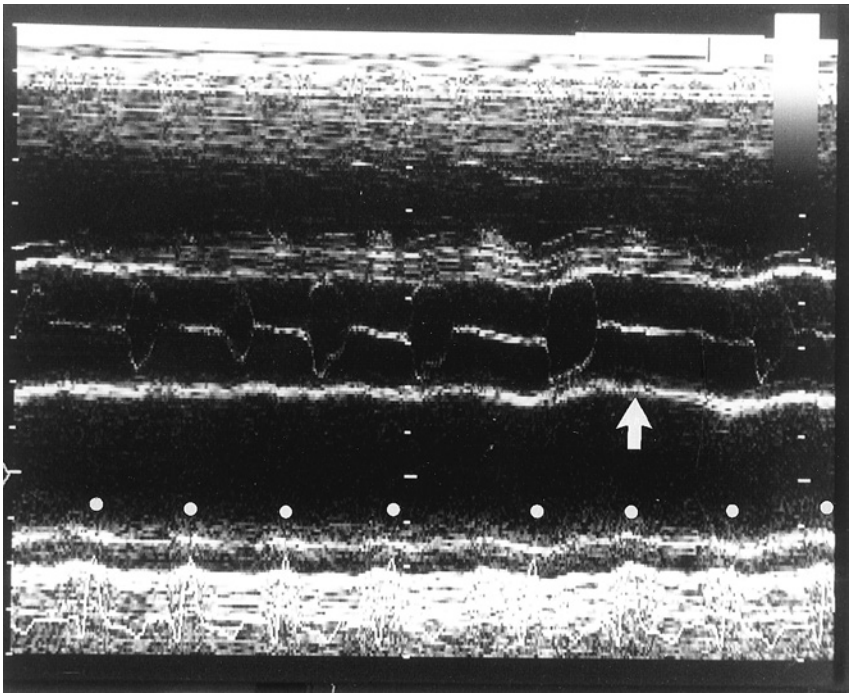

FIG 4.1
M-mode echocardiogram at the aortic root level in a Doberman Pinscher with dilated cardiomyopathy atrial fibrillation (AF) illustrates variable (or absent) opening of the aortic valve; this is caused by the AF-induced variation in ventricular filling leading to irregularly reduced stroke volume. Variable-intensity pulses and pulse deficits result. The motion of two aortic valve leaflets is seen within the parallel aortic root echoes. Irregular and abbreviated aortic valve opening occurs after most QRS complexes (indicated by white dots), but the aortic valve does not open at all after the sixth QRS complex from the left *(arrow)*.

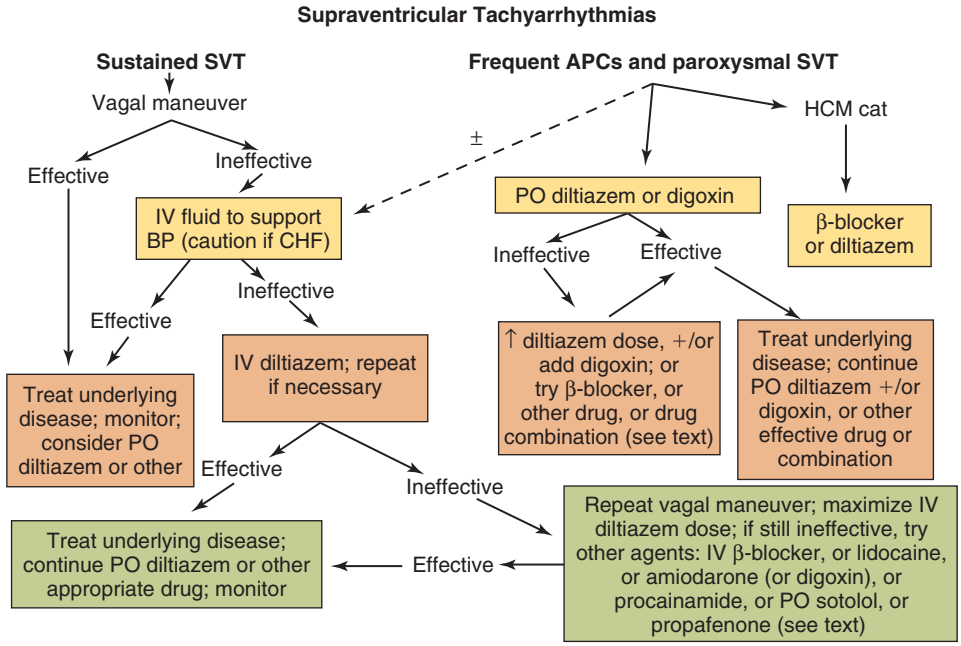

FIG 4.2

conduction and increase refractoriness. Another approach is IV amiodarone or procainamide. Digoxin is not used in cases with preexcitation. Although it slows AV conduction, it can accelerate conduction in the accessory pathway and provoke ventricular tachycardia or fibrillation. Procainamide and quinidine may prevent AVRT because they lengthen the refractory period of the accessory pathway. Although high-dose procainamide, with or without a β-blocker or diltiazem, has prevented recurrent tachycardia in some cases, oral procainamide is no longer available in the United States. Intracardiac electrophysiologic mapping and catheter ablation of accessory pathways have been used successfully to abolish refractory AVRT in dogs, although this technique is not widely available.

Atrial tachycardia caused by a persistent automatic ectopic focus can be particularly difficult to suppress. If the antiarrhythmic strategies outlined in the preceding paragraphs are unsuccessful, the goal of therapy shifts to ventricular rate control. By prolonging AV conduction time and refractoriness, fewer atrial impulses are conducted, and ventricular rate is slowed (and often becomes irregular). Therapy with combinations of diltiazem or a β-blocker and digoxin, sotalol, or amiodarone can be effective. The animal with persistent automatic atrial tachycardia could be a candidate for a cardiac ablation procedure, if available. Alternatively, heart rate control could be achieved by AV node ablation with permanent pacemaker implantation.

Vagal maneuver

A vagal maneuver can help the clinician differentiate among tachycardias caused by an ectopic automatic focus, those dependent on a reentrant circuit involving the AV node, or excessively rapid sinus node activation. The vagal maneuver may transiently slow or intermittently block AV conduction, exposing abnormal P′ waves, and thus allow an ectopic atrial focus to be identified. Vagal maneuvers can terminate reentrant SVTs involving the AV node by interrupting the reentrant circuit. The maneuver tends to temporarily slow the rate of sinus tachycardia.

A vagal maneuver is performed either by firmly massaging the area over the carotid sinuses (below the mandible in the jugular furrows) or by applying firm bilateral ocular pressure for 15 to 20 seconds. Although initial attempts often are unsuccessful, repeating the vagal maneuver after antiarrhythmic drug injection may be more effective. Diltiazem, a β-blocker, digoxin, and other agents can increase a vagal maneuver's effect. The maneuver can be potentiated further in dogs by administering intramuscular (IM) morphine sulfate (0.2 mg/kg) or IV edrophonium chloride (but have atropine and an endotracheal tube readily available).

Ventricular Tachyarrhythmias

Occasional VPCs in an otherwise asymptomatic animal are not treated. Moderately frequent single VPCs generally do not require antiarrhythmic drug treatment either, if underlying heart function is reasonably normal. However, specific guidelines as to whether, when, and how best to treat intermittent ventricular tachyarrhythmias remain undefined. Besides their expense, antiarrhythmic drugs can have serious adverse effects, can provoke additional arrhythmias (proarrhythmic effects), and may not be efficacious. Pretreatment and posttreatment 24- to 48-hour ambulatory ECG recordings showing at least a 70% to 80% reduction in arrhythmia frequency provide the best indicator of a drug's efficacy in suppressing an arrhythmia. Intermittent ECG recordings cannot truly differentiate between drug effect (or lack thereof) and the spontaneous, marked variability in arrhythmia frequency that occurs commonly. However, in-hospital ECG recordings of 15 seconds to several minutes in duration often are used as a pragmatic, if not thorough, attempt to monitor arrhythmias.

Several factors influence the decision to use ventricular antiarrhythmic drug therapy. These factors include the nature of the animal's underlying disease, the perceived severity of the arrhythmia, and evidence of hemodynamic compromise. Diseases such as DCM, arrhythmogenic right ventricular cardiomyopathy (ARVC), HCM, and subaortic stenosis, among others, frequently are associated with sudden death from arrhythmias. Therefore ventricular antiarrhythmic therapy would appear most urgent in animals with these diseases. However, the efficacy of a particular therapy to prolong survival and suppress the arrhythmia is difficult to accurately assess. Traditional guidelines for instituting ventricular antiarrhythmic therapy have been based on frequency, prematurity, and variability of the QRS configuration of the arrhythmia. Characteristics thought to imply increased electrical instability include rapid paroxysmal or sustained ventricular tachycardia, multiform (polymorphic) VPC configuration, or close coupling of VPCs to preceding complexes (R-on-T phenomenon). However, clear evidence that these guidelines predict greater risk of sudden death in all patients is lacking. It is probably more important to consider the animal's underlying heart disease and whether the arrhythmia is causing signs of hypotension or low cardiac output. Animals that are hemodynamically unstable or have a disease associated with sudden cardiac death are treated earlier and more aggressively.

Acute therapy for ventricular tachycardia

Sustained ventricular tachycardia should be treated aggressively because it can lead to marked decrease in arterial blood pressure, especially at faster rates. Lidocaine (IV) generally is the first-choice drug for controlling serious ventricular tachyarrhythmias in dogs. It is effective against arrhythmias caused by several underlying mechanisms and has minimal adverse hemodynamic effects. Because the effects of an IV lidocaine bolus last only about 10 to 15 minutes, constant-rate infusion (CRI) is warranted if the drug is effective. Small supplemental IV boluses can be given in addition to the CRI, if needed, to maintain therapeutic drug concentrations until steady state is achieved. IV infusion can be continued for several days, if necessary. When lidocaine is ineffective even at maximal recommended doses, several other strategies can be tried (Fig. 4.3).

IV amiodarone, oral sotalol, or oral mexiletine can be more effective in some cases. When using IV amiodarone,

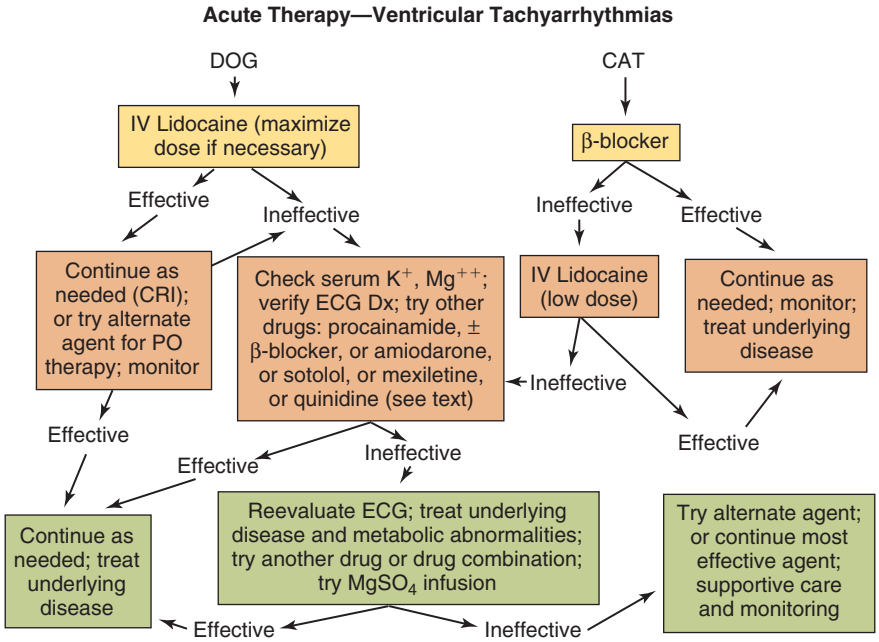

FIG 4.3

only the newer aqueous preparation (e.g., Nexterone; Baxter International) should be used. Older amiodarone formulations can cause marked hypotension and hypersensitivity reactions because of the solvents used (see p. 95). Alternatively, procainamide (IV or IM) or quinidine (IM or PO) can be tried next. Effects of a single IM or oral loading dose should occur within 2 hours. If this is effective, lower doses can be given every 4 to 6 hours IM (or PO, if available). If ineffective, the dose can be increased or another antiarrhythmic drug chosen. Quinidine is not given IV because of its hypotensive effects; it also is not recommended in patients on digoxin or that have prolonged QT intervals. If the arrhythmia has not been controlled, a β-blocker can be added.

Cats with frequent ventricular tachyarrhythmias usually are given a β-blocker first. Alternatively, low doses of lidocaine can be administered. However, cats can be quite sensitive to the neurotoxic effects of this drug. Procainamide or sotalol also can be used.

Digoxin is not used to treat ventricular tachyarrhythmias. It can predispose to the development of ventricular arrhythmias. Patients with heart failure and/or supraventricular arrhythmias that are being treated with digoxin and that develop frequent or repetitive VPCs may need additional antiarrhythmic drug therapy (e.g., lidocaine) or digoxin withdrawal, as well as serum digoxin measurement. Ancillary KCl supplementation (if serum $K^+ \leq 4$ mEq/L) with or without $MgSO_4$ can increase antiarrhythmic efficacy.

Close ECG and patient monitoring and further diagnostic testing should follow initial therapy. Total suppression of persistent ventricular tachyarrhythmias is not expected. The patient's clinical status, the underlying disease(s), the success of the drug in controlling the arrhythmia, and the drug dosage (that is, whether it could be increased within recommended dosage range) all influence the decision whether to continue or discontinue current treatment or to use a different drug. Clinical status and results of diagnostic testing also guide decisions about chronic oral therapy.

If the ventricular tachyarrhythmia appears refractory to initial treatment attempts, one or more of the following considerations may be helpful:

1. Reevaluate the ECG—could the rhythm have been incorrectly diagnosed initially? For example, SVT with an intraventricular conduction disturbance (aberrant ventricular conduction) can mimic ventricular tachycardia. In such cases, IV diltiazem is usually more effective than lidocaine.
2. Reevaluate the serum K^+ (and Mg^{++}) concentration. Hypokalemia reduces the efficacy of class I antiarrhythmic drugs (such as lidocaine, procainamide, quinidine) and can predispose to the development of arrhythmias. If the serum K^+ concentration is less than 3 mEq/L, KCl can be infused at 0.5 mEq/kg/h; for serum K^+ between 3 to 3.5 mEq/L, KCl can be infused at 0.25 mEq/kg/h. A serum K^+ concentration in the high normal range is the goal. If the serum Mg^{++} concentration is less than 1 mg/dL, $MgSO_4$ or $MgCl_2$, diluted in D_5W, can be administered at 0.75 to 1 mEq/kg/day by CRI.
3. Try amiodarone (IV), sotalol (PO), or a β-blocker in conjunction with a class I drug (such as esmolol, propranolol,

or atenolol with procainamide or lidocaine) or a class IA drug with a IB drug (such as procainamide with lidocaine or mexiletine).
4. Maximize the dose of the antiarrhythmic drug having the greatest effect.
5. Consider the possibility that the drug therapy is exacerbating the rhythm disturbance (proarrhythmia). Polymorphic ventricular tachycardia (torsades de pointes) has been associated with quinidine, procainamide, and other drug toxicities.
6. $MgSO_4$ may be effective in animals with ventricular tachyarrhythmias associated with digoxin toxicity or with suspected polymorphous ventricular tachycardia (torsades de pointes). A slowly administered IV bolus of 25 to 40 mg/kg, diluted in D_5W, followed by an infusion of the same dose over 12 to 24 hours, has been suggested. Given that $MgSO_4$ contains 8.13 mEq magnesium per gram, a similar magnesium dose is provided by calculating 0.15 to 0.3 mEq/kg.
7. If the animal is tolerating the arrhythmia well, continue supportive care, correct other abnormalities as possible, and continue cardiovascular monitoring alone or with the most effective antiarrhythmic drug.
8. Direct current (DC) cardioversion or ventricular pacing may be available at some centers; ECG-synchronized equipment and anesthesia or sedation are required. High-energy, nonsynchronized shock (defibrillation) can be used for rapid polymorphic ventricular tachycardia or flutter degenerating into fibrillation.

Chronic oral therapy for ventricular tachyarrhythmias

The same drug that was most effective during acute therapy, or a similar one, often is continued orally when longer-term therapy is necessary. Although suppression of ventricular ectopy is one aim, reducing the risk of sudden arrhythmic death is the main goal for long-term therapy. Whereas the class IB drugs (lidocaine and mexiletine) appear to raise the fibrillation threshold more than the class IA agents (procainamide and quinidine), class III agents appear to have greater antifibrillatory effects than the class I drugs. Concurrent disease should be treated as thoroughly as possible. It is likely that animals with arrhythmias associated with underlying heart disease also benefit from β-blocker, ACEI, and other therapies, as do people. However, β-blockers alone do not appear effective in suppressing ventricular tachyarrhythmias in Doberman Pinschers with cardiomyopathy. Fish oil (omega-3 fatty acid) supplements appear to reduce the frequency of VPCs in Boxers with ARVC and possibly in other patients as well.

Several strategies are used for long-term oral therapy of patients with ventricular tachyarrhythmias. Presently, the most favored options include sotalol, mexiletine with atenolol, mexiletine with sotalol, or amiodarone. These are likely to provide a greater antifibrillatory effect than class I agents alone. The potential for serious adverse effects with long-term or high-dose use must be considered.

Frequent reevaluation is important for patients on long-term antiarrhythmic therapy (for any rhythm disturbance). When possible, continuous 24- to 48-hour ambulatory ECG recordings are most accurate for assessing efficacy. Although clearly not an ideal strategy, the patient's owner also can be shown how to use a stethoscope or palpate the chest wall to count the number of "skipped" beats per minute at home to approximate the frequency of arrhythmic events (either single or paroxysms). The decision to continue or discontinue successful antiarrhythmic therapy also is based on consideration of the clinical situation and any underlying cardiac disease.

Atrial Fibrillation

AF most often develops when there is marked atrial enlargement. It is a serious arrhythmia, especially when the ventricular response rate is high. Predisposing conditions include DCM, advanced degenerative mitral valve disease, congenital malformations that cause atrial enlargement, and hypertrophic or restrictive cardiomyopathy in cats. Clinical heart failure is common in these animals. AF is characterized by an irregular and usually rapid ventricular response rate. When little time is available for ventricular filling, stroke volume is compromised. Furthermore, atrial contraction (the "atrial kick"), which is especially important to ventricular filling at faster heart rates, is lost. In patients with underlying cardiac dysfunction, cardiac output tends to decrease considerably when AF develops. Therefore it is important to control the ventricular response rate (i.e., the heart rate) as soon as possible.

Long-lasting conversion to sinus rhythm is uncommon in the face of marked underlying cardiac disease, even after successful electrical cardioversion. Therefore treatment in most cases is directed at reducing the ventricular response rate by slowing AV conduction (Fig. 4.4). A slower heart rate allows more time for ventricular filling and lessens the relative importance of atrial contraction. In-hospital heart rates of fewer than 150 (or <180 in cats) beats/min are desirable. The patient's ventricular rate should be documented by ECG recording; counting the heart rate by auscultation or palpation can be highly inaccurate in animals with AF. Resting heart rate at home, which some owners can monitor, is a better indicator of drug effectiveness. Heart rates of 70 to 110 beats/min in dogs and 80 to 140 beats/min in cats are probably acceptable.

Therapy for atrial fibrillation

When the heart rate exceeds 180 to 200 beats/min at rest, especially in the setting of heart failure, it is important to expediently reduce the ventricular rate. IV diltiazem acts more quickly than oral dosing, but caution must be used especially in patients with DCM because the drug has negative inotropic effects. Tiny doses are used if given IV, along with immediate institution of pimobendan therapy (if not currently being given). Blood pressure, as well as heart rate, should be monitored. A more conservative approach is to use oral loading dose(s) of diltiazem, although the onset of effect is more gradual. Diltiazem's negative inotropic effect is

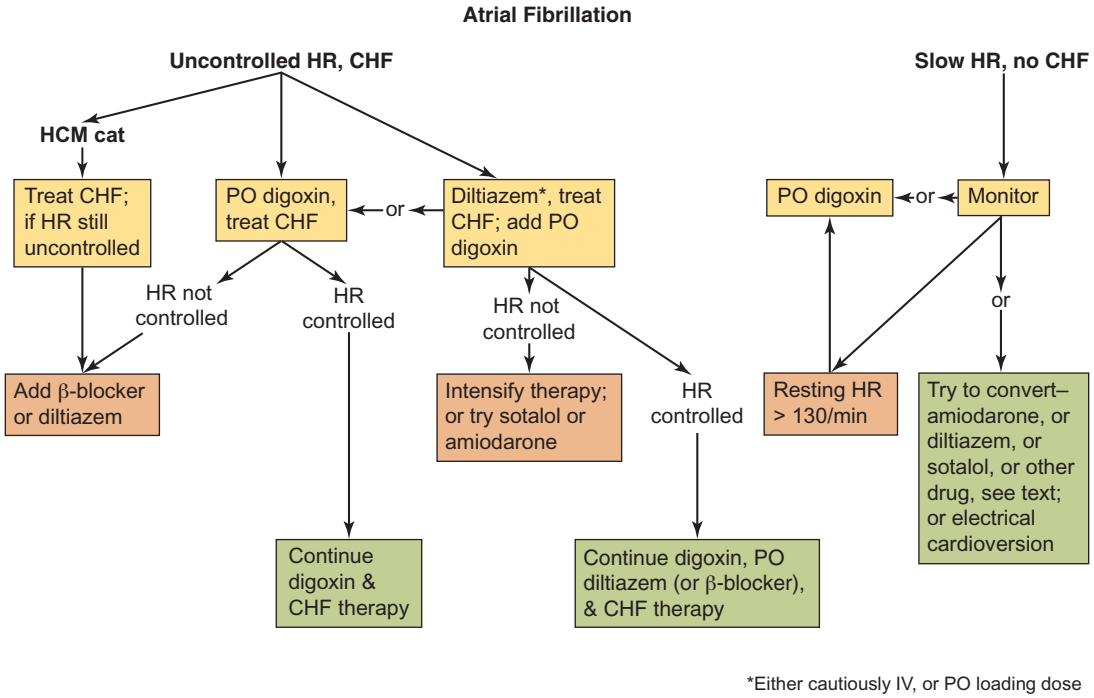

FIG 4.4
A therapeutic approach to atrial fibrillation. See Table 4.2 for drug doses and text for more information. *AF,* Atrial fibrillation; *CHF,* congestive heart failure; *HCM,* hypertrophic cardiomyopathy; *HR,* heart rate.

less than that of verapamil (which should not be used in CHF) or an IV β-blocker, although esmolol could be cautiously tried if necessary because of its short half-life. Oral digoxin at maintenance doses could be used for initial heart rate control (see Table 3.3), especially in dogs without CHF. However, twice the eventual oral maintenance dosage can be given for 1 to 2 days for more rapid effect, and this strategy can be used for dogs with CHF as well. Although IV digoxin has been used, it is generally avoided because of toxicity concerns. Acidosis and hypoxemia associated with severe pulmonary edema could increase myocardial sensitivity to digoxin-induced arrhythmias; furthermore, rapid IV digoxin administration can promote peripheral vasoconstriction by increasing central sympathetic output. If IV digoxin must be used, for lack of other options, it must be given slowly and in small doses. When dobutamine or dopamine infusion is necessary to support myocardial function during acute CHF management (see p. 63 and Box 3.1), a β-blocker usually is avoided. Diltiazem (cautiously IV, or PO) is recommended, but if unavailable, a PO loading dose of digoxin could be used. Ultimately, the combination of both diltiazem and digoxin typically is used because this has been shown to control heart rate in AF better than either agent alone.

Digoxin alone does not fully control the heart rate in many animals with AF. Increases in sympathetic tone from CHF, exercise, or excitement can override the vagal effect of digoxin on AV conduction. Either diltiazem or a β-blocker can be added PO, initially at a conservative dose and then titrated upward as needed to adequately slow AV conduction and control ventricular rate. The potential myocardial depressant effects of β- and Ca^{++}-blockers warrant caution in patients with myocardial failure. Concurrent pimobendan therapy or allowing 1 to 2 days of digoxin therapy before adding or increasing the dose is recommended. Digoxin is not used in cats with HCM and AF; a β-blocker or diltiazem is used instead. Amiodarone and sotalol are other agents that can be used for heart rate control in dogs. Occasionally, conversion to sinus rhythm occurs in response to amiodarone or even diltiazem therapy. In experimental dog models, fish oil administration has reduced the occurrence of AF.

When AF develops in patients that also have ventricular preexcitation, AV nodal blocking drugs (Ca^{++}-blockers, digoxin, and possibly β-blockers) should not be used because they can paradoxically increase the ventricular response rate. Amiodarone is recommended in these cases; sotalol or procainamide also can be used.

Electrical cardioversion of AF is successful in some animals, although not usually those with marked atrial enlargement. Use of biphasic current delivery combined with amiodarone (or other drug) therapy may increase effectiveness. However, most animals with significant underlying heart disease revert to AF.

Lone Atrial Fibrillation

AF sometimes develops in large or giant-breed dogs without cardiomegaly or other evidence of structural heart disease. This is known as "lone AF." AF with a slow ventricular response rate can be an incidental finding in such dogs. AF

occasionally occurs transiently, usually in association with trauma or surgery. Acute AF without signs of heart disease or failure may convert to sinus rhythm spontaneously or in response to drug therapy or electrical cardioversion. Drugs that might be effective include amiodarone, diltiazem (e.g., PO for ≈3 days), or possibly sotalol or other class III or IC agents. Acute-onset AF associated with high vagal tone may convert with IV lidocaine. Quinidine PO or IM has been used for acute AF conversion in large dogs without signs of heart disease, but adverse effects can include increased ventricular response rate from the drug's vagolytic effects, ataxia, and, most seriously, seizures or polymorphic ventricular tachycardia. If effective, the drug is discontinued after sinus rhythm is achieved. Dogs that do not convert to sinus rhythm are given either digoxin or diltiazem for rate control. Alternatively, if the ventricular rate is consistently low at rest, dogs can be monitored periodically without therapy, but rapid heart rates are still likely with exercise or excitement. Lone AF precedes the development of DCM in some cases.

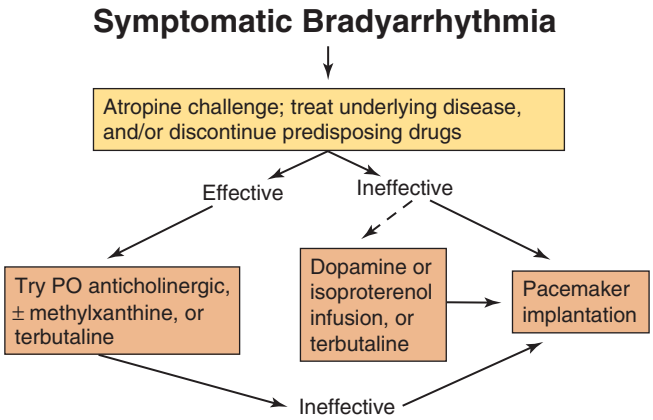

FIG 4.5
A therapeutic approach to managing symptomatic bradyarrhythmias. See Box 3.1 and Table 4.2 for drug doses and text for more information.

BRADYARRHYTHMIAS

Sinus Bradycardia

Slow sinus rhythm (or arrhythmia) can be a normal finding, especially in athletic dogs. Sinus bradycardia also has been associated with various drugs (e.g., xylazine, thorazine tranquilizers, some anesthetic agents, medetomidine, digoxin, calcium entry blockers, β-blockers, parasympathomimetic drugs), trauma or diseases of the CNS, organic disease of the sinus node, hypothermia, hyperkalemia, and hypothyroidism, among other disorders. Conditions that increase vagal tone (for example, respiratory or gastrointestinal [GI] disease or a mass involving the vagosympathetic trunk) can induce sinus bradycardia. Chronic pulmonary disease often is associated with pronounced respiratory sinus arrhythmia.

In most cases with sinus bradycardia, the heart rate increases in response to exercise or atropine administration, and no clinical signs are associated with the slow heart rate. Symptomatic dogs usually have a heart rate slower than 50 beats/min and/or pronounced underlying disease. Because sinus bradycardia and sinus bradyarrhythmia are extremely rare in cats, a search for underlying cardiac or systemic disease (such as hyperkalemia) is warranted in any cat with a slow heart rate.

When sinus bradycardia is associated with signs of weakness, exercise intolerance, syncope, or worsening underlying disease, an anticholinergic (or adrenergic) agent is given (Fig. 4.5). If sinus bradycardia is the result of a drug effect, discontinuation, dosage reduction, or other therapy should be used, as appropriate (e.g., reversal of anesthesia, calcium salts or atropine for calcium entry blocker overdose, dopamine or atropine for β-blocker toxicity). If there is inadequate increase in heart rate with medical therapy, temporary or permanent pacing is indicated (see Suggested Readings).

Sick Sinus Syndrome

Sick sinus syndrome is a condition of erratic SA function characterized by episodic weakness, syncope, and, sometimes, convulsive syncope (Stokes-Adams seizures) triggered by cerebral hypoxia. Older female Miniature Schnauzers and West Highland White Terriers most commonly are affected, but the syndrome also is seen in Dachshunds, Cocker Spaniels, Pugs, and mixed-breed dogs. Affected dogs have episodes of marked sinus bradycardia with sinus arrest (or SA block). Sick sinus syndrome is extremely rare in cats.

Abnormalities of the AV conduction system can coexist, causing the activity of subsidiary pacemakers to be depressed and leading to prolonged periods of asystole. Some affected dogs also have paroxysmal SVTs, prompting the name *bradycardia-tachycardia syndrome* (Fig. 4.6). Premature complexes can be followed by long pauses before sinus node activity resumes, indicating a prolonged sinus node recovery time. Intermittent periods of accelerated junctional rhythms and variable junctional or ventricular escape rhythms also occur.

Clinical signs result from bradycardia and sinus arrest, paroxysmal tachycardia, or both. Signs can mimic seizures stemming from neurologic or metabolic disorders. Concurrent degenerative mitral valve disease also is often present. Some dogs have evidence of CHF, usually secondary to mitral valve regurgitation, although the arrhythmias may be a complicating factor.

ECG abnormalities frequently are pronounced in dogs with long-standing sick sinus syndrome. Nevertheless, some dogs have one or more normal resting ECGs. Prolonged visual ECG monitoring or 24-hour ambulatory ECG can help establish a definitive diagnosis. An atropine challenge test is done in dogs with persistent bradycardia (see p. 97). The normal response is an increase in the heart rate of 150% or to more than 130 to 150 beats/min. Dogs with sick sinus syndrome generally have a subnormal response.

Therapy with an anticholinergic agent, methylxanthine bronchodilator, or terbutaline given orally might temporarily help some animals that respond positively to atropine challenge. Yet anticholinergic or sympathomimetic drugs

FIG 4.6
Electrocardiogram from an 11-year-old female Miniature Schnauzer with sick sinus syndrome illustrates typical bradycardia and tachycardia. The top portion of this continuous recording shows persistent sinus arrest with three different escape complexes, followed by an atrial premature complex. A 1-mV calibration mark is seen in the middle of the top strip. The bradycardia is interrupted by a run of atrial tachycardia at a rate of 250 beats/min, with 1 : 1 atrioventricular conduction initially; but starting in the middle of the bottom strip, every other P′ wave is blocked (2 : 1 atrioventricular conduction).

used to accelerate the sinus rate also can exacerbate tachyarrhythmias. Conversely, drugs used to suppress these supraventricular tachyarrhythmias can magnify the bradycardia. However, cautious use of diltiazem or digoxin could be helpful against paroxysmal SVT in some dogs, as long as sinus node function is not further depressed. Sick sinus syndrome with frequent or severe clinical signs is best managed by permanent artificial pacing (see sources in Suggested Readings for further details on pacing). Dogs that remain symptomatic because of paroxysmal SVT can more safely be given appropriate antiarrhythmic therapy once a normally functioning pacemaker is in place.

Atrial Standstill

Persistent atrial standstill is a rhythm disturbance characterized by loss of effective atrial electrical activity (with no P waves and a flat baseline); a junctional or ventricular escape rhythm controls the heart. This bradyarrhythmia is rare in dogs and extremely rare in cats. Most cases have occurred in English Springer Spaniels with muscular dystrophy, although infiltrative and inflammatory disease of the atrial myocardium also can result in atrial standstill. Organic disease of the atrial myocardium can involve the ventricular myocardium as well; persistent atrial standstill may be a harbinger of progressive cardiac disease.

Medical treatment for persistent atrial standstill rarely is rewarding; however, an anticholinergic drug or infusion of dopamine or isoproterenol sometimes will temporarily accelerate the escape rhythm. If ventricular tachyarrhythmias result from this treatment, the drug should be discontinued or the dose reduced. Oral terbutaline also may have some beneficial effect. Antiarrhythmic agents are contraindicated in these cases because they could suppress the escape focus in addition to the tachyarrhythmia. Permanent pacemaker implantation is the treatment of choice, although the prognosis is poor in dogs with concurrent ventricular myocardial dysfunction.

Hyperkalemia can mimic atrial standstill and should be ruled out in animals without P waves. The apparent lack of atrial electrical and mechanical activity ("silent atrium") caused by hyperkalemia is reversible with treatment. Sinus node activity (and P waves) become evident as the serum K^+ concentration returns to normal.

Atrioventricular Conduction Block

Second-degree, or intermittent, AV block usually causes an irregular heart rhythm. In contrast, the ventricular escape rhythm that occurs with third-degree (complete) AV block usually is quite regular, although premature beats or shifts in the ventricular escape focus can cause some irregularities. AV conduction disturbances can result from certain drugs (such as α_2 agonists, opioids, digoxin), high vagal tone, or organic disease of the AV node. Diseases that have been associated with AV conduction disturbances include aortic valve endocarditis, HCM, neoplastic infiltration of the myocardium, and myocarditis. Idiopathic heart block can occur in middle-aged and older dogs; congenital third-degree AV block also has been reported in dogs. Symptomatic third-degree AV block is less common in cats, but evidence of any AV conduction disturbance should prompt further

diagnostic evaluation, because most cases have been associated with HCM. Complete AV block occasionally is found in older cats without detectable organic heart disease.

Type I second-degree AV block and first-degree AV block are associated frequently with high vagal tone or drug effects in dogs. These animals often are asymptomatic; exercise or anticholinergic drug (atropine or glycopyrrolate) administration usually abolishes the conduction disturbance. High-grade second-degree AV block (many blocked P waves) and complete (3°) heart block usually cause lethargy, exercise intolerance, weakness, syncope, and other signs of low cardiac output. These signs become severe at heart rates consistently below 40 beats/min in dogs. CHF develops secondary to chronic bradycardia in some cases, especially if other cardiac disease is present.

An atropine challenge test (p. 97) is used to determine the degree of vagal influence on the AV block. Oral anticholinergic (or sympathomimetic) therapy can be attempted in symptomatic animals that are atropine-responsive (see Fig. 4.5). However, atropine and oral anticholinergic therapy often is ineffective, especially with high-grade second-degree AV block, so artificial pacing usually is indicated. An emergency infusion of dopamine (see Box 3.1) or isoproterenol might increase the ventricular escape rate in animals with high-grade second- or third-degree block, although it may also provoke ventricular tachyarrhythmias. Oral isoproterenol usually is ineffective. A thorough cardiac workup is indicated before permanent artificial pacemaker implantation because some underlying diseases (progressive myocardial disease, endocarditis) are associated with a poor prognosis, even after pacing. Temporary transvenous pacing could be attempted for 1 to 2 days in questionable cases to assess the animal's response to a normal heart rate before permanent pacemaker surgery is performed. More information on pacing therapy is found in Suggested Readings.

BOX 4.4

Formulas to Calculate Constant-Rate Infusion

Method 1

(Allows for "fine-tuning" fluid and drug administration rate)
Determine desired drug infusion rate: µg/kg/min × kg body weight = µg/min (A)
Determine desired fluid infusion rate: mL/hour ÷ 60 = mL/min (B)
(A) ÷ (B) = µg/min ÷ mL/min = µg drug/mL of fluid
Convert from µg to mg of drug needed (1 µg = 0.001 mg)
Mg drug/mL fluid × mL of fluid in bag (or bottle, etc.) = mg of drug to add to the fluid container

Method 2

(For total dose over a 6-hour period, must also calculate fluid volume and administration rate)
Total dose in mg to infuse over a 6-hour period = body weight (kg) × dose (µg/kg/min) × 0.36

Method 3 (for Lidocaine)

(Faster but less helpful if fluid rate is important or if fine drug-dosage adjustments are necessary)
For CRI of 44 µg/kg/min of lidocaine, add 25 mL of 2% lidocaine to 250 mL of D_5W
Infuse at 0.25 mL/25 lb of body weight/min

ANTIARRHYTHMIC AGENTS

Antiarrhythmic drugs can act by slowing the rate of a tachycardia, terminating a reentrant arrhythmia, or preventing abnormal impulse formation or conduction. These effects occur through modulation of tissue electrophysiologic properties and/or autonomic nervous system effects. The traditional (Vaughan-Williams) antiarrhythmic drugs are classified according to their main electrophysiologic effects on cardiac cell action potentials (Table 4.1). Although this classification system has several shortcomings (for example, some drugs with antiarrhythmic effects are excluded, several drugs have the multiclass effects, and attention to ion channel mechanisms is lacking), clinical reference to this classification persists. See Table 4.2 and Box 4.4 for antiarrhythmic drug dosages and CRI calculation methods.

Class I agents tend to slow conduction and decrease automaticity and excitability by means of their membrane-stabilizing effects; older ventricular antiarrhythmic drugs belong to this class. Class II drugs include the β-adrenergic antagonists (β-blockers), which act by inhibiting the effects of catecholamines on the heart. Class III drugs prolong the effective refractory period of cardiac action potentials without decreasing conduction velocity; they may be most effective in suppressing reentrant arrhythmias and in preventing VF. Class IV drugs are the calcium entry blockers; ventricular arrhythmias usually are not responsive to these agents, but they are important against supraventricular tachyarrhythmias. Antiarrhythmic agents within this classification scheme are contraindicated in animals with complete AV block and should be used only cautiously in animals with sinus bradycardia, sick sinus syndrome, and first- or second-degree AV block. Sometimes a designation of Class V is used for drugs with antiarrhythmic effects that work by other mechanisms than described for the original four classes.

CLASS I ANTIARRHYTHMIC DRUGS

Class I antiarrhythmic drugs block membrane Na^+ channels and depress the action potential upstroke (phase 0), which slows conduction velocity along the cardiac cells. They have been subclassified according to differences in other electrophysiologic characteristics. These differences (see Table 4.1) can influence their efficacy against specific arrhythmias. Most of the class I agents depend on extracellular K^+ concentration for their effects, and they lose effectiveness in patients with hypokalemia.

TABLE 4.1

Classification and Effects of Antiarrhythmic Drugs

CLASSIFICATION	DRUG	MECHANISM AND ECG EFFECTS
Class I		Decreases fast inward Na^+ current; membrane-stabilizing effects (decreased conductivity, excitability, and automaticity)
IA	Quinidine Procainamide	Moderately decreases conductivity, increases action potential duration; can prolong QRS complex and Q-T interval
IB	Lidocaine Mexiletine Phenytoin	Little change in conductivity, decreases action potential duration; QRS complex and Q-T interval unchanged
IC	Flecainide Propafenone	Markedly decreases conductivity without change in action potential duration
Class II	Atenolol Propranolol Esmolol Metoprolol Carvedilol Others	β-adrenergic blockade—reduces effects of sympathetic stimulation (no direct myocardial effects at clinical doses)
Class III	Sotalol Amiodarone Ibutilide Dofetilide Others	Selectively prolongs action potential duration and refractory period; antiadrenergic effects; Q-T interval prolonged
Class IV	Verapamil Diltiazem Others	Decreases slow inward Ca^{++} current (greatest effects on SA and AV nodes)
Other Antiarrhythmic Agents	Digoxin	Antiarrhythmic action results mainly from indirect autonomic effects (especially increased vagal tone)
	Atropine Glycopyrrolate Others	Anticholinergic agents oppose vagal effects on SA and AV nodes (glycopyrrolate and other drugs also have this effect)

AV, Atrioventricular; *ECG,* electrocardiogram; *SA,* sinoatrial.

Lidocaine

Lidocaine HCl generally is the first-choice IV ventricular antiarrhythmic agent in dogs. It usually is not effective against supraventricular arrhythmias, with the exception of some recent-onset, vagally induced AF or tachycardias. At recommended doses, it has little effect on sinus node rate, AV conduction, and refractoriness. Lidocaine suppresses automaticity in normal Purkinje fibers and diseased myocardial tissue, slows conduction, and reduces the supernormal period (during which the cell can be reexcited before complete repolarization occurs). It has greater effects on diseased and hypoxic cardiac cells and at faster stimulation rates. The electrophysiologic effects of lidocaine are influenced by extracellular potassium concentration. Hypokalemia may render the drug ineffective, and hyperkalemia intensifies its depressant effects on cardiac membranes. Lidocaine produces little or no depression of contractility at therapeutic doses when administered slowly IV. The lidocaine congener mexiletine similarly produces minimal negative inotropic and hypotensive effects. However, toxic concentrations of lidocaine can cause hypotension.

Lidocaine undergoes rapid hepatic metabolism by cytochrome P-450 (CYP) enzyme activity; some metabolites might contribute to its antiarrhythmic and toxic effects. Lidocaine is not effective orally because of its virtually complete first-pass hepatic elimination. IV administration, usually as slow boluses followed by CRI, is most effective. Antiarrhythmic effects after IV bolus occur within 2 minutes and abate within 10 to 20 minutes. CRI without a loading dose produces steady-state concentrations in 4 to 6 hours. The half-life is less than 1 hour in the dog. An initial bolus of 2 mg/kg is used in dogs and can be repeated two to three times if necessary. Lower doses should be used in cats to avoid toxicity (loading dose of 0.25-0.5 mg/kg slowly IV). The half-life in cats is 1 to 2 hours. Therapeutic plasma concentrations are thought to range from 1.5 to 6 μg/mL in dogs. Only lidocaine without epinephrine should be used for antiarrhythmic therapy. If IV access is not possible, IM administration could be used but is less effective.

The most common toxic effect of lidocaine in dogs is CNS excitation. Signs include agitation, disorientation or ataxia, muscle twitches, nystagmus, and generalized seizures; nausea also can occur. Worsening of arrhythmias (proarrhythmic effect) is seen occasionally, as with any drug that has cardiac electrophysiologic effects. There are anecdotal reports of respiratory depression and arrest after lidocaine administration to unconscious patients. Cats are particularly sensitive to the drug's toxic effects and can develop seizures, respiratory arrest, bradyarrhythmias, and sudden death. In the event of toxicity, lidocaine should be discontinued until the signs of toxicity disappear; a lower infusion rate may then be instituted. IV diazepam (0.25-0.5 mg/kg) is used to control lidocaine-induced seizures. Hepatic disease can

TABLE 4.2

Dosage of Antiarrhythmic Drugs

AGENT	DOSAGE
Class I	
Lidocaine	Dog: initial boluses of 2 mg/kg slowly IV, up to 8 mg/kg (over ≥10 min); or rapid IV infusion at 0.8 mg/kg/min; if effective, then 25-80 mcg/kg/min CRI Cat: initial bolus of 0.25-0.5 (- 1) mg/kg slowly IV; can repeat boluses of 0.15-0.25 mg/kg, up to total of 4 mg/kg; if effective, 10-40 mcg/kg/min CRI
Procainamide	Dog: 2 mg/kg IV over 2 minutes; repeat if necessary, up to cumulative dose of 20 mg/kg; 10-50 mcg/kg/minute CRI; 6-20 (up to 30) mg/kg IM q4-6h (PO, if available, 10-20 mg/kg q 8-12 [sustained-release prep.] hours) Cat: 1.0-2.0 mg/kg IV over 2 minutes, repeat if necessary, up to cumulative dose of 10 mg/kg; 10-20 mcg/kg/min CRI; 7.5-20 mg/kg IM q(6-)8h
Quinidine	Dog: 6-20 mg/kg IM q6h (loading dose, 14-20 mg/kg); 6-16 mg/kg PO q6h; sustained action preparations, 8-20 mg/kg PO q8h Cat: 6-16 mg/kg, IM or PO, q8h
Mexiletine	Dog: 4-6 (-8) mg/kg PO q8h Cat: —
Phenytoin	Dog: 10 mg/kg slowly IV; 20-50 mg/kg PO q8h Cat: do not use
Propafenone	Dog: 2-4 (up to 6?) mg/kg PO q8h (start low) Cat: —
Flecainide	Dog: 1-2 (up to 4?) mg/kg PO q(8-)12h (start low; not advised if CHF or impaired LV function present) Cat: —
Class II	
Atenolol	Dog: 0.2-1 mg/kg PO q12(-24)h, start low Cat: Same, or 6.25(-12.5) mg/cat PO q12(-24)h
Propranolol	Dog: 0.02 mg/kg initial bolus slowly IV (up to maximum of 0.1 mg/kg); initial oral dose, 0.1-0.2 mg/kg PO q8h, up to 1 mg/kg q8h Cat: Same IV instructions; 2.5 up to 10 mg/cat PO q8-12h
Esmolol	Dog: 50-100 mcg/kg IV over 5 minutes (loading dose), followed by infusion of 25-50 mcg/kg/min Cat: same
Metoprolol	Dog: initial dose, 0.1-0.2 mg/kg PO q24(-12)h, up to 1(-2) mg/kg q8(-12)h Cat: 2 up to 15 mg/cat PO q8(-12)h, start low
Class III	
Sotalol	Dog: 1-3 (up to 5?) mg/kg PO q12h Cat: 10-20 mg/cat PO q12h (or 2-4 mg/kg PO q12h)
Amiodarone	Dog: PO loading: 10 (up to 15) mg/kg PO q12h for 4-7 days, then same dose q24h for 7 days, then reduce to maintenance dose PO maintenance: 5-7.5 mg/kg PO q24h For IV administration use aqueous formulation (Nexterone, 1.5 mg/mL), not standard amiodarone, see p. 95): 3-5 mg/kg slow IV over 15 min; can continue 0.05 mg/kg/min CRI if needed Cat: IV aqueous formulation (1.5 mg/mL): 2.5 mg/kg slow IV bolus over 15 minutes (optimal dose uncertain)

TABLE 4.2

Dosage of Antiarrhythmic Drugs—cont'd

AGENT	DOSAGE
Class IV	
Diltiazem	Dog: Acute IV for rapid rate control of AF: 0.05-0.10 mg/kg IV over 2-5 minutes, can repeat if needed. Acute IV for SVT: 0.1-(0.2) mg/kg over 2-5 minutes IV, can repeat to cumulative IV dose of 0.3-0.4 mg/kg; monitor blood pressure. CRI (if frequent SVT recurrence): 0.002-0.006 mg/kg/min (or 0.12-0.35 mg/kg/h) PO loading dose: 0.5 mg/kg PO followed by 0.25 mg/kg PO q1h to a total of 1.5(-2.0) mg/kg or conversion Oral maintenance: initial dose 0.5-1 mg/kg (up to 2-3 mg/kg) PO q8h Extended release (diltiazem ER): 1-4 (up to 6) mg/kg PO q12h Cat: Same?; Or 1.5-2.5 mg/kg (or 7.5-10 mg/cat) PO q8h; sustained-release preparations: diltiazem ER, 30 mg/cat/day (one half of a 60 mg controlled-release tablet within the 240-mg gelatin capsule), can increase to 60 mg/day in some cats if necessary Cardizem-CD, 10 mg/kg/day (45 mg/cat ≅ 105 mg of Cardizem-CD ≅ amount that fits into small end of No. 4 gelatin capsule)
Verapamil	Dog: initial dose, 0.02-0.05 mg/kg slowly IV, can repeat q5min up to a total of 0.15(-0.2) mg/kg; 0.5-2 mg/kg PO q8h. (*Note:* diltiazem preferred instead) Cat: initial dose, 0.025 mg/kg slowly IV, can repeat q5min up to a total of 0.15(-0.2) mg/kg; 0.5-1 mg/kg PO q8h. (*Note:* diltiazem preferred instead)
Anticholinergic	
Atropine	Dog: 0.02-0.04 mg/kg IV, IM, SC; 0.04 mg/kg PO q6-8h Cat: same Atropine challenge test: 0.04 mg/kg IV (see text, p. 97)
Glycopyrrolate	Dog: 0.005-0.01 mg/kg, IV or IM; 0.01-0.02 mg/kg SC Cat: same
Propantheline	Dog: 0.25-0.5 mg/kg or 3.73-7.5 (-15) mg/dog PO q8-12h Cat: —
Hyoscyamine	Dog: 0.003-0.006 mg/kg PO q8h Cat: —
Sympathomimetic	
Isoproterenol	Dog: 0.04-0.08 mcg/kg/min CRI Cat: same
Theophylline (extended rel.)	Dog: 10 mg/kg PO q12h Cat: 10-15 mg/kg q24h
Terbutaline	Dog: 0.14 mg/kg, or 2.5-5 mg/dog, PO q8-12h Cat: 0.1-0.2 mg/kg, or 0.625-1.25 mg/cat, PO q12h
Other Agents	
Digoxin	See Table 3.3 for PO dosing; see Box 3.1 and p. 85 for IV
Edrophonium	Dog: 0.05-0.1 mg/kg IV (have atropine and endotracheal tube available) Cat: same?
Phenylephrine	Dog: 0.004-0.01 mg/kg IV Cat: same?

CRI, Constant-rate infusion; —, effective dosage not known.

slow the drug's metabolism. Drugs that decrease liver blood flow (such as propranolol, cimetidine, and chloramphenicol) also slow lidocaine's metabolism and predispose to toxicity. Animals with heart failure could have reduced hepatic blood flow and so might require a lower dosage of the drug.

Procainamide

Procainamide HCl has electrophysiologic effects similar to those of quinidine. These include both direct and indirect (vagolytic) effects. Procainamide is indicated for the treatment of premature ventricular (and sometimes atrial)

depolarizations and tachycardias. It is less effective than quinidine for atrial tachyarrhythmias. Procainamide prolongs the effective refractory period and slows accessory pathway conduction in dogs with orthodromic AVRT. Procainamide should be used only with caution in animals with hypotension.

Procainamide is well absorbed orally in the dog, with a half-life of 2.5 to 4 hours; sustained-release procainamide's half-life was 3 to 6 hours. Unfortunately, oral procainamide is no longer available in the United States, but it may be elsewhere. The drug undergoes hepatic metabolism and renal excretion in proportion to the creatinine clearance. Procainamide can be given IM without marked hemodynamic effect, but rapid IV injection can cause hypotension and cardiac depression, although to a much lesser degree than IV quinidine. Administration by CRI can be used if the arrhythmia responds to an IV bolus; a steady state is reached in 12 to 22 hours. Therapeutic plasma concentration range is thought to be 4 to 10 μg/mL.

The toxic effects of procainamide are similar to those of quinidine (see later) but usually are milder. GI upset and prolongation of the QRS or QT intervals can occur. Procainamide can enhance the ventricular response rate to AF (that is, the heart rate) if used without diltiazem, digoxin, or a β-blocker. More serious toxic effects include hypotension, depressed AV conduction (sometimes causing 2° or 3° AV block), and proarrhythmia. The latter can cause syncope or VF. Hypotension should respond to IV fluid, and catecholamine or calcium-containing solutions.

Quinidine

Quinidine, the prototype IA drug, has been used to treat ventricular and some supraventricular tachyarrhythmias. In large dogs with recent-onset AF and normal ventricular function (lone AF), quinidine might cause conversion to sinus rhythm. This drug must be used cautiously in animals with heart failure or hyperkalemia. The characteristic electrophysiologic effects of quinidine are depression of automaticity and conduction velocity, and prolongation of the effective refractory period. Corresponding dose-dependent ECG changes include PR, QRS, and QT prolongation. Quinidine also has indirect vagolytic effects. At low doses, these vagolytic effects can increase the sinus rate or the ventricular response rate to AF by antagonizing the drug's direct effects. As with other class I agents, hypokalemia reduces quinidine's antiarrhythmic effectiveness.

The drug is well absorbed orally but is rarely used now for chronic oral therapy because of its frequent adverse effects. Quinidine is metabolized extensively by the liver; the half-life is about 6 hours in dogs and 2 hours in cats. Quinidine is highly protein-bound; severe hypoalbuminemia can predispose to toxicity. Cimetidine, amiodarone, and antacids can also predispose to toxicity by slowing the drug's elimination. Quinidine can precipitate digoxin toxicity (when used concurrently) by displacing digoxin from skeletal muscle binding sites and reducing its renal clearance. IV administration is not recommended because of quinidine's propensity to cause vasodilation (by means of nonspecific α-adrenergic receptor blockade), cardiac depression, and hypotension. The oral and IM routes usually do not cause adverse hemodynamic effects, but close monitoring is warranted initially. Therapeutic blood concentrations (2.5-5 μg/mL) usually are achieved in 12 to 24 hours after oral or IM administration. Slow-release sulfate (83% active drug), gluconate (62% active drug), and polygalacturonate (80% active drug) salts of quinidine prolong the drug's absorption and elimination. The sulfate salt is more rapidly absorbed than the gluconate; peak effect is usually achieved 1 to 2 hours after oral administration.

Marked QT prolongation, right bundle branch block, or QRS widening by more than 25% of pretreatment value suggests quinidine toxicity; various conduction blocks and ventricular tachyarrhythmias are other manifestations. The QT prolongation implies increased temporal dispersion of myocardial refractoriness; this predisposes to torsades de pointes (see p. 41) and VF. Transient episodes of these serious arrhythmias are thought to underlie syncopal attacks in people taking quinidine. Lethargy, weakness, and CHF can result from the negative inotropic and vasodilatory effects of the drug and subsequent hypotension. Cardiotoxicity and hypotension can be partially reversed by sodium bicarbonate (1 mEq/kg IV), which temporarily decreases serum K^+ concentration, enhances quinidine's binding to albumin, and reduces its cardiac electrophysiologic effects. GI signs (e.g., nausea, vomiting, diarrhea) are common with orally administered quinidine. Thrombocytopenia (reversible after quinidine discontinuation) can occur in people and possibly in dogs and cats.

Mexiletine

Mexiletine HCl is similar to lidocaine in its electrophysiologic, hemodynamic, toxic, and antiarrhythmic properties. It can be effective in suppressing ventricular tachyarrhythmias in dogs. The combination of sotalol or a traditional β-blocker with mexiletine may be more efficacious and associated with fewer adverse effects than mexiletine alone (by allowing lower dosage). The drug is easily absorbed when administered orally, but delayed gastric emptying, narcotics, and magnesium-aluminum hydroxide antacids reportedly slow its absorption in people. Mexiletine undergoes hepatic metabolism (influenced by liver blood flow) and some renal excretion (which is slower if the urine is markedly alkaline). Cimetidine can have variable effects on mexiletine plasma concentration; however, omeprazole and famoditine are unlikely to affect its metabolism. Moderate to severe liver disease can impair mexiletine's metabolism. Hepatic microsomal enzyme inducers can accelerate its clearance. The half-life in dogs is from 4.5 to 7 hours (depending to some degree on the urine pH). Approximately 70% of the drug is protein-bound. The therapeutic serum concentration is thought to range from 0.5 to 2 μg/mL (as in people). The effects of mexiletine in cats are not well known. Adverse effects have included vomiting, anorexia, tremor, disorientation, sinus bradycardia, and thrombocytopenia.

Phenytoin

The only indication for phenytoin as an antiarrhythmic agent is for digoxin-induced ventricular tachyarrhythmias in dogs that are not responsive to lidocaine or other agents. Thus it is now almost never used. Electrophysiologically, it is similar to lidocaine, but it also has some slow-calcium channel inhibitory and CNS effects that contribute to its effectiveness against digitalis-induced arrhythmias. Slow IV infusion (of 10 mg/kg) and oral administration (of 20-50 mg/kg PO q8h) have minimal hemodynamic effects; however, oral bioavailability is poor. Rapid IV injection can depress myocardial contractility, exacerbate arrhythmias, and cause vasodilation, hypotension, or respiratory arrest related to the propylene glycol vehicle. The half-life of phenytoin in the dog is about 3 hours. The drug is metabolized in the liver; drugs that inhibit CYP enzyme activity increases phenytoin's serum concentration. IV administration of phenytoin has been associated with bradycardia, AV block, ventricular tachycardia, and cardiac arrest. CNS toxicity signs include depression, nystagmus, disorientation, and ataxia. The drug is not used in cats because of its long half-life (>40 hours) and toxicity.

Other Class I Agents

Flecainide and propafenone are class IC agents. Flecainide prolongs the sinus cycle length and AV conduction time and refractoriness. It also has a potassium current (delayed rectifier, I_K) blocking effect similar to class III agents; however, action potential prolongation is offset by its Na^+ channel blocking effect, so little change in action potential duration occurs. Because of its effects to prolong refractoriness and slow conduction, it can increase risk for proarrhythmia and sudden death, especially at high doses and in patients with prior myocardial damage. Propafenone increases AV node refractory period, slows intraatrial conduction, and reduces ventricular excitability. It also has weak β- and calcium channel blocking activity, and a vagolytic effect. Adverse effects in people include lightheadedness, nausea, vomiting, and proarrhythmia. Higher doses of these agents depress automaticity in the sinus node and specialized conducting tissues. Vasodilation, myocardial depression, and severe hypotension have occurred after IV injection. Bradycardia, intraventricular conduction disturbances, and consistent (although transient) hypotension, as well as nausea, vomiting, and anorexia, have occurred in dogs. Proarrhythmia is a serious potential adverse effect of these agents. Flecainide can be useful against paroxysmal SVT or AF but is not used for long-term therapy of AF, or in patients with myocardial dysfunction, ventricular hypertrophy, valvular disease, or ischemic heart disease. Propafenone has been effective in suppressing various SVTs, including those involving an accessory pathway.

CLASS II ANTIARRHYTHMIC DRUGS: β-ADRENERGIC BLOCKERS

Class II antiarrhythmic drugs act by blocking catecholamine effects. They slow heart rate, reduce myocardial O_2 demand, and increase AV conduction time and refractoriness. The antiarrhythmic effect of β-blockers relates to β_1-receptor blockade rather than direct electrophysiologic effects. They are often used in combination with a class I agent (such as procainamide or mexiletine), although their negative inotropic effect demands caution when used in animals with myocardial failure. β-receptor blockers are used in animals with supraventricular and ventricular tachyarrhythmias (especially those induced by enhanced sympathetic tone), certain congenital and acquired ventricular outflow obstructions, hyperthyroid heart disease, HCM, and other diseases or toxicities that cause excessive sympathetic stimulation. A β-blocker, rather than diltiazem, sometimes is used in conjunction with digoxin to slow the ventricular response rate to AF. A β-blocker, such as atenolol or propranolol, is considered the first-line antiarrhythmic agent in cats for both supraventricular and ventricular tachyarrhythmias.

β-adrenergic receptors have been classified into subtypes. β_1-receptors are located mainly in the myocardium and mediate increases in contractility, heart rate, AV conduction velocity, and automaticity in specialized fibers. Extracardiac β_2-receptors mediate bronchodilation and vasodilation, as well as renin and insulin release. There also are some β_2- and β_3-receptors in the heart. "Nonselective" β-blockers inhibit catecholamine binding to both β_1- and β_2-adrenergic receptors. Other β-blockers are more selective; they antagonize mainly one or the other receptor subtype (Table 4.3). The first-generation β-blockers (e.g., propranolol) have nonselective β-blocking effects. Second-generation agents (e.g., atenolol, metoprolol) are relatively β_1 selective. The third-generation β-blockers affect both β_1 and β_2 receptors but also antagonize α_1 receptors and may have other effects. A few β-blockers have some degree of intrinsic sympathomimetic activity.

The clinical antiarrhythmic effect of class II drugs is thought to relate to β_1-receptor blockade rather than to direct electrophysiologic mechanisms. In normal animals β-receptor blockers have little negative inotropic effect. However, they must be used cautiously in animals with underlying myocardial disease because increased sympathetic drive may be necessary to maintain cardiac output; marked depression of cardiac contractility, conduction, or heart rate can result in such cases, and CHF could be precipitated. β-blockers generally are contraindicated in patients with sinus bradycardia, sick sinus syndrome, high-grade AV block, or severe CHF and in animals also receiving a Ca^{++}-blocking drug. Nonselective β-blockers could increase peripheral vascular resistance (because of unopposed α-adrenergic effects) and provoke bronchoconstriction. β-blockers also can mask the early signs of acute hypoglycemia in diabetics (such as tachycardia, blood pressure changes) and reduce the release of insulin in response to hyperglycemia. Because the effect of β-blockers depends on the level of sympathetic activation, individual patient response is quite variable. Therefore initial dosages should be low and titrated upward cautiously, as needed.

TABLE 4.3

Characteristics of Selected β-Blockers

DRUG	ADRENERGIC RECEPTOR SELECTIVITY	LIPID SOLUBILITY	MAIN ROUTE OF ELIMINATION
Atenolol	β_1	0	RE
Carvedilol	β_1, β_2, α_1	+	HM
Esmolol	β_1	0	BE
Labetalol	β_1, β_2, α_1	++	HM
Metoprolol	β_1	++	HM
Nadolol	β_1, β_2	0	RE
Pindolol*	β_1, β_2	++	B
Propranolol	β_1, β_2	++	HM
Sotalol†	β_1, β_2	0	RE
Timolol	β_1, β_2	0	RE

B, Both renal excretion and hepatic metabolism are important; *BE,* blood esterases; *HM,* hepatic metabolism; *RE,* renal excretion.
*Has intrinsic sympathomimetic activity.
†Also has class III antiarrhythmic activity.

β-blockers enhance the depression of AV conduction produced by Ca^{++}-blockers, class I antiarrhythmic drugs, and digoxin. Use of a β-blocker and a Ca^{++}-blocker simultaneously can markedly decrease heart rate and myocardial contractility. Because of possible β-receptor upregulation (increased number or affinity of receptors) associated with long-term β-blockade, therapy should not be discontinued abruptly. Chronic β-blocker therapy might increase risk for hypotension and bradycardia during anesthesia.

Atenolol

Atenolol is a selective β_1-blocker. It is used commonly to slow sinus rate and AV conduction and to suppress sympathetically mediated ventricular premature beats. The half-life of atenolol is slightly more than 3 hours in dogs and about 3.5 hours in cats. Its oral bioavailability in both species is high (≈90%). Atenolol is excreted in the urine; renal dysfunction delays its clearance. Atenolol's β-blocking effect lasts more than 12 hours but less than 24 hours in normal cats. This drug is hydrophilic. Adverse CNS effects are unlikely because atenolol does not readily cross the blood-brain barrier. As with other β-blockers, weakness or exacerbation of heart failure can occur.

Propranolol

Propranolol HCl is a nonselective β-blocker. It is not recommended for patients with pulmonary edema, asthma, or chronic small airway disease because of the potential for bronchoconstriction caused by β_2-receptor antagonism.

Propranolol undergoes extensive first-pass hepatic metabolism, and oral bioavailability is low; however, bioavailability increases with hepatic enzyme saturation. Propranolol reduces hepatic blood flow, which prolongs its elimination as well as that of other drugs dependent on liver blood flow for their metabolism (such as lidocaine). Feeding delays oral absorption and increases drug clearance after IV dosing (by increasing hepatic blood flow). The half-life of propranolol in the dog is only about 1.5 hours (0.5-4.2 hours in cats); active metabolites exist. Dosing every 8 hours appears to be adequate in both species. IV propranolol is used mainly for refractory ventricular tachycardia (in conjunction with a class I drug) and for emergency treatment of atrial or junctional tachycardia.

Toxicity most often is related to excessive β-blockade; this can develop at relatively low doses in some animals. Bradycardia, heart failure, hypotension, bronchospasm, and hypoglycemia can occur. Infusion of a catecholamine (dopamine or dobutamine) will help reverse these effects. Propranolol and other lipophilic β-blockers can cause CNS effects such as depressed attitude and disorientation.

Esmolol

Esmolol HCl is an ultra-short-acting β_1-selective agent. It is metabolized rapidly by blood esterases and has a half-life of less than 10 minutes. Steady state occurs in 5 minutes after a loading dose, or 30 minutes without. Esmolol's effects end within 10 to 20 minutes after infusion is stopped. This drug is used for acute therapy of tachyarrhythmias and feline hypertrophic obstructive cardiomyopathy.

Other β-Blockers

Many other β-blocking drugs are available. Their receptor selectivity and pharmacologic characteristics vary. Sotalol is a β-blocker that also prolongs action potential duration at higher doses; therefore it is usually considered a class III agent (see later). Certain β-blockers have been useful in people with chronic, stable myocardial failure by reducing the cardiotoxic effects of excessive sympathetic stimulation,

improving cardiac function, and increasing survival time. These include the third-generation β-blocker, carvedilol; the second-generation agent, metoprolol; and some others. Despite theoretical and some experimental benefit, β-blocker therapy has not been shown to delay CHF or increase survival in dogs and cats.

Carvedilol blocks β_1-, β_2-, and α_1-adrenergic receptors; has antioxidant effects; reduces endothelin release; has some Ca^{++}-blocking effect; and is also thought to promote vasodilation by affecting either NO or prostaglandin mechanisms. Oral doses in dogs produce a wide range of peak plasma concentrations. Carvedilol is eliminated mainly through hepatic metabolism; the terminal half-life in dogs is less than 1 to 2 hours (i.e., shorter than in people), and the drug is highly protein-bound. Its β-blocking effect lasts for 12 hours, and some residual effect persists for up to 24 hours, consistent with active metabolite(s). In healthy dogs, low doses of carvedilol cause minimal hemodynamic effect, but, as with all β-blockers, animals in heart failure may not tolerate even small doses.

Metoprolol tartrate is another β_1-selective agent. It is well absorbed orally, but bioavailability is reduced by a large first-pass effect. There is minimal protein-binding. The drug is metabolized in the liver and excreted in the urine. Half-life is 1.6 hours in dogs and 1.3 hours in cats.

CLASS III ANTIARRHYTHMIC DRUGS

Common features of class III drugs include prolongation of the cardiac action potential and effective refractory period without a decrease in conduction velocity. Their effects are mediated by inhibition of potassium channels responsible for repolarization (delayed rectifier current). These agents are useful against ventricular arrhythmias, especially those caused by reentry. Class III drugs have antifibrillatory effects as well. They share some characteristics of other antiarrhythmic drug classes in addition to their class III effects.

Sotalol

Sotalol HCl is a nonselective β-blocker that has class III effects at higher doses. Its oral bioavailability is high, although absorption is reduced when given with food. Sotalol's half-life is about 5 hours in dogs. It is eliminated unchanged by the kidneys, and renal dysfunction prolongs elimination. Sotalol's β-blocking effect outlasts its plasma half-life. The drug has minimal hemodynamic effects, although it can cause slowed sinus rate, first-degree AV block, and hypotension. Proarrhythmia can occur (as with all antiarrhythmic agents), including torsades de pointes (a type of multiform ventricular tachycardia). Sotalol's class III effects occur at higher doses in dogs than in people. Doses used clinically in dogs may be producing primarily β-blocking effects. A high incidence of proarrhythmia (especially torsades de pointes), which is of concern in people taking sotalol, has not been reported clinically in dogs. Experimentally, in dogs with hypokalemia, co-administration of mexiletine reduced the proarrhythmic potential.

Sotalol may worsen heart failure in animals with DCM. However, sotalol is thought to have less negative inotropic effect than propranolol. Other adverse effects of sotalol have included hypotension, depression, nausea, vomiting, diarrhea, and bradycardia. There are sporadic anecdotal reports of aggression that resolved after sotalol was discontinued. Sotalol may induce or worsen neurogenic bradycardia in some Boxers with ventricular tachycardia. Like other β-blockers, sotalol therapy should not be discontinued abruptly.

Amiodarone

Amiodarone HCl is thought to produce its antiarrhythmic effects by prolonging the action potential duration and effective refractory period in both atrial and ventricular tissues. Although considered a class III agent, it shares properties with all three other antiarrhythmic drug classes. Amiodarone is an iodinated compound that also has noncompetitive α_1- and β-blocking effects, as well as Ca^{++} channel-blocking effects. The β-blocking effects occur soon after administration, but maximal class III effects (and prolongation of action potential duration and QT interval) are not achieved for weeks with chronic administration. Its Ca^{++}-blocking effects may inhibit triggered arrhythmias by reducing afterdepolarizations. Therapeutic doses slow the sinus rate, decrease AV conduction velocity, and minimally depress myocardial contractility and blood pressure. Indications for amiodarone include refractory atrial and ventricular tachyarrhythmias, especially reentrant arrhythmias using an accessory pathway. The IV form has been used for ventricular tachycardia and AF. However, use of the standard (older) IV formulation often precipitates hypotension and anaphylactoid reactions, related to the solvents (polysorbate 80 and benzyl alcohol) used to keep the drug in solution. Therapy for acute hypersensitivity reaction has included discontinuing the drug, and using diphenhydramine (e.g., 1 mg/kg IV), a corticosteroid (e.g., prednisolone 1-2 mg/kg IV), IV fluids and other supportive care as needed. Although antihistamine pretreatment, conservative dosing, and slow injection over 10 to 20 minutes have been helpful in some cases, use of standard amiodarone IV is NOT currently recommended. A newer amiodarone formulation (Nexterone) without polysorbate 80 and benzyl alcohol is available and thought to be safer.

The pharmacokinetics of amiodarone are complex. Chronic oral use is associated with a prolonged time to steady state (of several weeks), concentration of drug in myocardial and other tissues, and accumulation of an active metabolite (desethylamiodarone). Therapeutic serum concentration range is thought to be 1 to 2.5 μg/mL. Amiodarone has less of a proarrhythmic effect than other agents and could reduce the risk of sudden death because of its uniform prolongation of repolarization throughout the ventricles, as well as suppression of Purkinje fiber automaticity. In normal dogs IV amiodarone does not adversely affect contractility at cumulative doses less than 12.5 to 15 mg/kg. However, the potential exists for more profound cardiac depression and

hypotension in dogs with myocardial disease. Amiodarone use is not described in cats.

Amiodarone is associated with many potential adverse effects. Hepatopathy, GI abnormalities, and a positive Coombs test have been reported in Dobermans receiving amiodarone. Other long-term adverse effects can include depressed appetite, GI upset, pneumonitis leading to pulmonary fibrosis, thyroid dysfunction, thrombocytopenia, and neutropenia. Hypersensitivity reactions (with acute erythema, angioedema, pruritus, agitation), hypotension, or tremors have occurred in dogs, especially with IV administration (of the older formulation). Other adverse effects observed in people have included corneal microdeposits, photosensitivity, bluish skin discoloration, and peripheral neuropathy. Amiodarone can increase the serum concentration of digoxin, diltiazem, and possibly procainamide and quinidine.

Other Class III Agents

Ibutilide fumarate is somewhat effective for converting recent-onset AF in people, but there is little veterinary experience with this drug. In experimental dog studies, it suppressed sinus and AV node conduction, increased refractoriness, and prolonged the QT interval; it was only moderately effective in suppressing AF and has caused torsades de pointes. Dofetilide is another drug that selectively blocks the rapid component of the repolarizing K^+ current. It too is used in people for converting AF and to maintain sinus rhythm, but it may be more effective in preventing rather than terminating AF. Experimentally in dogs it prolongs the QT interval and can induce torsades de pointes, although it does not exacerbate left ventricular dysfunction. Dofetilide is metabolized in the liver and has both hepatic and renal clearance; the half-life is about 4.5 hours in dogs.

CLASS IV ANTIARRHYTHMIC DRUGS: CALCIUM ENTRY BLOCKERS

The Ca^{++} entry blockers are a diverse group of drugs that have the common property of decreasing cellular Ca^{++} influx by blocking transmembrane L-type calcium channels. As a group, these drugs can cause coronary and systemic vasodilation, enhance myocardial relaxation, and reduce cardiac contractility. The dihydropyridine group of Ca^{++}-blockers (such as amlodipine) primarily have vasodilating effects and do not appreciably alter cardiac conduction or contractility. The nondihydropyridine group (including diltiazem) slows conduction in tissues dependent on the slow inward Ca^{++} current, such as the sinus and AV nodes, thereby exerting some antiarrhythmic effects.

Possible adverse effects of Ca^{++}-blockers include reduced contractility, hypotension, depression, anorexia, lethargy, bradycardia, and AV block. Low initial doses are used and increased as needed to effect or to maximal recommended dose. Contraindications to Ca^{++} channel blocker use include sinus bradycardia, AV block, sick sinus syndrome, myocardial failure (for agents with pronounced negative inotropic effect), and digoxin toxicity. They usually are not prescribed in patients receiving a β-blocker because of additive negative effects on contractility, AV conduction, and heart rate. An overdose or exaggerated response to a Ca^{++}-blocker is treated with supportive care, including atropine for bradycardia or AV block, dopamine or dobutamine (see Box 3.1) and furosemide for heart failure, and dopamine or IV calcium salts for hypotension.

Diltiazem

Diltiazem HCl is a benzothiazepine Ca^{++} channel blocker. It slows AV conduction, causes potent coronary and mild peripheral vasodilation, and has a lesser negative inotropic effect than the prototypical Ca^{++} entry blocker, verapamil. Diltiazem is often combined with digoxin to further slow the ventricular response rate to AF in dogs with heart failure. It is indicated for other supraventricular tachyarrhythmias as well. Diltiazem has been used in cats with HCM, based on its potential to decrease heart rate, contractility, and myocardial oxygen demand and to enhance myocardial relaxation and perfusion. However, diltiazem has not been shown to improve clinical outcome.

Peak effects are seen within 2 hours of oral dosing; effects last at least 6 hours in dogs. Extensive first-pass effect limits bioavailability, especially in dogs. The half-life of diltiazem in the dog is just over 2 hours, but chronic dosing prolongs it because of enterohepatic circulation. In cats, the half-life is about 2 to 3 hours; plasma concentrations peak within 30 to 90 minutes and effects last for 8 hours, although much variability in pharmacokinetics exists among individual cats. The therapeutic range is 50 to 300 ng/mL. Diltiazem is metabolized in the liver; active metabolites exist. Drugs that inhibit hepatic CYP enzyme systems decrease the metabolism of diltiazem. Propranolol and diltiazem decrease each other's clearance when used simultaneously. Diltiazem ER is a sustained-release preparation; the 240 mg capsules contain four tablets of 60 mg each. Doses of 30 to 60 mg q24h produced serum concentrations >200 ng/mL for 24 hours in cats, although some cats on the lower dose reached <50 ng/mL by 24 hours. The 60-mg dose (~9-15 mg/kg) caused lethargy, GI signs, and weight loss in about one third of cats on chronic therapy. Another sustained-release preparation (Cardizem-CD capsules) at 10 mg/kg daily in cats produces plasma concentrations that peak in 6 hours and remain in the therapeutic range for 24 hours. A dose of 45 mg per cat is approximately equal to 105 mg of Cardizem-CD (or the amount that fits into the small end of a No. 4 gelatin capsule; a 300-mg capsule provides about 6.5 doses); this is given once daily.

Adverse effects of diltiazem are uncommon at therapeutic doses, although anorexia, nausea, and bradycardia may occur. Rarely, other GI, cardiac, and neurologic adverse effects develop. High liver enzyme activities and anorexia occur sporadically in cats. Some cats have become aggressive or shown other personality change when treated with diltiazem.

Verapamil

Verapamil HCl is a phenylalkylamine with potent cardiac effects, however it is rarely used now in dogs and cats; diltiazem is far preferred. Verapamil causes dose-related slowing of the sinus rate and AV conduction. Although it can be effective for supraventricular and atrial tachycardias, it has important negative inotropic and some vasodilatory effects that can cause cardiac decompensation, hypotension, and even death in animals with underlying myocardial disease. If used, a low IV dose is given very slowly; this can be repeated at 5- (or more) minute intervals if no adverse effects have occurred and the arrhythmia persists. Blood pressure should be monitored because of the potential for hypotension. Verapamil should not be used in animals with heart failure. Toxic effects of verapamil include sinus bradycardia, AV block, hypotension, reduced myocardial contractility, and cardiogenic shock. Verapamil reduces the renal clearance of digoxin.

Other Calcium Channel Blockers

Amlodipine besylate is a dihydropyridine Ca^{++}-blocker recommended as the first-line antihypertensive agent in cats. It is also used in some hypertensive dogs (see Chapter 11), usually with an ACEI. Amlodipine also is used to provide additional afterload reduction for dogs with chronic refractory heart failure from mitral valve disease (see Table 3.3). Amlodipine is not useful as an antiarrhythmic agent. Nifedipine is another potent vasodilator without antiarrhythmic effects.

SO-CALLED CLASS V DRUGS

Digoxin

Digoxin is mainly considered a positive inotropic drug (see Chapter 3); however, it also is used to slow the ventricular response rate (heart rate in animals with AF). Digoxin also can suppress some supraventricular premature depolarizations. These effects are mediated by the drug's enhancement of parasympathetic tone, which mainly affects the SA and AV nodes and atrial tissue, and its direct effects that prolong AV nodal conduction and refractory period.

Ivabradine

Ivabradine is a selective sinus node "funny" current (I_f) inhibitor that causes a dose-related slowing of heart rate. It has minimal effect on other ion channels and cardiac mechanical function. Heart rate reduction can reduce myocardial oxygen requirement and improve coronary perfusion. Ivabradine could prove useful for heart rate control in cats with cardiomyopathy or animals with heart failure and persistent sinus tachycardia despite reasonable control of congestive signs. However, currently there is little clinical veterinary experience with this agent. Ivabradine and its major active metabolite appear to reach peak plasma concentrations in ~1 hour after oral dosing in dogs and cats, with peak negative chronotropic effect in ~3 hours. Plasma half-life of ivabradine is ~2 hours in dogs and ~3.5 hours in cats. Ivabradine is metabolized by hepatic cytochrome P450 enzyme pathways. Dosing at 12-hour intervals appears appropriate in healthy cats. The drug should be avoided in patients with sick sinus syndrome.

ANTICHOLINERGIC DRUGS

Atropine and Glycopyrrolate

Anticholinergic drugs increase sinus node rate and AV conduction when vagal tone is increased (see Table 4.2). Parenteral atropine or glycopyrrolate is indicated for bradycardia or AV block induced by anesthesia, CNS lesions, and certain other diseases or toxicities. Atropine is a competitive muscarinic receptor antagonist. It is used to determine whether excess vagal tone is responsible for bradyarrhythmias caused by sinus and/or AV nodal dysfunction via the *atropine challenge test* (or *atropine response test*). Response to atropine challenge is most consistent with IV administration of 0.04 mg/kg. An ECG is recorded within 5 to 10 minutes after atropine injection. If the heart rate has not increased by at least 150%, the ECG is repeated 15 to 20 minutes after atropine injection; sometimes, an initial vagomimetic effect on the AV node lasts longer than 5 minutes. The normal sinus node response is a rate increase to 150 to 160 beats/min (or >135 beats/min). However, a positive atropine response test may not predict oral anticholinergic therapy efficacy. Atropine has little to no effect on bradyarrhythmias caused by intrinsic disease of the sinus or AV node.

Atropine given by any parenteral route can transiently exacerbate vagally mediated AV block when the atrial rate increases faster than AV conduction can respond. However, IV administration causes the fastest and most consistent onset and resolution of the exacerbated block, as well as the most rapid post-bradycardia heart rates, compared with the IM and SC routes. Unlike atropine, glycopyrrolate does not have centrally mediated effects and its effects are longer lasting than those of atropine.

Oral Anticholinergic Drugs

Some animals that respond to parenteral atropine or glycopyrrolate will also respond to an oral anticholinergic agent. Clinical signs may be relieved in these animals, at least for a time. Nevertheless, most animals with symptomatic bradyarrhythmias eventually require permanent pacemaker implantation to effectively control heart rate. Propantheline bromide and hyoscyamine sulfate are commonly used, but other oral anticholinergic agents also are available. Individual dosage is adjusted to effect. Oral absorption of propantheline is variable; food may decrease drug absorption.

Vagolytic drugs can aggravate paroxysmal supraventricular tachyarrhythmias (as in sick sinus syndrome) and should be used only cautiously as chronic therapy in those patients. Other adverse effects of anticholinergic therapy include vomiting, dry mouth, constipation, keratoconjunctivitis sicca, increased intraocular pressure, and drying of respiratory secretions.

SYMPATHOMIMETIC DRUGS

Isoproterenol HCl is a β-receptor agonist that has been used to treat symptomatic AV block or bradycardia refractory to atropine, although electrical pacing is safer and more effective. It can also be effective for torsades de pointes, although it could exacerbate this arrhythmia in some. Because of its affinity for β_2-receptors, isoproterenol can cause hypotension. It is not used for treating either heart failure or cardiac arrest. Isoproterenol can be arrhythmogenic, as can other catecholamines. The lowest effective dose (see Table 4.2) is used, and the animal is monitored closely for arrhythmias. Oral administration is not effective because of marked first-pass hepatic metabolism.

Terbutaline sulfate is a β_2-receptor agonist that could have a mild stimulatory effect on heart rate when given orally. Methylxanthine bronchodilators (such as aminophylline and theophylline) increase heart rate in some dogs with sick sinus syndrome or AV block when used at higher doses.

OTHER DRUGS

Edrophonium chloride is a short-acting anticholinesterase with nicotinic and muscarinic effects. Although mainly used for diagnosing myasthenia gravis, it slows AV conduction, which can help in the diagnosis and resolution of some cases of acute SVT. The drug's effect begins within 1 minute and lasts up to 10 minutes after IV injection. Adverse effects are primarily cholinergic and include GI (vomiting, diarrhea, salivation), respiratory (bronchospasm, respiratory paralysis, edema), cardiovascular (bradycardia, hypotension, cardiac arrest), and muscular (twitching, weakness) signs. Atropine and supportive care are used if necessary.

Phenylephrine HCl is an α-adrenergic agonist that increases blood pressure by peripheral vasoconstriction. A baroreflex-mediated increase in vagal tone slows AV conduction and is thought to underlie its effects on SVT. Phenylephrine's pressor effect begins rapidly after IV injection and persists for up to 20 minutes. The drug is contraindicated in patients with hypertension or ventricular tachycardia. Extravasation can cause ischemic necrosis of surrounding tissue.

CHAPTER 5

Congenital Cardiac Disease

GENERAL CONSIDERATIONS

Common congenital cardiac malformations, as well as some that occur more sporadically, are described in this chapter. Most congenital heart defects produce an audible murmur (Fig. 5.1), although some serious malformations do not. Murmurs caused by congenital disease range in intensity from very loud to very soft depending on the type and severity of the defect and on hemodynamic factors. In addition to murmurs of congenital disease, clinically irrelevant "innocent" murmurs are relatively common in puppies and kittens. The physiologic cause of these murmurs is incompletely understood but may involve mismatch in growth rate between the heart and great vessels, relative anemia, or high sympathetic tone compared to adult animals. Innocent murmurs are usually soft systolic ejection–type murmurs heard best at the left heart base; their intensity may vary with heart rate or body position. Innocent murmurs tend to get softer and usually disappear by about 4 months of age. Murmurs caused by congenital disease usually persist beyond 6 months of age and may get louder with time, although this is not always the case. Careful examination and auscultation are important, not only in animals intended for breeding but also in working dogs and pets. Puppies and kittens with a soft left basilar systolic murmur and no other clinical or radiographic signs can be auscultated repeatedly as they grow to determine whether the murmur disappears. Further diagnostic tests are indicated in puppies or kittens with a murmur that is loud (audible on both sides of the chest), is heard loudest on the right hemithorax, or has a diastolic component, or with any murmur that persists beyond 4 to 6 months of age. Additional reasons to pursue diagnostic testing early include patients with clinical signs and those for which economic or breeding-potential decisions are pending.

Congenital heart defects most often involve either a valve (or valve region) or an abnormal communication between the systemic and pulmonary circulations. Abnormally formed valves can be insufficient, stenotic, or both. Other malformations can exist, and multiple anomalies occur in some patients. Congenital malformations vary widely in type and severity. The patient's prognosis and options for therapy depend on the definitive diagnosis and severity. Initial noninvasive testing usually includes thoracic radiographs, a complete echocardiogram (M-mode, two-dimensional [2-D], and color and spectral Doppler), and sometimes an electrocardiogram (ECG). A packed cell volume (PCV) is indicated in cases of right-to-left shunting to document erythrocytosis. Cardiac catheterization with selective angiocardiography can be useful to define some structural abnormalities and is used to guide transvascular interventional procedures. Surgical repair or palliation, balloon valvuloplasty, transcatheter shunt occlusion, or other interventional techniques may be helpful for some cases.

Patent ductus arteriosus (PDA), pulmonic stenosis (PS), and subaortic stenosis (SAS) have been identified in different surveys as the most common congenital cardiovascular anomalies in the dog. Persistent right aortic arch (a vascular ring anomaly), ventricular septal defect (VSD), malformations (dysplasia) of the atrioventricular (AV) valves, atrial septal defect (ASD), and tetralogy of Fallot (T of F) occur less frequently but are not rare. The most common congenital malformation in cats is VSD; other lesions include AV valve dysplasias, stenotic lesions (SAS and PS), ASD, T of F, and PDA. An AV septal (endocardial cushion) defect occurs more commonly in cats and consists of all or some of the following: a high VSD, a low ASD, and malformations of one or both AV valves. Endocardial fibroelastosis, mainly in Burmese and Siamese cats, also has been reported. Congenital malformations are more prevalent in male than female cats. Congenital malformations in both species can occur as isolated defects, which is most often the case, or in various combinations.

The prevalence of congenital defects is higher in purebred than in mixed-breed animals. In some studies, a polygenic inheritance pattern has been suggested, although there is more recent focus on a single major gene effect influenced by other modifying genes. Recognized breed predispositions are listed in Table 5.1; animals of other breeds can be affected with any of these defects as well.

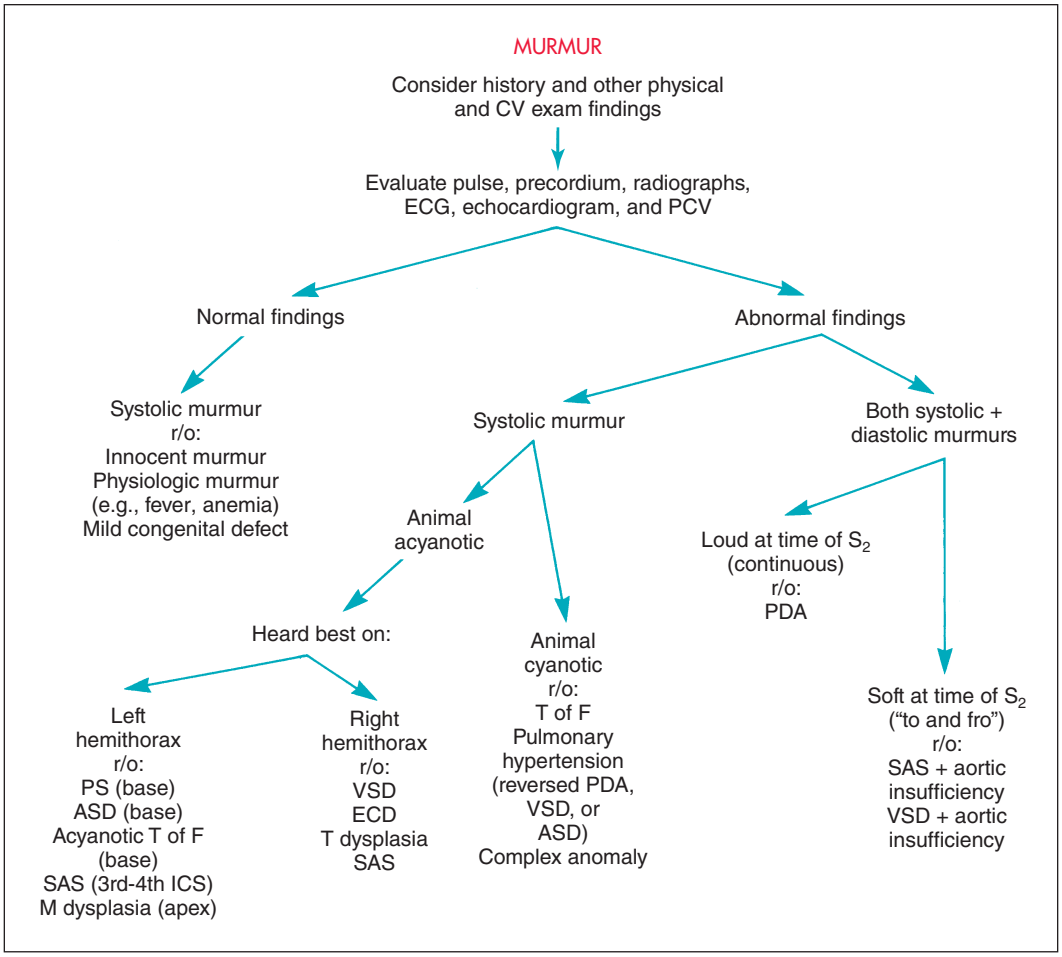

FIG 5.1

EXTRACARDIAC ARTERIOVENOUS SHUNT

The most common congenital arteriovenous shunt is PDA. Rarely, similar hemodynamic and clinical abnormalities are caused by an aorticopulmonary window (a communication between the ascending aorta and pulmonary artery) or some other functionally similar communication in the hilar region.

PATENT DUCTUS ARTERIOSUS

Etiology and Pathophysiology

The ductus normally constricts to become functionally closed within hours of birth. Structural changes and permanent closure occur over the ensuing weeks. The ductal wall in animals with an inherited PDA is histologically abnormal and contains less smooth muscle and a greater proportion of elastic fibers, similar to the aortic wall. It is therefore unable to constrict effectively. When the ductus fails to close, blood shunts through it from the descending aorta into the pulmonary artery. Because aortic pressure normally is higher than pulmonic pressure throughout the cardiac cycle, shunting occurs continuously during both systole and diastole. This left-to-right shunt causes a volume overload of the pulmonary circulation, left atrium (LA), and left ventricle (LV). The shunt volume is directly related to the pressure difference (gradient) between the two circulations and the diameter of the ductus.

Hyperkinetic ("bounding") arterial pulses are characteristic of PDA. Blood runoff from the aorta into the pulmonary system allows diastolic aortic pressure to decrease rapidly below normal. The widened pulse pressure (difference between systolic and diastolic pressure) causes palpably stronger arterial pulses (Fig. 5.2).

TABLE 5.1

Breed Predispositions for Congenital Heart Disease

DISEASE	BREED
Patent ductus arteriosus	Maltese, Pomeranian, Shetland Sheepdog, English Springer Spaniel, Keeshond, Bichon Frise, Toy and Miniature Poodles, Yorkshire Terrier, Collie, Cocker Spaniel, German Shepherd Dog, Chihuahua, Kerry Blue Terrier, Labrador Retriever, Newfoundland, Welsh Corgi; female > male
Subaortic stenosis	Newfoundland, Golden Retriever, Rottweiler, Boxer, German Shepherd Dog, Great Dane, German Short-Haired Pointer, Bouvier des Flandres, Samoyed (valvular aortic stenosis: Bull Terrier)
Pulmonic stenosis	English Bulldog (male > female), Mastiff, Samoyed, Miniature Schnauzer, West Highland White Terrier, Cocker Spaniel, Beagle, Labrador Retriever, Basset Hound, Newfoundland, Airedale Terrier, Boykin Spaniel, Chihuahua, Scottish Terrier, Boxer, Chow, Miniature Pinscher, other terriers & spaniels
Ventricular septal defect	English Bulldog, English Springer Spaniel, Keeshond, West Highland White Terrier; cats
Atrial septal defect	Samoyed, Doberman Pinscher, Boxer
Tricuspid dysplasia	Labrador Retriever, German Shepherd Dog, Boxer, Weimaraner, Great Dane, Old English Sheepdog, Golden Retriever; other large breeds (male > female?); cats
Mitral dysplasia	Bull Terrier, German Shepherd Dog, Great Dane, Golden Retriever, Newfoundland, Mastiff, Dalmatian, Rottweiler (?); cats (male > female)
Tetralogy of Fallot	Keeshond, English Bulldog
Persistent right aortic arch	German Shepherd Dog, Great Dane, Irish Setter

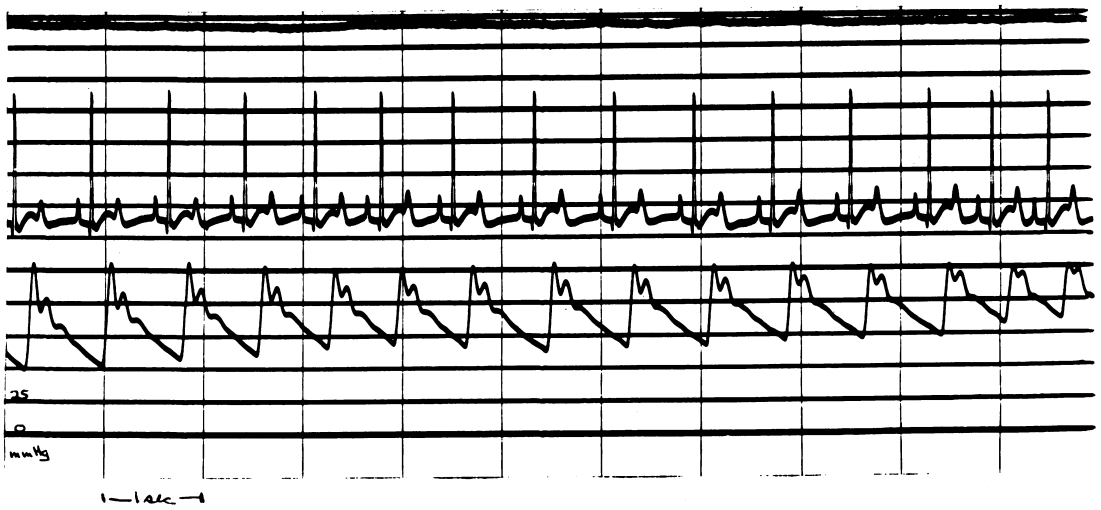

FIG 5.2
Continuous femoral artery pressure recording during surgical ligation of a patent ductus arteriosus in a Poodle. The wide pulse pressure (left side of trace) narrows as the ductus is closed (right side of trace). Diastolic arterial pressure rises because blood runoff into the pulmonary artery is curtailed. (Courtesy Dr. Dean Riedesel.)

Compensatory mechanisms that promote increased heart rate and volume retention maintain adequate systemic blood flow. However, the LV is subjected to a great hemodynamic burden, especially when the ductus is large, because the increased stroke volume is pumped into the relatively high pressure aorta. Left ventricular (LV) and mitral annulus dilation in turn cause mitral regurgitation and further volume overload. Excess fluid retention, declining myocardial contractility stemming from the chronic volume overload, and arrhythmias contribute to the development of left-sided congestive heart failure (CHF).

In rare cases, excessive pulmonary blood flow from a large ductus causes pulmonary vascular changes, abnormally high resistance, and pulmonary hypertension (see p. 114). As

pulmonary artery pressure rises toward aortic pressure, progressively less blood shunting occurs. If pulmonary artery pressure exceeds aortic pressure, shunt reversal (right-to-left flow) occurs. Approximately 15% of dogs with PDA have reversed (right-to-left) shunting. However, as most such shunts are already "reversed" (right-to-left) by the time of first evaluation, it is difficult to know whether these patients have retained fetal pulmonary vascular resistance (congenital pulmonary hypertension) causing right-to-left shunting from birth or whether shunt flow actually reversed postnatally following pulmonary vascular changes from volume overload.

Clinical Features

The left-to-right shunting PDA is by far the most common form; clinical features of reversed PDA are described on page 115. The prevalence of PDA is higher in certain breeds of dogs; a polygenic inheritance pattern is thought to exist, particularly in miniature Poodles. The prevalence is two or more times greater in female than male dogs. Most animals are asymptomatic when first diagnosed, although some patients may present with clinical signs of left-sided CHF including exercise intolerance, tachypnea, or cough. A continuous murmur heard best high at the left base (see p. 11), often with a precordial thrill, is typical for a left-to-right PDA; sometimes only the systolic component of the murmur is heard more caudally near the mitral valve area. Other findings include hyperkinetic (bounding, "water hammer") arterial pulses and pink mucous membranes.

Diagnosis

Radiographs usually show cardiac elongation (left heart dilation), left atrial (LA) and auricular enlargement, and pulmonary overcirculation (Table 5.2). A bulge often is evident in the descending aorta ("ductus bump"), main pulmonary trunk, or both (Fig. 5.3). The triad of all three bulges (i.e., pulmonary trunk, aorta, and left auricle), located in that order from the 1 to 3 o'clock position on a dorsoventral (DV) radiograph, is a classic finding but not always seen. Animals with left-sided CHF also show evidence of pulmonary edema. Characteristic ECG findings suggest LV and LA enlargement, including wide P waves, tall R waves, and often deep Q waves in leads II, aVF, and CV_6LL. Changes in the ST-T segment secondary to LV enlargement can occur. However, the ECG is normal in some animals with PDA. Most patients have normal sinus rhythm, although ventricular or supraventricular arrhythmias (including atrial fibrillation) can occur.

Echocardiography also shows left heart enlargement and pulmonary trunk dilation. LV fractional shortening can be normal or decreased, and the E point–septal separation is often increased. The ductus itself can be difficult to visualize because of its location between the descending aorta and pulmonary artery; angulation from the left cranial short axis view usually is most helpful. Doppler interrogation documents continuous, turbulent flow into the pulmonary artery (Fig. 5.4). The maximum aortic-to-pulmonary artery pressure gradient can be estimated using velocity of systolic PDA flow. Cardiac catheterization generally is unnecessary for

TABLE 5.2

Radiographic Findings in Common Congenital Heart Defects

DEFECT	HEART	PULMONARY VESSELS	OTHER
PDA	LAE, LVE; left auricular bulge; ±increased cardiac width	Overcirculated	Bulge(s) in descending aorta + pulmonary trunk; ±pulmonary edema
SAS	±LAE, LVE	Normal	Wide cranial cardiac waist (dilated ascending aorta)
PS	RAE, RVE; reverse D	Normal to undercirculated	Pulmonary trunk bulge
VSD	LAE, LVE; ±RVE	Overcirculated	±Pulmonary edema; ±pulmonary trunk bulge (large shunts)
ASD	RAE, RVE	±Overcirculated	±Pulmonary trunk bulge
T dys	RAE, RVE; ±globoid shape	Normal	Caudal cava dilation; ±pleural effusion, ascites, hepatomegaly
M dys	LAE, LVE	±Venous hypertension	±Pulmonary edema
T of F	RVE, RAE; reverse D	Undercirculated; ±prominent bronchial vessels	Normal to small pulmonary trunk; ±cranial aortic bulge on lateral view
PRAA	Normal	Normal	Focal leftward and ventral tracheal deviation ± narrowing cranial to heart; wide cranial mediastinum; megaesophagus (±aspiration pneumonia)

ASD, Atrial septal defect; *LAE,* left atrial enlargement; *LVE,* left ventricular enlargement; *M dys,* mitral dysplasia; *PDA,* patent ductus arteriosus; *PRAA,* persistent right aortic arch; *PS,* pulmonic stenosis; *RAE,* right atrial enlargement; *RVE,* right ventricular enlargement; *SAS,* subaortic stenosis; *T dys,* tricuspid dysplasia; *T of F,* tetralogy of Fallot; *VSD,* ventricular septal defect.

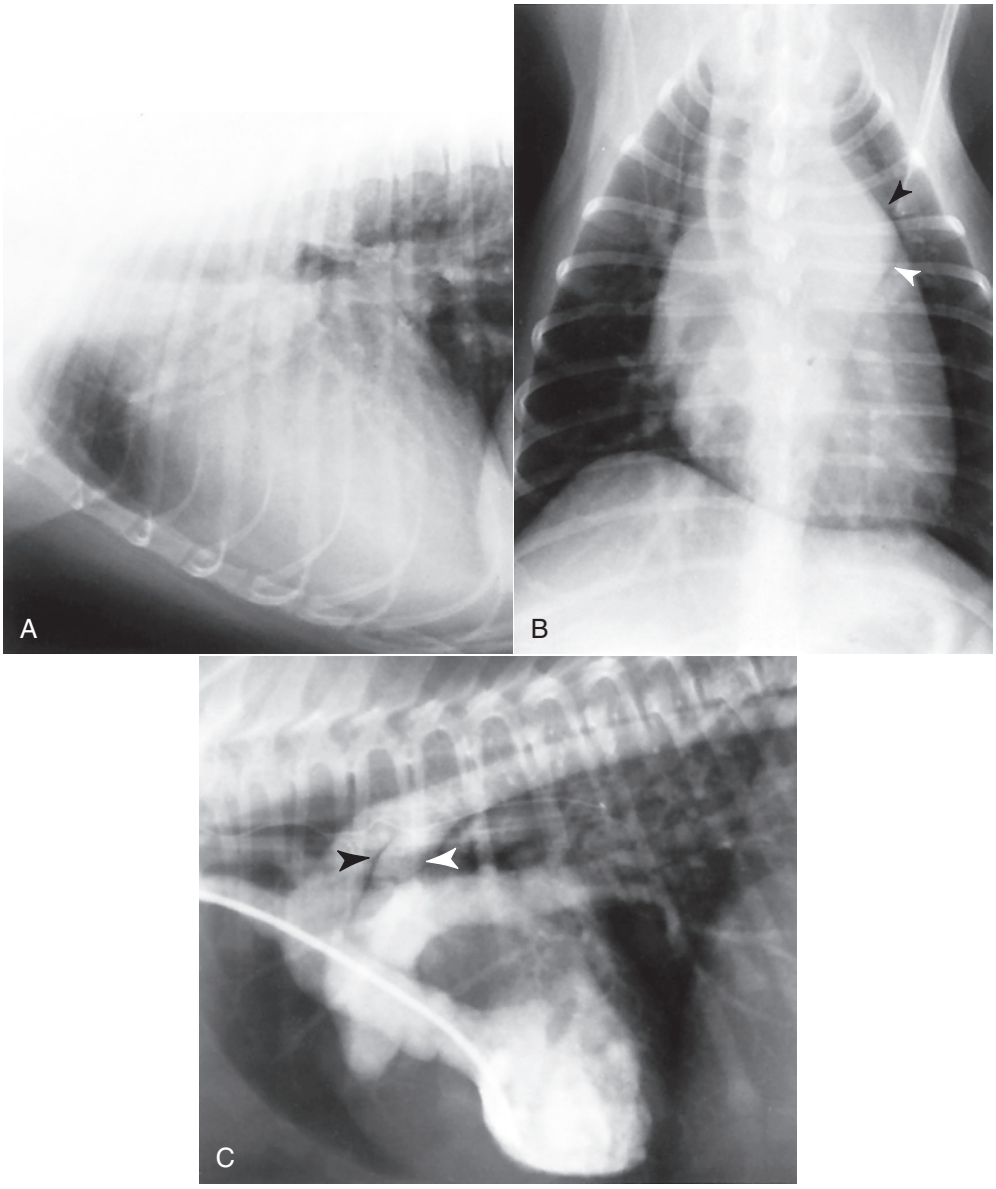

FIG 5.3
Lateral **(A)** and dorsoventral (DV) **(B)** radiographs from a dog with a patent ductus arteriosus. Note the large and elongated heart and prominent pulmonary vasculature. A large bulge is seen in the descending aorta on the DV view (*arrowheads* in **B**). **(C)** Angiocardiogram obtained using a left ventricular injection outlines the left ventricle, aorta, patent ductus *(arrowheads),* and pulmonary artery.

diagnosis, although it is important during interventional procedures. Angiocardiography shows left-to-right shunting through the ductus and facilitates measurement of the minimal ductal diameter (see Fig. 5.3, *C*).

Treatment and Prognosis

Closure of a left-to-right PDA is recommended as soon as is feasible in almost all cases, either by surgical or transcatheter methods. Surgical ligation via left lateral thoracotomy is successful in most cases. A perioperative mortality of about 5% has been reported. Several methods of transcatheter PDA occlusion are available and involve placement of a vascular occluding device within the ductus, such as the Amplatz canine ductal occluder (ACDO) or wire coils with attached thrombogenic tufts. Vascular access usually is via the femoral artery, although some have used a venous approach to the ductus. Where available, transcatheter PDA occlusion offers a much less invasive alternative to surgical ligation. Overall, ACDO occlusion has shown the highest success and lowest complication rates among occlusion methods and is considered the treatment of choice; however, the minimal device size (3 mm) is a limitation for very small puppies. Complications can occur with both surgical and interventional closure, including hemorrhage, residual ductal flow, and aberrant

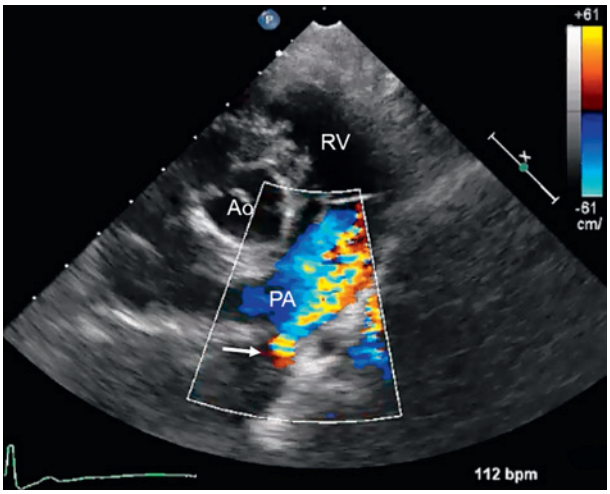

FIG 5.4
Continuous turbulent flow into the pulmonary artery from the area of the patent ductus arteriosus *(arrow)* is illustrated in a color flow Doppler image from the left cranial parasternal position, in an adult female Boston Terrier. *Ao,* Aorta; *PA,* main pulmonary artery; *RV,* right ventricle.

device embolization. Reverse remodeling of LV and LA enlargement occurs in most dogs after successful occlusion. Although LV systolic dimension and function may never completely normalize, residual changes generally are clinically insignificant. A normal life span can be expected after uncomplicated ductal closure.

Animals with left-sided CHF are treated with furosemide, pimobendan, an angiotensin-converting enzyme inhibitor (ACEI), rest, and dietary sodium restriction (see Chapter 3). Arrhythmias are treated as needed. Ductal closure is recommended as soon as feasible once CHF is stabilized. Tapering or discontinuation of CHF medications may be possible following successful closure.

If the ductus is not corrected, prognosis depends on ductal size and the level of pulmonary vascular resistance. Left-sided CHF is the eventual outcome for most patients that do not undergo ductal closure; more than 50% of affected dogs die within the first year of life. In animals with pulmonary hypertension and shunt reversal, ductal closure generally is contraindicated because the ductus acts as a "pop-off" valve for the high right-sided pressures. Ductal ligation in animals with reversed PDA is unlikely to produce improvement and can lead to acute right ventricular (RV) failure.

VENTRICULAR OUTFLOW OBSTRUCTION

Ventricular outflow obstruction can occur at the semilunar valve, just below the valve (subvalvular), or above the valve in the proximal great vessel (supravalvular). SAS and PS are most common in dogs and cats. Stenotic lesions impose a pressure overload on the affected ventricle, requiring higher systolic pressure and a slightly longer time to eject blood across the narrowed outlet. A systolic pressure gradient is generated across the stenotic region, as downstream pressure is normal. The magnitude of this gradient is related to the severity of the obstruction and strength of ventricular contraction.

Concentric myocardial hypertrophy typically develops in response to a systolic pressure overload; some dilation of the affected ventricle also can occur. Ventricular hypertrophy can impede diastolic filling (by increasing ventricular stiffness) or lead to secondary AV valve regurgitation. Heart failure results when ventricular diastolic and atrial pressures are elevated. Cardiac arrhythmias can contribute to the onset of CHF. Furthermore, the combination of outflow obstruction, paroxysmal arrhythmias, and/or inappropriate bradycardia reflexively triggered by ventricular baroreceptor stimulation can result in signs of low cardiac output. These signs are more often associated with severe outflow tract obstruction and include exercise intolerance, syncope, and sudden death.

SUBAORTIC STENOSIS

Etiology and Pathophysiology

Subvalvular narrowing caused by a fibrous or fibromuscular ring is the most common type of LV outflow stenosis in dogs. Certain larger breeds of dog are predisposed to this defect, including Newfoundlands, Golden Retrievers, and Rottweilers. SAS is thought to be inherited as an autosomal dominant trait with modifying genes that influence its phenotypic expression; a causative genetic mutation has been identified in Newfoundland dogs. SAS occurs occasionally in cats; supravalvular lesions have been reported in this species as well. Valvular aortic stenosis is reported in Bull Terriers.

The spectrum of SAS severity varies widely; three grades of SAS have been described in Newfoundland dogs. The mildest (grade I) causes no clinical signs or murmur and only subtle subaortic fibrous tissue ridging seen on postmortem examination. Moderate (grade II) SAS causes mild clinical and hemodynamic evidence of the disease, with an incomplete fibrous ring below the aortic valve found at postmortem. Dogs with grade III SAS have severe disease and a complete fibrous ring around the outflow tract. Some cases have an elongated, tunnel-like obstruction. Malformation of the mitral valve apparatus can exist as well, and a component of dynamic LV outflow tract obstruction (with or without systolic anterior motion of the mitral valve) might be important in some dogs.

Unlike many other congenital heart defects, the lesion itself is not present at birth; rather, patients are born with abnormal tissue in the subvalvular region of the conotruncal septum that retains the ability to proliferate and undergo chondrogenic differentiation. The obstructive lesion of SAS therefore develops postnatally during the first several months of life and may continue to worsen until the dog is fully grown (1-2 years of age). Murmur intensity therefore often increases over time and usually increases dynamically with exercise or excitement. Because of such factors, as well as the presence of physiologic murmurs in some animals,

definitive diagnosis and genetic counseling to breeders can be difficult.

The severity of the stenosis determines the degree of LV pressure overload and resulting concentric hypertrophy. Coronary perfusion is easily compromised in animals with severe LV hypertrophy. Myocardial capillary density can become inadequate as hypertrophy progresses. Furthermore, the high systolic wall tension, along with coronary narrowing, can cause systolic flow reversal in small coronary arteries. These factors contribute to intermittent myocardial ischemia and secondary fibrosis. Clinical sequelae include arrhythmias, syncope, and sudden death. Many animals with SAS also have aortic or mitral valve regurgitation because of related malformations or secondary changes; this imposes an additional volume overload on the LV. Left-sided CHF develops in some cases. Animals with SAS are thought to be at higher risk for aortic valve endocarditis because of jet lesion injury to the underside of the valve (see p. 132 and Figs. 6.5 and 6.6).

Clinical Features

Most patients with SAS are asymptomatic on initial presentation. Clinical signs of fatigue, exercise intolerance or exertional weakness, syncope, or sudden death occur in about one third of dogs with SAS. Low-output signs can result from severe outflow obstruction, tachyarrhythmias, or sudden reflex bradycardia and hypotension resulting from the activation of ventricular mechanoreceptors. Signs of left-sided CHF can develop, usually in conjunction with concurrent mitral or aortic regurgitation, other cardiac malformations, or acquired endocarditis. Dyspnea is the most commonly reported sign in cats with SAS.

The characteristic murmur of SAS is a harsh systolic ejection murmur heard near the aortic valve area at the left heart base, with or without a precordial thrill. This murmur often radiates equally or more loudly to the right heart base because of the orientation of the aortic arch. The murmur typically is heard over the carotid arteries as well and, in severe cases, sometimes even radiates to the calvarium. Aortic regurgitation can produce a diastolic murmur at the left base or may be inaudible. Other common physical examination findings in dogs with moderate to severe stenosis include weak and late-rising femoral pulses *(pulsus parvus et tardus)*, although concurrent severe aortic regurgitation can increase the arterial pulse strength. There may be evidence of pulmonary edema or arrhythmias.

In mild cases, a soft, poorly radiating ejection murmur at the left and sometimes right heart base may be the only abnormality found on physical examination. Low-grade functional LV outflow murmurs that are not associated with SAS are common in normal Greyhounds, other sighthounds, and Boxers; presence of such physiologic flow murmurs can complicate diagnosis of SAS.

Diagnosis

Radiographic abnormalities (see Table 5.2) can be subtle, especially in animals with mild SAS. The LV can appear normal or enlarged; mild to moderate LA enlargement is more likely with severe SAS or concurrent MR. Poststenotic dilation in the ascending aorta can cause a prominent cranial waist in the cardiac silhouette (especially on a lateral view) and cranial mediastinal widening. The ECG often is normal, although evidence of LV hypertrophy (left axis deviation) or enlargement (tall R waves) can be present. Depression of the ST segment in leads II and aVF can occur from myocardial ischemia or secondary to hypertrophy; exercise induces further ischemic ST-segment changes in some animals. Ventricular tachyarrhythmias are common.

Echocardiography reveals the extent of LV hypertrophy and subaortic narrowing. A discrete tissue ridge below the aortic valve is evident in many animals with moderate to severe disease (Fig. 5.5). Increased LV subendocardial

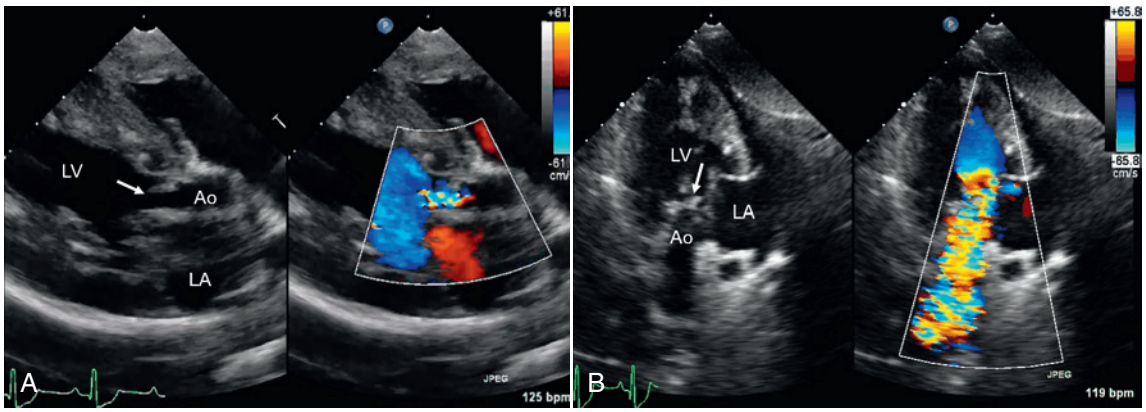

FIG 5.5
Right parasternal long-axis **(A)** and subcostal **(B)** echocardiographic images from a 3-month-old male Rottweiler with severe subaortic stenosis. Note the ridge of tissue causing a tunnel-like defect *(arrow)* below the aortic valve, creating a fixed outflow tract obstruction. Color Doppler reveals turbulent, high-velocity flow through the left ventricular outflow tract and ascending aorta in systole **(B),** as well as mild aortic insufficiency **(A).** *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

echogenicity (probably from fibrosis) is common in animals with severe obstruction; systolic anterior motion of the anterior mitral leaflet and mid-systolic partial aortic valve closure suggest concurrent dynamic LV outflow obstruction. Ascending aorta dilation, aortic valve thickening, and LA enlargement with hypertrophy may also be seen. In mildly affected animals, 2-D and M-mode findings may be unremarkable. Doppler echocardiography reveals systolic turbulence originating below the aortic valve and extending into the aorta, as well as high peak systolic outflow velocity (see Fig. 5.5). Some degree of aortic or mitral regurgitation is common. Spectral Doppler studies are used to estimate the stenosis severity by calculating the pressure gradient across the LV outflow tract (between the LV and aorta). A pressure gradient of <50 mm Hg is defined as mild stenosis, 50 to 80 mm Hg is moderate stenosis, and >80 mm Hg indicates severe stenosis. The LV outflow tract should be interrogated from more than one position to achieve the best possible alignment with blood flow. The subcostal (subxiphoid) position usually yields the highest-velocity signals, although the left apical position is optimal in some animals. Doppler-estimated systolic pressure gradients in unanesthetized animals are usually 40% to 50% higher than those recorded during cardiac catheterization under anesthesia.

The Doppler-estimated aortic outflow velocity might be only equivocally high in animals with mild SAS, especially with suboptimal Doppler beam alignment. With optimal alignment, aortic root velocities of less than 1.9 m/sec are typical in normal unsedated dogs; velocities over approximately 2.25 m/sec are generally considered abnormal. Peak velocities in the equivocal range between these values could indicate the presence of mild SAS, especially if other evidence of disease exists, such as a subaortic ridge, aortic regurgitation, or disturbed flow in the outflow tract or ascending aorta with an abrupt increase in velocity. This mainly is of concern when selecting animals for breeding. In some breeds (e.g., Boxer, Golden Retriever, Greyhound), outflow velocities in this equivocal range (1.8-2.25 m/sec) are common in normal dogs. This could reflect breed-specific variation in LV outflow tract anatomy or response to sympathetic stimulation, rather than SAS. A limitation of using the estimated pressure gradient to assess outflow obstruction severity is the dependence of this gradient on blood flow. Factors causing sympathetic stimulation and increased cardiac output (e.g., excitement, exercise, fever) will increase outflow velocities, whereas myocardial failure, cardiodepressant drugs, and other causes of reduced stroke volume will decrease recorded velocities. Cardiac catheterization and angiocardiography rarely are used now to diagnose or quantify SAS, except in conjunction with balloon dilation of the stenotic area.

Treatment and Prognosis

Several palliative surgical techniques have been attempted in dogs with severe SAS. Although some have reduced the LV systolic pressure gradient and possibly improved exercise ability, because of high complication rates, expense, and lack of a long-term survival advantage, surgery is not recommended. Likewise, transvascular balloon dilation of the stenotic area can reduce the measured gradient in some dogs; however, significant survival benefit has not been documented with this procedure. More recently, a combined valvuloplasty procedure involving cutting balloon valvuloplasty followed by high-pressure balloon dilation has been tried, with the goal of "scoring" (disrupting) the fibrous ring to make the subvalvular region more amenable to balloon dilation. This procedure can reduce LV pressure gradient and appears to be safe, although serious complications can occur. However, some degree of re-stenosis is common by 6 to 12 months postprocedure. As with other interventions for SAS, long-term survival benefit of this combined cutting and high-pressure balloon dilation procedure has not been documented.

Medical therapy with a β-blocker has been advocated in patients with moderate to severe SAS, to reduce myocardial oxygen demand and minimize the frequency and severity of arrhythmias. Animals with a high pressure gradient, marked ST-segment depression, frequent ventricular premature beats, or a history of syncope might be more likely to benefit from this therapy. Whether β-blockers prolong survival is unclear. Exercise restriction is advised for animals with moderate to severe SAS. Prophylactic antibiotic therapy is recommended for animals with SAS before any procedures with the potential to cause bacteremia (e.g., dentistry) are done, although the efficacy of this practice in preventing endocarditis is unclear.

The prognosis in dogs and cats with severe stenosis (pressure gradient > 80 mm Hg) is guarded. Median survival time is approximately 4.5 years, with a bimodal age distribution describing cause of death. Sudden death is more common in dogs younger than 3 years of age; overall, approximately 20% of dogs with SAS die suddenly. In contrast, infective endocarditis and CHF are more likely to develop later in life (8-10 years) in surviving dogs. Atrial and ventricular arrhythmias and worsened mitral regurgitation are complicating factors. Dogs with mild stenosis (pressure gradient < 50 mm Hg) could live a normal life span without clinical signs.

PULMONIC STENOSIS

Etiology and Pathophysiology

PS is more common in small breeds of dogs. Some cases of valvular PS result from simple fusion of the valve cusps, but valve dysplasia is more common. Dysplastic valve leaflets are variably thickened, asymmetric, and partially fused, with or without a hypoplastic valve annulus. RV pressure overload leads to concentric hypertrophy, as well as secondary dilation of the RV. Severe ventricular hypertrophy promotes myocardial ischemia and its sequelae. Excessive muscular hypertrophy in the infundibular region below the valve can create a dynamic subvalvular component to the stenosis. Other variants of PS, including supravalvular stenosis and RV muscular partition (double-chamber RV), occur rarely.

Turbulence caused by high-velocity flow across the stenotic orifice leads to poststenotic dilation in the main

pulmonary trunk. Right atrial (RA) dilation from secondary tricuspid insufficiency and high RV filling pressure predisposes to atrial tachyarrhythmias and right-sided CHF. The combination of PS and a patent foramen ovale or ASD can allow right-to-left shunting at the atrial level.

A single anomalous coronary artery has been described in some Bulldogs and other brachycephalic breeds with PS and is thought to contribute to the outflow obstruction. In such cases, palliative surgical procedures and balloon valvuloplasty can cause death secondary to transection or avulsion of the major left coronary branch that wraps circumferentially around the stenotic pulmonic valve annulus.

Clinical Features

Many dogs with PS are asymptomatic when diagnosed, although some have right-sided CHF or a history of exercise intolerance or syncope. Clinical signs might not develop until the animal is several years old, even in those with severe stenosis. Physical examination findings characteristic of moderate to severe stenosis include a prominent right precordial impulse and a systolic ejection murmur heard best high at the left heart base, with or without precordial thrill. The murmur can radiate cranioventrally and to the right in some cases but usually is not heard over the carotid arteries. An early systolic click sometimes is identified; this is probably caused by abrupt checking of a fused valve at the onset of ejection. A murmur of tricuspid insufficiency or arrhythmias can be heard in some cases. Femoral pulses are typically normal and mucous membranes usually pink. Ascites, jugular venous distension or pulsation, and other signs of right-sided CHF are present in some cases. Occasionally, cyanosis accompanies right-to-left shunting through a concurrent atrial or VSD.

Diagnosis

Radiographic findings typically seen with PS are outlined in Table 5.2. Marked RV hypertrophy shifts the cardiac apex dorsally and to the left. The heart can appear as a "reverse D" shape on a DV or ventrodorsal (VD) view. A variably sized pulmonary trunk bulge (poststenotic dilation) is best seen at the 1 o'clock position on a DV or VD view (Fig. 5.6). The size of the poststenotic dilation does not necessarily correlate with the severity of the pressure gradient. Diminutive peripheral pulmonary vasculature and/or a dilated caudal vena cava may be apparent. ECG changes are more common with moderate to severe stenosis. These include an RV hypertrophy pattern, right axis deviation, and sometimes an RA enlargement pattern or tachyarrhythmias.

Echocardiographic findings characteristic of moderate to severe stenosis include RV concentric hypertrophy and enlargement. The interventricular septum appears flattened when pressure in the RV exceeds that in the LV and pushes it toward the left; paradoxical septal motion may occur. Secondary RA enlargement is common as well, especially with concurrent tricuspid regurgitation (TR). A thickened, asymmetric, or otherwise malformed pulmonic valve usually can be identified (see Fig. 5.7), although the outflow region sometimes is narrow and difficult to clearly visualize. Poststenotic dilation of the main pulmonary trunk is expected. Ascites or pleural effusion accompany secondary right-sided CHF. Doppler evaluation along with anatomic findings provide an estimate of PS severity. The pressure gradient between the RV and PA is estimated by measuring peak blood flow velocity across the valve. PS generally is considered mild if the Doppler-derived gradient is <50 mm Hg, moderate if pressure gradient is 50 to 80 mm Hg, and severe if it is >80 mm Hg. Cardiac catheterization and angiocardiography also can be used to assess the pressure gradient across the stenotic valve, diameter of the valve annulus, and other anatomic features. Doppler-estimated systolic pressure gradients in unanesthetized animals usually are 40% to 50% higher than those recorded during cardiac catheterization.

Treatment and Prognosis

Balloon valvuloplasty is recommended for palliation of severe (and sometimes moderate) stenosis, especially if infundibular hypertrophy is not excessive. This procedure can reduce or eliminate clinical signs and improves long-term survival in severely affected animals. Balloon valvuloplasty, done in conjunction with cardiac catheterization and angiocardiography, involves passing a specially designed balloon catheter across the valve and inflating the balloon to enlarge the stenotic orifice. Pulmonary valves with mild to moderate thickening and simple fusion of the leaflets with normal annulus size are likely to be easier to effectively dilate. Dysplastic valves with annular hypoplasia can be more difficult to dilate effectively, but good results are possible in some cases. Successful balloon valvuloplasty is generally defined as at least 50% reduction in prevalvuloplasty pressure gradient or reduction to pressure gradient of less than 50 mm Hg. Various surgical procedures also have been used to palliate moderate to severe PS in dogs, including pulmonary arteriotomy for valvulotomy and patch grafting, or placement of a valved RV-PA conduit. Balloon valvuloplasty usually is attempted before a surgical procedure because it is less risky. Animals with a single anomalous coronary artery generally should not undergo balloon or surgical dilation procedures because of increased risk of death, although conservative ballooning reportedly has been palliative in a few cases. Placement of a valved RV-PA conduit to bypass the pulmonic valve could be an option for such patients. Coronary anatomy can be evaluated initially using echocardiography, but definitive diagnosis of coronary artery anomalies may require either aortic root angiography or computed tomography with angiography.

Exercise restriction is advised for animals with moderate to severe stenosis. β-blocker therapy could be helpful in cases of moderate to severe PS, especially in those with prominent RV infundibular hypertrophy and a dynamic component to their right ventricular outflow tract (RVOT) obstruction. β-blockade also decreases myocardial oxygen demand and arrhythmias, improves coronary perfusion, and

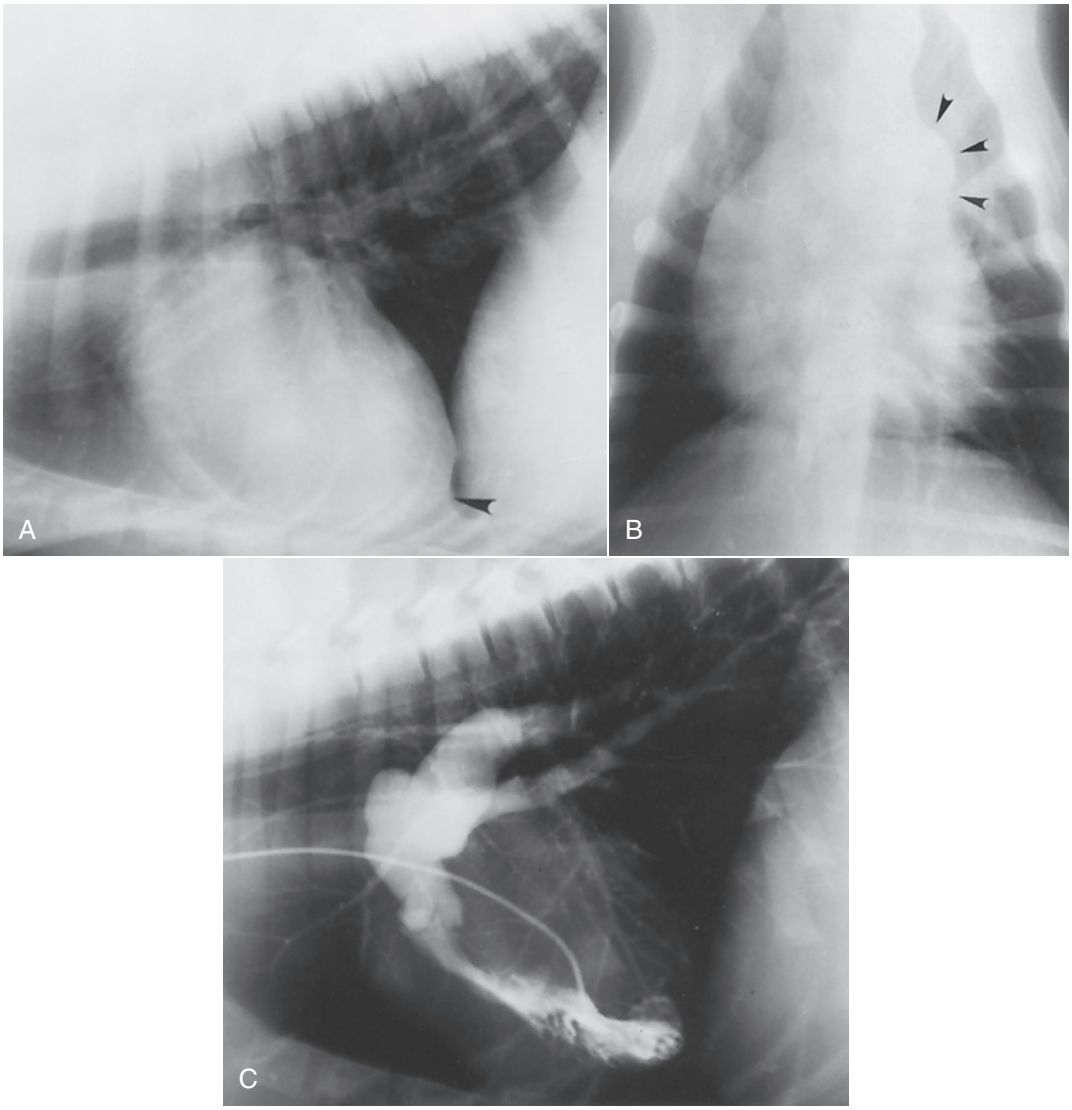

FIG 5.6
Lateral **(A)** and dorsoventral (DV) **(B)** radiographs from a dog with pulmonic stenosis, showing right ventricular enlargement (apex elevation on lateral view [*arrowhead* in **A**] and reverse D configuration on DV view) along with a pulmonary trunk bulge (*arrowheads* in **B**) seen on a DV view. **(C)** Angiocardiogram using a selective right ventricular injection demonstrates poststenotic dilation of the main pulmonary trunk and pulmonary arteries. The thickened pulmonic valve is closed in this diastolic frame.

can reduce syncope. Signs of CHF are managed medically with abdomino- or thoracocentesis, furosemide, pimobendan, an ACEI, and spironolactone (see Chapter 3).

The prognosis in patients with PS is variable and depends on the severity of the lesion and any complicating factors. Life span often is normal in those with mild PS, whereas animals with severe PS often die within 3 years of diagnosis. Sudden death occurs in some; development of right-sided CHF is more common. The prognosis is considerably worse in animals with TR, atrial fibrillation or other tachyarrhythmias, or CHF. Successful balloon dilation improves prognosis in dogs with severe PS; some dogs may live normal life spans after the procedure.

INTRACARDIAC SHUNT

Blood flow volume across an intracardiac shunt depends on the size of the defect and the pressure gradient driving flow across it. In most cases, flow direction is from left to right, causing pulmonary overcirculation. A volume overload is imposed on all heart chambers that receive "extra" shunted blood flow. Compensatory increases in blood volume and cardiac output occur in response to the partial diversion of blood away from the systemic circulation. If right heart pressures increase due to increased pulmonary resistance or a concurrent PS, shunt flow may equilibrate or reverse (i.e., become right to left).

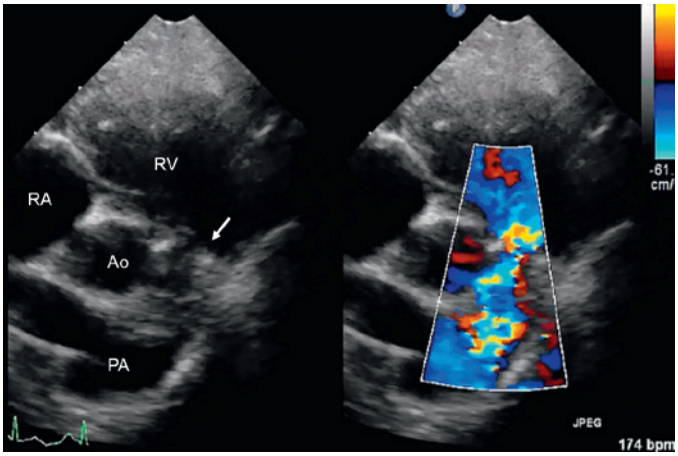

FIG 5.7
Right parasternal short-axis echocardiographic image at the level of the heart base from a 3-month-old female English Bulldog with severe pulmonic stenosis. Thickened, partially fused leaflets of the malformed pulmonary valve *(arrow)* cause turbulent, high-velocity flow across the pulmonic valve on color Doppler. Note the severe right ventricular enlargement and hypertrophy. *Ao,* Aortic root; *PA,* main pulmonary artery; *RA,* right atrium; *RV,* right ventricle.

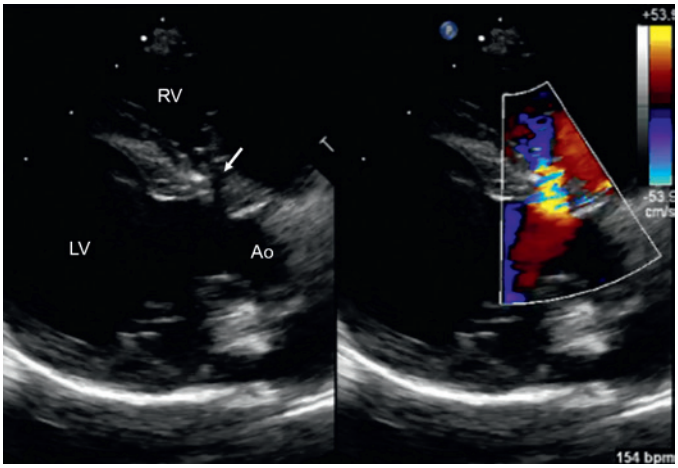

FIG 5.8
Right parasternal long-axis echocardiographic image in a 4-month-old male Bassett Hound. A small perimembranous ventricular septal defect (*arrow*) can be seen just below the aortic root. Color Doppler in systole reveals turbulent flow (from left to right) through the defect. *Ao,* Aortic root; *LV,* left ventricle; *RV,* right ventricle.

VENTRICULAR SEPTAL DEFECT

Etiology and Pathophysiology

Most VSDs are located in the membranous part of the septum, just below the aortic valve and beneath the septal tricuspid leaflet (perimembranous VSD). VSDs also occur sporadically in other septal locations, including the muscular septum (muscular VSD), below and between AV valves (inlet VD), and just below the pulmonary valve (juxta-arterial, outlet, or supracristal VSD). A VSD may be accompanied by other AV septal (endocardial cushion) malformations, especially in cats. Usually, VSDs cause volume overloading of the pulmonary circulation, LA, LV, and RV outflow tract. However, because most VSDs occur very high in the RV outflow tract (in the membranous septum), significant volume overload of the RV itself is rare. Small defects may be clinically unimportant. Moderate to large defects tend to cause left heart dilation and can lead to left-sided CHF. A very large VSD causes the ventricles to function as a common chamber and induces RV dilation and hypertrophy. Pulmonary hypertension secondary to overcirculation is more likely to develop with large shunts. Some animals with perimembranous or juxta-arterial VSDs also have aortic regurgitation, with diastolic prolapse of a valve leaflet. Presumably this occurs because the deformed septum provides inadequate support for the aortic root. Aortic regurgitation places an additional volume load on the LV.

Clinical Features

Most animals with VSDs are asymptomatic at time of diagnosis. If clinical disease does occur, the most common manifestations are exercise intolerance and signs of left-sided CHF. The characteristic auscultatory finding is a holosystolic murmur, heard loudest at the cranial right sternal border (which corresponds to the usual direction of shunt flow). A large shunt volume can produce a murmur of relative or functional PS (systolic ejection murmur at the left base). With concurrent aortic regurgitation, a corresponding diastolic decrescendo murmur may be audible at the left base. A split S_2 sound may be audible due to delayed closure of the pulmonic valve, though this is usually obscured by the loud heard murmur.

Diagnosis

Radiographic findings associated with VSD vary with the size of the defect and the shunt volume (see Table 5.2). Large shunts typically cause left heart enlargement, main pulmonary artery enlargement, and pulmonary overcirculation.

The ECG may be normal or suggest LA or LV enlargement. In some cases, disturbed intraventricular conduction is suggested by "fractionated" or splintered QRS complexes or right bundle-branch block. An RV enlargement pattern usually indicates a large defect, pulmonary hypertension, or a concurrent RV outflow tract obstruction.

Echocardiography allows visualization of the defect. Perimembranous VSDs usually are seen best just below the aortic valve in the right parasternal long-axis LV outflow view (Fig. 5.8). The septal tricuspid leaflet is located to the right of the defect. Because echo "dropout" at the thin membranous septum can mimic a VSD, the area of a suspected defect should be visualized in more than one plane. The size of the VSD often is indexed to aortic diameter. Color Doppler is used to demonstrate shunt flow across the defect (see Fig. 5.8). Spectral Doppler assessment of

peak shunt flow velocity is used to estimate the systolic pressure gradient between the LV and RV. Small (restrictive) VSDs cause a high-velocity shunt flow (≈4.5-5 m/sec) because of the normally large systolic pressure difference between the ventricles. Lower peak shunt velocity (nonrestrictive VSD) implies increased RV systolic pressure, either from PS or pulmonary hypertension. Left heart dilation is evident when the shunt is large; RV dilation occurs uncommonly as most VSDs are located high in the interventricular septum with blood shunting nearly immediately into the RV outflow tract. Echocardiography should be repeated when patients reach adult size (usually approximately 1 year of age).

Cardiac catheterization, oximetry, and angiocardiography uncommonly are performed clinically but can allow measurement of intracardiac pressures, indicate the presence of an oxygen step-up at the level of the RV outflow tract, and show the pathway of abnormal blood flow.

Treatment and Prognosis

Small restrictive VSDs (less than 40% of aortic diameter, shunt velocity greater than 4.5 m/s) have an excellent prognosis; animals typically live a normal life span with no treatment required. There are sporadic reports of spontaneous VSD closure within the first 2 years of life, either from myocardial hypertrophy around the VSD or a seal formed by the septal tricuspid leaflet or a prolapsed aortic leaflet. Animals with large nonrestrictive VDSs (greater than 60% of aortic diameter, shunt velocity less than 4.0 m/s) have a more guarded prognosis; left-sided CHF is the most common outcome, although in some cases pulmonary hypertension with shunt reversal develops instead. Animals that develop clinical complications related to a large VSD typically display clinical signs at an early age. In a large retrospective case series of VSDs in dogs and cats, the vast majority of patients with VSDs (81%) were asymptomatic at time of diagnosis and remained asymptomatic throughout an average 12-year life span.

For asymptomatic patients with a small restrictive VSD, no treatment is indicated. For patients with a larger nonrestrictive VSD, left-sided CHF is managed medically when and if it occurs. Definitive therapy for large nonrestrictive VSDs generally requires cardiopulmonary bypass for open-heart surgery (patch grafting). Transcatheter delivery of an occlusion device can be successful in medium- to large-breed dogs with muscular VSDs; other VSD locations generally are less amenable to interventional closure due to proximity of the defect to the aortic or pulmonic valve. Historically, large left-to-right shunts sometimes have been palliated by surgically placing a constrictive band around the pulmonary trunk to create a mild supravalvular PS. This raises RV systolic pressure in response to the increased outflow resistance, decreasing shunt volume from the LV to RV. However, an excessively tight band can cause right-to-left shunting (functionally analogous to a T of F). Palliative surgery should not be attempted in the presence of pulmonary hypertension and shunt reversal.

ATRIAL SEPTAL DEFECT

Etiology and Pathophysiology

Several types of ASD exist. Those located in the region of the fossa ovalis (ostium secundum defects) are more common in dogs. An ASD in the lower interatrial septum (ostium primum defect) is likely to be part of the AV septal (endocardial cushion or common AV canal) defect complex, especially in cats. Other ASD locations (sinus venosus or coronary sinus defects) are rare. Animals with ASD commonly have other cardiac malformations as well. In most cases of ASD, blood shunts from the LA to RA and results in a volume overload to both the right heart and pulmonary circulation. However, if PS or pulmonary hypertension is present, right-to-left shunting and cyanosis can occur. Patent foramen ovale, where embryonic atrial septation has occurred normally but the overlap between the septum primum and septum secundum does not seal closed, is not considered a "true" ASD, but is a common cause of right-to-left shunting in the presence of abnormally high RA pressure (as in PS or pulmonary hypertension).

Clinical Features

The clinical history in animals with an ASD is usually nonspecific. Physical examination findings associated with an isolated ASD often are unremarkable. Because the pressure difference between right and left atria is minimal, no murmur is expected across the ASD, although large left-to-right shunts can cause a murmur of relative PS. Fixed splitting (i.e., with no respiratory variation) of the second heart sound (S_2) is the classic auscultatory finding, caused by delayed pulmonic and early aortic valve closures. Rarely, a soft diastolic murmur of relative tricuspid stenosis might be audible. Large ASDs can lead to signs of right-sided or biventricular CHF.

Diagnosis

Right heart enlargement, with or without pulmonary trunk dilation, is found radiographically in patients with large shunt volumes (see Table 5.2). Pulmonary overcirculation can be apparent unless pulmonary hypertension has developed. Left heart enlargement is not generally evident unless another defect such as mitral insufficiency is present. The ECG can be normal or show evidence of RV and RA enlargement.

Echocardiography is likely to show RA and RV dilation, with or without paradoxical interventricular septal motion; larger ASDs can be visualized. Care must be taken not to confuse the thinner fossa ovalis region of the interatrial septum with an ASD, because echo dropout also occurs here. Doppler echocardiography can allow identification of smaller shunts that cannot be clearly visualized on 2-D examination, but venous inflow streams can complicate this. An agitated saline contrast study can be used to identify right-to-left shunting ASDs. Although rarely performed clinically, cardiac catheterization shows an oxygen step-up at the level of the right atrium (RA). Abnormal flow through the shunt might be evident after the injection of contrast material into the pulmonary artery.

Treatment and Prognosis

Large shunts can be treated with open-heart surgery and patch-grafting under cardiopulmonary bypass, similarly to VSDs. Ostium secundum defects can sometimes be treated with transcatheter device occlusion depending on patient size, ASD size, and presence of an adequate rim of atrial septal tissue around the defect. Otherwise, animals are managed medically if CHF develops. The prognosis is variable and depends on shunt size, concurrent defects, and the level of pulmonary vascular resistance.

ATRIOVENTRICULAR VALVE MALFORMATION

MITRAL DYSPLASIA

Congenital malformations of the mitral valve apparatus can be variable and include the following: shortened, fused, or overly elongated chordae tendineae; direct attachment of the valve cusp to a papillary muscle; thickened, cleft, or shortened valve cusps; prolapse of valve leaflets; abnormally positioned or malformed papillary muscles; and excessive dilation of the valve annulus. Mitral valve dysplasia (MD) is most common in large-breed dogs and also occurs in cats; MD is the most common concurrent congenital malformation among dogs with SAS. Valvular regurgitation is the predominant functional abnormality, and it may be severe; the pathophysiology and sequelae resemble those of acquired mitral regurgitation (see p. 119). Left-sided CHF is the most common clinical manifestation. Mitral valve stenosis occurs uncommonly; when present, the ventricular inflow obstruction increases LA pressure and can precipitate the development of pulmonary edema. Mitral regurgitation usually accompanies stenosis.

Clinical signs associated with MD are similar to those seen with degenerative mitral valve disease, except for the younger patient age. Reduced exercise tolerance, respiratory signs of left-sided CHF, inappetence, and atrial arrhythmias (especially atrial fibrillation) are common in affected animals. Mitral regurgitation typically causes a holosystolic murmur heard best at the left apex. Animals with severe MD, especially those with stenosis, can also develop syncope with exertion, postcapillary pulmonary hypertension, and, occasionally, signs of right-sided (in addition to left-sided) CHF.

Radiographic, ECG, echocardiographic, and catheterization findings are similar to those of patients with acquired mitral insufficiency. Echocardiography can depict the specific mitral apparatus malformations, as well as the degree of chamber enlargement and functional changes. Animals with mitral stenosis have a typical mitral inflow pattern with prolonged high velocity, reflecting the diastolic pressure gradient between LA and LV.

Therapy consists of medical management for CHF. Animals with mild to moderate mitral valve dysfunction may do well clinically for years. However, for those with severe mitral regurgitation or stenosis, the prognosis is poor. Surgical valve reconstruction or replacement under cardiopulmonary bypass might be possible in some cases.

TRICUSPID DYSPLASIA

Animals with tricuspid dysplasia (TD) have variable malformations of the tricuspid valve and related structures, similar to those of MD. The tricuspid valve can be displaced ventrally into the ventricle (an Ebstein-like anomaly) in some cases. TD is identified most frequently in large-breed dogs, particularly in Labrador Retrievers, and in males; cats are also affected. Tricuspid valve dysplasia occurs concurrently with PS in some dogs.

The pathophysiologic features of TD are the same as those of acquired TR. Severe cases result in marked enlargement of the right heart chambers. Progressive increase in RA and RV end-diastolic pressures eventually result in right-sided CHF. Tricuspid stenosis can occur but is rare.

The historical signs and clinical findings likewise are similar to those of degenerative tricuspid disease. Initially, the animal may be asymptomatic. However, exercise intolerance, abdominal distention resulting from ascites, dyspnea resulting from pleural effusion, anorexia, and cardiac cachexia often develop. The right-sided holosystolic murmur of TR is characteristic. However, not all cases have an audible murmur because the dysplastic leaflets may gap so widely in systole that there is little resistance to backflow and therefore minimal turbulence. Jugular pulsations are common. Additional signs that accompany right-sided CHF include jugular vein distention, muffled heart and lung sounds, and ballotable abdominal fluid.

Radiographs demonstrate RA and RV enlargement. The round appearance of the heart shadow in some cases is similar to that seen in patients with pericardial effusion or dilated cardiomyopathy. A distended caudal vena cava, pleural or peritoneal effusion, and hepatomegaly suggest right-sided CHF.

RV and occasionally RA enlargement patterns are seen on ECG. A splintered QRS complex configuration may be seen. Atrial fibrillation or other atrial tachyarrhythmias occur commonly. Evidence for ventricular preexcitation is seen in some cases, particularly in patients with the Ebstein-like anomaly.

Echocardiography reveals right heart dilation, which can be massive. Malformations of the valve apparatus can be evident in several views (Fig. 5.9), although the left apical four-chamber view is especially useful. Doppler flow patterns are similar to those of MD. Intracardiac electrocardiography is necessary to confirm an Ebstein anomaly, which is suggested by ventral displacement of the tricuspid valve annulus; a ventricular electrogram recorded on the RA side of the valve is diagnostic. CHF and arrhythmias are managed medically. Periodic abdomino- or thoracocentesis may be necessary in animals with cavitary effusions that cannot be controlled with medication and diet. The prognosis depends on degree of valve dysfunction. Dogs with severe TR and marked cardiomegaly have a guarded to poor prognosis, but some dogs survive for many years. Surgical replacement of

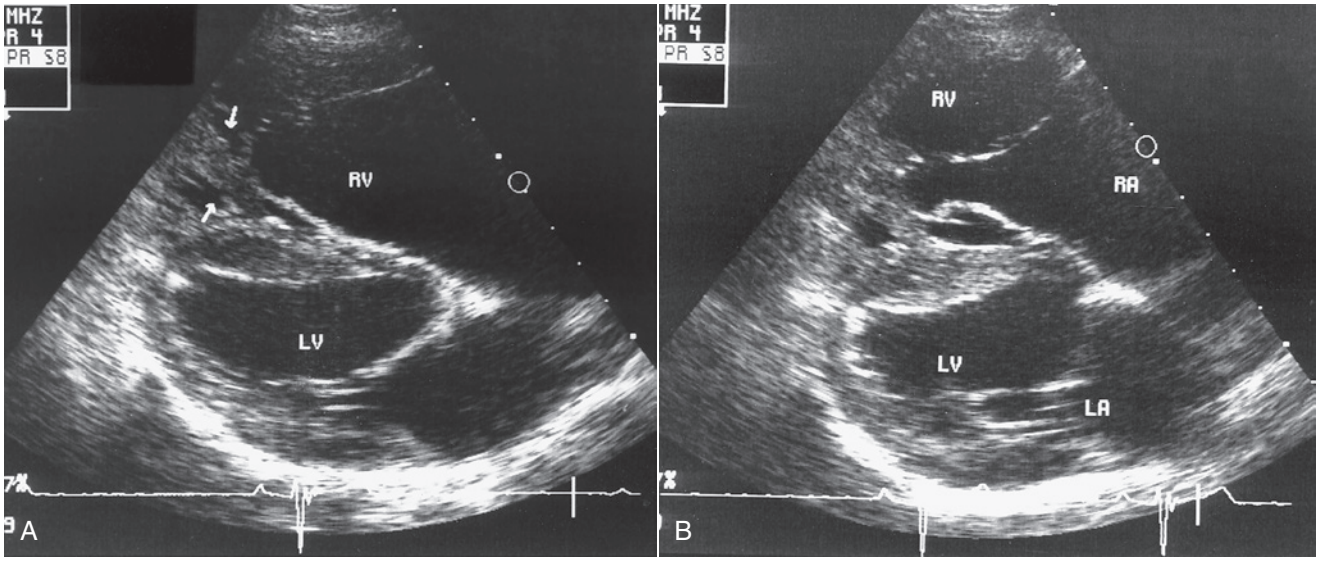

FIG 5.9
Right parasternal long-axis echo images from a 1-year-old male Labrador Retriever with tricuspid valve dysplasia in diastole **(A)** and systole **(B).** The valve annulus appears to be ventrally displaced; the leaflet tips are tethered to a malformed, wide papillary muscle (*arrows* in **A**). Wide leaflet tip separation in systole **(B)** caused severe tricuspid regurgitation and clinical congestive heart failure. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

the tricuspid valve under cardiopulmonary bypass has been described in a small number of dogs. Balloon dilation has occasionally been successful for treating tricuspid stenosis.

CARDIAC ANOMALIES CAUSING CYANOSIS

Malformations that allow deoxygenated blood to reach the systemic circulation (right-to-left shunts) result in hypoxemia. Right-to-left shunting requires (1) the presence of an anomalous connection between the systemic and pulmonary circulations, and (2) suprasystemic right heart pressures, usually due to pulmonary hypertension or PS. Visible cyanosis occurs when the desaturated hemoglobin concentration is greater than 5 g/dL. Arterial hypoxemia stimulates increased red blood cell production, leading to a compensatory erythrocytosis that increases oxygen carrying capacity. However, blood viscosity and resistance to flow also rise with the increase in PCV. Severe erythrocytosis (PCV ≥ 65%) results in hyperviscosity, which can lead to microvascular sludging, poor tissue oxygenation, intravascular thrombosis, hemorrhage, and cardiac arrhythmias. Erythrocytosis can become extreme, with a PCV of greater than 80% in some animals.

Usually the earliest clinical sign in animals with cyanotic heart disease is exercise-induced weakness or syncope. Such "hypercyanotic" events occur because exercise stimulates systemic vasodilation to increase blood flow to skeletal muscles; the resulting decrease in systemic vascular resistance transiently increases right-to-left shunt volume. Later complications of cyanotic heart disease generally are related to hyperviscosity associated with erythrocytosis, including metabolic and hemostatic abnormalities, seizures, and cerebrovascular accidents. The possibility of a venous embolus crossing the shunt to the systemic circulation poses another danger in these cases. Despite the pressure overload on the right heart, CHF is rare in cyanotic heart disease; the shunt provides an alternate pathway for high pressure flow.

Anomalies that most often cause cyanosis in dogs and cats include T of F, PS in conjunction with an intracardiac shunt (VSD or ASD), or pulmonary arterial hypertension in conjunction with an intracardiac or extracardiac shunt (PDA, VSD, or ASD). Other complex but uncommon anomalies such as transposition of the great vessels or truncus arteriosus also send deoxygenated blood to the systemic circulation.

TETRALOGY OF FALLOT

Etiology and Pathophysiology

T of F is classically defined by its four components: VSD, PS, a dextropositioned aorta, and RV hypertrophy. However, T of F is actually caused by a single embryologic defect: incomplete rotation and faulty partitioning of the conotruncus during septation of the great vessels. The malalignment of the aorta and pulmonary artery with respect to the interventricular septum causes a large nonrestrictive VSD, obstruction of the RV outflow tract (PS), and an aortic root that extends over the right side of the interventricular septum; all of these components facilitate RV-to-aortic shunting. The PS usually is subvalvular or infundibular, but can involve the valve; in some cases, the pulmonary artery is hypoplastic or

not open at all (atretic). RV hypertrophy occurs in response to the pressure overload imposed by the PS and systemic arterial circulation. The volume of blood shunted from the RV into the aorta depends on the balance of outflow resistance caused by the fixed PS compared with systemic arterial resistance, which varies with exercise and autonomic tone. Pulmonary vascular resistance is generally normal in animals with T of F. A polygenic inheritance pattern for T of F has been identified in the Keeshond. The defect also occurs in other dog breeds, particularly terrier breeds, and in cats.

Clinical Features

Exertional weakness, dyspnea, syncope, cyanosis, and stunted growth are common in the history. Physical examination findings are variable, depending on the relative severity of the malformations. Cyanosis may be seen at rest in some animals, whereas others are cyanotic only with exercise. The precordial impulse is usually of equal intensity or stronger on the right chest wall than on the left. A holosystolic murmur at the right sternal border consistent with a VSD, a systolic ejection murmur at the left base compatible with PS, or both may be heard on auscultation. However, some animals have no audible murmur because hyperviscosity associated with erythrocytosis diminishes blood turbulence and therefore murmur intensity.

Diagnosis

Thoracic radiographs depict variable cardiomegaly, usually of the right heart (see Table 5.2). The main pulmonary artery usually appears small, in contrast to typical valvular PS. Reduced pulmonary vascular markings are common. The malpositioned aorta can create a cranial bulge in the heart shadow on lateral view. RV hypertrophy causes dorsal displacement of the cardiac apex on lateral views and an upturned cardiac apex on VD views, leading to a classically described "boot-shaped" heart. The ECG typically suggests RV enlargement, although a left axis deviation has been seen in some affected cats.

Echocardiography depicts the VSD, a large aortic root shifted rightward and overriding the ventricular septum, PS, and RV hypertrophy. Doppler studies reveal the right-to-left shunt and high-velocity stenotic pulmonary outflow jet. An echo-contrast study can also document the right-to-left shunt. Typical clinicopathologic abnormalities include increased PCV and arterial hypoxemia.

Treatment and Prognosis

Definitive repair of T of F requires open-heart surgery. Palliative surgical procedures can increase pulmonary blood flow by creating a left-to-right shunt. Anastomosis of a subclavian artery to the pulmonary artery (a modified Blalock-Taussig shunt) is the most commonly used palliative procedure in small animals.

Severe erythrocytosis and clinical signs associated with hyperviscosity (e.g., weakness, shortness of breath, seizures) can be treated with periodic phlebotomy (see p. 116) or, alternatively, hydroxyurea (see p. 116). The goal is to maintain PCV at a level where clinical signs are minimal (a general goal is 62%-65%); further reduction of PCV (into the normal range) can exacerbate signs of hypoxia. A β-blocker such as atenolol or propranolol might help reduce clinical signs in some dogs with T of F by decreasing sympathetic tone, RV (muscular) outflow obstruction, and myocardial oxygen consumption. Additionally, β-blockers help limit exercise-induced peripheral vasodilation that can exacerbate right-to-left shunting and cause hypercyanotic episodes. Exercise restriction is also advised. Drugs with systemic vasodilator effects should not be given. Supplemental O_2 has negligible benefit in patients with T of F.

The prognosis for animals with T of F depends on the severity of PS and erythrocytosis. Mildly affected animals and those that have had a successful palliative surgical shunting procedure may survive well into middle age. Nevertheless, progressive hypoxemia, erythrocytosis, and sudden death at an earlier age are common. Overall median survival time following diagnosis is approximately 2 years.

PULMONARY HYPERTENSION WITH SHUNT REVERSAL

Etiology and Pathophysiology

In dogs and cats, pulmonary overcirculation typically results in left-sided CHF. Left-to-right shunts rarely lead to reactive vasoconstriction and pulmonary arterial hypertension in small animals, because the low-resistance pulmonary vascular system (with significant capacity for collateral circulation) normally can accept a large increase in blood flow without marked rise in pulmonary arterial pressure. However, a small percentage of dogs and cats with shunts do develop pulmonary arterial hypertension causing shunt reversal (right-to-left shunting). It is not clear why pulmonary hypertension develops in some animals, although the defect size in affected animals is usually quite large. Possibly the high fetal pulmonary resistance may not regress normally in these animals, or their pulmonary vasculature may react abnormally to an initially large left-to-right shunt flow. In any case, irreversible histologic changes are present in the pulmonary arteries that increase vascular resistance. These include intimal thickening, medial hypertrophy, and characteristic plexiform lesions.

As pulmonary vascular resistance increases, pulmonary artery pressure rises and the extent of left-to-right shunting diminishes. If right heart and pulmonary pressures exceed those of the systemic circulation, the shunt reverses direction and deoxygenated blood flows into the aorta. These changes typically develop in very young animals (usually by 6 months of age), supporting the notion that pulmonary hypertension in these cases may represent retention of fetal pulmonary vascular resistance. The term *Eisenmenger physiology* refers to severe pulmonary hypertension with shunt reversal; affected animals with clinical signs sometimes are described as having *Eisenmenger syndrome*.

Right-to-left shunts that result from pulmonary hypertension cause pathophysiologic and clinical sequelae similar

to those resulting from T of F. The major difference is that the impediment to pulmonary flow occurs at the level of the pulmonary arterioles rather than at the pulmonic valve. Clinical manifestations include hypoxemia, cyanosis (worsened with exercise), RV hypertrophy and enlargement, and erythrocytosis and its sequelae. Right-sided CHF is uncommon but can develop in response to secondary myocardial failure or tricuspid insufficiency. The right-to-left shunt potentially allows venous emboli to cross into the systemic arterial system and cause stroke or other arterial embolization.

Clinical Features

The history and clinical presentation of animals with pulmonary hypertension and shunt reversal are similar to those associated with T of F. Exercise intolerance, shortness of breath, syncope (especially in association with exercise or excitement), and sudden death are common. Cyanosis might be evident only during exercise or excitement. Intracardiac shunts cause equally intense cyanosis throughout the body, whereas a reversed PDA causes cyanosis of the caudal mucous membranes alone (differential cyanosis). In reversed PDA, normally oxygenated blood flows to the cranial body via the brachycephalic trunk and left subclavian artery (from the aortic arch); because the ductus is located in the descending aorta, the caudal body receives desaturated blood (Fig. 5.10). Rear limb weakness is common in animals with reversed PDA.

A murmur typical of the underlying defect(s) might be heard. However, in many cases, no murmur is audible because right and left heart pressures are nearly equivalent, minimizing pressure gradient and thus velocity of shunting blood flow. Additionally, high blood viscosity caused by erythrocytosis minimizes turbulence. There is no continuous murmur in patients with reversed PDA. Pulmonary hypertension often causes a loud and "snapping" or split S_2 sound. Other physical examination findings can include a pronounced right precordial impulse and jugular pulsations.

Diagnosis

Thoracic radiographs typically reveal right heart enlargement, a prominent pulmonary trunk, and tortuous, proximally widened pulmonary arteries. A bulge in the descending aorta is common in dogs with reversed PDA. In animals with a reversed PDA or VSD, the left heart may be enlarged as well. The ECG usually suggests RV and sometimes RA enlargement, with a right axis deviation.

Echocardiography reveals the RV hypertrophy, intracardiac anatomic defects, and sometimes a large ductus, as well

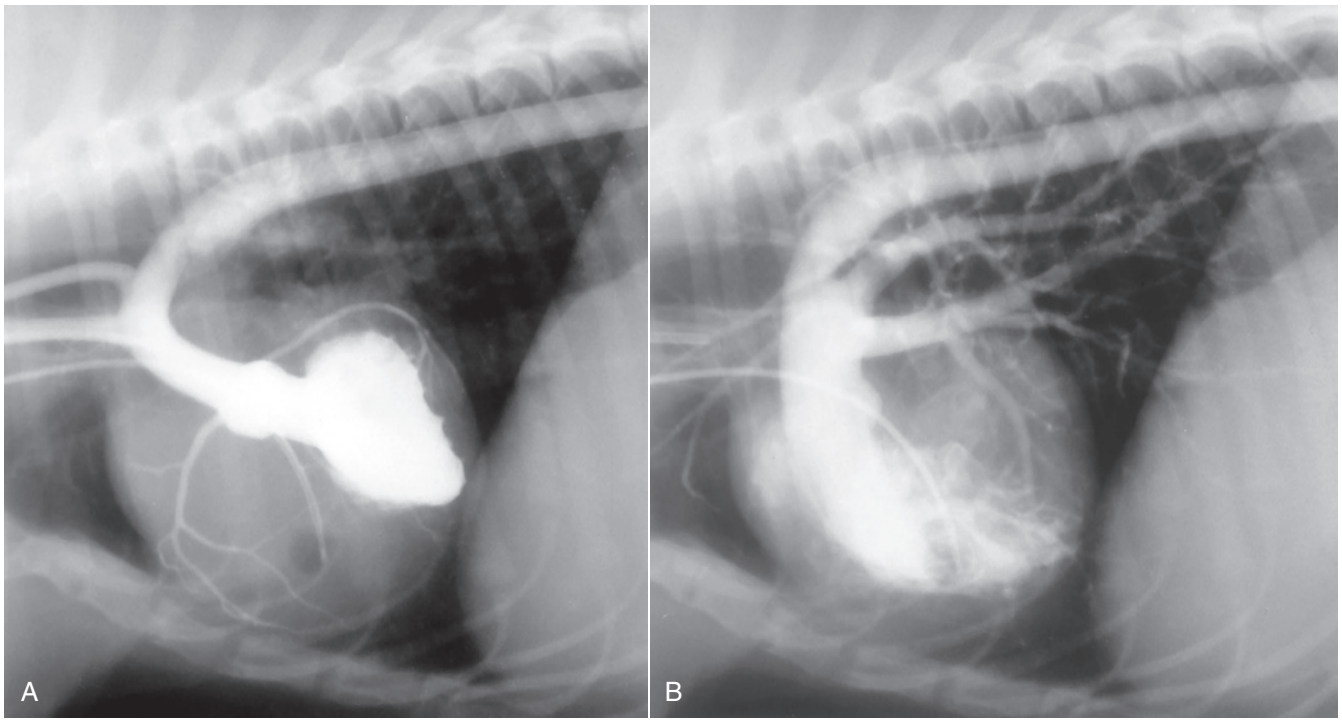

FIG 5.10
Angiocardiograms from an 8-month-old female Cocker Spaniel with patent ductus arteriosus, pulmonary hypertension, and shunt reversal. Left ventricular injection **(A)** shows dorsal displacement of the left ventricle by the enlarged right ventricle. Note the dilution of radiographic contrast solution in the descending aorta (from mixing with nonopacified blood from the ductus) and the prominent right coronary artery. Right ventricular injection **(B)** illustrates right ventricular hypertrophy and pulmonary trunk dilation secondary to severe pulmonary hypertension. Opacified blood courses through the large ductus into the descending aorta.

as pulmonary trunk dilation. Doppler or echo-contrast study can confirm an intracardiac right-to-left shunt. Imaging the abdominal aorta during venous echo-contrast injection can show reversed PDA flow. Peak RV (and in the absence of PS, pulmonary artery) pressure can be estimated by measuring the peak velocity of a TR jet. Pulmonary insufficiency flow can be used to estimate diastolic pulmonary artery pressure. Cardiac catheterization can confirm the diagnosis and quantify the pulmonary hypertension and systemic hypoxemia.

Treatment and Prognosis

Therapy is aimed at reducing pulmonary arterial pressure, as well as managing secondary erythrocytosis to minimize signs of hyperviscosity. Exercise restriction is also advised.

Sildenafil citrate is a selective phosphodiesterase-5 inhibitor that reduces pulmonary resistance via nitric oxide–dependent pulmonary vasodilation. It can reduce the degree of right-to-left shunting in dogs with pulmonary hypertension, leading to improved clinical signs and exercise tolerance, as well as decreased erythrocytosis. Doses of 1 to 3 mg/kg q12h or q8h generally are well tolerated and may produce some reduction in Doppler-estimated pulmonary artery pressure. Adverse effects of sildenafil can include possible hypotension, cutaneous flushing, nasal congestion, or sexual adverse effects, especially in intact animals. Other vasodilator drugs tend to produce systemic effects that are similar to or greater than those on the pulmonary vasculature; therefore they are of little benefit and possibly detrimental.

Erythrocytosis can be managed by periodic phlebotomy or use of oral hydroxyurea. Ideally, the PCV is maintained at a level where the patient's signs of hyperviscosity (e.g., rear limb weakness, shortness of breath, lethargy) are minimal. A PCV of about 62% to 65% has been recommended, but this may not be optimal for all cases.

One method of performing phlebotomy is to remove 5 to 10 mL blood per kilogram of body weight. Another calculation involves removing blood volume in relation to actual and desired hematocrit as follows: Phlebotomy volume = body weight (kg) × 0.08 (percent blood volume) × 1000 mL/kg × (actual hematocrit – desired hematocrit)/(actual hematocrit). Regardless of which calculation is chosen, it is generally advisable to replace the blood with an equal volume of isotonic fluid to avoid significant hemodynamic shifts. In most patients with marked erythrocytosis, a large bore needle (>18G) must be used.

Hydroxyurea therapy (40-50 mg/kg by mouth q48h or 3×/week) can be a useful alternative to periodic phlebotomy in patients with secondary erythrocytosis. A complete blood cell count and platelet count should be monitored weekly or biweekly to start. Possible adverse effects of hydroxyurea include anorexia, vomiting, bone marrow hypoplasia causing cytopenias, alopecia, and pruritus. Depending on the patient's response, the dose can be divided q12h on treatment days, administered twice weekly, or administered at less than 40 mg/kg.

The prognosis is generally poor in animals with pulmonary hypertension and shunt reversal, although some patients do well for years with medical management. Surgical closure of a reversed shunt is generally contraindicated, because the shunt acts as a "pop-off" valve for high pulmonary and right heart pressures. The acute increase in PA pressure following shunt correction can cause RV myocardial failure and death. Shunt correction can only be considered if sildenafil therapy effectively lowers PA pressure below systemic pressure such that the shunt direction becomes left to right. There are rare reports of successful correction of reversed PDAs following sildenafil therapy.

OTHER CARDIOVASCULAR ANOMALIES

VASCULAR RING ANOMALIES

Various vascular malformations originating from the embryonic aortic arch system can occur. These can entrap the esophagus and sometimes the trachea within a vascular ring at the dorsal heart base. Persistent right aortic arch is the most common vascular ring anomaly in the dog. This developmental malformation surrounds the esophagus dorsally and to the right with the aortic arch, to the left with the ligamentum arteriosum, and ventrally with the base of the heart. Different vascular ring anomalies can occur as well. In addition, other vascular malformations such as a left cranial vena cava or PDA may accompany a vascular ring anomaly. Vascular ring anomalies are rare in cats.

The vascular ring prevents solid food from passing normally through the esophagus. Clinical signs of regurgitation and stunted growth commonly develop within 6 months of weaning. Esophageal dilation occurs cranial to the ring; food may be retained in this area. Sometimes the esophagus dilates caudal to the stricture as well, indicating that altered esophageal motility coexists.

The animal's body condition score may be normal initially, but progressive debilitation ensues. A palpably dilated cervical esophagus (containing food or gas) is evident at the thoracic inlet in some cases. Fever and respiratory signs including coughing, wheezing, and cyanosis usually signal secondary aspiration pneumonia. However, in some cases a double aortic arch can cause stridor and other respiratory signs secondary to tracheal stenosis. Vascular ring anomalies by themselves do not result in abnormal cardiac sounds.

Thoracic radiographs show a leftward tracheal deviation near the cranial heart border on DV view. Other common signs include a widened cranial mediastinum, focal narrowing and/or ventral displacement of the trachea, air or food in the cranial thoracic esophagus, and sometimes evidence of aspiration pneumonia. A barium swallow allows visualization of the esophageal stricture over the heart base and cranial esophageal dilation (with or without caudal esophageal dilation).

Surgical division of the ligamentum arteriosum (or other vessel if the anomaly is not a persistent right aortic arch) is the recommended therapy. In some cases, a retroesophageal left subclavian artery or left aortic arch is also present and must be divided to free the esophagus. Medical management

consists of frequent small, semisolid, or liquid meals eaten in an upright position. This feeding method may be necessary indefinitely. Persistent regurgitation occurs in some dogs despite successful surgery, suggesting a permanent esophageal motility disorder.

COR TRIATRIATUM

Cor triatriatum is an uncommon malformation caused by an abnormal membrane that divides either the right (dexter) or the left (sinister) atrium into two chambers. Cor triatriatum dexter occurs sporadically in dogs, often in combination with PS. Cor triatriatum sinister has been described rarely in cats; functional consequences are similar to mitral valve stenosis.

Cor triatriatum dexter results from failure of the embryonic right sinus venosus valve to regress. The caudal vena cava and coronary sinus empty into the RA caudal to the intra-atrial membrane; the tricuspid orifice is within the cranial RA "chamber." Obstruction to venous flow through the opening in the abnormal membrane elevates vascular pressure in the caudal vena cava and the structures that drain into it.

Large- to medium-size breeds of dog are most often affected. Persistent ascites that develops at an early age is the most prominent clinical sign. Exercise intolerance, lethargy, distended cutaneous abdominal veins, and sometimes diarrhea are reported as well. Neither a cardiac murmur nor jugular venous distention is a feature of this anomaly.

Thoracic radiographs indicate caudal vena cava distention without generalized cardiomegaly. The diaphragm may be displaced cranially by massive ascites. The ECG usually is normal. Echocardiography reveals the abnormal membrane and prominence of the caudal RA chamber and vena cava. Doppler studies show the flow disturbance within the RA and allow estimation of the intra-RA transmembrane pressure gradient.

Successful therapy requires enlarging the membrane orifice or excising the abnormal membrane to remove flow obstruction. A minimally invasive option is percutaneous balloon dilation of the membrane orifice. A small cutting balloon can be used to score the orifice opening before dilation with a larger balloon. Alternatively, a surgical approach using inflow occlusion, with or without hypothermia, can be used to excise the membrane or break it down using a valve dilator.

ENDOCARDIAL FIBROELASTOSIS

Diffuse fibroelastic thickening of the LV and LA endocardium, with dilation of the affected chambers, characterizes endocardial fibroelastosis. This congenital abnormality has been reported occasionally in cats, especially Burmese and Siamese. Left-sided or biventricular heart failure commonly develops early in life. A mitral regurgitation murmur may be present. Criteria for LV and LA enlargement are seen on radiographs, ECG, and echocardiogram. Evidence for reduced LV myocardial function may be present. Definitive antemortem diagnosis is difficult.

OTHER VASCULAR ANOMALIES

A number of venous anomalies have been described, but most are not clinically relevant. The persistent left cranial vena cava is a fetal venous remnant that courses lateral to the left AV groove and empties into the coronary sinus of the caudal RA. Although it causes no clinical signs, its presence may complicate surgical exposure of other structures at the left heart base. Portosystemic venous shunts are common and can lead to hepatic encephalopathy, as well as other signs. These malformations are thought to be more prevalent in the Yorkshire Terrier, Pug, Miniature and Standard Schnauzers, Maltese, Pekingese, Shih Tzu, and Lhasa Apso breeds and are discussed in Chapter 38.

CHAPTER 6

Acquired Valvular and Endocardial Disease

DEGENERATIVE ATRIOVENTRICULAR VALVE DISEASE

Chronic degenerative atrioventricular (AV) valve disease is the most common cause of heart failure in the dog; it is estimated to cause more than 70% of the cardiovascular disease recognized in this species. Almost all small-breed dogs develop some degree of valve degeneration as they age; many dogs of larger breeds do as well. Degenerative valve disease also has been called endocardiosis, mucoid or myxomatous valvular degeneration, chronic valvular fibrosis, and other names. Because clinically relevant degenerative valve disease is rare in cats, this chapter focuses on canine chronic valvular disease. The mitral valve is affected most often and to a greater degree, therefore degenerative valve disease usually is referred to as chronic (or degenerative or myxomatous) mitral valve disease (CMVD). Degenerative lesions also affect the tricuspid valve in many dogs; however, isolated tricuspid involvement is uncommon. Thickening of the aortic and pulmonic valves sometimes is observed in older animals but rarely causes more than mild insufficiency.

The preclinical phase of CMVD is prolonged. Early valve lesions are evident only on post-mortem exam. As the degenerative process continues, valve insufficiency (regurgitation) with progressively worsening mitral regurgitation (MR) and volume overloading of the adjacent atrium and ventricle eventually develop over a period of years. Although many affected dogs do develop congestive heart failure (CHF) and other complications, many others do not.

ETIOLOGY AND PATHOPHYSIOLOGY

Multiple factors are involved in the development of CMVD. Although the structural and cellular changes have been fairly well delineated, the molecular mechanisms and biochemical changes involved are less clear. Studies have shown differential expression of multiple genes, with some being upregulated and others downregulated. Affected genes appear related to cell signaling, metabolism, extracellular matrix, inflammation, cardiovascular development, basement membrane structure, and other functions. Some functions of downregulated genes relate to formation of force-resistant collagen bundles, basement membrane structure, matrix metalloproteinases involved in collagen maturation and elastic fiber formation, and sarcoplasmic reticular calcium reuptake.

Chronic mechanical stress on valve leaflet edges from repeated impact is thought to play a role in initiating the myxomatous degeneration process. Subsequent alterations in valve interstitial and endothelial cell phenotype and function are important to this process. These changes cause disruptions in normal extracellular matrix homeostatic mechanisms, leading to characteristic changes in the organization, quantity, and distribution of extracellular matrix components. The major mediator of myxomatous degeneration appears to be activated valve interstitial cells, which become transformed from their normal fibroblastic phenotype into a myofibroblastic, α-smooth muscle actin-positive staining form (αSMA). The increase in these transformed cells promotes valve matrix remodelling. Altered activity of the various catabolic extracellular matrix enzymes (such as matrix metalloproteinases, collagenases, and elastases) occurs during the process of valve degeneration, which leads to increased collagen, decreased elastin, and increasing valve stiffness. Transforming growth factor-β (TGF-β) and serotonin (5-HT) signaling also appear to be involved in CMVD pathogenesis. Localized production of TGF-β occurs in affected valves, and expression of TGF-β subtypes and their receptors is increased. Through a mechanism involving TGF-β, 5-HT induces the transformation of valve interstitial cells into their activated form. Valve endothelial cell signaling, basement membrane damage, phenotypic changes in valve endothelial cells, and increased release of vasoactive substances are involved in the pathogenesis of CMVD. Several mediators are known to increase activity of matrix metalloproteinases, including angiotensin II, endothelin, norepinephrine and other catecholamines, tumor necrosis factor (TNF)α, interleukin-1β, and possibly oxidative and mechanical stresses.

Progressive thickening of the valve spongiosa layer occurs as deposition of glycosaminoglycans (GAGs), proteoglycans,

and other components increases. In addition, the normal layered arrangement of collagen within the valve fibrosa layer becomes altered and attenuated, as GAG infiltration disrupts collagen bundles. Altered collagen fiber orientation within the valve leaflets affects mechanical strain forces during the cardiac cycle, and, in turn, influences various cellular functions. The altered collagen fibril organization results in mechanically weaker and less flexible valves. Myxomatous changes are most severe in the free edge to distal third of the valve leaflets. The leaflets thicken and lengthen as CMVD progresses. Myxomatous degeneration of the chordae reduces their tensile strength and can predispose to rupture.

Gross pathologic valve changes develop gradually with age. Early lesions consist of small nodules on the free margins of the valve. Over time these become larger, coalescing plaques that thicken and distort the valve. This myxomatous interstitial degeneration causes valvular nodular thickening and deformity, weakening the valve and its chordae tendineae. Redundant tissue between chordal attachments often bulges (prolapses) like a parachute toward the atrium. Mitral valve prolapse may be important in the pathogenesis of the disease, at least in some breeds. In severely affected regions, the valve surface also becomes damaged, and endothelial cells are lost in some areas. Despite loss of valvular endothelial integrity, however, thrombosis and endocarditis are rare complications.

Affected valves gradually begin to leak because their edges do not coapt properly. Regurgitation usually develops slowly over months to years. Pathophysiologic changes relate to volume overload on the affected side of the heart after the valve or valves become incompetent, with progressive atrial and ventricular chamber enlargement. Mean atrial pressure usually remains fairly low during this time, unless a sudden increase in regurgitant volume (e.g., ruptured chordae) occurs. Secondary atrial jet lesions and endocardial fibrosis then develop. In patients with advanced disease, partial- or even full-thickness atrial tears can form. As valve degeneration worsens, a progressively larger volume of blood moves ineffectually back and forth between the ventricle and atrium, diminishing the forward flow to the aorta. Compensatory neurohormonal mechanisms are activated and augment blood volume to meet the circulatory needs of the body (see Chapter 3); these include increased sympathetic activity and renin-angiotensin-aldosterone system (RAAS) activation. Natriuretic peptide production also increases in advanced disease.

Dilation and remodeling of the affected ventricle (and atrium) gradually occurs in response to growing end-diastolic wall stress. A multitude of changes in left ventricular (LV) gene expression have been shown, many related to upregulated proinflammatory responses, collagen degradation, and reduced interstitial matrix production. The LV remodeling process is characterized by degradation and loss of the normal collagen weave between the cardiomyocytes, thought largely due to increased production of matrix metalloproteinases and chymase from mast cells. Chymase, rather than angiotensin-converting enzyme (ACE), is the enzyme responsible for interstitial production of angiotensin II in the myocardium, which contributes to continued ventricular remodeling. The interstitial collagen loss allows myocardial fiber slippage and, along with myocardial cell elongation, hypertrophy, and changes in LV geometry, produces the typical progressive eccentric (dilation) hypertrophy pattern of chronic volume overloading. Stretching of the valve annulus as the ventricle dilates contributes to further valve regurgitation and volume overload.

The compensatory changes in heart size and blood volume allow most dogs to remain asymptomatic for a prolonged period. Left atrial (LA) enlargement may become massive before any signs of decompensation appear, and some dogs never show clinical signs of heart failure. The rate at which the regurgitation worsens, as well as the degree of atrial distensibility and ventricular contractility, influences how well the disease is tolerated. A gradual increase in atrial, pulmonary venous, and capillary hydrostatic pressures stimulates compensatory increases in pulmonary lymphatic flow. Overt pulmonary edema develops when the capacity of the pulmonary lymphatic system is exceeded. Pulmonary hypertension (PH) secondary to chronically increased LA and pulmonary venous pressure, and worsening tricuspid regurgitation (TR) can lead to right-sided CHF signs. In addition to pulmonary venous hypertension, other factors contributing to increased pulmonary vascular resistance can include hypoxic pulmonary arteriolar vasoconstriction, impaired endothelium-dependent vasodilation, and chronic neurohumoral activation.

Ventricular pump function usually is maintained fairly well until late in the disease, even in the face of severe congestive signs. Nevertheless, studies of isolated myocardial cells from dogs with subclinical MR show reduced contractility, abnormal Ca^{++} kinetics, and evidence of oxidative stress. Progressive myocardial dysfunction exacerbates ventricular dilation and valve regurgitation and therefore can worsen CHF. Assessment of LV contractility in animals with MR is complicated by the fact that the commonly used clinical indices (echocardiographic fractional shortening or ejection fraction) overestimate contractility because they are obtained during ejection and are therefore affected by the reduced ventricular afterload caused by MR. Estimation of the end-systolic volume index (ESVI) and some other echo/Doppler indices also can be helpful in assessing LV systolic and diastolic function (see p. 25).

Chronic valvular disease also is associated with intramural coronary arteriosclerosis, microscopic intramural myocardial infarctions, and focal myocardial fibrosis. The extent to which these changes cause clinical myocardial dysfunction is not clear because senior dogs without valvular disease also have similar vascular lesions.

COMPLICATING FACTORS

Although CMVD usually progresses slowly, certain complicating events can precipitate acute clinical signs in dogs with previously compensated disease (Box 6.1). For example,

BOX 6.1

Potential Complications of Chronic Mitral Valve Disease

Causes of Acutely Worsened Pulmonary Edema

- Arrhythmias
  - Frequent atrial premature complexes
  - Paroxysmal atrial/supraventricular tachycardia
  - Atrial fibrillation
  - Frequent ventricular tachyarrhythmias
- Ruptured chordae tendineae
- Iatrogenic volume overload
  - Excessive volumes of IV fluids or blood
  - High-sodium fluids
- Erratic or improper medication administration
- Insufficient medication for stage of disease
- Increased cardiac workload
  - Physical exertion
  - Anemia
  - Infections/sepsis
  - Hypertension
  - Disease of other organ systems (e.g., pulmonary, renal, liver, endocrine)
  - Hot, humid environment
  - Excessively cold environment
  - Other environmental stresses
  - High salt intake
  - Myocardial degeneration and poor contractility

Causes of Reduced Cardiac Output or Weakness

- Arrhythmias (see previously)
- Ruptured chordae tendineae
- Cough-syncope
- Pulmonary hypertension
- Secondary right-sided heart failure
- Left atrial tear
  - Intrapericardial bleeding
  - Cardiac tamponade
- Myocardial degeneration and poor contractility
- Hypertension
- Anemia or other systemic disease

tachyarrhythmias may be severe enough to cause decompensated CHF, syncope, or both. Frequent atrial premature contractions, paroxysmal atrial tachycardia, or atrial fibrillation can reduce ventricular filling time and cardiac output, increase myocardial oxygen needs, and worsen pulmonary congestion and edema. Ventricular tachyarrhythmias also occur but are less common.

Acute rupture of diseased chordae tendineae acutely increases regurgitant volume and can quickly precipitate fulminant pulmonary edema and signs of low cardiac output in previously asymptomatic or compensated dogs. Ruptured minor chordae tendineae can be an incidental finding in some dogs. Marked LA enlargement itself might contribute to left mainstem bronchus compression or collapse, and stimulate persistent coughing even in the absence of CHF. Concurrent airway inflammatory disease and bronchomalacia are common in small-breed dogs with chronic MR.

Massive left (or right) atrial distention can result in partial- or full-thickness tearing. Atrial wall rupture can cause acute cardiac tamponade or an acquired atrial septal defect. There appears to be a higher prevalence of this complication in male Cocker Spaniels, Dachshunds, and possibly Miniature Poodles. In Cavalier King Charles Spaniels, the prevalence seems to be similar between females and males. Severe valve disease, marked atrial enlargement, atrial jet lesions, and ruptured first-order chordae tendineae are common findings in these cases.

CLINICAL FEATURES

Middle-aged and older small to mid-size breeds are most often affected; a strong hereditary basis is thought to exist, and disease prevalence and severity increase with age. The majority of small-breed dogs older than 10 years of age are affected. Common breeds include Cavalier King Charles Spaniels, Toy and Miniature Poodles, Miniature Schnauzers, Chihuahuas, Pomeranians, Fox Terriers, Cocker Spaniels, Pekingese, Dachshunds, Boston Terriers, Miniature Pinschers, and Whippets. An especially high prevalence and early onset of CMVD occurs in Cavalier King Charles Spaniels, in which the disease is suspected to be a complex autosomal polygenic trait with variable penetrance. The overall prevalence of MR murmurs and degenerative valve disease appears similar in male and female dogs, but males have earlier onset and faster disease progression. Some large-breed dogs are also affected, although the degree of valve thickening and prolapse tends to be less pronounced than in small-breed dogs. German Shepherd Dogs may be overrepresented. Larger-breed dogs also are prone to dilated cardiomyopathy (DCM, which may coexist) or are more susceptible to myocardial dysfunction secondary to chronic volume overload.

Many dogs with CMVD have no clinical signs, even with fairly advanced disease. In those that do, early signs of CHF usually include reduced exercise tolerance, and tachypnea or cough with exertion. Because a persistent increase in baseline respiratory rate (RR) often signals the onset of pulmonary interstitial edema before other signs develop, owner monitoring of resting (sleeping) RR is useful even in dogs with early evidence of disease (see Chapter 3, p. 74). Coughing might occur at night and in the early morning, as well as with activity. However, the genesis of coughing in many dogs with CMVD could relate more to concurrent chronic airway disease, rather than CHF itself. A study of dogs with CMVD showed CHF (as assessed by radiographic evidence of pulmonary edema) was not significantly associated with coughing; however, an abnormal airway pattern as well as enlarged LA size were. A persistent cough without progressive increase in RR and effort usually is associated with airway disease, rather than CHF. The cough caused by airway compression or collapse often is described as dry or "honking." Severe pulmonary edema causes obvious respiratory distress, often with a soft, moist cough. Signs of severe pulmonary edema can develop gradually or acutely. Intermittent episodes of symptomatic pulmonary edema interspersed with periods of

compensated heart failure occurring over months to years are also common.

Episodes of transient weakness or acute collapse (syncope) are more common in dogs with advanced disease. These could occur from tachyarrhythmias, an acute vasovagal response, PH, or an atrial tear. Coughing spells can precipitate syncope, as can exercise or excitement. Signs of right-sided CHF usually are associated with severe TR, PH, or both. These include abdominal distension (ascites, hepatomegaly) and respiratory distress from pleural effusion. Gastrointestinal (GI) signs could accompany splanchnic congestion. Only rarely does noticeable peripheral tissue edema develop in dogs with CMVD.

The typical auscultatory finding is a holosystolic murmur heard best in the area of the left apex (left fourth to sixth intercostal space). The murmur can radiate in any direction. Mild regurgitation can be inaudible or cause a murmur only in early systole (protosystolic). Exercise and excitement often increase the intensity of soft MR murmurs. Louder murmurs have been associated with more advanced disease; in dogs with massive regurgitation and severe heart failure, however, the murmur can be soft or even inaudible. Occasionally, the murmur sounds like a musical tone or whoop. Some dogs with early MVD have an audible mid- to late-systolic click, with or without a soft murmur. In dogs with advanced disease and myocardial failure, an S_3 gallop might be audible at the left apex. TR typically causes a holosystolic murmur best heard at the right apex. Features that aid in differentiating a TR murmur from radiation of an MR murmur to the right chest wall include jugular vein pulsations, a precordial thrill over the right apex, and a different quality to the murmur heard over the tricuspid region.

Pulmonary sounds can be normal or abnormal. Accentuated, harsh breath sounds and end-inspiratory crackles (especially in ventral lung fields) develop as pulmonary edema worsens. Fulminant pulmonary edema causes widespread inspiratory, as well as expiratory, crackles and wheezes. Some dogs with chronic MR have abnormal lung sounds caused by underlying pulmonary or airway disease rather than CHF. Although not a pathognomonic finding, dogs with CHF often have sinus tachycardia, whereas marked sinus arrhythmia is common in those with chronic pulmonary disease. Pleural effusion may cause diminished pulmonary sounds ventrally.

Other physical examination findings may be normal or noncontributory. Heart rate and rhythm generally are normal, although sinus tachycardia is more typical as CHF develops. Arrhythmias are more likely to occur with advanced disease. Peripheral capillary perfusion and arterial pulse strength usually are good, although pulse deficits might be present in dogs with tachyarrhythmias. A palpable precordial thrill accompanies loud (grade 5-6/6) murmurs. Jugular vein distention and pulsations are not expected in dogs with MR alone. In animals with TR, especially PH, jugular pulses occur during ventricular systole; these are more evident after exercise or in association with excitement. Jugular venous distention results from elevated right heart filling pressures. Jugular pulsations and distention are more evident with cranial abdominal compression (positive hepatojugular reflux). Ascites or hepatomegaly may be evident in dogs with right-sided CHF.

Concurrent diseases that could be confused with decompensated CHF from CMVD include tracheal collapse, chronic bronchitis, bronchiectasis, pulmonary fibrosis, pulmonary neoplasia, pneumonia, pharyngitis, heartworm disease, DCM in larger breeds, and infective endocarditis (which is rare with CMVD).

DIAGNOSIS

CLINICOPATHOLOGIC FINDINGS

Routine clinical laboratory tests often are normal or reflect changes consistent with CHF or concurrent extracardiac disease. Elevations in natriuretic peptide concentrations tend to reflect increasing disease severity. Dogs with high levels (e.g., NT-proBNP ≥ 1500 pmol/L) are more likely to have CHF (or develop it sooner) and have a worse prognosis. Elevations in circulating cardiac troponin I (cTnI) also occur in moderate to severe CMVD and increase with severity of clinical signs. This could be a marker for myocardial fibrosis in chronic heart disease.

RADIOGRAPHY

Thoracic radiographs are normal in dogs with early (stage B1) CMVD. As MR severity increases, progressive LA and then LV enlargement develops (stage B2), usually over a period of years (Fig. 6.1). Dorsal elevation of the carina and, as LA size increases, dorsal main bronchus displacement occur. Severe LA enlargement can cause the appearance of carina and left mainstem bronchus compression (Fig. 6.1, *C*). Fluoroscopy might demonstrate dynamic airway collapse (of the left main bronchus or other regions) during coughing or even quiet breathing because concurrent airway disease is common in these cases. Extreme dilation of the LA can result over time, even without clinical heart failure. The vertebral heart score (VHS) increases with the growing volume overload. In coughing dogs with CMVD, a VHS ≤ 11.4 v suggests a noncardiac cause; dogs with cardiac or mixed-origin cough tend to have higher VHS. The rate of change in VHS, as well as the echocardiographic dimensions of LA and LV in both diastole and systole, becomes greatest at the onset of CHF. The increase in cardiac size occurs most rapidly within the 12 months preceding CHF onset. Variable right heart enlargement occurs in association with chronic TR, but this may be masked by left heart and pulmonary changes associated with concurrent MVD.

Pulmonary venous congestion can be an early sign of left-sided congestive failure. However, visibly distended pulmonary veins are not always appreciable. Interstitial edema occurs with the onset of left-sided CHF. Radiographic findings associated with early pulmonary edema can appear similar to those caused by chronic airway or pulmonary disease. With CHF, progressive interstitial and alveolar

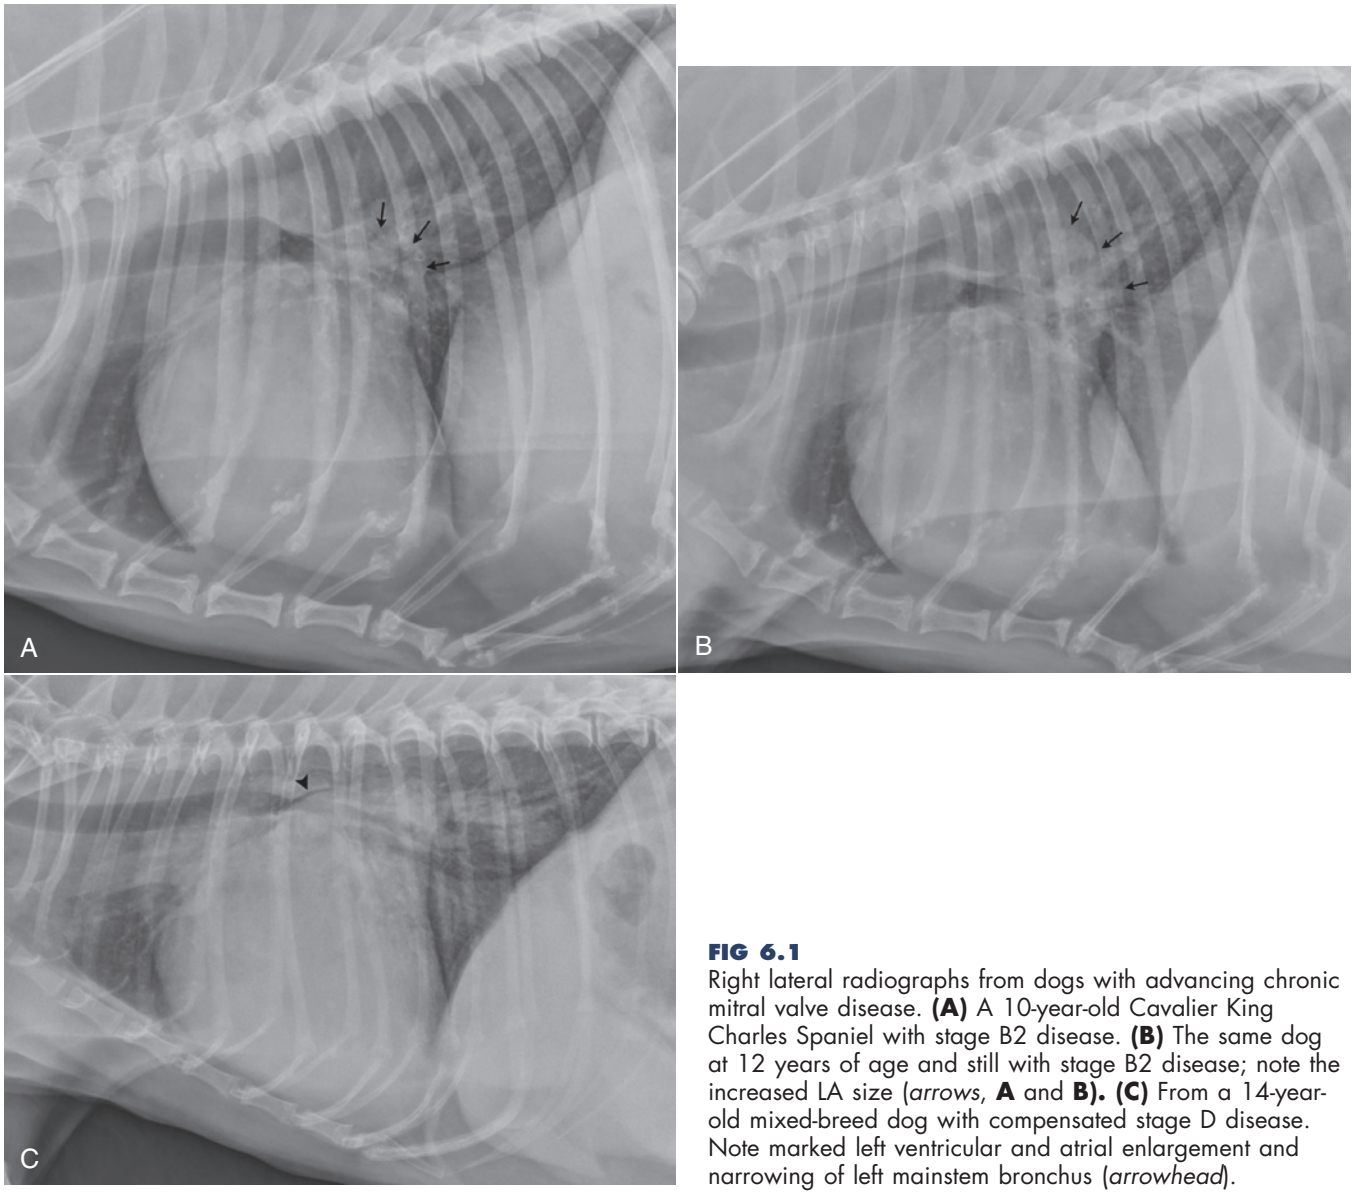

FIG 6.1
Right lateral radiographs from dogs with advancing chronic mitral valve disease. **(A)** A 10-year-old Cavalier King Charles Spaniel with stage B2 disease. **(B)** The same dog at 12 years of age and still with stage B2 disease; note the increased LA size (*arrows*, **A** and **B**). **(C)** From a 14-year-old mixed-breed dog with compensated stage D disease. Note marked left ventricular and atrial enlargement and narrowing of left mainstem bronchus (*arrowhead*).

pulmonary edema follow. Although cardiogenic pulmonary edema in dogs typically has a hilar, dorsocaudal, and bilaterally symmetric pattern, an asymmetric distribution is seen in many dogs; this might relate to may relate to the angulation of the MR jet. The presence and severity of pulmonary edema do not necessarily correlate with the degree of cardiomegaly. Acute, severe MR (for example, from rupture of chordae tendineae) can cause severe edema with minimal LA enlargement. Conversely, slowly worsening MR can produce massive LA enlargement with no evidence of CHF. Early signs of right-sided heart failure include caudal vena cava distention, pleural fissure lines, and hepatomegaly. Overt pleural effusion and ascites occur with advanced failure.

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) might suggest LA or biatrial enlargement and LV dilation (see p. 45), although the tracing is often normal. Echocardiography is a much more sensitive tool for detecting chamber enlargement. An RV enlargement pattern is occasionally seen in dogs with severe TR. Arrhythmias, especially sinus tachycardia, supraventricular premature complexes, paroxysmal or sustained supraventricular tachycardias, ventricular premature complexes, and atrial fibrillation are common in dogs with advanced disease. These arrhythmias can be associated with decompensated CHF, weakness, or syncope.

ECHOCARDIOGRAPHY

Echocardiography shows valve structural changes and chamber enlargement secondary to valve insufficiency, and it allows ventricular function estimation. Color flow Doppler imaging shows the direction and extent of disturbed flow in the atrium. In early CMVD, only mild mitral leaflet thickening, with or without a small MR jet, and normal chamber size are typical. As the disease progresses, the affected valve

cusps become thicker. Mild mitral prolapse is seen early in some dogs. Mitral prolapse usually involves the anterior leaflet or both leaflets. Its severity tends to increase with worsening disease (Fig. 6.2). Sometimes, a ruptured chorda tendineae or flail leaflet tip is seen during systole (Fig. 6.2, C). Color flow Doppler imaging allows semiquantitative assessment of MR severity, based on the width of the regurgitant jet at its origin along the closed valve, as well as how much of the atrial area is affected by the disturbed flow pattern (Fig. 6.3). More quantitative calculation of MR severity can be obtained by the proximal isovelocity surface area (PISA) method (see Suggested Readings list), although there are multiple potential inaccuracies and it is not often done clinically.

The degree of atrial and ventricular dilation increases as the volume overload secondary to worsening valve regurgitation increases. Large LA size and LA/aortic root (Ao) ratio are associated with worse prognosis. Increased LV end diastolic dimension (LVIDd) also has been associated with negative outcome. A ratio of LVIDd/Ao diameter ≥3 was identified as an independent risk factor for first onset CHF. As the LV dilates from the increasing volume overload, it becomes more spherical in shape. This LV enlargement and geometric change are associated with increased risk for CHF and may contribute to impaired pump function. As the LV becomes more spherical, the increased mitral annulus size leads to even greater MR and risk of decompensation to CHF.

RV and RA dilation develop with TR and PH; RV chamber dilation is more prominent than RV wall hypertrophy with PH secondary to CMVD. Paradoxical septal motion can occur with marked RV volume overload and interferes with FS assessment. Spectral Doppler interrogation of TR peak velocity is the easiest way to estimate presence and severity of PH (see Chapter 2, p. 30). Where a measurable TR jet is not present, other echo parameters can suggest PH, including pulmonary annulus dilation, PR jet velocity, right pulmonary artery distensibility index, decreased PA acceleration time to deceleration time (AT/DT), increased (corrected for body weight) RVIDd, and increased LA:Ao. See Chapter 10 and Suggested Readings for additional information.

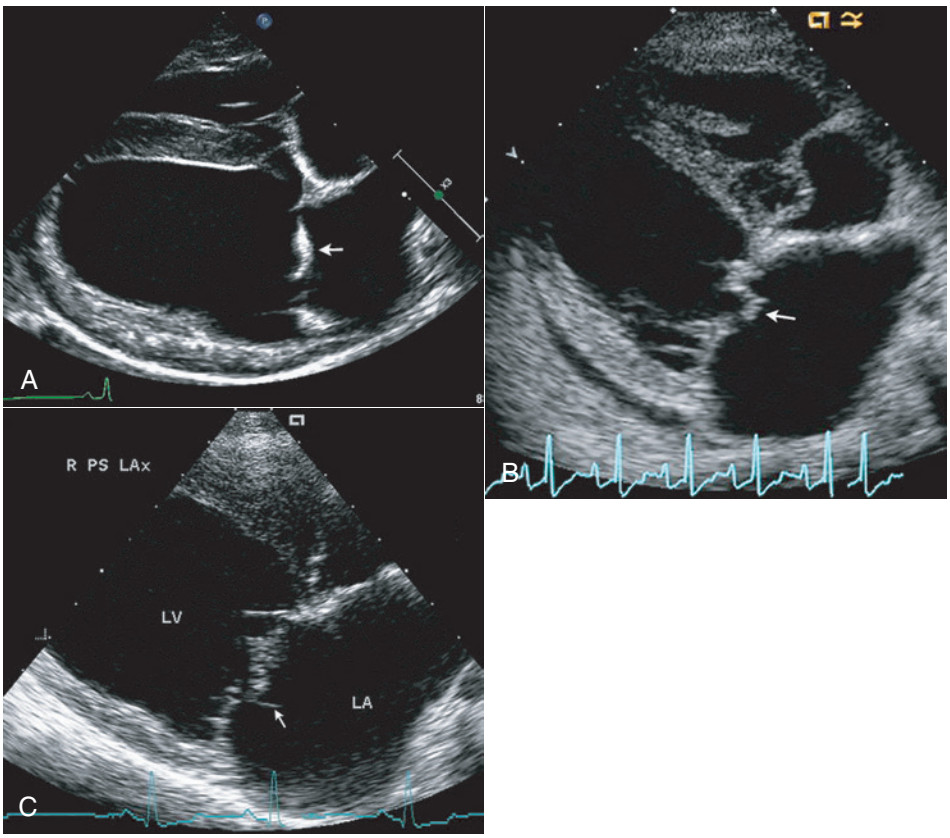

FIG 6.2
(A) Thick, mildly prolapsing mitral valve *(arrow)* is seen from the right long-axis view in a mixed-breed dog with early (stage B1) chronic mitral valve disease. **(B)** Pronounced prolapse of the anterior mitral leaflet *(arrow)* and left atrial enlargement in a 10-year-old Miniature Schnauzer with severe degenerative mitral valve disease (stage C). The tricuspid valve also is thickened, and there is a small amount of pericardial effusion. **(C)** Chorda tendineae rupture is evident by the flail segment *(arrow)* seen in the enlarged left atrium of a 12-year-old English Pointer.

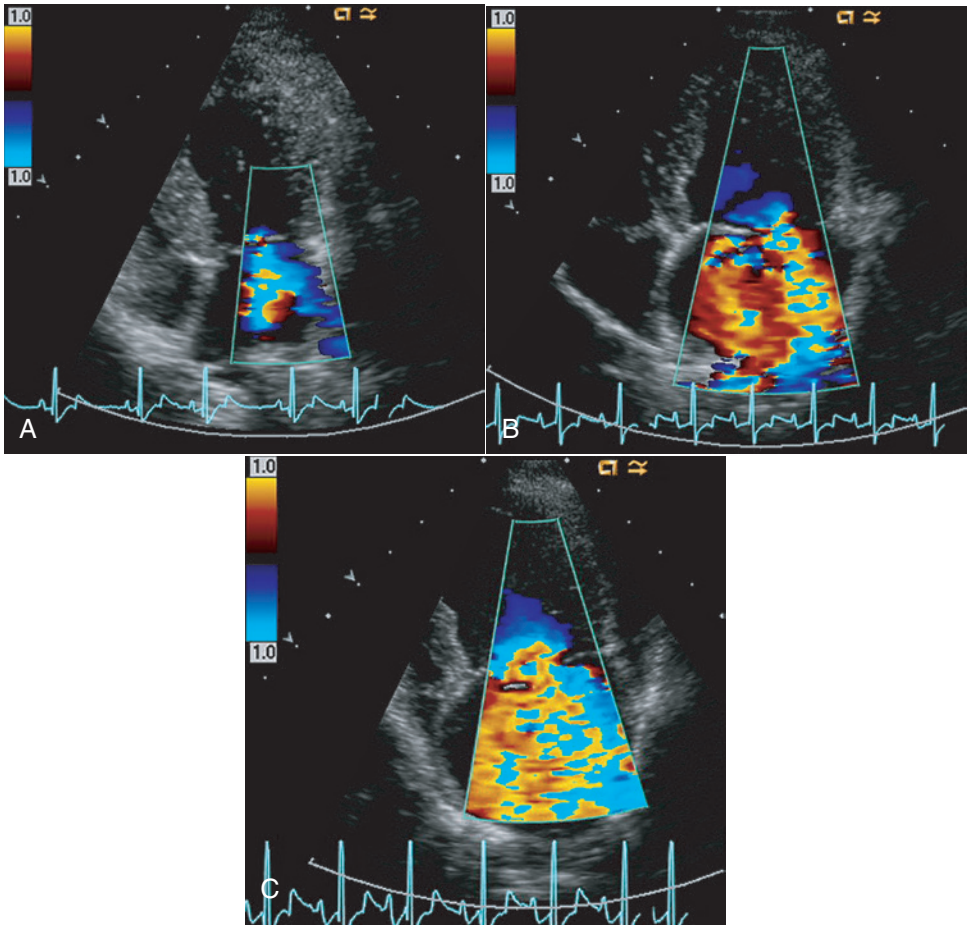

FIG 6.3
Varying degrees of MR severity in three dogs with chronic mitral valve disease, seen with color flow Doppler imaging from the left apical 4-chamber view (the LV is at top of each image, LA at bottom). **(A)** Mild MR in a 10-year-old Miniature Schnauzer. **(B)** Moderately severe MR in a different, older Miniature Schnauzer. **(C)** Severe MR, from the same dog as in Fig. 6.2, *B*. Comparing **(A)** with **(C)**, note the increasing width of the flow disturbance at its origin at the mitral valve, the greater color mixing (representing turbulent flow) and intensity within the left atrium, and also the prominent left atrial enlargement in **(B)** and **(C)**. *Note:* Color is visible only within the sector outlined by the green line. *LA,* Left atrium; *LV,* left ventricle; *MR,* mitral regurgitation.

LV wall and septal motion usually appear quite vigorous with moderate to severe MR, because in most cases overall pump function is well preserved until late in the disease. Small to no EPSS and a high FS are seen (Fig. 6.4). Although diastolic LV dimension increases with MR, when contractility is good, systolic dimension remains normal. An increasing LV systolic dimension implies impaired myocardial contractility; this can occur even before CHF develops. Declining systolic function can be identified on serial echocardiography exams; however, changes in ventricular loading associated with CMVD can interfere. For example, shortening and ejection fractions generally are increased with severe MR, even in the presence of CHF and declining myocardial contractility. The ESVI normalizes LV end systolic volume to body surface area. This index has been used to estimate myocardial systolic function in patients with valve insufficiency because it is minimally influenced by preload changes. ESVI derived from long-axis two-dimensional (2-D) images optimized for maximal LV size, using the method of discs, is considered more accurate than volume estimation derived from a single M-mode LV dimension measurement. Spectral Doppler interrogation of MR jet acceleration rate also can be used to estimate LV contractility (dP/dtmax), and MR peak velocity can be used to estimate the systolic pressure gradient between LA and LV, although an eccentric jet angle and mitral prolapse can impair accuracy.

Pericardial fluid (blood), with or without signs of cardiac tamponade (see Chapter 9), can be evident if a full thickness LA tear has occurred. Mild pericardial effusion (transudate) also can develop with right-sided congestive failure. Pericardial effusion secondary to CHF generally does not cause tamponade.

Spectral Doppler imaging of mitral inflow velocity and isovolumic relaxation time (IVRT), and tissue Doppler

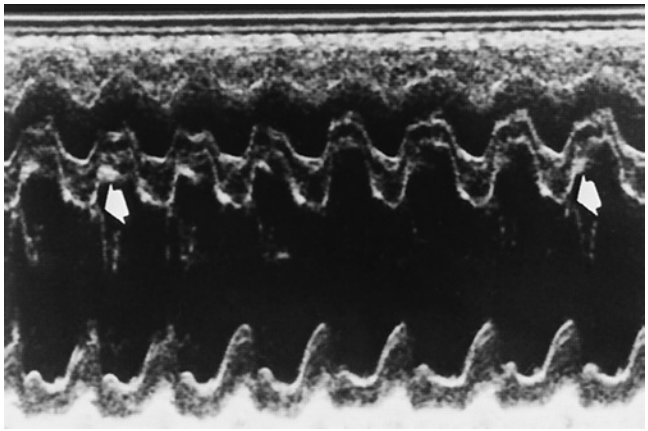

FIG 6.4
M-mode echocardiogram from a male Maltese with advanced mitral valve regurgitation and congestive heart failure. Note vigorous septal and left ventricular posterior wall motion (fractional shortening = 50%) and lack of mitral valve E point–septal separation *(arrows)*.

(TDI) measurement of lateral or septal annulus velocity help characterize LV diastolic function and LV filling pressure. Discrimination of disease-induced mild diastolic dysfunction is difficult, because many older dogs have the delayed relaxation pattern of mitral inflow (E/A<1). However, pseudonormal and restrictive inflow patterns are common in dogs with advanced CMVD, especially those with CHF. Mitral E velocities well over 1 m/s are common with advanced CMVD. However, mitral inflow pattern by itself is not a sensitive correlate for identifying high LA pressure and pulmonary edema. Nor is the ratio of early LV inflow to annular tissue velocity ratio, E/Ea (also expressed as E/E' and E/Em), useful for predicting LA filling pressure (or CHF) in dogs with CMVD. However, the early mitral inflow velocity to IVRT ratio (E:IVRT) is more useful in identifying elevated LA (LV filling) pressure in dogs with MR. This index combines peak mitral E velocity (determined mainly by LV filling pressure and relaxation) and IVRT (dependent mostly on LV relaxation). An E:IVRT >2.5 has been proposed as a cut-off value for predicting CHF in dogs with CMVD.

Treatment and Prognosis

Goals of preclinical (stage B) CMVD management are to delay the onset of CHF, and to identify and treat the early signs of decompensation before fulminant pulmonary edema develops. For dogs that already have developed CHF (stage C), therapy is aimed at controlling signs of congestion, enhancing forward blood flow, reducing regurgitant volume, and diminishing excessive NH activation. Ultimately, the goal is to provide good quality of life while extending survival time. Box 6.2 outlines treatment guidelines for CMVD based on level of disease progression.

PRECLINICAL (STAGE B) CVMD

It is important to assess the severity of MR and cardiac remodelling. This helps determine risk for CHF and guide recommendations for monitoring, management, and reevaluation. Thoracic radiographs and NT-proBNP are useful for this. However, especially as the disease advances, echocardiography becomes more important to assess LA and LV size, ventricular function, and other factors.

STAGE B1

Thoracic radiographs, blood pressure (BP) measurement, and plasma NT-proBNP or echocardiography generally are recommended yearly to monitor dogs with stage B1 disease; although semiannual rechecks for large-breed dogs with advancing CMVD are considered prudent because of their tendency to develop reduced myocardial function sooner. Routine preventative healthcare should be continued, including heartworm disease prophylaxis, vaccinations, dental prophylaxis, etc. Concurrent medical problems should be identified and managed as appropriate. Owner education about the disease process and early signs of heart failure is important.

Clients should be taught how to assess their pet's resting (ideally, sleeping) RR to establish that individual's normal baseline, and, as the disease advances, to help screen for possible early signs of decompensation (see Chapter 3, p. 73 and Box 3.2, p. 74). No specific cardiac therapy currently is recommended for dogs in stage B1. For dogs with elevated BP, an ACE inhibitor (ACEI) is recommended to maintain normal arterial pressure and cardiac afterload. Normal exercise and activity, as well as a normal diet, can be maintained at this stage although avoiding high-salt foods and treats is recommended. Extremely obese dogs could benefit from weight reduction during this preclinical stage; however, a mildly overweight state is not considered problematic and could be helpful later if chronic CHF therapy becomes necessary.

STAGE B2

Dogs with measurable left heart enlargement but without ever having developed clinical signs of CHF are in stage B2 CMVD. Monitoring and routine healthcare recommendations for these dogs are similar to those for stage B1, except recheck frequency is increased to every 6 to 9 months, or sometimes more often for markedly advanced disease. In addition to a thorough physical examination and BP check, thoracic radiographs and echocardiogram or NT-proBNP are done to monitor progression; echocardiography provides more specific information about cardiac enlargement and function. Screening for concurrent medical problems also is advised. Home monitoring, as described for stage B1 dogs, should be continued with greater attention.

Pimobendan (Vetmedin) at the standard label dose currently is recommended for dogs with stage B2 CMVD. Pimobendan has been shown to delay the onset of CHF (by a median of 15 months) and prolong survival without

BOX 6.2

Treatment Guidelines for Chronic Mitral Valve Disease

Stage B1 (Asymptomatic, No or Minimal Cardiac Enlargement)

Client education (about disease process and early heart failure signs)
Routine health maintenance
- Blood pressure measurement
- Baseline chest radiographs, ±echocardiogram or NT-proBNP, and yearly rechecks
- Maintain normal body weight/condition
- Regular exercise, as tolerated
- Heartworm testing and prophylaxis in endemic areas

Manage other medical problems (including mild/moderate hypertension!)
Avoid high-salt foods
Have client begin monitoring RRR to establish normal baseline for that animal (see Box 3.2, p. 74)

Stage B2 (Asymptomatic, Progressive Cardiac Enlargement Evident)

Client education (see stage B1)
Routine health maintenance
- Blood pressure measurement
- Chest radiographs, echocardiogram, or NT-proBNP yearly (or every 6 months, if advanced disease or large-breed dog)
- Maintain normal body weight/condition
- Regular mild to moderate activity, as tolerated
- Avoid excessively strenuous activity
- Heartworm testing and prophylaxis in endemic areas

Manage other medical problems (if arterial blood pressure elevated, institute ACEI therapy)
Avoid high-salt foods; consider introducing moderately salt-restricted diet now
**New recommendation: institute pimobendan therapy (0.2-0.3 mg/kg q12h) in stage B2
Have client continue monitoring RRR periodically to help detect onset of early CHF signs (see Box 3.2, p. 74)

Stage C (Chronic/Outpatient Care; No Current CHF Signs [Stage C1] or Mild to Moderate CHF Signs [Stage C2])*

Considerations as previously noted
Furosemide, as needed
Pimobendan
ACEI
Spironolactone
Antiarrhythmic therapy, if necessary (see Chapter 4)
If CHF signs: complete exercise restriction until after signs fully resolve
If no current CHF signs: regular mild (to moderate) activity, as tolerated; avoid strenuous exercise
Moderate dietary salt restriction
Continue home monitoring of RRR to help detect early signs of CHF decompensation (see Box 3.2, p. 74)

Stage C (Acute/Hospitalized Care Needed; Severe CHF Signs [Stage C3])*

Supplemental O_2
Cage rest and minimal patient handling
Furosemide (more aggressive doses, parenteral)
Pimobendan (continue or add as soon as PO administration possible; or use IV, if available)
Vasodilator therapy (consider intravenous [IV] nitroprusside or (IV or PO) hydralazine, ± topical nitroglycerin
±Sedation, as needed
Antiarrhythmic therapy, if necessary
See Box 3.1 for other recommendations
Thoracocentesis, if moderate- to large-volume pleural effusion

Stage D (Chronic Recurrent or Refractory Heart Failure) Strategies for in-Hospital or Outpatient Care as Needed)*

Ensure that standard therapies for stage C are being given at optimal doses and intervals, including furosemide, ACEI (q12h), pimobendan, spironolactone (see Chapter 3, p. 74)
Rule out systemic arterial hypertension, arrhythmias, anemia, and other complications
Increase furosemide dose/frequency as needed (check renal function and electrolyte status); may be able to decrease somewhat in several days after signs resolve
Enforced rest until after signs abate
Additional afterload reduction (such as amlodipine [or hydralazine]); monitor blood pressure
Other strategies to consider:
- Increase pimobendan dosage (up to q8h frequency, +/or up to 0.4-0.5 mg/dose)
- Switch from furosemide to torsemide (initial dose at 1/10-1/12 of total daily furosemide dose, divided)
- ± Add a thiazide diuretic (if not using torsemide) – use low dose, monitor renal function and electrolytes closely!
- ± Add digoxin, if not currently prescribed; monitor serum concentration

Antiarrhythmic therapy, if indicated (see Chapter 4)
If pulmonary hypertension with signs of R-CHF or collapse, add sildenafil (1-3 mg/kg q8-12h PO)
Add (or increase dose of) second diuretic (e.g., spironolactone, hydrochlorothiazide)
Thoracocentesis (or abdominocentesis) as needed
Consider bronchodilator trial or cough suppressant for persistent dry cough
Further restrict dietary salt intake; verify that drinking water is low in sodium

*See Tables 3.2 and 3.3 and Box 3.1, pp. 60, 62, and 64, for further details and doses.

increasing adverse events compared to placebo in dogs with stage B2 CMVD. Current evidence suggests that initiating ACEI therapy at stage B2 does not significantly delay CHF onset in most dogs. Nevertheless, some controversy remains and, especially for dogs with advanced CMVD and severe left heart enlargement, an ACEI might provide some benefit toward delaying CHF. In any case, for dogs with systemic hypertension, ACE inhibition is recommended as first-line therapy to moderate BP. Regular (mild to moderate) exercise should be maintained as tolerated. Strenuous exercise that provokes shortness of breath or excessive fatigue is to be avoided. Gradual transition to a diet moderately reduced in salt, but also well balanced and with adequate protein content, is recommended. Although some experimental studies found a possible myocardial protective effect from β-blocker therapy, clinical β-blocker therapy trials in dogs with stage B2 MVD have not delayed CHF onset. Therefore routine β-blocker use is not recommended.

CHF ONSET IN CMVD (STAGE C)

The onset of congestive signs appears gradually in some dogs, but in others fulminant pulmonary edema or episodes of syncope can develop rapidly. Therapy should be guided by clinical status and whether any complicating factors are present. Medical therapy is the mainstay for dogs that have experienced decompensated CHF. Although surgical valve repair or replacement is sometimes an option and might be available at some referral centers, treatment for most dogs is solely medical. Clinical compensation (no congestive signs) for months to years can be possible with appropriate therapy, although frequent reevaluation and medication adjustment become necessary as the disease progresses. Intermittent episodes of decompensation (congestive signs) are common in dogs on long-term heart failure therapy; often these can be successfully managed.

Furosemide, pimobendan, and an ACEI comprise the standard, so-called "triple therapy" for dogs that have developed CHF. However, spironolactone often is added to these three other medications for chronic CHF, so perhaps "quadruple therapy" is a more apt description. Pimobendan usually is well tolerated and, when compared directly to an ACEI, has greater benefit for long-term heart failure management. Generally, an ACEI and pimobendan are used together for CHF management, although whether their benefits are additive is unclear. Pimobendan and ACEIs both can reduce LA pressure. Spironolactone may reduce the risk of cardiac death or euthanasia because of CHF in dogs with CMVD. Some dogs can develop serum electrolyte disturbances or azotemia while on spironolactone, so checking for these 1 to 2 weeks after initiating therapy and periodically thereafter is recommended. If for some reason pimobendan cannot be used, digoxin could be added instead, especially in advanced disease or for management of atrial tachyarrhythmias. Conservative doses are used and serum concentrations measured to avoid toxicity (see Chapter 3, p. 70, and Table 3.3).

No exercise should be allowed until signs of CHF fully resolve. During chronic, compensated disease, however, mild to moderate regular activity can be beneficial. Strenuous exercise is best avoided. At-home monitoring is important because decompensation can occur unexpectedly. A persistent increase in resting respiratory rate (RRR) can signal early decompensation with pulmonary edema. If decompensated CHF develops, therapy is intensified or adjusted as needed while searching for any complicating factors that may need to be addressed. Box 6.2 lists strategies for modifying or intensifying CHF therapy. Dogs with a persistent dry cough from primary airway disease or mainstem bronchus compression, and no pulmonary edema, might require antitussive therapy (e.g., hydrocodone bitartrate [0.25 mg/kg PO q4-12h] or butorphanol [0.5 mg/kg PO q6-12h]).

MILD TO MODERATE SIGNS OF CHF

Early signs of decompensation usually include persistent increases in RRR at home, shortness of breath, increased respiratory effort or excessive panting, or decreased willingness to exercise. A new or increased cough also might be noted. The history and physical examination, thoracic radiographs, NT-proBNP, and/or echocardiography can help the clinician differentiate CHF from other causes. BP measurement and routine laboratory tests can be useful for identifying other complications.

The individual patient's clinical signs and response to therapy guide the aggressiveness of CHF therapy. Furosemide is instituted when clinical signs and radiographic evidence of pulmonary edema first appear. Higher and more frequent doses are indicated for more severe edema. When the signs of failure are controlled, the dose and frequency of furosemide gradually are reduced to find the lowest effective levels for long-term therapy in that patient. Although furosemide alone might be prescribed initially as a therapeutic trial in some cases (see later in this chapter), for chronic heart failure treatment furosemide monotherapy is not recommended and does not meet standard of care.

Mild clinical signs with pulmonary venous congestion and/or only mild pulmonary edema on radiographs often responds well to PO furosemide (e.g., 1-2 mg/kg q12h), an ACEI given q24h, and pimobendan at standard dose (see Table 3.3, p. 64). A diet moderately reduced in salt is recommended. If the client can restrict activity at home, the patient might be more comfortable there. No exercise should be allowed until the next reevaluation, usually in 5 to 7 days unless problems arise sooner. Then, if all CHF signs have resolved, mild (to moderate) activity can be slowly reintroduced. Recheck exams should assess clinical status, BP, renal function, and serum electrolytes; depending on clinical findings and case progression, repeat thoracic radiographs, ECG, NT-proBNP, and echocardiogram might be appropriate as well.

Some dogs show signs suggesting early CHF; without clear radiographic evidence for pulmonary edema, however,

making the diagnosis is unclear. The presence of pulmonary lobar venous distension suggests that CHF is imminent, however this is not always seen. When it is unclear if respiratory signs are caused by heart failure or a noncardiac cause, an initial furosemide trial (e.g., 1-2 mg/kg PO q8-12h) for 2 to 3 days can be helpful. Plasma NT-proBNP measurement also can be useful. Some clinicians add an ACEI during the therapeutic trial for suspected CHF. Cardiogenic pulmonary edema usually responds rapidly, so if CHF was the cause, the owner should see rapid improvement in RR and effort as well as reduced (cardiogenic) cough. In these cases, triple therapy is instituted along with recommendation for moderate dietary salt restriction. Depending on the individual case, it may be possible to reduce the dose of furosemide somewhat, using RRR monitoring as a guide. On the other hand, coughing or other respiratory signs that persist despite furosemide trial makes a diagnosis of CHF unlikely. Nevertheless, confusion is still possible in some cases because a cough from airway irritation may resolve spontaneously, or furosemide may have a mild antiinflammatory or antitussive effect.

MODERATE TO SEVERE SIGNS OF CHF

Fulminant pulmonary edema with shortness of breath at rest is a true emergency. Aggressive therapy, but with gentle handling, is crucial in these fragile patients. Cage rest, supplemental oxygen, high-dose (e.g., 2-4 mg/kg q1-4h initially) parenteral furosemide, and vasodilator therapy are indicated (see Box 3.1, p. 62). Intravenous (IV) nitroprusside or hydralazine (PO or IV) can be used for acute therapy for rapid arteriolar vasodilating effect. BP must be closely monitored. A low dose is used in animals already receiving an ACEI. Amlodipine is another alternative, although onset of action is slower. Amlodipine can significantly decrease LA pressure and MR regurgitant jet severity compared to ACEI, however up to four days are needed for full effect. Topical nitroglycerin can be used in combination with an arteriolar dilator in an attempt to reduce pulmonary venous pressure by direct venodilation. Pimobendan dosing is begun (or continued) as soon as possible.

Heart rate and rhythm should be monitored. For the control of supraventricular tachyarrhythmias, diltiazem or a β-blocker (see Table 4.2, p. 90) can be used instead of or in addition to digoxin. Although several days are needed to achieve therapeutic digoxin serum concentration with oral maintenance doses, IV digoxin is not recommended. Therapy for ventricular tachyarrhythmias is warranted in occasional cases. For dogs with CMVD that require BP support or when myocardial function is poor, other more potent inotropic agents (e.g., dobutamine or dopamine) can be given IV (see Box 3.1, p. 62).

Mild sedation is used to reduce anxiety (e.g., butorphanol; see Box 3.1, p. 62). Patient handling should be minimized, and radiographs and other diagnostic procedures postponed until the respiratory status is more stable. A bronchodilator (e.g., theophylline, aminophylline) sometimes is used when bronchospasm induced by severe pulmonary edema is suspected; although the efficacy of this is unclear, these agents may help support respiratory muscle function. Bronchodilators can potentially increase the risk for tachyarrhythmias, though. In dogs with moderate- to large-volume pleural effusion, thoracocentesis should be done as expeditiously as possible to improve pulmonary function; ascites severe enough to impede respiration also should be drained. Close monitoring for the patient's response to therapy and any adverse effects (e.g., hypotension, azotemia, electrolyte abnormalities, arrhythmias, drug toxicity, and so on) is important for optimizing care (see Chapter 3, p. 65 for additional information). Mild to moderate azotemia is common after aggressive diuretic therapy. Slow oral "self-rehydration" is effective for most patients. Because it can exacerbate congestive signs, parenteral fluid therapy is avoided whenever possible (see Chapter 3, p. 65, section of monitoring and follow-up after acute CHF treatment).

TRANSITION TO HOME CARE

After the patient is stabilized, medications are adjusted over the next several days to weeks to determine the best regimen for long-term treatment. Furosemide is titrated to the lowest dose and longest interval that controls signs of congestion. RRR monitoring over time helps guide this (see p. 74). An ACEI is recommended for chronic therapy if another vasodilator was used initially. The ACEI can be dosed once daily to start as the patient is weaned off the other (arteriolar) vasodilator over a couple days. The ACEI can be increased to q12h dosing over the next several days to a week. Client education about the purpose and potential adverse effects of prescribed medications, RRR monitoring, diet, activity restrictions, follow-up schedule, and other recommendations is important.

MONITORING HEART FAILURE THERAPY

Continued monitoring is important, especially for renal function, serum electrolyte concentrations, BP, and recurrent congestive signs. Intermittent arrhythmias can trigger decompensated congestive failure, as well as episodes of transient weakness or syncope. Cough-induced syncope, atrial rupture, or other causes of reduced cardiac output also can occur. Despite periodic recurrence of CHF signs, with proper management many dogs with CMVD enjoy a good quality of life for several months to years after signs of failure first appear. Dogs with recently diagnosed or decompensated CHF should be rechecked more frequently (every few days to every week or so) until their condition is stable; those with chronic heart failure that is well controlled can be reevaluated less often but usually at least three to four times per year.

COMMON COMPLICATIONS

END-STAGE/REFRACTORY (STAGE D) HEART FAILURE

Recurrent acute CHF should be treated in-hospital as described previously (see Box 3.1, p. 62). Pleural and abdominal effusions are drained as needed to maintain patient

comfort. Other strategies for intensifying home therapy are discussed in Chapter 3, p. 74.

PULMONARY HYPERTENSION

The development and severity of PH associated with high pulmonary venous pressure (so-called *postcapillary PH*) increases with advancing CMVD severity. It is most common in dogs with stage C disease. Usually, PH associated with CMVD is of mild to moderate severity, although a minority of dogs with CMVD has severe PH. Although PH seen with CMVD usually is related to chronic pulmonary venous hypertension, increased precapillary vascular resistance from hypoxia-induced pulmonary arteriolar vasoconstriction can occur with pulmonary edema or concurrent pulmonary disease. Reactive pulmonary vascular remodeling can contribute to PH, especially in dogs with severe disease. Moderate and severe PH increases right heart strain, promotes RV dilation (and hypertrophy), and contributes to tricuspid annulus dilation and worsening TR. Dogs with CVMD and moderate to severe PH are likely to have worse outcomes.

Dogs with mild to moderate PH can be asymptomatic or have some degree of exercise intolerance or other clinical signs consistent with CMVD. Especially with severe PH, clinical signs can include cough, respiratory difficulty, R-CHF signs (ascites, pleural effusion), lethargy, weakness, syncope, prerenal azotemia, and cyanosis. Concurrent arrhythmias can exacerbate these signs. On auscultation, the animal's systolic murmur might be louder over the tricuspid region, with or without a loud or split S_2 sound. Pulmonary crackles can relate either to pulmonary edema or concurrent chronic lung disease in these dogs. The diagnosis of PH is generally made by echocardiography, although radiographs can be suggestive (see Chapters 2 and 10, pp. 30 and 191).

Management of CVMD with PH first centers on standard CHF therapy to reduce pulmonary venous pressure by controlling pulmonary edema and improving forward cardiac output. Pimobendan, besides supporting myocardial function and systemic vasodilation, also has some pulmonary vasodilating effect via phosphodiesterase (PDE)-3 inhibition. Additional therapy with a PDE-5 inhibitor (such as sildenafil) generally is reserved for dogs with PH that have persistent signs of R-CHF or syncope. Sildenafil (1-3 mg/kg q8h) usually is started at a lower dose q(8-)12h then titrated upward over several days to a week based on clinical response. Concurrent administration of an L-arginine supplement (100 mg/kg q8h PO) is thought to enhance sildenafil's efficacy, because this amino acid is a substrate for nitric oxide production. Doppler (TR maximum velocity) and other echo observations can help assess the effect of sildenafil treatment, although a decrease in TR Vmax or smaller RV is not always documented despite clinical improvement. Systemic BP should be monitored, especially in patients receiving another vasodilator along with an ACEI, even though sildenafil primarily affects the pulmonary vasculature. Occasionally, dogs with severe PH and advanced CMVD can develop worsened pulmonary edema after initial sildenafil treatment, especially at higher doses; rapid reduction in pulmonary vascular resistance with an increase in pulmonary blood flow is thought to be the cause in these cases. Therefore close monitoring for increasing RRR, cough, and other respiratory signs is warranted when beginning sildenafil therapy. An increase in dose and/or frequency of pimobendan administration is another strategy that could enhance pulmonary vasodilation.

ARRHYTHMIAS

The onset or worsening of paroxysmal or sustained tachyarrhythmias can precipitate weakness, syncope, and congestive signs in a previously stable patient. The arrhythmia may be evident on physical examination and further identified on resting ECG; however, ambulatory ECG monitoring may be needed for definitive diagnosis and to guide antiarrhythmic therapy. Conversely, an intermittent bradyarrhythmia may underlie episodic weakness in syncope in some dogs. See Chapter 4 for management.

RUPTURED CHORDAE TENDINEAE

Affected animals tend to be older, male small-breed dogs, although chordal rupture also occurs in females. Rupture of a primary (marginal) chorda tendineae often provokes acute pulmonary edema, and prognosis can be poor in such cases. Rupture of a minor (second- or third-order) chorda sometimes is an incidental finding on echocardiogram or at necropsy. Factors that influence the clinical outcome include the size and location of the ruptured chord, the degree of valve regurgitation, LA compliance, and LV function.

LA RUPTURE

Older, male Miniature Poodles, Cocker Spaniels, Cavalier King Charles Spaniels (CKCS), Dachshunds, and Shetland Sheepdogs are thought to have higher prevalence of LA tearing, but mixed breed and other dogs also are affected. Full-thickness tearing of the LA wall is an uncommon but devastating complication of CMVD. Acute intrapericardial bleeding generally causes rapid onset of cardiac tamponade (see Chapter 9) and often is fatal. Acute weakness or collapse is typical; other signs could include cough, dyspnea, and respiratory or cardiac arrest. Most of these dogs have advanced CMVD, with severe LA enlargement, atrial jet lesions, and often ruptured first-order chordae tendineae. Pericardial effusion, usually with tamponade, is seen on echocardiography in almost all cases. There may be clots in the fluid. Echocardiography also may show an intraluminal thrombus attached to the LA wall, with either a partial or full thickness tear. In rare cases, an LA tear occurs in the interatrial septum rather than the lateral LA wall.

In dogs with tamponade, a cautious attempt at pericardiocentesis might relieve the tamponade, although the decrease in intrapericardial pressure could trigger further bleeding, especially if a clot seal is disturbed. Prognosis generally is poor in these cases, even with aggressive supportive care and immediate surgical attempt to close the rupture. However, if

the intrapericardial bleed is modest and the dog appears relatively stable, conservative management might be successful. This involves cage rest, BP support, continued CHF therapy, and removal of a small volume of pericardial fluid only if required for signs of tamponade. Over time, the rupture could seal and pericardial blood would be reabsorbed. For dogs with echo evidence of an intraluminal thrombus in the LA, there is presumably increased risk for arterial thromboembolism (ATE). However, it is unclear whether the benefit of antiplatelet therapy to reduce ATE potentially outweighs the risk of worsening intrapericardial bleeding, if a full thickness tear is present or develops. Dogs that survive are prone to another LA tear.

CHRONIC AIRWAY DISEASE

Chronic bronchitis and collapsing trachea are common in older small breed dogs. Associated signs are sometimes difficult to differentiate from CHF signs. At home, RRR monitoring, changes in exercise tolerance and activity level, and thoracic radiographs are helpful in this regard. For dogs with a new or worsening cough, especially a dry honking cough, that maintain normal RRR at home, empiric therapy (e.g., antibiotic trial, bronchodilator, and finally antiinflammatory doses of glucocorticoid) or further diagnostic testing can be offered (e.g., radiographs with airway fluoroscopy, tracheal wash or bronchoscopy with bronchoalveolar lavage, and culture of airway secretions). For persistent dry cough in the absence of pulmonary edema, a cough suppressant (e.g., hydrocodone or butorphanol) can be helpful. This may only be needed intermittently when the dog is having a "bad day" of coughing. It is important that the owner continue to monitor RRR and be alert to possible episodes of recurrent pulmonary edema.

ABNORMAL BLOOD PRESSURE

Systemic hypertension, although not caused by CMVD, can complicate its treatment. Because hypertension can exacerbate MR and cardiac workload, BP should be checked at each visit. If elevated, and if ACEI dose is already maximized, an arteriolar vasodilator (e.g., amlodipine) is added. Care should be taken to verify that the high BP readings are not just related to excitement.

Conversely, hypotension can occur with excessive dosing of an arteriolar vasodilator, dehydration, persistent arrhythmias, and/or poor contractility. Although uncommon, LA rupture with cardiac tamponade causes acute and profound hypotension

RENAL DYSFUNCTION

Impaired renal function is common in older dogs with CMVD; it can be difficult to manage when there are increasing congestive signs. The lowest effective doses of furosemide are used. Optimizing forward cardiac output also helps preserve renal perfusion. BP should be monitored, and high levels managed as possible. An arteriolar vasodilator (e.g., amlodipine) added to standard therapy can help improve forward cardiac output and renal perfusion as long as hypotension is avoided. If spironolactone or another diuretic is also being used, it should be reduced or discontinued, depending on the level and progression of azotemia. Likewise, some cases can tolerate a slight decrease in furosemide dose without precipitating pulmonary edema; however, close monitoring (RRR and other signs) is required. Alternatively, the dose or frequency of ACEI could be decreased. Increasing pimobendan to q8h dosing also might help by improving renal perfusion. It is important to verify that the patient does not have a treatable underlying disease that may be affecting renal function, such as ascending urinary tract infection. Mild azotemia can be acceptable as long as the patient feels good and is eating well. Electrolytes should be monitored. If the azotemic patient is receiving digoxin, serum concentrations should be monitored more often to avoid toxicity. The digoxin dose may need to be reduced or discontinued.

Prognosis

The prognosis for dogs with CMVD can be quite variable. Most dogs remain in a preclinical stage for years, and some never develop CHF. The median survival time for dogs with more advanced (stage B2) disease could be slightly more than 2 years. Although some suggest that median survival times in dogs with moderate CHF might range from about 1 to 3 years, the therapy used, complications that develop, or even breed may influence this. However, for dogs with advanced CHF, survival times between 6 to 9 months are probably more likely. Yet some dogs with advanced stage C disease do well for many months, or even a couple of years, with appropriate therapy. Despite periodic episodes of CHF decompensation or other complications, quality of life can be good most of the time. Nevertheless, some dogs die or are euthanized during the first onset of CHF. Estimates of cardiac death from CMVD have ranged from around 40% to almost 70% of cases. Nevertheless, management strategies for CHF are becoming more effective in controlling clinical signs and increasing survival time. Factors that have been associated with disease progression or worse prognosis include older age, male gender, more severe valve lesions and degree of valve leaflet prolapse or MR, ruptured chordae, severe LA and LV enlargement, reduced LV systolic function, and elevated natriuretic peptide levels.

Risk factors for first onset CHF are mainly related to increased heart size and associated high circulating NT-proBNP concentration. One study identified NT-proBNP concentrations ≥1500 pmol/L, end-diastolic LV dimension indexed to aortic root diameter (LVIDd:Ao) ≥3, and VHS >12 v as independent risk factors for first onset CHF in stage B dogs with CMVD, with failure likely to occur within the subsequent 3 to 6 months. The rate at which heart size increases has been observed to accelerate within the 6 to 12 months before clinical CHF onset.

Prognostic indicators of reduced survival after CHF onset also relate to left heart enlargement, and high circulating NT-proBNP and cardiac troponin I concentrations, although a decrease in circulating NT-proBNP concentration after CHF therapy is thought to be a positive sign. LA

enlargement may be the strongest echocardiographic predictor of reduced survival. However, evidence for reduced LV contractility or moderate to severe PH also suggests worse prognosis.

INFECTIVE ENDOCARDITIS

Infection of the cardiac valves and other endocardial tissue is relatively uncommon; however, it causes severe systemic as well as cardiac consequences. Infective endocarditis occurs more often in dogs than in cats. It can be difficult to diagnose, especially before severe valve damage has occurred. CHF is a common sequela; however, other consequences include thromboembolic (TE) events, multiorgan infection and abscessation, immune-mediated polyarthritis and glomerulonephritis, arrhythmias, and sometimes sudden death. Because of the widely disparate manifestations, endocarditis has been called the "great imitator."

Etiology and Pathophysiology

Multiple factors play a role in the development of infective endocarditis, including endothelial damage, disturbed blood flow, hemostatic and immune responses, bacteremia, and bacterial virulence. Bacteremia, either persistent or transient, is necessary for endocardial infection to occur. The likelihood of a cardiac infection becoming established is increased when organisms are highly virulent or the bacterial load is heavy. Recurrent bacteremia may occur with infections of the skin, mouth, urinary tract, prostate, lungs, or other organs. Dentistry procedures are known to cause a transient bacteremia, although rarely is endocarditis a consequence. Other procedures presumed to cause transient bacteremia in some cases include endoscopy, urethral catheterization, anal surgery, and other so-called "dirty" procedures. Sometimes the predisposing cause of infective endocarditis is never identified.

The aortic and mitral valves are affected most often. The endocardial surface of the valve is infected directly from the blood flowing past it. Endothelial damage, with platelet and fibrin aggregation, probably serves as a nidus for circulating bacterial colonization in most cases. Highly virulent organisms or a heavy bacterial load increase the risk of cardiac infection. Virulent bacteria can invade normal valves, but previously damaged valves are at greater risk, especially with persistent bacteremia. Such damage may result from mechanical trauma (such as jet lesions from turbulent blood flow or catheter-induced endocardial injury). For example, dogs with subaortic stenosis are at greater risk for aortic valve endocarditis because the high velocity systolic jet can damage the endothelium on the underside of the aortic valve. However, there is no clear evidence linking CMVD with a higher risk for infective endocarditis of the mitral valve.

The most common organisms identified in dogs with endocarditis have been *Staphylococcus* spp., *Streptococcus* spp., and *Escherichia coli.* Various *Bartonella* species, especially *B. vinsonii* subsp. *berkhoffii* and *B. henselae,* have been increasingly identified in dogs as well as cats with endocarditis. *Bartonella* is an important cause of culture-negative endocarditis in some geographic areas, where it could be responsible for 20% to 30% of cases. Dogs infected with *Bartonella* may harbor more than one species and also may be coinfected with *Ehrlichia, Babesia,* and/or *Rickettsia* spp. Yet in dogs with endocarditis from other more common bacteria, coinfection with *Bartonella* appears to be rare. Besides endocarditis, other consequences of *Bartonella* infection include myocarditis, polyarthritis, meningoencephalitis, and granulomatous inflammation in lymph nodes and other tissues. Endocarditis-causing *Bartonella* spp. appear to preferentially affect the aortic valve, although the mitral valve occasionally is involved. *Bartonella* infection appears less likely to cause fever and is often associated with worse survival. Other organisms less frequently isolated from infected valves in dogs include *Corynebacterium (Arcanobacterium)* spp., *Pasteurella* spp., *Pseudomonas aeruginosa, Erysipelothrix rhusiopathiae (E. tonsillaris),* and others, including anaerobic *Propionibacterium* and *Fusobacterium* spp. Rarely, fungal organisms (usually associated with a foreign body) are involved. There are only rare reports of endocarditis in cats; in addition to *Bartonella* spp., *Streptococcus* spp., *Staphylococcus* spp., *E. coli*, *Pseudomonas*, and anaerobic bacteria have been identified in this species.

Endothelial disruption stimulates platelet activation and a local coagulation response, with resulting aggregate of fibrin, platelets, red blood cells, and leukocytes. Circulating bacteria adhere to and colonize this initially sterile clot. Bacterial clumping caused by the action of an agglutinating antibody can facilitate attachment to the valves; some colonizing bacteria secrete enzymes that damage valve tissue. Ulceration of the valve endothelium and subendothelial collagen exposure stimulate platelet aggregation and coagulation cascade activation, leading to the formation of vegetative lesions. These vegetations consist mainly of aggregated platelets, fibrin, blood cells, and bacteria. Newer vegetations are friable, but with time the lesions become fibrous and may calcify. As additional fibrin is deposited over bacterial colonies, they become protected from normal host defenses and many antibiotics. Some organisms, including *S. aureus* and *Bartonella* spp., are internalized by endothelial cells, conferring more protection from the immune system. Although vegetations usually involve the valve leaflets, lesions may extend to the chordae tendineae, sinuses of Valsalva, mural endocardium, or adjacent myocardium. Vegetations cause valve deformity, including perforations or tearing of the leaflet(s), and result in valve insufficiency. Rarely, large vegetations may cause the valve to become stenotic. *Streptococcus* spp. appears to more commonly affect the mitral valve. *Bartonella* spp. infects the aortic valve most often, causing somewhat different lesions of fibrosis, mineralization, endothelial proliferation, and neovascularization.

Endothelial damage and mechanical valve trauma also can cause nonbacterial thrombotic endocarditis. This is a sterile accumulation of platelets and fibrin on the valve

surface. Nonseptic (so-called "bland") emboli can break off from such vegetations and cause infarctions elsewhere. Subsequent bacteremia can cause a secondary infective endocarditis too.

Valve damage generally causes progressively worsening valve regurgitation with secondary volume overload. Signs of CHF can develop acutely or gradually, depending on the extent and progression of valve damage, and whether both mitral and aortic valves or other predisposing factors are involved. LV diastolic and LA pressures can rise relatively quickly, leading to rapid onset of pulmonary edema. Aortic endocarditis, especially, is likely to cause acute CHF and fulminant pulmonary edema. Left heart dilation can be minimal when disease progression is rapid or multiple valves are involved. In the few cases where vegetative lesions also cause valve stenosis, cardiac workload and risk of CHF are further increased.

Cardiac function can be compromised by myocardial injury resulting from coronary arterial embolization causing myocardial infarction and abscess formation, or from direct extension of the infection into the myocardium. Reduced contractility and atrial or ventricular tachyarrhythmias often result. Aortic valve endocarditis lesions may extend into the AV node and cause partial or complete AV block. Arrhythmias can cause weakness, syncope, and sudden death or contribute to the development of CHF.

Fragments of vegetative lesions often break loose. Embolization of other body sites can cause infarction or metastatic infection, which results in diverse clinical signs. Larger and more mobile vegetations (based on echocardiographic appearance) are associated with a higher incidence of embolic events in people and, presumably, also in animals. Emboli can be septic or bland (noninfective). Septic arthritis, diskospondylitis, urinary tract infections, and renal and splenic infarctions are common in affected animals. Local abscess formation resulting from septic thromboemboli contributes to recurrent bacteremia and fever. Hypertrophic osteopathy has also been associated with bacterial endocarditis. Circulating immune complexes and cell-mediated responses contribute to the disease syndrome. Sterile polyarthritis, glomerulonephritis, vasculitis, and other forms of immune-mediated organ damage are common.

Clinical Features

The prevalence of bacterial endocarditis is low in dogs (estimates range widely from 0.05% to over 6%) and even lower in cats. Most reports suggest larger (>15 kg) dogs are at greater risk, although middle-aged medium-breed dogs sometimes are affected. German Shepherd Dogs and possibly Boxers, Golden Retrievers, and Labrador Retrievers might be overrepresented. Male dogs are affected more commonly than females.

Either the aortic or the mitral valve is involved in virtually all cases; the prevalence of mitral endocarditis may be slightly greater than that of aortic endocarditis. Both valves are affected in some cases. Subaortic stenosis is a known risk factor for aortic valve endocarditis. Although some animals with endocarditis have evidence of past or concurrent infection, a clear history of predisposing factors often is absent. Possible relationship between severe periodontal disease and risk of endocarditis is unclear; small breeds of dog, which often are affected with severe periodontal disease and CMVD, have a low prevalence of endocarditis. Neutropenic and otherwise immunocompromised animals may be at greater risk for endocarditis.

The combination of fever, lameness, and a cardiac murmur (especially if new, altered in quality, or diastolic in timing) should strongly raise suspicion of infective endocarditis. Nevertheless, the clinical signs of endocarditis are variable and relate to the underlying infection, immune-mediated effects, TE events, and progressive valvular or myocardial dysfunction. The presenting signs can result from left-sided CHF or arrhythmias; however, cardiac signs often are overshadowed by signs of systemic infarction, infection, immune-mediated disease (including polyarthritis), or a combination of these. Nonspecific signs of lameness or stiffness (possibly shifting from one limb to another), lethargy, trembling, recurrent fever, weight loss, inappetence, vomiting, diarrhea, and weakness may be the predominant complaints. A majority of cases with bacterial endocarditis are febrile or have waxing/waning temperature spikes, although some are normothermic (especially those with *Bartonella* endocarditis). Palpable joint effusion may be present. A cardiac murmur is heard in most dogs with endocarditis, although an audible murmur can be absent if the endocarditis lesions have caused only minimal or no valve regurgitation. Murmur characteristics depend on the valve involved. Ventricular tachyarrhythmias are common, but supraventricular tachyarrhythmias or AV block (especially with aortic valve infection) also occur. Infective endocarditis often mimics immune-mediated disease. Dogs with endocarditis are commonly evaluated for a "fever of unknown origin." Some of the consequences of infectious endocarditis are outlined in Box 6.3.

Signs of CHF in an unexpected clinical setting or in an animal with a murmur of recent onset may herald infective valve damage, especially if other suggestive signs are present. However, a "new" murmur can be a manifestation of noninfective acquired disease (e.g., CMVD, cardiomyopathy), a previously undiagnosed congenital disease, or physiologic alterations (e.g., fever, anemia). Conversely, endocarditis may develop in an animal known to have a murmur caused by another cardiac disease. Although a change in murmur quality or intensity over a short time frame may indicate active valve damage, physiologic causes of murmur variation are common. The onset of a diastolic murmur at the left heart base is suspicious for aortic valve endocarditis, especially if fever or other signs are present.

Diagnosis

It can be difficult to establish a definitive antemortem diagnosis. Presumptive diagnosis of infective endocarditis is made based on two or more positive blood cultures (or positive *Bartonella* testing; see Chapter 94), in addition to either

BOX 6.3

Potential Sequelae of Infective Endocarditis

Heart

Valve insufficiency or stenosis
- Murmur
- Congestive heart failure

Coronary embolization (aortic valve*)
- Myocardial infarction
- Myocardial abscess
- Myocarditis
- Decreased contractility (segmental or global)
- Arrhythmias

Myocarditis (direct invasion by microorganisms)
- Arrhythmias
- AV conduction abnormalities (aortic valve*)
- Decreased contractility

Pericarditis (direct invasion by microorganisms)
- Pericardial effusion
- Cardiac tamponade (?)

Kidney

Infarction
- Reduced renal function

Abscess formation and pyelonephritis
- Reduced renal function
- Urinary tract infection
- Renal pain

Glomerulonephritis (immune mediated)
- Proteinuria
- Reduced renal function

Musculoskeletal

Septic arthritis
- Joint swelling and pain
- Lameness

Immune-mediated polyarthritis
- Shifting-leg lameness
- Joint swelling and pain

Septic osteomyelitis
- Bone pain
- Lameness

Myositis
- Muscle pain

Hypertrophic pulmonary osteopathy

Brain and Meninges

Abscesses
- Associated neurologic signs

Encephalitis and meningitis
- Associated neurologic signs

Vascular System in General

Vasculitis
- Thrombosis
- Petechiae and small hemorrhages (e.g., eye, skin)

Obstruction
- Ischemia of tissues served, with associated signs

Lung

Pulmonary emboli (tricuspid or pulmonic valves, rare*)
Pneumonia (tricuspid or pulmonic valves, rare*)

Nonspecific

Sepsis
Fever
Anorexia
Malaise and depression
Shaking
Vague pain
Inflammatory leukogram
Mild anemia
±Positive antinuclear antibody test
±Positive blood cultures

*Diseased valve most commonly associated with abnormality.

echocardiographic evidence of vegetations or valve destruction. Endocarditis is likely even when blood culture results are negative or intermittently positive if there is echocardiographic evidence of vegetations or valve destruction along with a combination of other criteria (Box 6.4).

Clinical laboratory findings in all species usually reflect the presence of inflammation. Neutrophilia with toxic neutrophils or a left shift is typical of acute endocarditis; mature neutrophilia with or without monocytosis develops with time. Variable thrombocytopenia (mild to marked) occurs in more than half of affected dogs, as does mild nonregenerative anemia. In dogs diagnosed with bartonellosis, thrombocytopenia, eosinophilia, and monocytosis have been reported. Evidence for disseminated intravascular coagulation may be present in association with endocarditis. Common biochemical findings in dogs include hypoalbuminemia, elevated liver enzymes, azotemia, acidosis, and hyperglobulinemia. Urinalysis often shows hematuria, proteinuria, and pyuria. Because the kidneys are a possible source of primary and secondary bacterial infection, culturing the urine is also recommended. Urine protein/creatinine ratio is useful in cases with proteinuria; a high ratio can signal increased risk of TE from hypercoagulability related to urinary loss of plasma antithrombin. Rheumatoid factor and antinuclear antibody tests may be positive in dogs with subacute or chronic bacterial endocarditis.

Blood cultures should be done, although they are negative in about 40% to 70% of cases. Negative culture results do not rule out infective endocarditis, especially with chronic endocarditis, recent antibiotic therapy, intermittent bacteremia, or infection by fastidious or slow growing organisms. Ideally,

BOX 6.4

Criteria for Diagnosis of Infective Endocarditis*

Definite Endocarditis by Pathologic Criteria

Pathologic (postmortem) lesions of active endocarditis with evidence of microorganisms in vegetation (or embolus) or intracardiac abscess

Definite Endocarditis by Clinical Criteria

Two major criteria (below), or
One major and two to three minor criteria, or
Five minor criteria

Possible Endocarditis

Findings consistent with infectious endocarditis that fall short of "definite" but not "rejected"

Rejected Diagnosis of Endocarditis

Firm alternative diagnosis for clinical manifestations
Resolution of manifestations of infective endocarditis with 4 or fewer days of antibiotic therapy
No pathologic evidence of infective endocarditis at surgery or necropsy

Major Criteria

Positive blood cultures
- Typical microorganism for infective endocarditis from two separate blood cultures
- Persistently positive blood cultures for organism consistent with endocarditis (samples drawn >12 hours apart, or three or more cultures drawn ≥1 hour apart)

Evidence of endocardial involvement
- Positive echocardiogram for infective endocarditis (oscillating mass on heart valve or supportive structure or in path of regurgitant jet, or evidence of cardiac abscess)
- New valvular regurgitation, especially if more than mild aortic regurgitation; increase or change in preexisting murmur is not sufficient evidence

Minor Criteria

Subaortic stenosis or other predisposing cardiac condition (see p. 132)
Fever
Thromboembolic disease, including major arterial emboli, septic infarcts
Immune-mediated disease, including glomerulonephritis, polyarthritis, or positive antinuclear antibody or rheumatoid factor tests
Echocardiogram consistent with infective endocarditis, but not meeting major criteria above
High seroreactivity (e.g., titer ≥1 : 1024) or positive PCR test for *Bartonella* spp.†
Medium to large dog (>15 kg)†
Positive blood culture not meeting major criterion, as previously mentioned
(Rare in dogs and cats: repeated nonsterile IV drug administration)

*Adapted from modified Duke criteria for endocarditis.
†Proposed minor criterion for endocarditis in dogs.

three to four blood samples of at least 10 mL are collected aseptically over 24 hours for bacterial culture, with more than an hour elapsing between collections. Sampling during a fever spike or, if antibiotic therapy has already been given, at the time of drug trough concentration may increase diagnostic yield. A shorter sampling period of 3 to 4 hours could be used for critical patients before beginning empiric antibiotic therapy. Different venipuncture sites should be used for each sample. Blood collection from an indwelling IV catheter is not recommended. Both aerobic and anaerobic cultures have been recommended, although the value of routine anaerobic culture is questionable. Prolonged incubation (3-4 weeks) is recommended, because some bacteria are slow growing.

Bartonella spp are an important cause of culture-negative endocarditis in some regions. These organisms are especially difficult to identify on blood cultures. Use of specialized culture conditions and an enriched insect cell culture medium (Bartonella α Proteobacteria growth medium; BAPGM) or heart infusion agar may increase the likelihood of growing these organisms. Blood can be aseptically collected in plastic ethylene diamine tetraacetic acid (EDTA) tubes then frozen at -70° C until plated. Molecular testing using polymerase chain reaction (PCR) amplification of specific *Bartonella* gene segments is an important diagnostic tool. However, PCR amplification directly from blood or other body fluid samples often does not identify *Bartonella* DNA because of low circulating bacterial levels or intermittent bacteremia, and bacterial sequestration within endothelial cells and vegetative lesions. Positive results are more likely in immunosuppressed patients. A combined technique using preenrichment culture of aseptically collected blood (or body fluid or surgical tissue samples) in BAPGM followed by a high-sensitivity PCR assay can increase diagnostic yield and is commercially available (Galaxy Diagnostics Inc.; www.galaxydx.com). Aseptic handling of samples is important to avoid contamination. Serologic testing (including immunofluorescent antibody [IFA] or enzyme-linked immunosorbent assay [ELISA] tests) also can help, although *Bartonella* infection can cause variable seroreactivity. Some cases develop high titers to *Bartonella* spp., but others (~half of dogs) are not seroreactive. The particular *Bartonella*

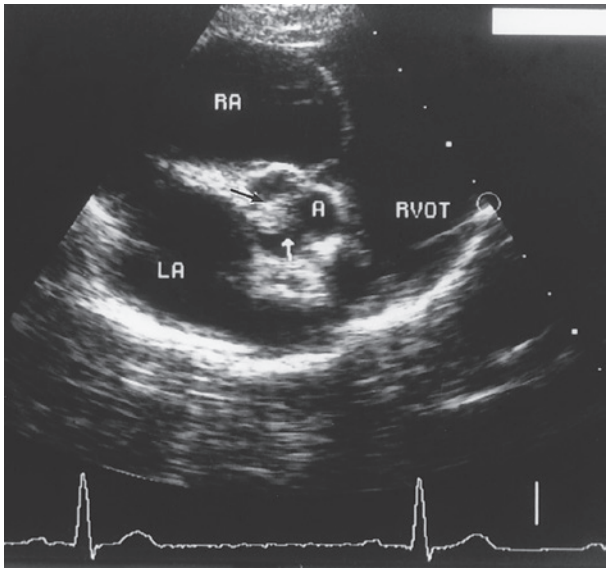

FIG 6.5
Right parasternal short-axis echocardiographic image at the aortic valve-left atrial level in a 2-year-old male Vizsla with congenital subaortic stenosis and pulmonic stenosis. Note the aortic valve vegetation *(arrows)* caused by infective endocarditis. *A,* Aorta; *LA,* left atrium; *RA,* right atrium; *RVOT,* right ventricular outflow tract.

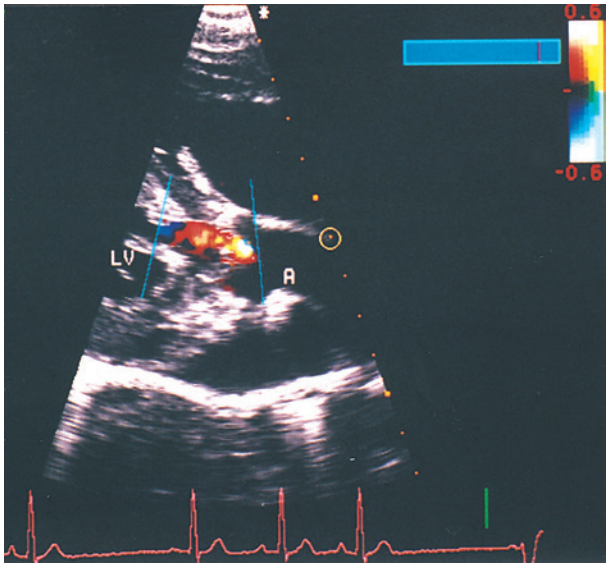

FIG 6.6
Right parasternal long axis, color flow Doppler image taken during diastole from the same dog as in Fig. 6.5. The "flame-like" jet of aortic regurgitation extends from the closed aortic valve into the left ventricular outflow tract. *A,* Aorta; *LV,* left ventricle.

species involved may influence seroreactivity. Seroreactivity (e.g., titer ≥1 : 64) to *B. vinsonii* subsp. *berkhoffii* in a dog with clinical signs of disease is evidence for exposure and likely an active *Bartonella* infection. However, follow-up culture or PCR documentation of infection is recommended. Dogs with a positive *Bartonella* antibody titer may also be positive for other tick-borne diseases such as *Anaplasma phagocytophilum*, *Ehrlichia canis*, or *Rickettsia rickettsi*, so screening for other tick-borne disease is advised.

Radiographic findings might be normal when valve damage is minimal. In cases with acute, severe valve regurgitation leading to CHF, pulmonary venous congestion and edema can occur with minimal or no cardiac chamber enlargement. Other cases have evidence of cardiomegaly, with or without pulmonary edema, or other organ involvement (such as diskospondylitis). Hypertrophic pulmonary osteopathy of the long bones, along with pulmonary infiltrates, has occurred rarely in dogs with endocarditis.

Echocardiography is especially supportive if oscillating vegetative lesions and abnormal valve motion can be identified (Fig. 6.5). The visualization of lesions depends on their size, location, and image resolution quality. Because false-negative and false-positive "lesions" may be found, cautious interpretation of images is important. Mild valve thickening and/or enhanced echogenicity can occur with early valve damage. Degenerative mitral valve disease can look similar in some cases, especially those with markedly thickened and knobby mitral leaflets; however, CMVD causes smooth valve thickening and also is more likely to occur in small-breed dogs. Nevertheless, differentiation of mitral vegetations from degenerative thickening can be impossible, especially in the early stages. Vegetative lesions appear as irregular dense masses that can be rough or shaggy, or have long flailing tendrils. Increased echogenicity of more chronic lesions can result from dystrophic calcification. As valve destruction progresses, ruptured chordae, flail leaflet tips, and other abnormal valve motion can be seen. Aortic regurgitation can cause fluttering of the anterior mitral valve leaflet during diastole as the regurgitant jet makes contact with this leaflet. Secondary effects of valve dysfunction include chamber enlargement from volume overload, as well as progressive myocardial dysfunction and arrhythmias. Spontaneous contrast within the left heart chambers is observed occasionally, probably related to hyperfibrogenemia and increased erythrocyte sedimentation. Doppler studies illustrate the flow disturbances (Fig. 6.6). The ECG can be normal or show premature ectopic complexes or tachycardia, conduction disturbances, or evidence of myocardial ischemia.

Treatment and Prognosis

Aggressive therapy with bactericidal antibiotics capable of penetrating fibrin and supportive care are indicated for infective endocarditis. Ideally, drug choice is guided by culture and in vitro susceptibility test results. However, to avoid treatment delay, broad-spectrum combination therapy usually is begun immediately after obtaining blood and urine culture samples (and blood for potential *Bartonella* testing). Therapy can be altered, if necessary, based on culture results. Culture-negative cases should be continued on the broad-spectrum regimen. Testing for *Bartonella* is advised in dogs

and cats with culture-negative endocarditis. Initial, empiric broad-spectrum combination therapy for infective endocarditis usually includes a β-lactam antibiotic such as a synthetic penicillin derivative (e.g., ampicillin [22-40 mg/kg IV q6-8h], or ticarcillin/clavulanate [50 mg/kg IV q6h]) or a cephalosporin (e.g., cefazolin [22-33 mg/kg IV q8h], or ceftriaxone [20 mg/kg IV q12h]), with either an aminoglycoside (amikacin [7-10 mg/kg IV q12h; or 20 mg/kg q24h], with fluid support) or a fluoroquinolone (enrofloxacin [5-10 mg/kg IV q12h]). The former provides a gram-positive spectrum and the latter, gram-negative. Clindamycin or metronidazole provides added anaerobic coverage. Antibiotics are best administered via IV for the first week or two to obtain higher and more predictable blood concentrations. Oral therapy can be used thereafter for the sake of practicality, assuming clinical and laboratory abnormalities are improved. Empirical options for continued oral therapy include either amoxicillin/clavulanate (20-25 mg/kg PO q8h) or cephalexin (25-30 mg/kg PO q8h), in combination with enrofloxacin (2.5-5 mg/kg PO q12h). For multiple-drug resistant bacteria requiring therapy with imipenem, SC administration following an initial 1- to 2-week course of IV administration has been recommended. In general, antimicrobial therapy is continued for at least 6 weeks, although therapy for 8 weeks is often recommended. However, aminoglycosides are discontinued after 7 to 10 days or sooner if renal toxicity develops. Close monitoring of the urine sediment is indicated to detect early aminoglycoside nephrotoxicity. Fluid therapy is given concurrently because of the concern for aminoglycoside nephrotoxicity. Furosemide should not be given during aminoglycoside treatment because it can exacerbate nephrotoxicity. Therefore aminoglycoside use is generally contraindicated in patients with CHF or underlying renal disease.

It is important to seek confirmation of suspected *Bartonella* endocarditis infection (see p. 135, discussed earlier) because treatment may require extremely long-term antibiotic therapy (e.g., for up to 3 months), using at least two antimicrobial drugs with different modes of action, in an attempt to eliminate the organism. Nevertheless, the most effective strategy for eliminating *Bartonella* in dogs and cats currently remains unproven. In vitro testing and reported antibiotic minimal inhibitory concentration (MIC) do not reflect efficacy against *Bartonella* in the host animal. Bacterial persistence can lead to recurrent clinical infection, especially with immunosuppression or concurrent disease process. Although previous recommendations have included use of azithromycin, this drug is no longer recommended as first-line therapy for *Bartonella* because of the rapid development of resistance to it.

For dogs with *Bartonella* endocarditis (or myocarditis), initial therapy with amikacin (15-30 mg/kg q24h IV, IM, or SC) for 7 to 10 days, combined with doxycycline ([5-]10 mg/kg q12h PO) has been recommended. Renal function must be closely monitored when using an aminoglycoside; this agent should not be used in certain patients (see previous discussion). After amikacin is discontinued, an oral fluoroquinolone is added. Currently recommended oral therapy for *Bartonella* infection includes doxycycline (5-10 mg/kg q12h PO; or minocycline at 10 mg/kg q12h PO), combined with enrofloxacin (5-20 mg/kg q24h PO) or pradofloxacin (5-10 mg/kg q24[-12]h PO; not approved for dogs in the United States) for 28 to 42 days (at least). In clinically stable *Bartonella* patients where initial IV therapy is not used, the recommendation has been made to start oral treatment with one drug (e.g., doxycycline at 5 mg/kg q12h), followed in 5 to 7 days with the addition of the second drug. However, this may not be possible in patients with endocarditis or myocarditis because of illness severity. This recommendation is based on the observation that, when both antibiotics are begun simultaneously for *Bartonella* infection, a reaction can occur within 4 to 7 days (or longer) which may include lethargy, fever, and vomiting (Jarisch-Herxheimer–like reaction). It is thought that the reaction, which can last a few days, relates to acute bacterial injury or death and host cytokine release. Unless the patient's clinical status continues to deteriorate from this reaction, the PO antibiotic strategy should be continued as planned and supportive care given as appropriate. The addition of antiinflammatory doses of a glucocorticoid may be helpful for patients experiencing this reaction; however, the glucocorticoid should be discontinued after a few days as those signs abate.

For cats with cardiac *Bartonella* infection, initial therapy with amikacin (10-14 mg/kg q24h IV, IM, or SC) for 7 to 10 days, combined with doxycycline ([5-]10 mg/kg q12h PO) has been recommended. Aminoglycoside precautions for patient selection and renal function monitoring are as for dogs (see previous discussion). When the amikacin is discontinued, oral pradofloxacin (5-10 mg/kg q24[-12]h PO) can be added. Currently recommended oral therapy for *Bartonella* infection includes doxycycline (5-10 mg/kg q12h PO; or minocycline at 8.8 mg/kg q12h PO), combined with pradofloxacin (5-10 mg/kg q24[-12]h PO) for 28 to 42 days (at least). Because higher doses and longer treatment duration generally are needed for treating *Bartonella* infection, and because cats are at risk for retinotoxicity when enrofloxacin is used at doses >5 mg/kg/day, this agent is no longer recommended for *Bartonella* infections in cats. Jarisch-Herxheimer–like reactions (see previous discussion) also can occur in cats.

Supportive care includes management for CHF (see Chapter 3) and arrhythmias (see Chapter 4), if present. Complications related to the primary source of infection, embolic events, or immune responses are addressed to the extent possible. Attention to hydration status, nutritional support, and general nursing care is also important. BP and renal function should be monitored, along with other parameters as indicated for the individual patient. Hypertension should be vigorously controlled (see Chapter 11). Even when BP is normal, modest additional afterload reduction with an arteriolar vasodilator can help support cardiac function, especially with advancing aortic or mitral valve regurgitation. Corticosteroids generally are contraindicated. The

effectiveness of aspirin in reducing vegetative lesion growth and incidence of embolic events is questionable.

For animals with positive blood (or urine) cultures, repeated cultures 1 to 2 weeks after starting antibiotic therapy and also 1 to 2 weeks after completion of antibiotic therapy are recommended. Patients with a positive Bartonella antibody titer can be retested in 4 weeks after starting antibiotic therapy to verify that titers are decreasing. Persistently elevated titers suggest that antibiotic strategy should be changed. Animals testing positive for *Bartonella* via serologic and BAPGM enrichment blood culture techniques before beginning antibiotic therapy should have these tests repeated at 2 and 6 weeks after therapy has been discontinued to evaluate treatment efficacy. Other tests or monitoring may be indicated depending on the type and severity of concurrent disease and secondary complications in the individual patient. Recheck echocardiograms during (for example, at 2 and 8 weeks after starting therapy) and a few weeks following the treatment period are indicated to monitor changes in vegetation size, valve function, chamber dimensions, and LV function. Even if antibiotic therapy is successful in resolving the infection, progressive cardiac enlargement and myocardial dysfunction are common because of residual valve damage and insufficiency. So continued cardiac monitoring is recommended. Radiographs, complete blood count (CBC) and serum biochemistry tests, and other tests are repeated as indicated for the individual patient.

Prognosis

Long-term prognosis generally is guarded to poor. Some dogs die within days to weeks; others that survive the acute stages are likely to die later from progressive CHF. Echocardiographic evidence of vegetations (especially of the aortic valve) and volume overload suggests a poor prognosis. Other negative prognostic indicators include *Bartonella* or gram-negative infections, renal or cardiac complications that respond poorly to treatment, septic embolization, and thrombocytopenia. Glucocorticoid therapy and inadequate antibiotic therapy can contribute to a poor outcome. Aggressive therapy may be successful if valve dysfunction is not severe and large vegetations are absent. CHF is the most common cause of death, although sepsis, systemic embolization, arrhythmias, or renal failure may be the proximate cause.

Antibiotic Prophylaxis

The use of prophylactic antibiotics is controversial. Experience in people suggests that most cases of infective endocarditis are not preventable. The risk of endocarditis from a specific (e.g., dental) procedure in humans is low compared with the cumulative risk associated with normal daily activities. However, in view of the increased occurrence of endocarditis with certain cardiovascular malformations (especially SAS), antimicrobial prophylaxis usually is recommended for these animals before dental or other "dirty" procedures (those involving the oral cavity or intestinal or urogenital systems). Antimicrobial prophylaxis also is advised for animals with an implanted pacemaker or other device, or with a history of endocarditis; it should be considered in immunocompromised animals as well. Recommendations have included high-dose ampicillin, amoxicillin, or a cephalosporin 1 hour before and 6 hours after oral or upper respiratory procedures; clindamycin before dental procedures; ampicillin with an aminoglycoside (given IV) one half hour before and 8 hours after GI or urogenital procedures; and ticarcillin or a first-generation cephalosporin (IV) 1 hour before and 6 hours after a procedure.

CHAPTER 7

Myocardial Diseases of the Dog

Heart muscle disease that leads to contractile dysfunction and cardiac chamber enlargement is an important cause of heart failure in dogs. Idiopathic or primary dilated cardiomyopathy (DCM) is most common and mainly affects the larger breeds. Arrhythmogenic right ventricular cardiomyopathy (ARVC), previously known as Boxer cardiomyopathy, is an important myocardial disease in Boxers but uncommon in other breeds. Secondary and infective myocardial diseases (see p. 150) occur less often. Hypertrophic cardiomyopathy (HCM) is recognized infrequently in dogs (see p. 152).

DILATED CARDIOMYOPATHY

Etiology and Pathophysiology

DCM is a disease characterized by poor myocardial contractility, with or without arrhythmias. Although considered idiopathic, DCM as an entity probably represents the end stage of different pathologic processes or metabolic defects involving myocardial cells or the intercellular matrix rather than a single disease. A genetic basis is thought to exist for many cases of idiopathic DCM, especially in breeds with a high prevalence or a familial occurrence of the disease. Large and giant breeds are most commonly affected, including Doberman Pinschers, Great Danes, Saint Bernards, Scottish Deerhounds, Irish Wolfhounds, Labrador Retrievers, Newfoundlands, Afghan Hounds, and Dalmatians. Some smaller breeds such as Cocker Spaniels can also be affected. The disease is rarely seen in dogs that weigh less than 12 kg. Doberman Pinschers appear to have the highest prevalence of DCM with an autosomal dominant pattern of inheritance. A causative genetic mutation on chromosome 14 has been associated with DCM in Doberman Pinschers; the affected protein codes for a mitochondrial protein associated with regulation of cardiac glucose metabolism, and mutation is associated with poor systolic function. Testing for the mutation is commercially available (North Carolina State University Veterinary Cardiac Genetics Laboratory; https://cvm.ncsu.edu/genetics/); however, penetrance of this mutation is only approximately 67%, and some Dobermans with DCM are homozygous-negative for this mutation. Multiple other mutations associated with DCM likely exist in Dobermans and other breeds. In at least some Great Danes, DCM appears to be an X-linked recessive trait. DCM in Irish Wolfhounds appears to be familial, with an autosomal recessive inheritance with sex-specific alleles. The familial DCM affecting young Portuguese Water Dogs has an autosomal recessive inheritance pattern and is rapidly fatal in puppies that are homozygous for the mutation.

Various biochemical defects, nutritional deficiencies, toxins, immunologic mechanisms, and infectious agents may be involved in the pathogenesis of DCM in different cases. Impaired intracellular energy homeostasis and decreased myocardial adenosine triphosphate (ATP) concentrations have been found in myocardial biochemical studies of affected Doberman Pinschers. Abnormal gene expression related to cardiac ryanodine receptor regulation and intracardiac Ca^{++} release has been reported in Great Danes with DCM. Idiopathic DCM has also been associated with prior viral infections in people. However, on the basis of polymerase chain reaction (PCR) analysis of myocardial samples from a small number of dogs with DCM, viral agents do not seem to be commonly associated with DCM in this species.

Decreased ventricular contractility (systolic dysfunction) is the major functional defect in dogs with DCM. Progressive cardiac chamber dilation (eccentric hypertrophy and remodeling) develops as systolic pump function and cardiac output worsen, and compensatory mechanisms become activated. Poor cardiac output can cause weakness, syncope, and ultimately cardiogenic shock. Increased diastolic stiffness also contributes to the development of high end-diastolic pressures, venous congestion, and congestive heart failure (CHF). Cardiac enlargement and papillary muscle dysfunction often cause poor systolic apposition of mitral and tricuspid leaflets, leading to mild to moderate valve insufficiency.

As cardiac output decreases, sympathetic, hormonal, and renal compensatory mechanisms become activated. These mechanisms increase heart rate, peripheral vascular

resistance, and volume retention (see Chapter 3). Chronic neurohormonal activation is thought to contribute to progressive myocardial damage, as well as to CHF. Coronary perfusion can be compromised by poor forward blood flow and increased ventricular diastolic pressure; myocardial ischemia further impairs myocardial function and predisposes to development of arrhythmias. Signs of low-output heart failure and left-sided, right-sided, or biventricular CHF (see Chapter 3) are common in dogs with DCM.

Atrial fibrillation (AF) often develops in dogs with DCM, particularly giant-breed dogs and dogs with severe left atrial (LA) enlargement. Approximately 30% of Doberman Pinschers and more than 80% of giant breed dogs with DCM have concurrent AF. In Irish Wolfhounds, AF may precede echocardiographic changes. Atrial contraction contributes importantly to ventricular filling, especially at faster heart rates. The loss of the "atrial kick" associated with AF reduces cardiac output and can cause acute clinical decompensation. Persistent tachycardia associated with AF probably also accelerates disease progression. Ventricular tachyarrhythmias are common as well and can cause syncope and sudden death. In Doberman Pinschers, serial Holter recordings have documented the appearance of ventricular premature complexes (VPCs) months to more than a year before early echocardiographic abnormalities of DCM were identified. Once left ventricular (LV) function begins to deteriorate, the frequency of tachyarrhythmias increases. Excitement-induced bradyarrhythmias have also been associated with low-output signs in Doberman Pinschers.

Dilation of all cardiac chambers is typical in dogs with DCM, although LA and LV enlargement usually predominate. The ventricular wall thickness may appear decreased compared with the lumen size. Flattened, atrophic papillary muscles and endocardial thickening also occur. Concurrent degenerative changes of the AV valves are generally only mild to moderate, if present at all. Histopathologic findings include scattered areas of myocardial necrosis, degeneration, and fibrosis, especially in the left ventricle (LV). Narrowed (attenuated) myocardial cells with a wavy appearance may be a common finding. Inflammatory cell infiltrates, myocardial hypertrophy, and fatty infiltration (mainly in Doberman Pinschers and Boxers with ARVC) are inconsistent features.

Clinical Findings

The prevalence of DCM increases with age, although most dogs with CHF are 4 to 10 years old. Among Doberman Pinschers, prevalence of DCM approaches 50% in dogs greater than 8 years of age. Male Doberman Pinschers generally show signs at an earlier age than females and are more likely to experience CHF.

DCM appears to develop slowly, with a prolonged preclinical (occult) stage that may evolve over several years before clinical signs become evident. Further cardiac evaluation is indicated for dogs with a history of reduced exercise tolerance, weakness, or syncope or in those in which an arrhythmia, murmur, or gallop sound is detected on routine physical examination. Occult DCM is often recognized through use of screening echocardiography and Holter monitoring, more commonly performed in breeding or show dogs. Some giant-breed dogs with mild to moderate LV dysfunction are relatively asymptomatic, even in the presence of AF.

Clinical signs of DCM may seem to develop rapidly, especially in sedentary dogs in which early signs may not be noticed. Sudden death before CHF signs develop is relatively common. Presenting complaints include any or all of the following: weakness, lethargy, tachypnea or dyspnea, exercise intolerance, cough (sometimes described as "gagging"), anorexia, abdominal distention (ascites), and syncope. Loss of muscle mass (cardiac cachexia), accentuated along the dorsal midline, may be severe in advanced cases.

Physical examination findings vary with the degree of cardiac decompensation. Some dogs with occult disease have normal physical examination findings. Others have a soft murmur of mitral or tricuspid regurgitation or an arrhythmia. Dogs with advanced disease and poor cardiac output have increased sympathetic tone and peripheral vasoconstriction, with pale mucous membranes and slowed capillary refill time. The femoral arterial pulse and precordial impulse often are weak and rapid. Uncontrolled AF and frequent VPCs cause an irregular and usually rapid heart rhythm, with frequent pulse deficits and variable pulse strength (see Fig. 4.1). Signs of left- and/or right-sided CHF include tachypnea, increased breath sounds, pulmonary crackles, jugular venous distention or pulsations, pleural effusion or ascites, and/or hepatosplenomegaly. Heart sounds may be muffled because of pleural effusion or poor cardiac contractility. An audible third heart sound (S_3 gallop) is a classic finding, although it may be obscured by an irregular heart rhythm. Soft to moderate-intensity systolic murmurs of mitral and/or tricuspid regurgitation are common.

RADIOGRAPHY

Diagnosis

The stage of disease, chest conformation, and hydration status influence the radiographic findings. Dogs with early occult disease are likely to be radiographically normal. Generalized cardiomegaly (predominately left heart enlargement) is evident in those with advanced DCM (Fig. 7.1). In Doberman Pinschers and other deep-chested breeds, the heart might appear minimally enlarged, except for the left atrium (LA). In other dogs, generalized cardiomegaly can be severe and can mimic the globoid cardiac silhouette typical of large pericardial effusions. Distended pulmonary veins and pulmonary interstitial or alveolar opacities accompany left-sided CHF with pulmonary edema. The distribution of pulmonary edema infiltrates in DCM often is diffuse (see Fig. 7.1). Pleural effusion, caudal vena cava distention, hepatomegaly, and ascites usually accompany right-sided CHF. Biventricular CHF is common.

ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) findings in dogs with DCM also are variable. Sinus rhythm usually is the underlying

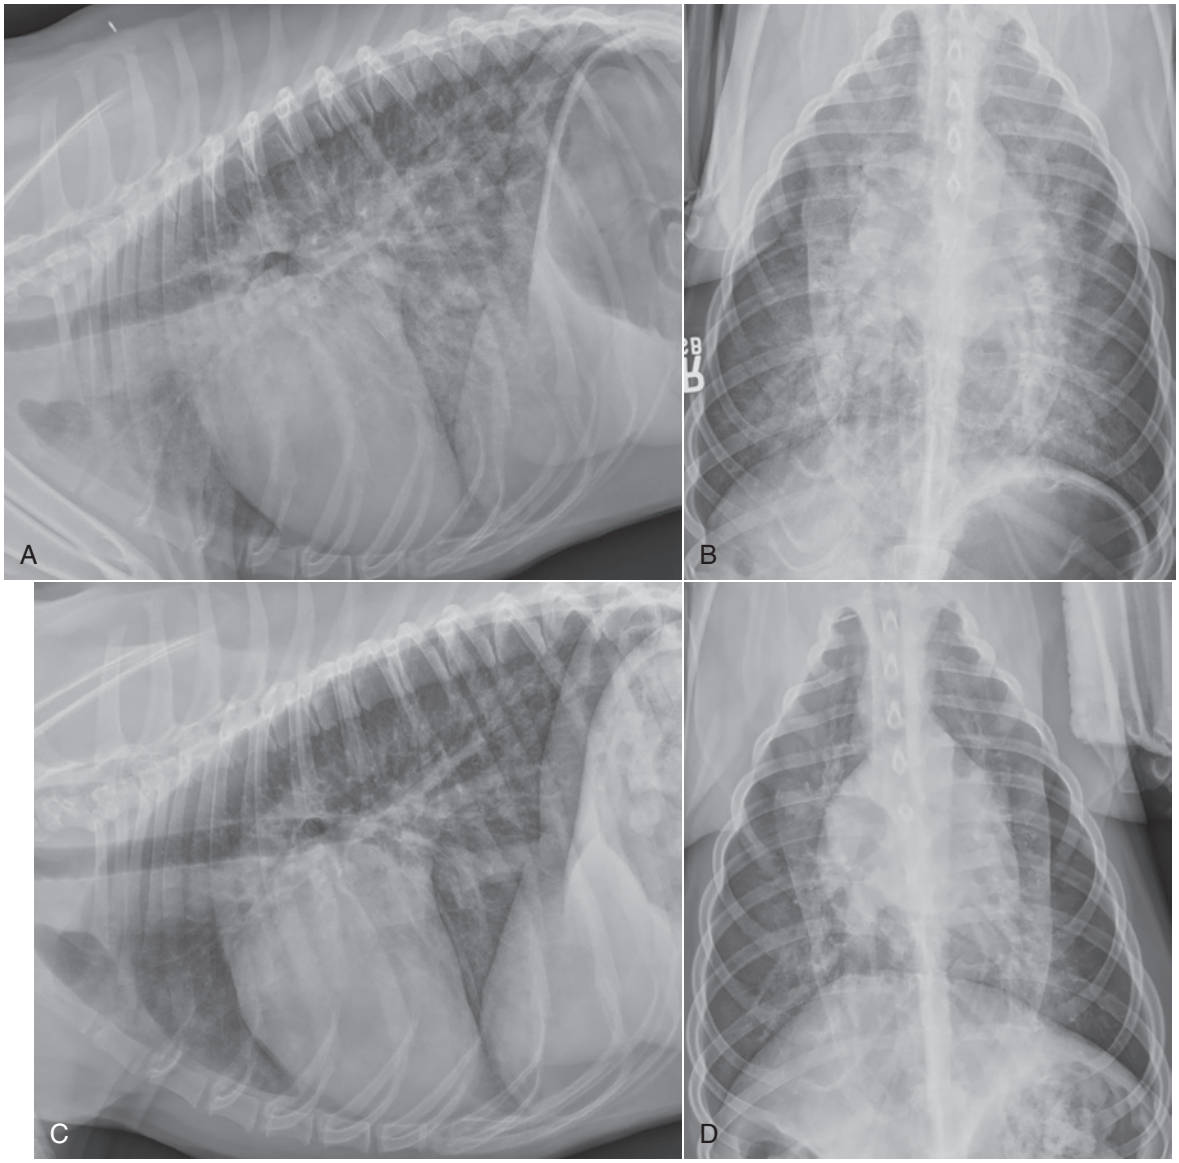

FIG 7.1
Radiographic example of dilated cardiomyopathy with congestive heart failure (and subsequent resolution) in a 5-year-old male Doberman Pinscher. Lateral **(A)** and dorsoventral **(B)** views showing left ventricular and left atrial enlargement, pulmonary venous distension, and moderate diffuse pulmonary edema, consistent with left-sided congestive heart failure. Following medical therapy for congestive heart failure, thoracic lateral **(C)** and dorsoventral **(D)** radiographs of the same patient show resolution of pulmonary edema, with persistent cardiomegaly.

rhythm, although AF is common, especially in Irish Wolfhounds and other giant breeds (see Fig. 2.30). Ventricular tachyarrhythmias, including multiform VPCs, ventricular couplets and triplets, or paroxysmal or sustained ventricular tachycardia are also common, particularly in Doberman Pinschers. Presence of VPCs during a 5-minute ECG is a specific (although insensitive) indicator of frequent VPCs on Holter monitor; even a single VPC noted in a Doberman is highly suggestive of occult DCM. The QRS complexes can be tall (consistent with LV dilation), normal in size, or small. Myocardial disease often causes a widened QRS complex with a slowed R-wave descent and slurred ST segment. A bundle-branch block pattern or other intraventricular conduction disturbance might be observed. The P waves in dogs with sinus rhythm frequently are widened and notched, suggesting LA enlargement.

Twenty-four-hour Holter monitoring is useful for documenting the presence and frequency of ventricular ectopy and can be used as a screening tool for DCM in Doberman Pinschers (see p. 48). The presence of more than 50 VPCs/day or any couplets or triplets is thought to predict future overt DCM in Doberman Pinschers. Some dogs with fewer

than 50 VPCs/day on initial evaluation also develop DCM after several years. The frequency and complexity of ventricular tachyarrhythmias appear to be negatively correlated with fractional shortening; sustained ventricular tachycardia has been associated with increased risk of sudden death. Variability in the number of VPCs between repeated Holter recordings in the same dog can be high (up to 85%). If available, the technique of signal-averaged electrocardiography can reveal the presence of ventricular late potentials, which could suggest an increased risk for sudden death in Doberman Pinschers with occult DCM.

ECHOCARDIOGRAPHY

Echocardiography is used to definitively diagnose DCM (and differentiate from pericardial effusion or chronic mitral valve disease), assess severity of systolic dysfunction, and document degree of cardiac chamber enlargement. Dilated cardiac chambers and poor ventricular systolic wall motion are characteristic findings in dogs with DCM (Fig. 7.2). In severe cases only, minimal wall motion is evident. Left heart enlargement predominates, although all chambers are usually affected to some degree. Echocardiographic indices of LV systolic function are decreased, including fractional shortening, fractional area change, and ejection fraction. LV systolic (as well as diastolic) dimension is increased compared with normal ranges for the breed; the LV appears more spherical, and mitral valve E point–septal separation is increased. LV free-wall and septal thicknesses are normal to decreased. The calculated end-systolic volume index (see p. 25) typically is greater than 80 mL/m^2 in dogs with overt DCM (<30 mL/m^2 is considered normal). Evidence for abnormal diastolic function also can be found in dogs with advanced disease. Mild to moderate centrally directed AV valve regurgitation usually is seen with Doppler echocardiography (Fig. 7.3).

Echocardiography is used to screen for occult myocardial disease also. Screening is complicated by the fact that apparently healthy Doberman Pinschers, Greyhounds, and some other athletic dogs can have slightly reduced fractional shortening compared with what is generally considered normal for most breeds. For asymptomatic Doberman Pinschers, the following echocardiographic criteria suggest occult DCM with a high risk for overt disease within 2 to 3 years: LVIDs greater than 4.6 cm (in dogs ≤42 kg) or greater than 5.0 cm (in dogs >42 kg), LVIDs greater than 3.8 cm, mitral valve E point–septal separation greater than 0.9 cm, or VPCs during initial examination (*LVID,* left ventricular internal diameter; *d,* diastole; *s,* systole).

Clinicopathologic Findings

Circulating concentrations of the natriuretic peptides (B-type natriuretic peptide [BNP] and atrial natriuretic peptide [ANP]) and cardiac troponin are elevated in Doberman Pinschers with occult DCM, and levels of these biomarkers rise as disease progresses and CHF develops. Among these biomarkers, NT-proBNP appears to have the best sensitivity and specificity for detecting occult DCM, particularly when echocardiographic abnormalities are present. However, NT-proBNP has wide biologic variability in normal dogs and is relatively insensitive for detecting occult DCM when ventricular arrhythmias precede echocardiographic changes. Thus the gold standard screening regimen for detecting occult DCM in individual dogs is combined Holter monitoring and echocardiography. In high-volume screening situations, a combination of Holter monitoring and NT-proBNP testing could be considered. Genetic screening is recommended in Doberman Pinschers intended for breeding.

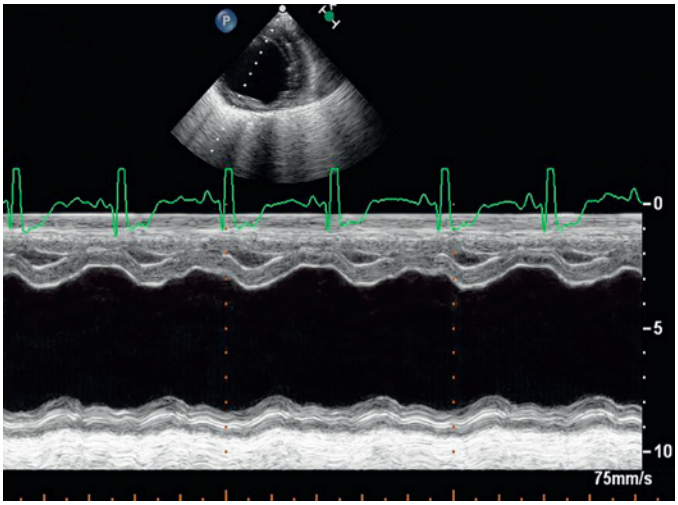

FIG 7.2
M-mode echocardiogram from a Doberman Pinscher with dilated cardiomyopathy at the level of the left ventricular papillary muscles. Note attenuated wall motion (fractional shortening ~18%) and the increased left ventricular dimensions in both diastole and systole.

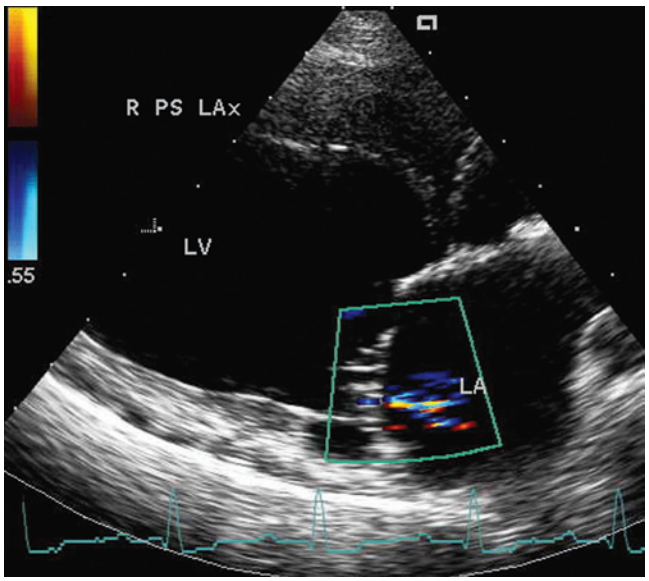

FIG 7.3
Mild mitral regurgitation is indicated by a relatively small area of disturbed flow in this systolic frame from a Standard Poodle with dilated cardiomyopathy. Note the LA and LV dilation. Right parasternal long axis view, optimized for the left ventricular inflow tract. *LA,* Left atrium; *LV,* left ventricle.

Other clinicopathologic findings are noncontributory in most cases, although prerenal azotemia from poor renal perfusion or mildly increased liver enzyme activities from passive hepatic congestion often occur in advanced disease. Severe CHF can be associated with hypoproteinemia, hyponatremia, and hyperkalemia. Hypothyroidism, with associated hypercholesterolemia, occurs in some dogs with DCM. Others have a low serum T_4 hormone concentration without hypothyroidism (euthyroid sick syndrome); normal thyroid-stimulating hormone (TSH) and free T_4 concentrations are common. Increased circulating neurohormones (e.g., norepinephrine, aldosterone, endothelin, in addition to the natriuretic peptides) occur mainly in DCM dogs with overt CHF.

STAGE B (OCCULT) DILATED CARDIOMYOPATHY

Treatment

Pimobendan has been shown to delay progression to CHF or sudden death in Doberman Pinschers with echocardiographic evidence of occult DCM. In a randomized, blinded, placebo-controlled study, pimobendan prolonged the preclinical period by approximately 9 months compared with placebo. It is unclear whether pimobendan would also be beneficial in Doberman Pinschers with ventricular arrhythmias only (before echocardiographic changes). Pimobendan also has been shown to delay progression to CHF or sudden death in Irish Wolfhounds with AF and/or echocardiographic evidence of occult DCM. Compared with benazepril or digoxin, pimobendan delayed the preclinical period in Irish Wolfhounds by approximately 2 years. It remains unknown whether the benefits of pimobendan in occult disease extend to other dog breeds commonly affected by DCM.

An angiotensin-converting enzyme inhibitor (ACEI) also is generally recommended for dogs with LV dilation or reduced LV systolic function. Preliminary evidence in Doberman Pinschers suggests this may delay the onset of CHF. Other therapy aimed at modulating early neurohormonal responses and ventricular remodeling processes have theoretical appeal, but their clinical usefulness is not clear. In particular, certain β-blockers have proven beneficial in humans with cardiomyopathy, but clinical trials demonstrating benefit in canine DCM are lacking. Carvedilol, a combined β-blocker and α-blocker with antioxidant properties, has largely fallen out of favor due to limited and unpredictable oral bioavailability in dogs.

The decision to use antiarrhythmic drug therapy in dogs with ventricular tachyarrhythmias is influenced by arrhythmia frequency and complexity seen on Holter recording, as well as presence or absence of clinical signs (episodic weakness, syncope). Various antiarrhythmic agents have been used, but the most effective regimen(s) and when to institute therapy remain unclear. A regimen that decreases arrhythmia frequency and severity and increases ventricular fibrillation threshold is desirable to decrease clinical signs and reduce risk of sudden death. Common first-line ventricular antiarrhythmic medications used in DCM include sotalol and/or mexiletine. Amiodarone or procainamide sometimes are used in refractory cases (see Chapter 4).

STAGE C (CLINICALLY EVIDENT) DILATED CARDIOMYOPATHY

Therapy is aimed at improving the patient's quality of life and prolonging survival to the extent possible by controlling signs of CHF, optimizing cardiac output, and managing arrhythmias. Pimobendan, an ACEI, and furosemide (dosed as needed) are used for most dogs (Box 7.1). Spironolactone is advocated as well. Antiarrhythmic drugs are used based on individual need.

Acute therapy

Dogs with acute CHF are treated as outlined in Box 3.1, with parenteral furosemide, supplemental oxygen, inotropic support, cautious use of a vasodilator, and other medications according to individual patient needs. Thoracocentesis is indicated if pleural effusion is suspected or identified.

Dogs with poor myocardial contractility, persistent hypotension, or fulminant CHF can benefit from additional inotropic support provided by intravenous (IV) infusion of dobutamine (or dopamine) for 1 to 3 days. Long-term use of strong positive inotropic drugs is thought to have detrimental effects on the myocardium. During infusion of these drugs, the patient must be observed closely for worsening tachycardia or arrhythmias (especially VPCs). If ventricular arrhythmias develop, the drug is discontinued or infused at up to half the original rate. In dogs with AF, catecholamine infusion is likely to increase the ventricular response rate because of enhanced AV conduction.

Rapid AF is treated with drugs to slow ventricular response rate. Diltiazem and digoxin are options for rate control in this setting; although both are available in IV and oral formulations, IV digoxin is avoided in most circumstances. Diltiazem is more effective at lowering heart rate, but its negative inotropic properties can further compromise systolic function in patients with advanced DCM; if the dog is not already receiving pimobendan, this drug should be administered as soon as possible. Digoxin is less potent for rate reduction, with slower onset of action, but has the benefit of being a mild positive inotrope. For long-term rate control, a combination of oral diltiazem and oral digoxin is preferred. Strategies for acute rate control include (see p. 84): (1) diltiazem loading (either PO or with small IV boluses, if necessary followed by cautious continuous rate infusion [CRI]), with transition to oral maintenance diltiazem and addition of oral digoxin; or (2) digoxin loading (PO loading with double the oral maintenance dose, or possibly cautious IV loading using small boluses hourly over 4 hours), with subsequent initiation of oral maintenance digoxin and addition of oral diltiazem. During an acute episode of CHF, the goal is to reduce ventricular response rate to 150 to 160 beats per minute to maximize cardiac output; more aggressive rate reduction is counterproductive and can lead to worsened cardiogenic shock.

BOX 7.1

Treatment Outline for Dogs With Dilated Cardiomyopathy

Occult CM (Stage B)

Client education (about disease process and early heart failure signs)
Routine health maintenance
Manage other medical problems
Pimobendan
ACE inhibitor
±Consider β-blocker titration (e.g., atenolol or metoprolol)
Antiarrhythmic therapy, if indicated (e.g., sotalol or mexiletine for ventricular tachyarrhythmias; digoxin and diltiazem combination therapy for atrial fibrillation; see Chapter 4)
Avoid high-salt foods; consider moderately salt-restricted diet
Monitor for early signs of CHF (e.g., resting respiratory rate [see p. 74], activity level)

Mild to Moderate Signs of CHF (Stage C, Chronic/Outpatient Care)*

Furosemide, dose as needed
Pimobendan
ACE inhibitor
Spironolactone
Antiarrhythmic therapy, if indicated (e.g., sotalol or mexiletine for ventricular tachyarrhythmias; digoxin and diltiazem combination therapy for atrial fibrillation; see Chapter 4)
Client education and manage concurrent problems, as previously mentioned
Complete exercise restriction until after signs abate
Moderate dietary salt restriction
Consider dietary supplement (fish oil, ±taurine or carnitine, if indicated)
Monitor resting respiratory rate (see p. 74) ±heart rate at home

Severe CHF Signs (Stage C, Acute/Hospitalized Care)*

Supplemental O_2
Cage rest and minimal patient handling
Furosemide (more aggressive doses, parenteral)
Pimobendan (continue or add as soon as oral administration possible)
Consider dobutamine, especially if persistent hypotension (see Box 3.1, p. 62)
Antiarrhythmic therapy, if necessary (e.g., lidocaine for ventricular tachycardia, PO loading or IV diltiazem (or digoxin) for uncontrolled AF, see text and Table 4.2, p. 90)
Consider cautious use of a vasodilator (nitroprusside, hydralazine, or amlodipine) for adjunct afterload reduction, if necessary, and if blood pressure is not low; beware hypotension
Thoracocentesis, if moderate- to large-volume pleural effusion

Chronic Recurrent or Refractory Heart Failure Strategies (Stage D)*

Ensure that therapies for stage C are being given at optimal doses and intervals, including furosemide, pimobendan, ACE inhibitor, spironolactone
Rule out complicating factors: arrhythmias, renal or other metabolic abnormalities, systemic arterial hypertension, anemia, and other complications
Increase furosemide dose/frequency as needed (and as renal function allows)
Increase pimobendan dose frequency to q8h and/or increase dose
Consider adding digoxin for additional inotropic support
Add (or increase dose of) adjunctive diuretics (e.g., spironolactone, hydrochlorothiazide); monitor renal function and electrolytes closely
Consider additional afterload reduction (e.g., amlodipine or hydralazine); monitor blood pressure closely
Strictly curtail exercise
Further restrict dietary salt intake
Thoracocentesis (or abdominocentesis) as needed
Hospitalize as needed for acute CHF therapy (see Box 3.1)
Manage arrhythmias, if present (see Chapter 4)

ACE, Angiotensin-converting enzyme; *AF,* atrial fibrillation; *CHF,* congestive heart failure; *IV,* intravenous.
*See text, Chapter 3, Tables 3.2 and 3.3 and Box 3.1 for further details and doses.

Clinical status in dogs with DCM can deteriorate rapidly, so close patient monitoring is important. Respiratory rate and character, lung sounds, pulse quality, heart rate and rhythm, peripheral perfusion, rectal temperature, body weight, renal function, mentation, pulse oximetry, and blood pressure should be monitored. Because ventricular contractility is abysmal in many dogs with severe DCM, these patients have little cardiac reserve; diuretic and vasodilator therapy can lead to hypotension and even cardiogenic shock.

Long-term therapy

Pimobendan (Vetmedin, Boehringer Ingelheim Vetmedica) is the oral positive inotrope of choice for long-term management of DCM and CHF. Pimobendan is a phosphodiesterase III inhibitor that increases contractility through a Ca^{++}-sensitizing effect; the drug also has vasodilator and other beneficial effects. Pimobendan improves clinical signs and survival in dogs with DCM and CHF. Starting dose is 0.2 to 0.3 mg/kg PO q12h. In progressive or refractory cases, pimobendan dose can be uptitrated to 0.5 mg/kg PO q8h. This higher dose recommendation is outside of the FDA approved labeling for pimobendan, and such off-label use should be explained to and approved by the client.

Furosemide is used at the lowest effective oral dosage for long-term therapy (see Table 3.3). Hypokalemia and other

electrolyte and acid-base abnormalities are common sequelae. Hypokalemia is often treated with addition of the potassium-sparing diuretic spironolactone, although dietary potassium supplementation can also be considered if needed.

An ACEI should be used in the chronic treatment of DCM and may attenuate progressive ventricular dilation and secondary mitral regurgitation. ACEIs have a positive effect on survival in patients with myocardial failure. These drugs minimize clinical signs and increase exercise tolerance. Enalapril or benazepril are used most commonly, but other ACEIs have similar effects.

Spironolactone is thought to be useful because of its aldosterone-antagonist properties as well as potential mild diuretic effects. Aldosterone is known to promote cardiovascular fibrosis and abnormal remodeling and, as such, contributes to the progression of cardiac disease. Spironolactone is therefore advocated as adjunctive therapy in combination with an ACEI, furosemide, and pimobendan for chronic DCM therapy.

For dogs with AF, a combination of oral diltiazem and oral digoxin is advocated for long-term control of ventricular response rate (see Table 4.2). Digoxin is a weak positive inotrope with neurohormonal modulating and antiarrhythmic effects. Although pimobendan has largely replaced digoxin for oral inotropic support, digoxin still is indicated for heart rate control in AF and can be given in conjunction with pimobendan. The recommended oral maintenance dose of digoxin is 0.003 to 0.005 mg/kg PO q12h, or approximately 0.125 mg total dose, PO, q12h for typical Dobermans (~40 kg). Toxicity is uncommon at these low doses, but monitoring is still recommended due to the narrow therapeutic index of this drug. Serum digoxin concentration should be measured 7 to 10 days after digoxin therapy is initiated or the dose is changed; serum samples should be drawn 6 to 8 hours after the last oral dose (see p. 70). Diltiazem is a cardiac-specific calcium-channel blocker that is very effective at slowing AV nodal conduction and thus decreasing heart rate in AF. Because of its negative inotropic effect, a low initial dose and gradual dosage titration to effect or a maximum recommended level is advised. Diltiazem is available in several dose formulations; typically, an extended-release formulation allowing twice daily dosing (Dilitazem ER/XR, Dilacor) is used for chronic administration.

Heart rate control in dogs with AF is important, but specific goals for rate control have yet to be firmly established. A maximum ventricular rate of 140 beats/min in the hospital (i.e., stressful) setting is the recommended target; lower heart rates (e.g., ≈100 beats/min or less) are expected at home. Because heart rate assessment by auscultation or chest palpation in dogs with AF often is highly inaccurate, an ECG recording is recommended. Femoral pulses should never be used to assess heart rate in the presence of AF. At-home rate assessment with Holter monitors or smartphone-based ECG applications may assist with dose adjustment.

Additional afterload reduction with amlodipine or hydralazine (see Table 3.3) could be useful as adjunct therapy for dogs with refractory CHF, although arterial blood pressure should be carefully monitored in such animals. Any vasodilator must be used cautiously in dogs with a low cardiac reserve because of the increased potential for hypotension. Hydralazine is more likely to precipitate hypotension and therefore reflex tachycardia and further neurohormonal activation. Therapy is initiated at a low dose; if this is well tolerated (monitored with blood pressure measurement), the next dose is increased to a low maintenance level. Signs of worsening tachycardia, weakened pulses, or lethargy can indicate the presence of hypotension.

A number of other therapies might be useful in certain dogs with DCM, although additional studies are necessary to define optimal recommendations. These include omega-3 fatty acids, L-carnitine (in dogs with low myocardial carnitine concentrations), taurine (in dogs with low plasma concentrations), long-term β-blocker therapy, or possibly others (see Chapter 3, p. 72). Advanced therapeutics, including gene transfer and stem cell transplantation, are under experimental investigation but are not currently recommended in clinical settings. Biventricular pacing to better synchronize ventricular contraction has improved clinical status in people with myocardial dysfunction, but there is little clinical experience with resynchronization therapy in dogs with DCM.

Monitoring

Owner education regarding the purpose, dosage, and adverse effects of each drug used is important. Monitoring the dog's resting respiratory (and heart) rate at home helps in assessing how well the CHF is controlled (see Chapter 3, p. 73). The time frame for reevaluation visits depends on the patient's status. Recheck visits once or twice a week may be necessary initially. Dogs with stable heart failure can be rechecked every 2 or 3 months. Current medications, diet, and any owner concerns should be reviewed. Patient activity level, appetite, and attitude, along with renal values and electrolytes, heart rate and rhythm, thoracic imaging to assess pulmonary edema or pleural effusion, blood pressure, body weight, and other appropriate factors should be evaluated and therapy adjusted as needed.

Prognosis

The prognosis for dogs with DCM is generally guarded. In Doberman Pinschers, occult disease tends to develop at 3 to 6 years of age, with ventricular arrhythmias preceding echocardiographic changes. Onset of CHF generally occurs within 2 to 3 years, although addition of pimobendan delays disease progression. Sudden death occurs in about 20% to 40% of affected Doberman Pinschers and may occur in the occult stage before CHF is present. Doberman Pinschers and Great Danes appear to have a worse prognosis than other breeds, with younger age of onset and more rapid progression of disease. Certain breeds, including Irish Wolfhounds and Cocker Spaniels, have more protracted preclinical periods and may live for years with mild to moderate LV systolic dysfunction. Prognosis following an episode of CHF is poor. Median survival time with treatment is in the realm of 4 to 6 months. Negative prognostic indicators include presence of pleural effusion, severity of LV

systolic dysfunction, presence of ventricular tachycardia or atrial fibrillation, and higher values of cardiac biomarkers. In individual cases, however, it is reasonable to assess the animal's response to initial treatment before pronouncing an unequivocally dismal prognosis. Overall prognosis for DCM, in both preclinical stages and in CHF, is improved with use of pimobendan.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

ARVC is the most common acquired heart disease of Boxer dogs. This inherited primary myocardial disease shares many similar features to those of ARVC in people. Histologic changes in the myocardium are more extensive than other canine cardiomyopathies and are characterized by fatty or fibrofatty infiltration, usually most severe in the right ventricle (RV) free wall. Atrophy of myofibers and myocardial fibrosis are also common. Focal areas of myocytolysis, necrosis, hemorrhage, and mononuclear cell infiltration may be seen. Ultrastructural abnormalities, including reduced numbers of myocardial gap junctions and desmosomes, are apparent throughout the myocardium (including the atria), suggesting that the disease process is not confined to the RV.

ARVC in Boxers is familial with an autosomal dominant inheritance pattern. A mutation in the striatin gene on chromosome 17, which encodes for a protein involved in cell-to-cell adhesion, has been associated with Boxer ARVC. Boxers with at least one copy of the striatin mutation are 40 times more likely to develop ARVC than homozygous negative dogs. Overall genetic penetrance of this mutation is approximately 80%, with nearly 100% of homozygous positive dogs affected. Yet the fact that this mutation is not present in all Boxers with ARVC and is present in some without ARVC suggests that it may collocate with, rather than being, the causative mutation. However, as in people, there may be a number of gene mutations associated with ARVC in different bloodlines. Genetic testing for the striatin gene mutation is available (North Carolina State University Veterinary Cardiac Genetics Laboratory; https://cvm.ncsu.edu/genetics/).

Clinical manifestations of ARVC can appear in three forms, although these are thought to represent the same underlying disease. Dogs with the occult form have ventricular arrhythmias without clinical signs. Dogs with overt ARVC have syncope or weakness associated with paroxysmal or sustained ventricular tachycardia, usually despite normal heart size and LV function. Approximately 10% of affected Boxers have a form of ARVC where ventricular tachyarrhythmias are accompanied by a DCM phenotype, with poor myocardial function that progresses to CHF, unless sudden death occurs first. Myocardial changes in the DCM phenotype typically involve both the LV and RV, and left-sided CHF is most common. Some dogs with normal LV systolic function at the time of ARVC diagnosis progress to develop the DCM phenotype later in life. Dogs that are homozygous-positive for the striatin mutation appear more likely to develop the DCM phenotype, although some heterozygous dogs also manifest this more severe form of ARVC.

Clinical Findings

Signs may appear at any age, but the median age at diagnosis is 6 years. Syncope is the most common clinical complaint. Ventricular tachyarrhythmias underlie most instances of syncope in Boxers with ARVC. However, another potential cause for syncope in young adult Boxers is neurocardiogenic (reflex-mediated) syncope, where a sudden surge in sympathetic activity triggers reflex vagal stimulation and inappropriate bradycardia and hypotension. Neurocardiogenic syncope can occur in normal Boxers and in Boxers with ARVC, and can potentially be exacerbated by use of sotalol or (other) β-blocker therapy.

The physical examination could be normal, although a soft left basilar systolic murmur is common in Boxers, whether ARVC is present or not. In many Boxers, this is a breed-related physiologic murmur related to aortic annular hypoplasia relative to body size, or it may be associated with underlying subaortic stenosis. In some dogs, a cardiac arrhythmia with pulse deficits is found on physical examination; in others, the resting heart rhythm is normal. When CHF occurs in dogs with DCM phenotype, left-sided signs are more common than ascites or other signs of right-sided heart failure; a mitral insufficiency murmur can be present in these cases as well.

Diagnosis

Radiographic findings are variable. Boxers with ARVC and normal myocardial function have no visible abnormalities. Those with DCM phenotype and CHF generally show evidence of cardiomegaly and pulmonary edema. Echocardiographic findings also vary between disease manifestations. Most Boxers with ARVC have normal cardiac size and function; dogs with DCM phenotype show reduced fractional shortening and chamber dilation, similar to other dogs with DCM.

The characteristic ECG finding is ventricular ectopy. VPCs occur singly, in pairs, in short runs, or as sustained ventricular tachycardia. Most ectopic ventricular complexes originate in the RV and thus appear upright in leads II and aVF (Fig. 7.4). However, some Boxers have multiform VPCs. Usually an underlying sinus rhythm exists; AF is less common. Supraventricular tachycardia, conduction abnormalities, and evidence of chamber enlargement also are sometimes seen on ECG, particularly in patients with the DCM phenotype.

Twenty-four-hour Holter monitoring is used to quantify the frequency and complexity of ventricular tachyarrhythmias and as a screening tool for Boxer ARVC. It also is recommended to evaluate the efficacy (and any proarrhythmic adverse effects) of antiarrhythmic drug therapy. Frequent VPCs and/or complex ventricular arrhythmias are characteristic findings in affected dogs. Absolute criteria for separating normal from abnormal Boxers are not entirely

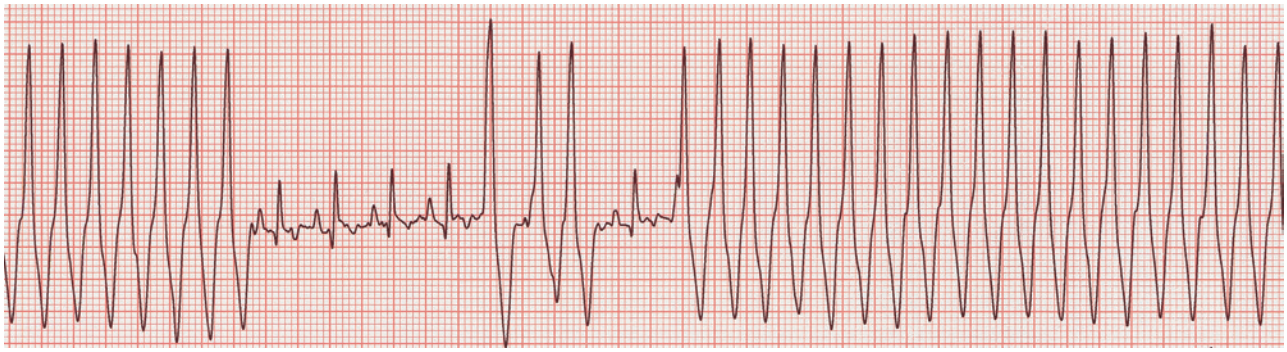

FIG 7.4
Paroxysmal ventricular tachycardia at a rate of almost 300 beats/min in a Boxer with arrhythmogenic right ventricular cardiomyopathy. Note the typical upright (left bundle branch block–like) appearance of the ventricular ectopic complexes in the caudal leads. Lead II, 25 mm/sec.

clear. However, Animal Registry of Certified Health guidelines (ARCH, http://www.archcertify.org/) suggest the following classifications: fewer than 50 single monomorphic VPCs/24-hour period is interpreted as normal; between 50 and 300 single monomorphic VPCs/24-hour period is equivocal (ARVC cannot be definitively diagnosed or excluded); and greater than 300 VPCs/24-hour period, or periods of couplets, triplets, or runs of ventricular tachycardia (VT), is abnormal and consistent with a diagnosis of ARVC. Frequent VPCs or episodes of ventricular tachycardia signal an increased risk for syncope and sudden death. The occurrence of ventricular arrhythmias appears to be widely distributed throughout the day, and there can be enormous variability (up to 85%) in the number of VPCs between repeated Holter recordings in the same dog. Longitudinal studies of Boxer dogs show that the onset of ventricular arrhythmias in ARVC is relatively abrupt, with a sudden increase in VPC number from <50 VPCs/24 hour in the year preceding ARVC diagnosis to an average of ~1200 VPCs/24 hour at time of diagnosis. The biomarkers cardiac troponin I and NT-proBNP do not reliably discriminate between normal and affected dogs, except possibly in dogs with DCM phenotype.

Annual Holter recordings are recommended beginning at age 2 to 3 years to screen for development and monitor progression of ARVC in Boxer dogs. Once Holter criteria for ARVC are met, annual echocardiography is also recommended to screen for development of DCM phenotype. Genetic testing for the striatin mutation is highly recommended for animals considered for breeding and may also provide prognostic information about an individual dog (particularly the likelihood of developing the DCM phenotype). Homozygous-positive dogs should not be bred, and heterozygous-positive dogs should be bred only to dogs negative for the striatin mutation. Dogs meeting Holter diagnostic criteria for ARVC (greater than 300 VPCs/24 hour or dogs with complex ventricular ectopy) also should not be bred, regardless of genotype.

Treatment

Antiarrhythmic treatment is indicated for Boxers with clinical signs from tachyarrhythmias (i.e., syncope). Asymptomatic dogs with Holter findings of greater than 1000 single VPCs/24 hour, ventricular tachycardia, or close coupling of VPCs to the preceding QRS on Holter monitoring are usually given antiarrhythmic therapy as well. However, the best regimen(s) and when to institute therapy are still not clear. Sotalol and mexiletine have each shown efficacy in reducing VPC frequency and complexity. Either of these drugs is generally considered acceptable first-line therapy for dogs with ARVC, and combination therapy is common. Other drugs that can be used or added in refractory cases include amiodarone, procainamide, or other β-blockers such as atenolol (see Chapter 4). The addition of an omega-3 fatty acid supplement might also reduce VPC frequency. Magnesium supplementation (usually in the form of magnesium oxide) is used occasionally.

The goals of antiarrhythmic drug therapy are to decrease number and complexity of VPCs, reduce frequency of syncope, and, ideally, reduce risk of sudden death. Holter monitoring is used to monitor efficacy of antiarrhythmic therapy; given biologic variability in daily VPC number in dogs with ARVC, a reduction in VPCs of at least 85% generally is needed to conclude adequate antiarrhythmic effect. Unfortunately, sudden death remains possible even with apparently good control of arrhythmias.

Therapy for dogs with DCM phenotype is similar to that described for dogs with idiopathic DCM. Pimobendan and ACEI are typically prescribed once LV systolic dysfunction is documented, although benefit of these drugs has not been evaluated in this specific setting. Once CHF occurs, furosemide and spironolactone are added. Antiarrhythmics are prescribed or continued as previously discussed; caution should be used with sotalol in the setting of DCM phenotype and acute CHF, because the mild β-blocking effects of this drug may exacerbate LV systolic dysfunction. Myocardial carnitine deficiency has been documented in some Boxers

with DCM phenotype and CHF. Some of these dogs have responded to oral L-carnitine supplementation.

Prognosis

The prognosis for Boxers with ARVC and normal systolic function is good with antiarrhythmic treatment. A longitudinal study showed no difference in life span between Boxers with and without ARVC (median survival time in both groups was between 10 and 11 years). In contrast, prognosis for Boxers with the DCM phenotype form of ARVC is guarded. Most dogs with DCM phenotype progress to CHF, and survival after onset of CHF is generally less than 6 months. Unfortunately, sudden death remains the most common cause of death in dogs with ARVC, regardless of LV systolic function, and antiarrhythmic treatment may ameliorate but does not eliminate this risk.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY IN DOGS OF OTHER BREEDS

A form of cardiomyopathy that mainly affects the RV has been observed rarely in English Bulldogs and other breeds. It appears similar to ARVC described in people and cats. Pathologic changes are characterized by widespread fibrous and fatty tissue replacement in the RV myocardium. Marked right heart dilation is typical. In certain geographic areas, trypanosomiasis is a possible differential diagnosis. Clinical manifestations are largely related to right-sided CHF and severe ventricular tachyarrhythmias; sudden death is a potential outcome.

SECONDARY MYOCARDIAL DISEASE

Poor myocardial function can result from a variety of identifiable insults and nutritional deficiencies. Myocardial infections (see p. 153), inflammation, trauma (see p. 155), ischemia, neoplastic infiltration, and metabolic abnormalities can impair normal contractile function. Hyperthermia, irradiation, electric shock, certain drugs, and other insults can also damage the myocardium. Some substances are known cardiac toxins.

MYOCARDIAL TOXINS

Doxorubicin

The antineoplastic drug doxorubicin induces both acute and chronic cardiotoxicity. Release of histamine with secondary catecholamine release appears to underlie acute toxicity, which is idiosyncratic and leads to transient ventricular or supraventricular arrhythmias during drug administration. Chronic cardiotoxicity appears to be mediated by DNA intercalation, inhibition of topoisomerase II, and free-radical production. The resulting myocardial damage is characterized histologically by vacuolization and degeneration of cardiomyocytes. Chronically, cellular toxicity leads to LV dilation and decreased LV systolic function, mimicking idiopathic DCM. Left-sided CHF is the eventual clinical outcome. Cardiac conduction defects (infranodal AV block and bundle branch block), as well as ventricular and supraventricular tachyarrhythmias, can also develop with chronic toxicity. ECG changes do not necessarily precede CHF.

Chronic doxorubicin-induced cardiotoxicity is directly related to the cumulative dose of doxorubicin administered. Echocardiographic changes and CHF are generally seen at cumulative doses of greater than 150 mg/m^2, although ECG changes can be seen at doses as low as 90 mg/m^2. Cardiotoxicity becomes particularly likely when cumulative dose of doxorubicin exceeds 240 mg/m^2. In dogs that have normal pretreatment cardiac function, clinical cardiotoxicity causing CHF is uncommon, occurring in an estimated 2% to 5% of treated dogs. Depending on the underlying neoplastic process (e.g., hemangiosarcoma), dogs may not live long enough to experience chronic toxicity from doxorubicin treatment. Although predicting whether and when clinical cardiotoxicity will occur is difficult, dogs with underlying cardiac abnormalities and those of breeds with a higher prevalence of idiopathic myocardial disease (e.g., Dobermans, Great Danes, Boxers) are thought to be at higher risk.

Echocardiography and ECG are used to diagnose doxorubicin cardiotoxocity. Increases in circulating cardiac troponin concentrations can also be seen. However, no screening modalities (biomarkers or imaging) have proven effective in predicting future cardiotoxicity. Whether and how frequently to screen dogs for cardiotoxicity during treatment depends on multiple factors, including breed, presence of preexisting heart disease, underlying neoplastic disease, and relative risk aversion of the oncologist and owner.

Various strategies have been employed in an attempt to decrease risk of cardiotoxicity with doxorubicin administration. In humans, giving doxorubicin as a prolonged continuous infusion (at least 6 hours) decreases drug toxicity; there is some evidence that in dogs, administering the drug diluted (0.5 mg/mL) over 1 hour may similarly decrease risk. Concurrent administration of the iron chelator dexrazoxane (Zinecard) prevents doxorubicin-induced lipid peroxidation and might also decrease risk of toxicity. However, application to veterinary medicine is somewhat limited due to expense of this drug. Other attempts have involved use of pegylated liposome-encapsulated doxorubicin or concurrent administration of antioxidants such as carvedilol or vitamin E and selenium.

Other toxins

Ethyl alcohol, especially if given IV for the treatment of ethylene glycol intoxication, can cause severe myocardial depression and death; slow administration of a diluted (≤20%) solution is advised. Other cardiac toxins include plant toxins (e.g., *Taxus,* foxglove, black locust, buttercups, lily-of-the-valley, gossypol); anesthetic drugs; catecholamines (including the feed additive ractopamine); and ionophores such as monensin. Other potential cardiac toxins recognized in humans include heavy metals (e.g., arsenic, lead, mercury); antineoplastic drugs (cyclophosphamide, 5-fluorouracil, interleukin-2, α-interferon); other drugs (e.g., thyroid hormone, cocaine, amphetamines, lithium);

and biologic toxins (wasp or scorpion stings, snake venom, spider bites).

METABOLIC AND NUTRITIONAL DEFICIENCY

L-carnitine

L-carnitine is an essential component of the mitochondrial membrane transport system for fatty acids, which are the heart's most important energy source. It also transports potentially toxic metabolites out of the mitochondria in the form of carnitine esters. L-carnitine-linked defects in myocardial metabolism have been found in some dogs with DCM. Rather than simple L-carnitine deficiency, one or more underlying genetic or acquired metabolic defects are suspected. There may be an association between DCM and carnitine deficiency in some families of Boxers, Doberman Pinschers, Great Danes, Irish Wolfhounds, Newfoundlands, and Cocker Spaniels. L-carnitine is mainly present in foods of animal origin. DCM has developed in some dogs fed strict vegetarian diets.

Plasma carnitine concentration is not a sensitive indicator of myocardial carnitine deficiency. Most dogs with myocardial carnitine deficiency, diagnosed via endomyocardial biopsy, have had normal or high plasma carnitine concentrations. Furthermore, the response to oral carnitine supplementation is inconsistent. Subjective improvement may occur, but few dogs have echocardiographic evidence of improved function. Dogs that do respond show clinical improvement within the first month of supplementation; there may be some degree of improvement in echo parameters after 2 to 3 months. L-carnitine supplementation does not suppress preexisting arrhythmias or prevent sudden death. See p. 73 for supplementation guidelines.

Taurine

Although most dogs with DCM are not taurine deficient, low plasma taurine concentration has been documented in some and appears particularly common in certain breeds. Low taurine, and sometimes carnitine, concentrations occur in Cocker Spaniels with DCM. Oral supplementation of these amino acids can improve LV size and function, as well as reduce the need for heart failure medications in this breed. Low taurine concentrations have also been found in some Newfoundlands, Golden Retrievers, Labrador Retrievers, Saint Bernards, and other dogs with DCM. Some such dogs have been fed low-protein lamb meal and rice, or vegetarian diets; others have been consuming diets with adequate taurine content. In particular, DCM has been identified in Dalmatians fed protein-restricted diets for prevention of breed-related urate urolithiasis.

Assessment of plasma or whole blood taurine concentration should be considered in "atypical" breeds affected with DCM or any dog with concern for nutritional deficiency based on diet history. Plasma taurine concentrations less than 40 nmol/mL and blood taurine concentrations less than 150 nmol/mL are generally considered deficient. Specific collection and submission guidelines should be obtained from the laboratory used. If taurine deficiency is documented, a trial of supplemental taurine for 3 to 4 months is recommended (see p. 73 for supplementation guidelines). However, the effect of taurine supplementation on disease progression is unclear. Taurine-deficient dogs may show echocardiographic improvement after supplementation; however, some degree of cardiac abnormality often persists, and there is questionable effect on survival time.

Other factors

Myocardial injury induced by free radicals may play a role in a number of diseases. Evidence for increased oxidative stress has been found in dogs with CHF and myocardial failure, but the clinical ramifications of this are unclear. Diseases such as hypothyroidism, pheochromocytoma, and diabetes mellitus have been associated with reduced myocardial function, but clinical CHF is unusual in dogs secondary to these conditions alone. Excessive sympathetic stimulation stemming from brain or spinal cord injury results in myocardial hemorrhage, necrosis, and arrhythmias (brain-heart syndrome). Muscular dystrophy of the fasciohumoral type (reported in English Springer Spaniels) can result in atrial standstill and heart failure. Canine X-linked (Duchenne) muscular dystrophy in Golden Retrievers and other breeds also has been associated with myocardial fibrosis and mineralization, with subsequent LV systolic dysfunction and CHF. Rarely, nonneoplastic (e.g., glycogen storage disease) and neoplastic (metastatic and primary) infiltrates interfere with normal myocardial function. Immunologic mechanisms also could play an important role in the pathogenesis of myocardial dysfunction in some dogs with myocarditis.

ISCHEMIC MYOCARDIAL DISEASE

Acute myocardial infarction resulting from coronary embolization is uncommon. An underlying disease associated with increased risk for thromboembolism, such as bacterial endocarditis, neoplasia, protein-losing nephropathy or enteropathy, immune-mediated hemolytic anemia, acute pancreatitis, disseminated intravascular coagulopathy, and/or corticosteroid use, underlies most cases. Sporadic reports of myocardial infarction have been associated with congenital ventricular outflow obstruction, patent ductus arteriosus, hypertrophic cardiomyopathy, and mitral insufficiency. Atherosclerosis of the major coronary arteries, which can accompany severe hypothyroidism in dogs, rarely leads to acute myocardial infarction. Clinical signs of acute major coronary artery obstruction are likely to include arrhythmias, pulmonary edema, marked ST segment change on ECG, and evidence of regional or global myocardial contractile dysfunction on echocardiogram. High circulating cardiac troponin concentrations and possibly creatine kinase activity occur after myocardial injury and necrosis.

Disease of small coronary vessels is recognized as well. Nonatherosclerotic narrowing of small coronary arteries could be more clinically important than previously assumed. Hyalinization of small coronary vessels and intramural myocardial infarctions have been described in dogs with chronic degenerative mitral valve disease; however, they can occur in older dogs without valve disease as well. Fibromuscular

arteriosclerosis of small coronary vessels also has been described. These changes in the walls of the small coronary arteries cause luminal narrowing and can impair resting coronary blood flow, as well as vasodilatory responses. Small myocardial infarctions and secondary fibrosis lead to reduced myocardial function. Various arrhythmias can occur. Eventual CHF is a cause of death in many cases with intramural coronary arteriosclerosis. Sudden death is a less common sequela. Larger breeds of dog may be predisposed, although Cocker Spaniels and Cavalier King Charles Spaniels appear to be commonly affected smaller breeds.

TACHYCARDIA-INDUCED CARDIOMYOPATHY

The term *tachycardia-induced cardiomyopathy* (TICM) refers to the progressive myocardial dysfunction, activation of neurohormonal compensatory mechanisms, and CHF that result from rapid, incessant tachycardias. The myocardial failure may be reversible if the heart rate can be normalized in time. Tachyarrhythmias inducing TICM usually are supraventricular in origin, since rapid incessant ventricular tachyarrhythmias typically lead to more hemodynamic instability (syncope, sudden cardiac death) before TICM develops. TICM has been described in several dogs with AV nodal reciprocating tachycardia associated with accessory conduction pathways that bypass the AV node (e.g., Wolff-Parkinson-White; see p. 44). Labrador Retrievers appear to be predisposed to accessory pathway-mediated supraventricular tachycardias and thus TICM; this often is in association with tricuspid dysplasia. Rapid artificial pacing (e.g., >200 beats/min) is a common model for inducing experimental myocardial failure that simulates DCM.

HYPERTROPHIC CARDIOMYOPATHY

Etiology and Pathophysiology

In contrast to cats, HCM is uncommon in dogs. Other causes of LV hypertrophy (subaortic stenosis, systemic hypertension, or other metabolic diseases) should always be excluded. A genetic basis for HCM is suspected in Pointers, although the disease occurs sporadically in other breeds. The pathophysiology is similar to that of HCM in cats (see Chapter 8). Abnormal, excessive myocardial hypertrophy increases ventricular stiffness and leads to diastolic dysfunction. The LV hypertrophy usually is symmetric, but regional variation in wall or septal thickness can occur. Compromised coronary perfusion is likely with severe ventricular hypertrophy. This leads to myocardial ischemia, which exacerbates arrhythmias, delays ventricular relaxation, and further impairs filling. High LV filling pressure predisposes to pulmonary venous congestion and edema. Besides diastolic dysfunction, systolic dynamic LV outflow obstruction occurs in the majority of affected dogs. Malposition of the mitral apparatus can contribute to systolic anterior mitral valve motion and LV outflow obstruction, as well as to mitral regurgitation. LV outflow obstruction increases ventricular wall stress and myocardial oxygen requirement while also impairing coronary blood flow. Heart rate elevations magnify these abnormalities.

Clinical Features

HCM is most commonly diagnosed in young to middle-aged large-breed dogs, often less than 3 years of age, although there is a wide age distribution. Males are more commonly affected. Most dogs diagnosed with HCM are presented for evaluation of an asymptomatic heart murmur. In some dogs, clinical signs of CHF, episodic weakness, and/or syncope might be evident. Sudden death without premonitory signs can occur. Ventricular arrhythmias secondary to myocardial ischemia are presumed to cause the low-output signs and sudden death. A systolic murmur, related to either LV outflow obstruction or mitral insufficiency, can be heard on auscultation. The systolic ejection murmur of ventricular outflow obstruction becomes louder when ventricular contractility is increased (e.g., with exercise or excitement) or when afterload is reduced (e.g., from vasodilator use). An S_4 gallop sound is heard in some affected dogs.

Diagnosis

Echocardiography is the best diagnostic tool for HCM. LV hypertrophy (more commonly symmetric) and LA enlargement are characteristic findings. Mitral regurgitation might be evident on Doppler studies. Systolic anterior motion of the mitral valve often is present, indicating dynamic LV outflow obstruction. Other causes of LV hypertrophy to be ruled out include congenital subaortic stenosis, systemic hypertension, thyrotoxicosis, chronic phenylpropanolamine administration, and pheochromocytoma. Thoracic radiographs can indicate LA and LV enlargement, with or without pulmonary edema. Some cases appear radiographically normal. ECG findings might include ventricular tachyarrhythmias and conduction abnormalities, such as AV or bundle branch blocks. Criteria for LV enlargement are variably present.

Treatment and Prognosis

The general goals of HCM treatment are to enhance myocardial relaxation and ventricular filling, control pulmonary edema, and suppress arrhythmias. A β-blocker such as atenolol (see p. 93) commonly is used to lower heart rate, prolong ventricular filling time, reduce ventricular contractility, and minimize myocardial oxygen requirement. β-blockers also can reduce dynamic LV outflow obstruction and may suppress arrhythmias induced by heightened sympathetic activity. A Ca^{++}-channel blocker such as diltiazem could also be considered to decrease heart rate and facilitate myocardial relaxation, although such drugs are less commonly chosen due to their vasodilatory effects. If CHF occurs, furosemide and an ACEI are indicated; pimobendan could be considered, particularly if myocardial failure develops, although presence of LV outflow obstruction is a relative contraindication to positive inotropic therapy. Exercise restriction is advised in dogs with HCM.

Prognosis for canine HCM is variable. Although some dogs develop clinical signs and CHF and others experience

sudden death, many affected dogs live a normal life span with stable disease and minimal to no clinical signs. There also are reports of young dogs (most commonly terrier breeds) in which dynamic LV outflow tract obstruction, systolic anterior motion of the mitral valve, and LV hypertrophy are documented at a young age (less than 1 year), but echocardiographic changes spontaneously regress after the dog reaches adulthood. Some of these dogs were treated with β-blockers (usually atenolol), yet others received no treatment. It is unknown whether these cases represent a variant of congenital HCM in dogs or a transient physiologic process associated with aging.

MYOCARDITIS

A wide variety of agents can affect the myocardium, although disease manifestations in other organ systems may overshadow the cardiac involvement. The heart can be injured by direct invasion of the infective agent, by toxins it elaborates, or by the host's immune response. Noninfective causes of myocarditis include cardiotoxic drugs and drug hypersensitivity reactions. Myocarditis can cause persistent cardiac arrhythmias and progressively impair myocardial function.

INFECTIVE MYOCARDITIS

Etiology and Pathophysiology

Viral myocarditis

Lymphocytic myocarditis has been associated with acute viral infections in experimental animals and people. Cardiotropic viruses can play an important role in the pathogenesis of myocarditis and subsequent cardiomyopathy in several species, but this is not recognized commonly in dogs. The host animal's immune responses to viral and nonviral antigens contribute to myocardial inflammation and damage.

A syndrome of parvoviral myocarditis was recognized in the late 1970s and early 1980s. It is characterized by a peracute necrotizing myocarditis and sudden death (with or without signs of acute respiratory distress) in apparently healthy puppies about 4 to 8 weeks old. Cardiac dilation with pale streaks in the myocardium, gross evidence of CHF, large basophilic intranuclear inclusion bodies, myocyte degeneration, and focal mononuclear cell infiltrates are typical necropsy findings. This syndrome is uncommon now, probably as a result of maternal antibody production in response to virus exposure and vaccination. Parvovirus may cause a form of DCM in young dogs that survive neonatal infection; viral genetic material has been identified in some canine ventricular myocardial samples in the absence of classic intranuclear inclusion bodies.

Canine distemper virus may cause myocarditis in young puppies, but multisystemic signs usually predominate. Histologic changes in the myocardium are mild compared with those in the classic form of parvovirus myocarditis. Experimental herpesvirus infection of pups during gestation also causes necrotizing myocarditis with intranuclear inclusion bodies leading to fetal or perinatal death.

West Nile virus is uncommon in dogs but has been reported to cause severe lymphocytic and neutrophilic myocarditis and vasculitis, with areas of myocardial hemorrhage and necrosis. Vague clinical signs can include lethargy, poor appetite, arrhythmias, neurologic signs, and fever. Immunohistochemistry, reverse transcription polymerase chain reaction (RT-PCR), serology, and virus isolation have been used in diagnosis.

Bacterial myocarditis

Bacteremia and bacterial endocarditis or pericarditis can cause focal or multifocal suppurative myocardial inflammation or abscess formation. Localized infections elsewhere in the body may be the source of the organisms. Clinical signs include malaise, weight loss, and, inconsistently, fever. Arrhythmias and cardiac conduction abnormalities are common, but murmurs are rare unless concurrent valvular endocarditis or another underlying cardiac defect is present. Serial bacterial (or fungal) blood cultures, serology, or PCR may allow identification of the organism. Organisms reported to be implicated in bacterial myocarditis include *Staphylococcus, Streprotococcus, Citrobacter, Bacillus, Moraxella,* and others. *Bartonella vinsonii* subspecies have also been associated with cardiac arrhythmias, myocarditis, endocarditis, and sudden death. Serology and PCR using an enriched growth medium specific for *Bartonella* (*Bartonella* α Proteobacteria Growth Medium, BAPGM) are used for diagnosis.

Lyme carditis

Lyme disease (infection with the spirochete *Borrelia burgdorferi)* is often mentioned as a cause of myocarditis in dogs, although definitive diagnosis is rarely proven; systemic manifestations related to immune-complex deposition usually predominate (polyarthritis, glomerulonephritis, meningoencephalitis). The prevalence of this disease is higher in certain geographic areas, especially the northeastern, western coastal, and north central United States, as well as in Japan and Europe, among other areas. Lyme disease was the most common cause of canine myocarditis in a recent case series from Ireland. *Borrelia* is transmitted to dogs by ticks (especially *Ixodes* genus) and possibly other biting insects (see Chapter 69). High-grade AV block is the classic finding in dogs with Lyme disease. Syncope, CHF, reduced myocardial contractility, and ventricular arrhythmias are also reported in affected dogs. Pathologic findings of Lyme myocarditis include infiltrates of plasma cells, macrophages, neutrophils, and lymphocytes, with areas of myocardial necrosis. These are similar to findings in human Lyme carditis. A presumptive diagnosis is made on the basis of positive (or increasing) serum titers or a positive SNAP test and concurrent signs of myocarditis, with or without other systemic signs. Endomyocardial biopsy with immunohistochemical staining can confirm the diagnosis. Resolution of AV conduction block may or may not occur in dogs despite appropriate antimicrobial therapy, and temporary or permanent artificial pacing may be required.

Protozoal myocarditis

Trypanosoma cruzi, Toxoplasma gondii, Neosporum caninum, Babesia canis, Hepatozoon americanum, and *Leishmania* spp. are known to affect the myocardium (see p. 1525).

Trypanosomiasis (Chagas disease) is an important zoonosis in Central and South America; within the United States, the disease occurs mainly in young dogs in Texas, Louisiana, Oklahoma, Virginia, and other southern states. The possibility for human infection should be recognized; Chagas myocarditis is the most common cause of human cardiomyopathy in the world. The organism is transmitted by blood-sucking insects of the family Reduviidae and is enzootic in wild animals of the region. Amastigotes of *T. cruzi* cause myocarditis with a mononuclear cell infiltrate and disruption and necrosis of myocardial fibers. Acute, latent, and chronic phases of Chagas myocarditis have been described. The acute stage can involve lethargy, depression, and other systemic signs, as well as various tachyarrhythmias, AV conduction defects, or sudden death. Clinical signs are sometimes subtle. The disease is diagnosed in the acute stage by finding trypomastigotes in thick peripheral blood smears; the organism can be isolated in cell culture or by inoculation into mice. Animals that survive the acute phase enter a subclinical latent phase of variable duration. During this phase, the parasitemia resolves, and antibodies develop against both the organism and cardiac antigens. Chronic Chagas disease is characterized by progressive right-sided or generalized cardiomegaly and various arrhythmias. Ventricular tachyarrhythmias are most common, but supraventricular tachyarrhythmias may occur. Right bundle branch block and AV conduction disturbances are also reported. Ventricular dilation and reduced myocardial function are usually evident echocardiographically. End-stage disease is indistinguishable from idiopathic DCM, although the RV is generally preferentially affected in Chagas disease. Clinical signs of right-sided or biventricular failure are common, and sudden death can occur. Antemortem diagnosis in chronic cases is usually made with a combination of serologic testing and compatible clinical signs. Therapy in the acute stage is aimed at eliminating the organism and minimizing myocardial inflammation. Currently, the preferred treatment in both humans and dogs is benznidazole; in the United States, this drug is available only through the Centers for Disease Control and Prevention (CDC). In dogs with chronic Chagas disease, antiparasitic treatments do not affect outcome. Therapy is aimed at supporting myocardial function, controlling CHF, and suppressing arrhythmias. Prevention strategies in endemic areas include limiting contact with vectors and reservoirs, using insecticides, and screening canine blood donors.

Toxoplasmosis and neosporosis can cause clinical myocarditis in conjunction with generalized systemic infection, especially in the immunocompromised animal. The organism becomes encysted in the heart and various other body tissues after the initial infection. With rupture of these cysts, expelled bradyzoites induce hypersensitivity reactions and tissue necrosis. Other systemic signs, including encephalitis, pneumonia, and chorioretinitis, often overshadow signs of myocarditis. Diagnosis is based on serologic testing with rising antibody titers. Antiprotozoal therapy with clindamycin or trimethoprim sulfa is recommended.

Hepatozoon americanum, identified as a new species distinct from *Hepatozoon canis,* was originally found in dogs along the Texas coast but has a much wider range. Coyotes, rodents, and other wildlife are an important wild reservoir. Dogs become infected by ingesting the organism's tick host *(Amblyomma maculatum)* or through predation. Skeletal and cardiac muscles are the main tissues affected by *H. americanum.* A severe inflammatory reaction to merozoites released from ruptured tissue cysts leads to pyogranulomatous myositis and myocarditis. Clinical signs include stiffness, anorexia, fever, neutrophilia, periosteal new bone reaction, muscle atrophy, and often death.

Leishmaniosis, endemic in certain regions, can cause myocarditis, various arrhythmias, and pericardial effusion with cardiac tamponade, as well as other systemic and cutaneous signs. Babesiosis has also occasionally been reported to cause cardiac lesions in dogs, including myocardial hemorrhage, inflammation, and necrosis. Pericardial effusion and variable ECG changes may be noted.

Other causes

Rarely, fungi *(Aspergillus, Cryptococcus, Coccidioides, Blastomyces, Histoplasma, Paecilomyces, Inonota);* non-*Bartonella* rickettsiae *(Rickettsia rickettsii, Ehrlichia canis);* algae-like organisms (*Prototheca* spp.); and nematode larval migration (*Toxocara* spp.) cause myocarditis. Except for *Coccidioides immitis,* an important cause of pericarditis and pericardial effusion in the southwestern United States (see p. 1505), affected animals are usually immunosuppressed and have systemic signs of disease. Rocky Mountain spotted fever *(R. rickettsii)* occasionally causes fatal ventricular arrhythmias, along with necrotizing vasculitis, myocardial thrombosis, and ischemia.

NONINFECTIVE MYOCARDITIS

Occasionally myocarditis is diagnosed histopathologically with no obvious etiologic agent. Lymphocytic, lymphocytic-plasmacytic, and eosinophilic myocardial inflammation have been described with no infectious agents noted on histopathology or serologic screening. It is unknown whether myocarditis in these dogs is an immune-mediated or autoimmune process, or a response to an infectious agent that was not identifiable postmortem. Clinical findings in such cases often include high-grade AV block and sinus arrest, with sudden death being a common outcome.

Clinical Findings and Diagnosis

Unexplained onset of arrhythmias or CHF after a recent episode of infective disease or drug exposure is the classic clinical presentation of acute myocarditis. However, definitive diagnosis can be difficult because clinical and clinicopathologic findings are usually nonspecific and inconsistent. A database including complete blood count, serum biochemical profile with creatine kinase activity, serum cardiac troponin I (and NT-proBNP) concentration, thoracic and abdominal radiographs, and urinalysis are usually obtained. ECG changes may include an ST segment shift, T-wave or QRS voltage changes, AV conduction abnormalities, and

various other arrhythmias. Echocardiographic signs of poor regional or global ventricular systolic function, altered myocardial echogenicity, or pericardial effusion can be evident. In dogs with persistent fever, serial bacterial (or fungal) blood cultures could be useful. Serologic screening for specific infective causes might be helpful in some cases. Histopathologic criteria for a diagnosis of myocarditis include inflammatory infiltrates with myocyte degeneration and necrosis. Endomyocardial biopsy specimens are currently the only means of obtaining a definitive antemortem diagnosis, but if the lesions are focal, the findings may not be diagnostic.

Treatment

Unless a specific etiologic agent can be identified and treated, therapy for suspected myocarditis is largely supportive. Strict rest, antiarrhythmic drugs (see Chapter 4), therapy to support myocardial function and manage CHF signs (see Chapter 3), and other supportive measures are used as needed. Corticosteroids have not proven clinically beneficial in dogs with myocarditis and, considering the possible infective causes, are not recommended as nonspecific therapy. Exceptions would be confirmed immune-mediated disease, drug-related or eosinophilic myocarditis, or myocarditis unresponsive to other therapies. Nonsteroidal antiinflammatory drugs could be considered in some cases.

SEPSIS-INDUCED MYOCARDIAL DYSFUNCTION

Sepsis-induced myocardial dysfunction describes a syndrome of reversible myocardial depression that occurs in the setting of sepsis or other critical illness. This is a common and well-recognized phenomenon in human intensive care units and has also been described in dogs. The syndrome is characterized by ventricular dilation and systolic dysfunction (a DCM phenotype), and can involve both the LV and RV. Unlike idiopathic DCM, patients with sepsis-induced myocardial dysfunction have normal or even high cardiac output and low systemic vascular resistance. The underlying mechanisms are multifactorial and unclear but likely include release of proinflammatory cytokines, peroxynitrate toxicity, coronary hypoperfusion, catecholamine and calcium insensitivity, and mitochondrial or cytoskeletal abnormalities. Sepsis-induced myocardial dysfunction further compromises perfusion in patients with septic shock and can also lead to CHF. This syndrome is associated with worsened prognosis among humans with sepsis. Diagnosis is based on echocardiographic evidence of new LV dilation and systolic dysfunction in a critically ill patient. Cardiac biomarkers (particularly cardiac troponin I) can be used as screening tools to identify affected patients. Treatment involves inotropic support with either dobutamine or pimobendan, depending on the patient's level of hemodynamic compromise. If treatment for sepsis is successful and the patient survives the period of critical illness, ventricular size and function completely normalize (usually within 7-10 days).

Traumatic Myocarditis

Nonpenetrating or blunt trauma to the chest and heart is more common than penetrating wounds. Cardiac arrhythmias frequently are observed after such trauma. Cardiac damage can result from impact against the chest wall, compression, or acceleration-deceleration forces. Other possible mechanisms of myocardial injury and arrhythmogenesis include autonomic imbalance, ischemia, reperfusion injury, and electrolyte and acid-base disturbances. Thoracic radiographs, serum biochemistries, cardiac troponin I concentrations, ECG, and echocardiography are recommended in the assessment of these cases. Echocardiography can define preexisting heart disease, global myocardial function, and unexpected cardiovascular findings, but it may not identify small areas of myocardial injury.

Arrhythmias usually appear within 24 to 48 hours after trauma. VPCs, ventricular tachycardia, and accelerated idioventricular rhythm (with rates of 60-100 beats/min) are more common than supraventricular tachyarrhythmias or bradyarrhythmias in these patients. An accelerated idioventricular rhythm often is manifested only when the sinus rate slows; this rhythm is benign in most dogs with normal underlying heart function, does not require antiarrhythmic treatment, and disappears usually within a week of the trauma. More serious arrhythmias (e.g., with a faster rate) or hemodynamic deterioration may require antiarrhythmic therapy (see Chapter 4).

Avulsion of a papillary muscle, septal perforation, and rupture of the heart or pericardium have also been reported with cardiac trauma. Traumatic papillary muscle avulsion causes acute volume overload with acute onset of CHF. Signs of low-output failure and shock, as well as arrhythmias, can develop rapidly after cardiac trauma.

CHAPTER 8

Myocardial Diseases of the Cat

Myocardial disease in cats encompasses a diverse collection of idiopathic and secondary processes affecting the myocardium. The spectrum of anatomic and pathophysiologic features is wide. Disease characterized by myocardial hypertrophy is most common, although features of multiple pathophysiologic categories coexist in some cats. Restrictive pathophysiology often develops. Classic dilated cardiomyopathy (DCM) is now uncommon in cats; its features are similar to those of DCM in dogs (see Chapter 7). Myocardial disease in some cats does not fit neatly into the categories of hypertrophic, dilated, or restrictive cardiomyopathy (RCM), and therefore it is considered "unclassified" cardiomyopathy. Rarely, arrhythmogenic right ventricular cardiomyopathy (ARVC) is identified in cats. In contrast to dogs, arterial thromboembolism is a major complication in cats with myocardial disease (see Chapter 12).

HYPERTROPHIC CARDIOMYOPATHY

Etiology

The cause of primary or idiopathic hypertrophic cardiomyopathy (HCM) in cats is unknown, but a heritable abnormality is likely in many cases. Autosomal dominant inheritance has been identified in the Maine Coon, Ragdoll, Sphynx, and American Shorthair breeds. Disease prevalence is high in other breeds as well, including British Shorthairs, Norwegian Forest Cats, Scottish Folds, Bengals, Siberians, and Rex. There also are reports of HCM in littermates and other closely related domestic shorthair cats. In human familial HCM, many different genetic mutations involving sarcomeric proteins have been identified.

Two separate mutations in the cardiac myosin binding protein C gene have been associated with HCM in cats, one in Maine Coon cats and one in Ragdolls. However, these mutations exhibit incomplete penetrance and variable expressivity. Prevalence of the mutation in Maine Coons has been estimated at approximately 30% to 40%, with some geographic variation. Maine Coon cats homozygous for the mutation are likely to develop HCM (penetrance approximately 70%-80%), whereas heterozygotes are much less commonly affected. The prevalence of the Ragdoll mutation is estimated at approximately 20% to 30%, and Ragdoll cats homozygous for the mutation frequently are severely affected with HCM at an early age (often less than 2 years). The discrepancy in phenotype between homozygous and heterozygous cats suggests a "partial" or "incomplete" dominance pattern. Besides the two identified mutations, other mutations are likely involved because not all cats with evidence for HCM have the identified breed-specific mutation. Testing for these mutations is available and can be particularly helpful in directing breeding programs (contact https://cvm.ncsu.edu/genetics/).

In addition to mutations of genes that encode for myocardial contractile or regulatory proteins, possible causes of the disease include an increased myocardial sensitivity to or excessive production of catecholamines; an abnormal hypertrophic response to myocardial ischemia, fibrosis, or trophic factors; a primary collagen abnormality; and abnormalities of the myocardial calcium-handling process. Cats with HCM are skeletally larger and may be more likely to be obese compared with cats without HCM, possibly suggesting a role of early growth and nutrition in development of cardiomyopathy. Some cats with HCM have high serum growth hormone and insulin-like growth factor-1 (IGF-1) concentrations. Myocardial hypertrophy with foci of mineralization occurs in cats with hypertrophic feline muscular dystrophy, an X-linked recessive dystrophin deficiency similar to Duchenne muscular dystrophy in people; however, congestive heart failure (CHF) is uncommon in these cats. It is not clear whether viral myocarditis has a role in the pathogenesis of feline cardiomyopathy.

Pathophysiology

Abnormal sarcomere function is thought to underlie activation of abnormal cell signaling processes that eventually produce myocyte hypertrophy and disarray, as well as increased collagen synthesis. The characteristic result is thickening of the left ventricular (LV) wall and/or interventricular septum, but the extent and distribution of

hypertrophy in cats with HCM are variable. Many cats have symmetric hypertrophy, but some have asymmetric septal thickening, and a few have hypertrophy limited to the free wall or papillary muscles. The LV lumen usually appears small. Focal or diffuse areas of fibrosis occur within the endocardium, conduction system, or myocardium. Narrowing of small intramural coronary arteries is commonly noted and probably contributes to ischemia-related fibrosis. Areas of myocardial infarction and myocardial fiber disarray can be present. Cats with pronounced systolic anterior motion (SAM) of the anterior mitral leaflet could have a fibrous endocardial patch on the interventricular septum (IVS) where repeated valve contact has occurred.

Myocardial hypertrophy and the accompanying changes increase ventricular wall stiffness. Additionally, early active myocardial relaxation may be slow and incomplete, especially in the presence of myocardial ischemia or abnormal Ca^{++} kinetics. This further reduces ventricular distensibility and promotes diastolic dysfunction. The increased ventricular stiffness impairs LV filling and increases diastolic pressure. LV volume remains normal or decreased. Reduced ventricular volume results in a lower stroke volume, which may contribute to neurohormonal activation. Higher heart rates further interfere with LV filling, promote myocardial ischemia, and contribute to pulmonary venous congestion and edema by shortening the diastolic filling period. Contractility, or systolic function, usually is normal in cats with HCM. However, some cats experience progression to ventricular systolic failure and dilation.

Higher LV filling pressures lead to increased left atrial (LA) and pulmonary venous pressures. Progressive LA dilation, as well as pulmonary congestion and edema, can result. LA enlargement can become massive over time. Intracardiac thrombi can form, usually within the left auricle but occasionally in the body of the left atrium (LA) or left ventricle (LV), or attached to a ventricular wall. Arterial thromboembolism is a major complication of HCM and other forms of cardiomyopathy in cats (see Chapter 12). Mitral regurgitation develops in some affected cats and usually is associated with changes in LV geometry, abnormal papillary muscle structure, and/or mitral SAM that prevent complete valve closure. Valve insufficiency exacerbates increases in LA size and pressure.

Dynamic LV outflow obstruction occurs during systole in some cats with HCM. This variant is known as *hypertrophic obstructive cardiomyopathy* (HOCM). LV papillary muscle hypertrophy and abnormal LV or mitral valve geometry are thought to produce abnormal hemodynamic forces that pull the anterior mitral leaflet toward the IVS during ejection (SAM; see echocardiography images later). Excessive asymmetric hypertrophy of the basilar IVS can contribute to the dynamic obstruction. Both mitral valve SAM and basilar IVS hypertrophy can interfere with normal LV outflow. Systolic outflow obstruction increases LV pressure, wall stress, and myocardial oxygen demand and promotes myocardial ischemia as well as LV hypertrophy. SAM also causes or exacerbates mitral regurgitation. Increased LV outflow turbulence often causes an ejection murmur of variable intensity in these cats. Cats with HOCM are thus more likely to have heart murmurs than cats with nonobstructive HCM. A diastolic gallop sound (usually S_4) might be heard, associated with high LV filling pressure.

Several factors probably contribute to the development of myocardial ischemia in cats with HCM. These include narrowing of intramural coronary arteries, increased LV filling pressure, decreased coronary artery perfusion pressure, and insufficient myocardial capillary density for the degree of hypertrophy. Tachycardia contributes to ischemia by increasing myocardial O_2 requirements while reducing diastolic coronary perfusion time. Ischemia impairs early active ventricular relaxation, which further increases ventricular filling pressure, and over time leads to myocardial fibrosis. Ischemia can provoke arrhythmias and, potentially, sudden death.

If present, atrial fibrillation (AF) and other tachyarrhythmias further impair diastolic filling and exacerbate venous congestion; the loss of the atrial "kick" and the rapid heart rate associated with AF are especially detrimental. Ventricular tachycardia or other arrhythmias can lead to syncope or sudden death.

Eventually, pulmonary venous congestion and edema result from increasing LA pressure. Cavitary effusions also occur commonly in cats with HCM and CHF; in addition to pulmonary edema, approximately half of cats develop pleural effusion, and nearly 25% of cats have mild pericardial effusion. These effusions usually are modified transudates, although they can be (or become) chylous. These cavitary effusions, usually associated with right-sided CHF, often occur despite echocardiographic appearance of predominately left heart involvement. This pattern of fluid distribution could relate to feline-specific patterns of lymphatic drainage of body cavities, could suggest postcapillary pulmonary hypertension with reactive vasoconstriction, or might represent underdiagnosis of right heart dysfunction in HCM. Recent evidence suggests that up to 30% to 50% of cats with HCM may have right heart involvement, characterized by segmental or diffuse right ventricular hypertrophy and right atrial (RA) dilation. Cats that manifest CHF with pleural effusion have decreased LA function and larger RA volumes compared with cats that develop pulmonary edema exclusively.

Clinical Features

HCM is most commonly identified in middle-aged cats, with an average age at diagnosis of approximately 6 years; however, diagnosis at any age is possible. The disease has a male sex predilection. Overall prevalence of HCM in cats is estimated to be at least 15% and increases with age. Affected cats have a relatively long occult period before development of clinical disease. Many cats are not diagnosed until complications arise. The natural history of HCM is highly variable among cats. Some cats have relatively mild hypertrophy that does not worsen or cause clinical disease during the cat's lifetime. Other cats have more rapidly progressive disease. The overall median survival time for cats diagnosed with

asymptomatic HCM is estimated at 5 years. Between 20% to 40% of cats diagnosed with HCM will eventually develop CHF; between 5% to 10% suffer an arterial thromboembolism; and approximately 20% of cats with HCM experience sudden cardiac death.

Subclinical (occult) HCM can be detected using echocardiography. However, echocardiography is typically only undertaken in cats where a murmur, arrhythmia, or gallop sound is heard on routine examination. Heart murmur prevalence in apparently healthy cats ranges from 20% to more than 40% (see p. 11). Among cats with heart murmurs, the reported prevalence of HCM based on echocardiography has ranged from about 33% to more than 50%. Conversely, among cats diagnosed echocardiographically with HCM, the prevalence of heart murmurs varies from 30% to 80% in different reports. Most murmurs in HCM are caused by dynamic left ventricular outflow tract (LVOT) obstruction. Murmur auscultation is thus a crude screening test for subclinical HCM, and tends to preferentially identify cats with HOCM yet missing cases of nonobstructive HCM.

Symptomatic cats most often are presented for respiratory signs (indicating CHF) or acute thromboembolism (see p. 224). Respiratory signs include tachypnea, open-mouth breathing associated with activity, or dyspnea; unlike in dogs, coughing is an uncommon clinical sign of CHF in cats. Disease onset can seem acute in sedentary cats, even though pathologic changes have developed gradually. Occasionally, lethargy or anorexia is the only evidence of CHF. Some cats have syncope or sudden death in the absence of other signs. Stresses such as anesthesia, surgery, fluid administration, systemic illnesses (e.g., fever, anemia), recent injection of long-acting corticosteroids, or boarding can precipitate CHF in an otherwise compensated cat.

RADIOGRAPHY

Diagnosis

Although the cardiac silhouette appears normal in most cats with mild HCM, radiographic features of advanced HCM include prominent LA and variable LV enlargement (Fig. 8.1, *A* and *B*). Radiographically apparent LA enlargement generally occurs only when echocardiographic measurements suggest severe LA enlargement (ratio of LA to aortic size > 2.0). The classic valentine-shaped appearance of the heart on dorsoventral or ventrodorsal views is not always present, although usually the point of the LV apex is maintained. Vertebral heart score (VHS) can be useful when differentiating cardiac versus noncardiac causes of respiratory distress in cats; VHS of > 9.3v suggests significant heart disease (normal VHS in cats is about 7.5v). Enlarged and tortuous pulmonary veins might be noted in cats with chronically high LA and pulmonary venous pressure. However, the pattern of pulmonary vascular change is inconsistent in feline CHF; pulmonary artery enlargement reportedly occurs in approximately two thirds of cats with CHF and may be even more common than lobar vein enlargement. Left-sided CHF produces variable degrees of patchy interstitial or alveolar pulmonary edema infiltrates (Fig. 8.1, *C* and *D*). The radiographic distribution of pulmonary edema is variable; a diffuse or multifocal distribution throughout the lung fields is common, in contrast to the characteristic perihilar distribution of cardiogenic pulmonary edema seen in dogs. Pleural effusion also is common (Fig. 8.1, *E* and *F*).

ELECTROCARDIOGRAPHY

Most cats with HCM have an underlying normal sinus rhythm. Sinus tachycardia is common in hospital environments; either sinus tachycardia or bradycardia can occur in cats with CHF. Electrocardiogram (ECG) complex abnormalities that can be seen in cats with HCM include criteria for LA or LV enlargement and a left anterior fascicular block pattern (see Fig. 8.2 and Chapter 2). Occasional ventricular arrhythmias are common. A small study of Holter monitoring in cats showed that all cats with asymptomatic HCM had at least 1 ventricular premature complex (VPC) per day, though the overall number of VPCs was relatively low (geometric mean of 124 ventricular complexes/24 hours). More clinically significant arrhythmias such as AF or high-grade AV block can occur in cats with severe HCM (often with concurrent CHF). An ECG is too insensitive to be useful as a screening test for HCM but can be useful to characterize concurrent arrhythmias.

ECHOCARDIOGRAPHY

Echocardiography is the best means of diagnosis and differentiation of HCM from other disorders. The extent of hypertrophy and its distribution within the ventricular wall, septum, and papillary muscles is shown by two-dimensional (2-D) and M-mode echo studies (Fig. 8.3). Doppler techniques can demonstrate LV diastolic or systolic abnormalities. Widespread myocardial thickening is common, and the hypertrophy is often asymmetrically distributed among various LV wall, septal, and papillary muscle locations. Focal areas of hypertrophy also occur. Use of 2-D–guided M-mode echocardiography helps ensure proper beam position. Standard M-mode views and measurements are obtained, but thickened areas outside these standard positions also should be measured (using 2-D or perpendicularly aligned M-mode images). The 2-D right parasternal long-axis view is useful for measuring basilar IVS thickness. The diagnosis of early disease may be questionable in cats with mild or only focal thickening. Falsely increased thickness measurements (pseudohypertrophy) can occur with dehydration and sometimes tachycardia. Spurious diastolic thickness measurements also arise when the beam does not transect the wall/septum perpendicularly, when the septal tricuspid leaflet is included in the IVS measurement, or when the measurement is not taken at the end of diastole, as can happen without simultaneous ECG recording or when using 2-D imaging of insufficient frame rate. A (properly obtained) end-diastolic LV wall or septal thickness greater than 6.0 mm is considered diagnostic for LV hypertrophy in cats, though a thickness of 5.5 to 5.9 mm is likely abnormal except in cats of very large body size. Cats with severe HCM can have diastolic LV wall or

septal thicknesses of 8 mm or more, although the degree of hypertrophy is not necessarily correlated with the severity of clinical signs. Papillary muscle hypertrophy can be marked, and systolic LV cavity obliteration is observed in some cats with HCM. Increased echogenicity (brightness) of papillary muscles and subendocardial areas is thought to be a marker for chronic myocardial ischemia, with resulting fibrosis.

LV fractional shortening (FS) generally is normal to increased. However, some cats have mild to moderate LV dilation and reduced contractility (FS ≈ 23%-29%; normal FS is 35%-65%). Some cats eventually develop "end-stage" or "remodeled" HCM, where chronic severe ischemia and fibrosis lead to areas of LV wall thinning and reduced contractility. Echocardiographically, such cases can be difficult to distinguish from RCM or DCM, as LV hypertrophy becomes less dramatic. Excessive moderator bands (also known as "false tendons") appear as bright linear echoes spanning the LV cavity in various configurations. The functional significance of these moderator bands is unclear, but they seem to occur more commonly in cats with HCM compared with cats without structural heart disease. Although LV changes predominate, 30% to 50% of cats with HCM can have at least segmental RV hypertrophy, and some cats have RA dilation as well.

LA enlargement in cats with HCM can range from mild to marked (see Chapter 2 and Figs. 8.3, *A* and *D*, and 8.4). Prominent LA enlargement is expected in cats with clinical signs of CHF. Spontaneous echocontrast (swirling, smoky echoes) is visible within the enlarged LA of some cats. This is thought to result from blood stasis with cellular aggregations, and to be a harbinger of thromboembolism. A thrombus occasionally is visualized within the LA, usually in the auricle (see Fig. 8.4).

Cats with dynamic LV outflow tract obstruction often have SAM of the mitral valve (Fig. 8.5) or premature closure of the aortic valve leaflets on M-mode scans. Abnormalities of the mitral valve apparatus, including increased papillary muscle hypertrophy and anterior mitral leaflet length, have been associated with SAM and severity of dynamic LV outflow obstruction. Doppler modalities can demonstrate mitral regurgitation and LV outflow turbulence (Fig. 8.6). Continuous-wave Doppler can be used to demonstrate high-velocity and late-peaking blood flow through the LV outflow tract, confirming the dynamic obstruction. The left apical five-chamber view may be most useful.

Doppler-derived estimates of diastolic function are now routinely employed to define disease characteristics in HCM. Pulsed wave (PW) Doppler may show a delayed relaxation mitral inflow pattern (E wave:A wave velocity < 1) or evidence for more advanced diastolic dysfunction. Prolonged isovolumic relaxation time is associated with early diastolic dysfunction. Tissue Doppler imaging of the lateral or septal mitral valve annulus can detect reduced early annular motion in diastole, another hallmark of diastolic dysfunction. However, the rapid heart rate in many cats, as well as changes in loading conditions, often confounds accurate assessment of diastolic function.

Other causes of myocardial hypertrophy, particularly systemic hypertension and hyperthyroidism (see p. 167), should be excluded before a diagnosis of idiopathic HCM is made. Myocardial thickening in cats also can result from infiltrative disease (such as lymphoma). Variation in myocardial echogenicity or wall irregularities may be noted in such cases.

Clinicopathologic Findings

Routine clinical pathology tests often are noncontributory. The pleural effusion in cats with CHF usually is a modified transudate, although it can be chylous. Circulating cardiac troponins are higher in cats with moderate to severe HCM compared with unaffected cats, but low sensitivity and specificity limit diagnostic value of this test. NT-proBNP testing has proven diagnostically useful in two clinical settings involving HCM. First, elevated NT-proBNP (performed on blood or pleural fluid) can discriminated between CHF and noncardiac disease in cats presenting with respiratory distress. Various studies have identified diagnostic cutoff values

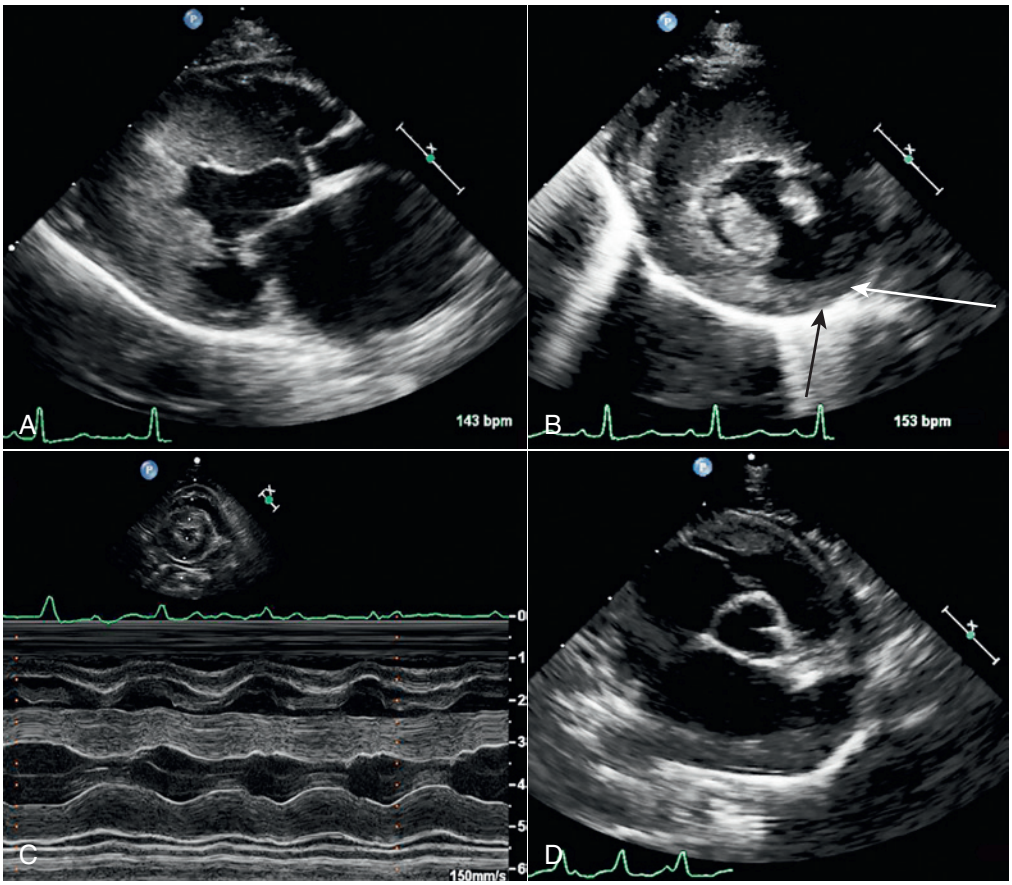

FIG 8.3
Echocardiographic examples of feline hypertrophic cardiomyopathy. Right parasternal four-chamber long-axis view **(A)** and short-axis view at the level of the left ventricular papillary muscles **(B)** from a 2-year-old male domestic longhair cat. The left ventricular free-wall and septal thicknesses are about 8 mm. There is a focal area of wall thinning in the basilar free wall (*arrows*), likely representing an area of previous infarction, and papillary muscle hypertrophy. Severe left atrial enlargement is also noted. M-mode image of the left ventricle **(C)** in a 3-year-old male domestic shorthair cat with hypertrophic cardiomyopathy and congestive heart failure. Thickening of the interventricular septum and left ventricular free wall are seen, as well as small volume pleural end pericardial effusion. Two-dimensional right parasternal short-axis view at the level of the heart base **(D)** in an 8-year-old male domestic shorthair cat with moderate left atrial enlargement. *Ao,* Aortic root; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *LVPW,* left ventricular posterior (free) wall; *RA,* right atrium; *RV,* right ventricle.

of 212 to 258 pmol/L, resulting in sensitivity and specificity of approximately 90%. A point-of-care test (SNAP proBNP, IDEXX Laboratories) has been developed for this purpose, with visual positive test result at >200 pmol/L. The other setting in which NT-proBNP has proven helpful is as a "second-line screening" test for cats with abnormal cardiovascular physical examination findings (heart murmur or arrhythmia). In this context, an elevated NT-proBNP (using a lower cutoff value than the SNAP test) can raise index of suspicion for HCM, helping to prioritize the value of echocardiography for a particular cat. A cutoff value of greater than 46 pmol/L had 86% sensitivity and 91% specificity for detecting occult HCM in one study. In other words, NT-proBNP elevation can increase clinical suspicion for HCM in an otherwise healthy cat with a heart murmur from ~30% to 50% (based on murmur alone) to more than 90%. However, as false positives occur, echocardiography is recommended for definitive diagnosis.

SUBCLINICAL HYPERTROPHIC CARDIOMYOPATHY (STAGE B DISEASE)

Treatment

Whether (and how) asymptomatic cats should be treated is controversial. It is unclear if disease progression can be slowed or survival prolonged by medical therapy before the onset of clinical signs. Various small studies using a β-blocker, diltiazem, an angiotensin-converting enzyme

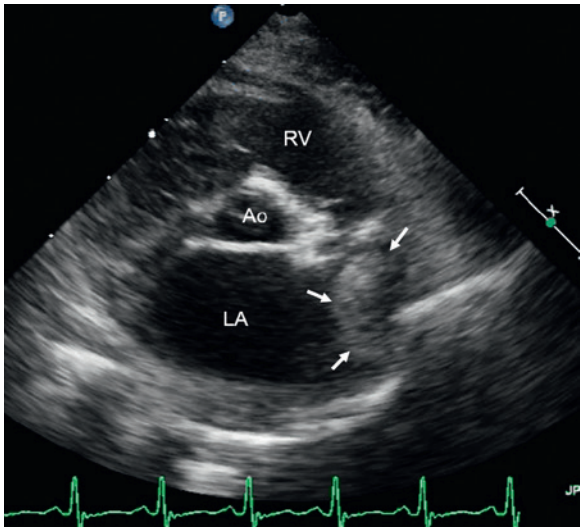

FIG 8.4

inhibitor (ACEI), or spironolactone have been performed, but clear benefit from any of these interventions has yet to be proven. With this in mind, some clinicians still suggest using a β-blocker in cats with evidence of substantial dynamic LV outflow obstruction or arrhythmias. In cats with marked, nonobstructive myocardial hypertrophy, particularly with evidence of myocardial fibrosis and remodeling, an ACEI might be suggested. For cats with LA enlargement, especially with spontaneous echocontrast, instituting antithrombotic prophylaxis with clopidogrel is prudent (see Chapter 12).

Avoidance of stressful situations likely to cause persistent tachycardia and reevaluation on a semiannual or annual basis are usually advised. Secondary causes of myocardial hypertrophy, such as systemic arterial hypertension and hyperthyroidism, should be ruled out (or treated, if found).

CONGESTIVE HEART FAILURE (STAGE C DISEASE)

Goals of therapy are to enhance ventricular filling, relieve congestion, control arrhythmias, minimize ischemia, and prevent thromboembolism (Box 8.1). Furosemide is used only at the dosage needed to help control congestive signs for long-term therapy. Moderate to severe pleural effusion is treated by thoracocentesis, with the cat restrained gently in sternal position (and sedated with butorphanol if needed).

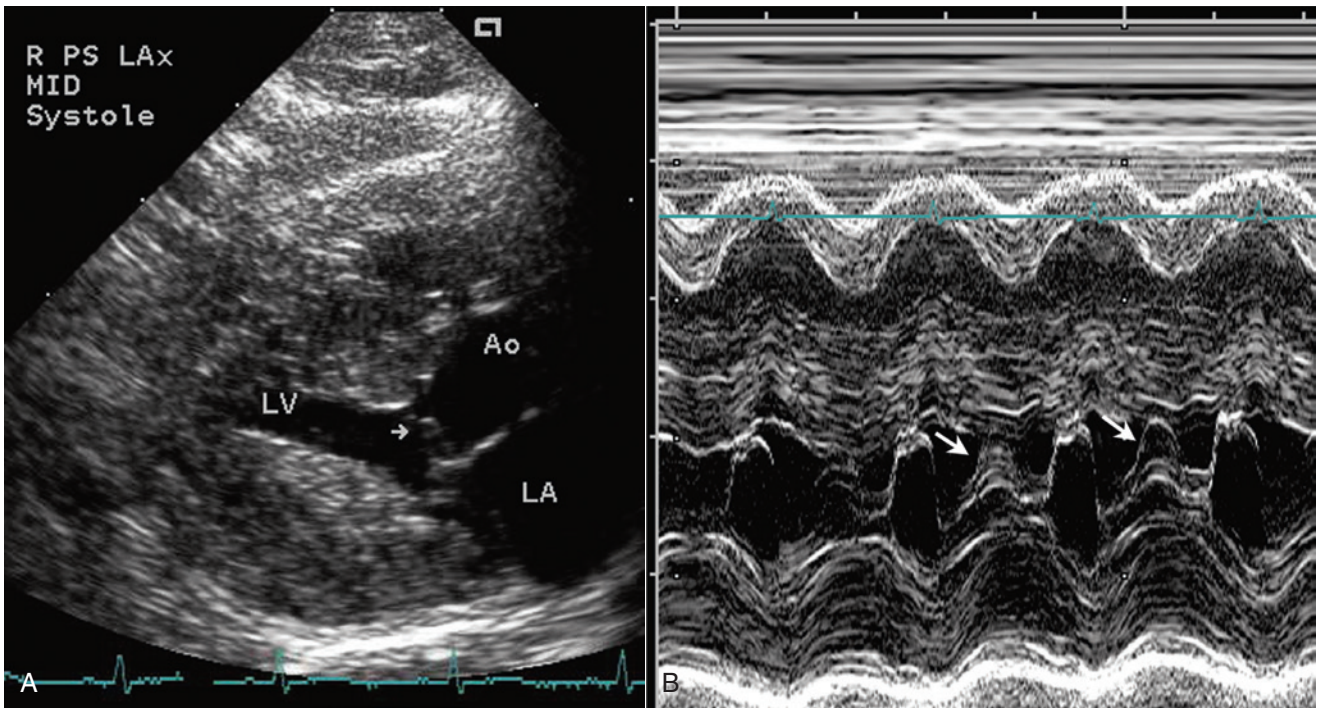

FIG 8.5
(A) Two-dimensional echo image in midsystole from a middle-aged domestic shorthair cat. Echoes from the anterior mitral leaflet appear within the LV outflow tract *(arrow)* because of abnormal systolic anterior (toward the septum) motion (SAM) of the valve. **(B)** The M-mode echocardiogram at the mitral valve level also shows the mitral SAM *(arrows). Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

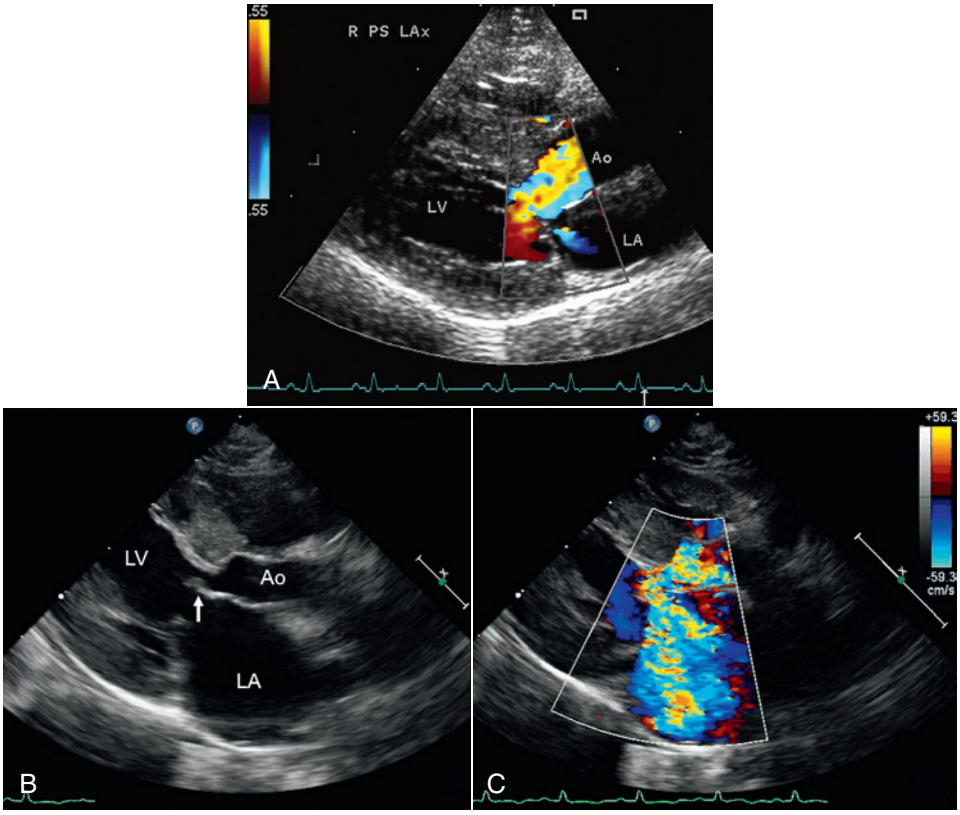

FIG 8.6
(A) Color flow Doppler image taken in systole from a male domestic longhair cat with hypertrophic obstructive cardiomyopathy. Note the turbulent flow just above where the thickened interventricular septum protrudes into the LV outflow tract and a small mitral insufficiency jet, typical with systolic anterior motion (SAM) of the anterior mitral leaflet. **(B)** and **(C)** show two-dimensional and corresponding color Doppler images from a male domestic shorthair cat with hypertrophic obstructive cardiomyopathy. There is hypertrophy of the basilar interventricular septum and severe left atrial enlargement. The anterior mitral leaflet's SAM (*arrow*, **B**) contributes to dynamic LV outflow obstruction. **(C)** Color Doppler imaging in midsystole reveals turbulent, high-velocity flow in the LV outflow tract and, in this cat, severe mitral regurgitation. Right parasternal long-axis view. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

Cats with severe pulmonary edema are given supplemental oxygen and parenteral furosemide, usually intramuscular (IM) initially (2 mg/kg q1-4h; see Box 3.1, p. 62 and p. 65), until an intravenous (IV) catheter can be placed without excessive stress to the cat. Butorphanol can be helpful to reduce anxiety that accompanies dyspnea and hospitalization (see Box 3.1). Nitroglycerin ointment can be used (q4-6h), although no studies of its efficacy in this situation have been done. Once initial medications have been given, the cat should be allowed to rest. The respiratory rate is noted initially and then every 15 to 30 minutes or so without disturbing the cat. Respiratory rate and effort are used to guide ongoing diuretic therapy. Catheter placement, blood sampling, radiographs, and other tests and therapies should be delayed until the cat's condition is more stable. Airway suctioning and mechanical ventilation with positive end-expiratory pressure can be considered in extreme cases.

The use of pimobendan in cats with CHF is the subject of ongoing study. In theory, positive inotropes such as pimobendan are not indicated in cats with HCM, because systolic function generally is well preserved and increased force of contraction could worsen dynamic outflow tract obstruction. However, pimobendan could improve cardiac output without increasing myocardial oxygen demand, and its balanced vasodilatory properties might be beneficial in both acute and chronic CHF regardless of underlying structural disease. Nevertheless, great caution is advised when HOCM is suspected or confirmed, because vasodilation, especially combined with increased contractility, could worsen the dynamic LV outflow obstruction and promote hypotension. If pimobendan is used in a cat with HOCM, blood pressure measurement and close monitoring for signs of hypotension are advised. Pimobendan is clearly indicated in cats with systolic dysfunction or cardiogenic shock, and several studies

BOX 8.1

Treatment Outline for Cats with Hypertrophic Cardiomyopathy

Severe, Acute Signs of Congestive Heart Failure*

Supplemental O_2
Minimize patient handling
Furosemide (parenteral)
Sedation (butorphanol)
Thoracocentesis, if pleural effusion present
Pimobendan (±; see p. 69, caution if LV outflow obstruction)
Antiarrhythmic therapy or heart rate control, if indicated†
±Nitroglycerin (cutaneous)
±Dobutamine (if needed for cardiogenic shock)
Monitor: respiratory rate, HR and rhythm, arterial blood pressure, renal function, serum electrolytes, etc.

Mild to Moderate Signs of Congestive Heart Failure*

Furosemide
ACE inhibitor
Pimobendan (±; see p. 69, caution if LV outflow obstruction)
Antithrombotic prophylaxis (clopidogreal ± anticoagulant)‡
Exercise restriction
Reduced-salt diet, if the cat will eat it
±β-blocker (e.g., atenolol) or diltiazem (see text)

Refractory Congestive Heart Failure Management*

Furosemide (optimize dosage and frequency)
ACE inhibitor
Pimobendan (caution if severe LV outflow tract obstruction)
Antithrombotic prophylaxis (clopidogrel ± anticoagulant)‡
Thoracocentesis as needed
±Spironolactone
±β-blocker or diltiazem
±Additional antiarrhythmic drug therapy, if indicated
±Hydrochlorothiazide (closely monitor renal function/electrolytes)
Home monitoring of resting respiratory rate and effort
Dietary salt restriction, if accepted
Monitor renal function, electrolytes, etc.
Manage other medical problems (rule out hyperthyroidism and hypertension if not done previously)

ACE, Angiotensin-converting enzyme; *CHF,* congestive heart failure; *HR,* heart rate; *IV,* intravenous; *LMWH,* low-molecular-weight heparin; *LV,* left ventricular.
*See text, Box 3.1 (p. 62), and Chapter 3 for further details.
†See text, Table 4.2 (p. 90), and Chapter 4 for further details.
‡See Chapter 12 for further details.

have demonstrated that the drug is well tolerated in cats. More recently, pimobendan has shown apparent long-term benefit and improved survival in "typical" HCM with normal systolic function. In a retrospective case control study of cats with HCM and CHF, cats that received pimobendan lived significantly longer (~21 months) compared with cats that did not receive pimobendan (~4 months). Further clarification regarding potential benefits of pimobendan on heart failure progression, optimal management, and survival time await results of prospective study. If pimobendan is elected for a cat with CHF, the drug is given as soon as oral medication is feasible, at the same initial dose as recommended for dogs (0.2-0.3 mg/kg PO q12h). For most average-sized cats, this dose equates to one 1.25 mg chewable tablet twice daily. Cats with poor cardiac output or cardiogenic shock can receive pimobendan every 8 hours during initial stabilization, if needed. Cats with more severe cardiogenic shock may require IV dobutamine (usually given as a continuous ratet infusion (CRI) of 1-5 mcg/kg/min). Adverse effects of dobutamine can include sinus tachycardia, ventricular ectopy, and seizures; if these occur, the infusion rate is halved or discontinued.

As respiratory distress resolves, furosemide can be continued at a reduced dose (≈1 mg/kg q8-12h). Once pulmonary edema is controlled, supplemental oxygen is withdrawn and the patient is transitioned to oral medications. The furosemide dose is gradually titrated downward to the lowest effective level. For example, a starting dose of 6.25 mg/cat q8-12h can be slowly reduced over days to weeks, depending on the cat's response. Some cats do well with once daily or every other day dosing, whereas others require furosemide several times per day. If instituted, oral pimobendan is continued at the starting dose. Once initial acute respiratory distress has resolved and the cat is eating and drinking, ACEI therapy should be added. An ACEI usually is prescribed in the hope of reducing neurohormonal activation and abnormal cardiac remodeling. Enalapril and benazepril are the agents used most often in cats, although others are available (see Chapter 3 and Table 3.3).

The decision to use other drugs is influenced by echocardiographic or other findings in the individual cat. β-blockers offer several theoretical benefits for cats with HCM, although clinical evidence for increased survival time is lacking, and the possibility of a negative effect in cats with CHF exists. Nevertheless, β-blockers can reduce heart rate (including ventricular response rate in AF), reduce or resolve dynamic LV outflow obstruction, and suppress tachyarrhythmias. Sympathetic inhibition also can reduce myocardial O_2 demand, which could be important in cats with myocardial ischemia or infarction. By inhibiting catecholamine-induced myocyte damage, β-blockers might reduce myocardial fibrosis. Although β-blockers slow active myocardial relaxation, an increase in ventricular filling time from their heart rate lowering effect might outweigh this. If a β-blocker is used, the selective β-1 blocker, atenolol, is most commonly chosen. β-blockers, especially nonselective agents like propranolol, are not recommended for cats in active CHF. Blockade of bronchial β-2 receptors could exacerbate bronchospasm, which might occur with pulmonary edema. Additionally, in cats with reduced myocardial contractility, the negative inotropic effect of β-blockers could promote acute CHF decompensation. For cats receiving atenolol (or other β-blocker) before CHF, the drug could be continued or its dosage

reduced by half during the acute episode. The most common indication for starting atenolol in a cat that previously has experienced CHF is rate control in AF; it also can be useful for suppressing other tachyarrhythmias.

Diltiazem also has theoretical benefits for cats with severe LV hypertrophy, although it likewise has not been shown to improve survival, and side effects can be problematic in some cats. Its Ca^{++}-blocking effect can modestly reduce heart rate and contractility (which reduces myocardial O_2 demand). Diltiazem promotes coronary vasodilation and may have a positive effect on myocardial relaxation. Longer-acting diltiazem products are more convenient for chronic use, although the serum concentrations achieved can be variable. Diltiazem ER (or XR; Dilacor), dosed at one half of an internal (60-mg) tablet from the 240-mg capsule q12h, or Cardizem CD, compounded and dosed at 10 mg/kg q24h, have been used most often. Similar to atenolol, the most common reason for initiating diltiazem therapy in a cat with previous CHF is rate control in AF. Occasionally, a β-blocker might be added to diltiazem therapy (or vice versa) to further reduce heart rate in cats with AF. However, care must be taken to prevent bradycardia or hypotension in animals receiving this combination.

The negative chronotropic drug ivabradine is another pharmacologic option that could prove helpful in controlling heart rate in cats with HCM. Ivabradine is a selective "funny" current (I_f) inhibitor. The I_f is important in sinus node (pacemaker) function. Activation of the I_f current increases membrane permeability to Na^+ and K^+, thereby increasing the slope of spontaneous phase 4 (diastolic) depolarization in sinus node cells, which increases the heart rate. Preliminary studies have shown ivabradine to produce dose-dependent heart rate reduction with minimal adverse effects. Specific recommendations await further study.

Long-term management of cats with CHF also includes therapy to reduce the likelihood of arterial thromboembolism (see Chapter 12). Dietary sodium restriction is recommended if the cat will accept such a diet, but it is more important to forestall anorexia.

CHRONIC REFRACTORY CONGESTIVE HEART FAILURE

Refractory pulmonary edema or pleural effusion is difficult to manage. Moderate to large pleural effusions should be treated by thoracocentesis. Various medical strategies may help slow the rate of abnormal fluid accumulation. These include increasing the dosage of furosemide (up to ≈4 mg/kg q8h), maximizing the dosage of an ACEI, adding or increasing dosage of pimobendan (up to ≈0.5 mg/kg q8h), using diltiazem or a β-blocker for greater heart rate control if AF or other tachyarrhythmias are present, adding spironolactone, or using an additional diuretic (e.g., hydrochlorothiazide; see Table 3.3). Spironolactone has been reported to cause facial pruritus and excoriations in some cats. Digoxin could be considered for additional heart rate control or for cats with severe systolic dysfunction; however, toxicity can occur easily. Frequent monitoring for azotemia, electrolyte disturbances, and other complications is warranted.

Prognosis

Several factors influence the prognosis for cats with HCM, including the speed with which the disease progresses, the occurrence of thromboembolic events and/or arrhythmias, and the response to therapy. Asymptomatic cats with only mild to moderate LV hypertrophy and atrial enlargement often live with no clinical signs for many years. Median survival time for all asymptomatic cats after diagnosis of HCM is approximately 5 years. Cats with marked LA enlargement and more severe hypertrophy appear to be at greater risk for CHF, thromboembolism, and sudden death. Median survival time for cats with CHF is between 1 and 2 years, although this varies greatly with individual response to therapy and patient compliance with medication administration. The prognosis is worse for older cats and cats with severe LA enlargement, severe LV hypertrophy, LV or LA systolic dysfunction, AF, and/or refractory CHF. Cats with low or high body weight may have a worse prognosis than those with normal weight. Thromboembolism confers a guarded prognosis (see p. 224) and recurrence of thromboembolism is common.

SECONDARY MYOCARDIAL HYPERTROPHY

Myocardial hypertrophy is a compensatory response to certain identifiable stresses or diseases. Marked LV wall and septal thickening and CHF can occur in some of these cases, mimicking idiopathic HCM. Secondary causes should therefore be ruled out whenever LV hypertrophy is identified before making a diagnosis of idiopathic HCM. The most common causes of secondary myocardial hypertrophy in cats are hyperthyroidism and systemic hypertension; less frequent causes include subaortic stenosis, hypersomatotropism (acromegaly), and infiltrative myocardial diseases.

Evaluation for hyperthyroidism is indicated in cats with myocardial hypertrophy or CHF older than 6 years of age. Hyperthyroidism alters cardiovascular function by its direct effects on the myocardium and through the interaction of heightened sympathetic nervous system activity and excess thyroid hormone on the heart and peripheral circulation. Cardiac effects of thyroid hormone include myocardial hypertrophy and increased heart rate and contractility. The metabolic acceleration that accompanies hyperthyroidism causes a hyperdynamic circulatory state characterized by increased cardiac output, oxygen demand, blood volume, and heart rate. Systemic hypertension can further stimulate myocardial hypertrophy. Manifestations of hyperthyroid heart disease often include a systolic murmur, hyperdynamic arterial pulses, a strong precordial impulse, sinus tachycardia, and various arrhythmias. Criteria for LV enlargement or hypertrophy often are found on ECG, thoracic radiographs, or echocardiogram. Signs of CHF develop in approximately

15% of hyperthyroid cats; most have normal to high FS, but a few have poor contractile function. Cardiac therapy, in addition to treatment of the hyperthyroidism, is indicated for cats with severe hyperthyroid heart disease. Treatment for CHF is the same as that described for HCM. Treatment for preclinical disease with marked LA enlargement also is similar to that for HCM, including thromboprophylaxis with clopidogrel and potentially, vasodilation with an ACEI. Concurrent systemic hypertension should be treated with amlodipine. A β-blocker can temporarily control many of the adverse cardiac effects of excess thyroid hormone, especially tachyarrhythmias; for this reason, atenolol is a common adjunct treatment for hyperthyroid heart disease. Cardiac therapy, including a β-blocker, is not a substitute for antithyroid treatment. Regression of myocardial hypertrophy ("reverse remodeling") can sometimes occur in cats after treatment for hyperthyroidism, particularly definitive treatment with I-131. Treatment with methimazole might or might not resolve or prevent hyperthyroid heart disease, presumably because periodic spikes in circulating thyroid hormone can still occur despite apparent disease control.

LV concentric hypertrophy is the expected response to increased ventricular systolic pressure (afterload). Systemic arterial hypertension (see Chapter 11) increases afterload because of high arterial pressure and resistance. Increased resistance to ventricular outflow also occurs with a fixed (e.g., congenital) subaortic stenosis. In addition, cardiac hypertrophy develops in cats with hypersomatotropism (acromegaly) as a result of the trophic effects of growth hormone on the heart. Increased myocardial thickness occasionally results from infiltrative myocardial disease, most notably from lymphoma. Cats with hypertensive heart disease, acromegalic heart disease, or myocardial lymphoma might require cardiac medications in addition to treatment for the underlying disease. In general, treatment for secondary myocardial hypertrophy is the same as that described for HCM.

RESTRICTIVE CARDIOMYOPATHY

Etiology and Pathophysiology

RCM is a myocardial disease phenotype associated with extensive endocardial, subendocardial, or myocardial fibrosis of unclear, but probably multifactorial, etiology. Characteristic features include diastolic dysfunction (restrictive filling physiology) and severe LA enlargement in the absence of myocardial hypertrophy. This condition could be a consequence of endomyocarditis or infiltrative neoplastic disease (e.g., lymphoma), or may be idiopathic; no specific familial associations or genetic mutations have been identified. It is important to remember that advanced HCM also is characterized by restrictive LV filling, and that chronic ischemia and fibrosis can result in an end-stage or "remodeled" HCM phenotype with minimal hypertrophy and focal areas of wall thinning. Thus without serial echocardiography it can be difficult to differentiate "true" RCM from end-stage remodeled HCM.

There are a variety of histopathologic findings in cats with RCM, including marked perivascular and interstitial fibrosis, intramural coronary artery narrowing, and myocyte hypertrophy, as well as areas of degeneration and necrosis. Some cats have extensive LV endomyocardial fibrosis with chamber deformity or fibrous tissue bridging between the septum and LV wall. In such cases, the mitral apparatus and papillary muscles may be fused to surrounding tissue or distorted. LA or biatrial enlargement is prominent in cats with RCM as a consequence of chronically high ventricular filling pressure from increased wall stiffness. The LV may be normal to reduced in size or mildly dilated. Intracardiac thrombi and systemic thromboembolism are common.

LV fibrosis impairs diastolic filling. Most affected cats have normal to only mildly reduced contractility, but this can progress with time as more functional myocardium is lost. Some cases develop regional LV dysfunction, possibly from myocardial ischemia or infarction. If mitral regurgitation is present, it is usually mild. Chronically elevated left heart filling pressures, combined with compensatory neurohormonal activation, lead to left-sided or biventricular CHF. The duration of subclinical disease progression in RCM is unknown.

Clinical Features

Middle-aged and older cats are most often diagnosed with RCM, though young cats are sometimes affected. Clinical features are similar to those seen with HCM. Preclinical disease might be discovered by detection of abnormal heart sounds or arrhythmias on routine examination or radiographic evidence of cardiomegaly. Clinical signs of CHF most commonly involve respiratory signs from pulmonary edema or pleural effusion; inactivity, poor appetite, vomiting, and weight loss also are common in the history. Clinical signs can be precipitated or acutely worsened by stress or concurrent disease that causes increased cardiovascular demand. Signs associated with thromboembolic events depend on the location and extent of vascular obstruction but can be severe (see Chapter 12, p. 224).

Physical examination might reveal a systolic murmur of mitral or tricuspid regurgitation, an S_4 gallop sound, and/or an arrhythmia. Pulmonary sounds can be abnormal in some cats with pulmonary edema, or muffled with pleural effusion. Femoral arterial pulses could be normal, slightly weak, or absent (if caudal aortic thromboembolism has occurred). Jugular vein distention and pulsation are common in cats with right-sided CHF. Acute signs of distal aortic (or other) thromboembolism may be the reason for presentation.

Diagnosis

Diagnostic test results are similar to those in cats with HCM. Routine clinicopathologic findings are nonspecific, although NT-proBNP can be useful in some clinical scenarios, as in HCM (see p. 162). Radiographs indicate LA or biatrial enlargement (sometimes massive) and LV or generalized

heart enlargement (Fig. 8.7). Typical radiographic findings in cats with CHF include pulmonary venous distension, infiltrates of pulmonary edema, pleural effusion, and sometimes hepatomegaly and ascites. Although normal sinus rhythm predominates, ECG abnormalities often include various arrhythmias such as ventricular or atrial premature complexes, supraventricular tachycardia, or AF. Wide QRS complexes, tall R waves, evidence of intraventricular conduction disturbances, or wide P waves also might be evident.

Echocardiography typically shows marked LA (and sometimes RA) enlargement with normal LV wall thickness. LV systolic function generally is normal (FS usually > 25%), although some cats have regional wall dysfunction. End-stage RCM can be associated with LV and RV dilation. Pulse-wave Doppler shows a restrictive pattern of mitral inflow, and tissue Doppler confirms severe diastolic dysfunction. Hyperechoic areas of fibrosis within the LV wall and/or endocardial areas sometimes are evident. Extraneous intraluminal echoes representing excess moderator bands are seen in some cases. Sometimes, extensive LV endocardial fibrosis, with scar tissue bridging between the free-wall and septum, constricts part of the ventricular chamber. An intracardiac thrombus might be found, usually in the left auricle or LA but occasionally in the LV. Mild mitral or tricuspid regurgitation often is present. As previously discussed, differentiation between RCM and end-stage remodeled HCM can be challenging. Cases that do not fit within the typical classification scheme often are termed "unclassified" cardiomyopathy (UCM) (see p. 171).

Treatment and Prognosis

Therapy for acute and chronic CHF is the same as for cats with HCM (see p. 164). Because cats with RCM do not typically have dynamic outflow tract obstruction, there is no contraindication to positive inotropic agents. Pimobendan is an appropriate therapy; severe cardiogenic shock can be managed with dobutamine. As with HCM, atenolol or diltiazem usually are added only as treatment for tachyarrhythmias, particularly AF. Sotalol could be used for refractory ventricular tachyarrhythmias. Management of thromboembolism is described in Chapter 12, p. 227.

The prognosis generally is guarded to poor for cats with RCM and CHF. Nevertheless, some cats survive more than a year after diagnosis. Thromboembolism and refractory pleural effusion commonly occur.

DILATED CARDIOMYOPATHY

Etiology

DCM has become uncommon in cats since the late 1980s, when taurine deficiency was identified as its major cause, and pet food manufacturers subsequently increased the taurine content of feline diets. Other factors besides a

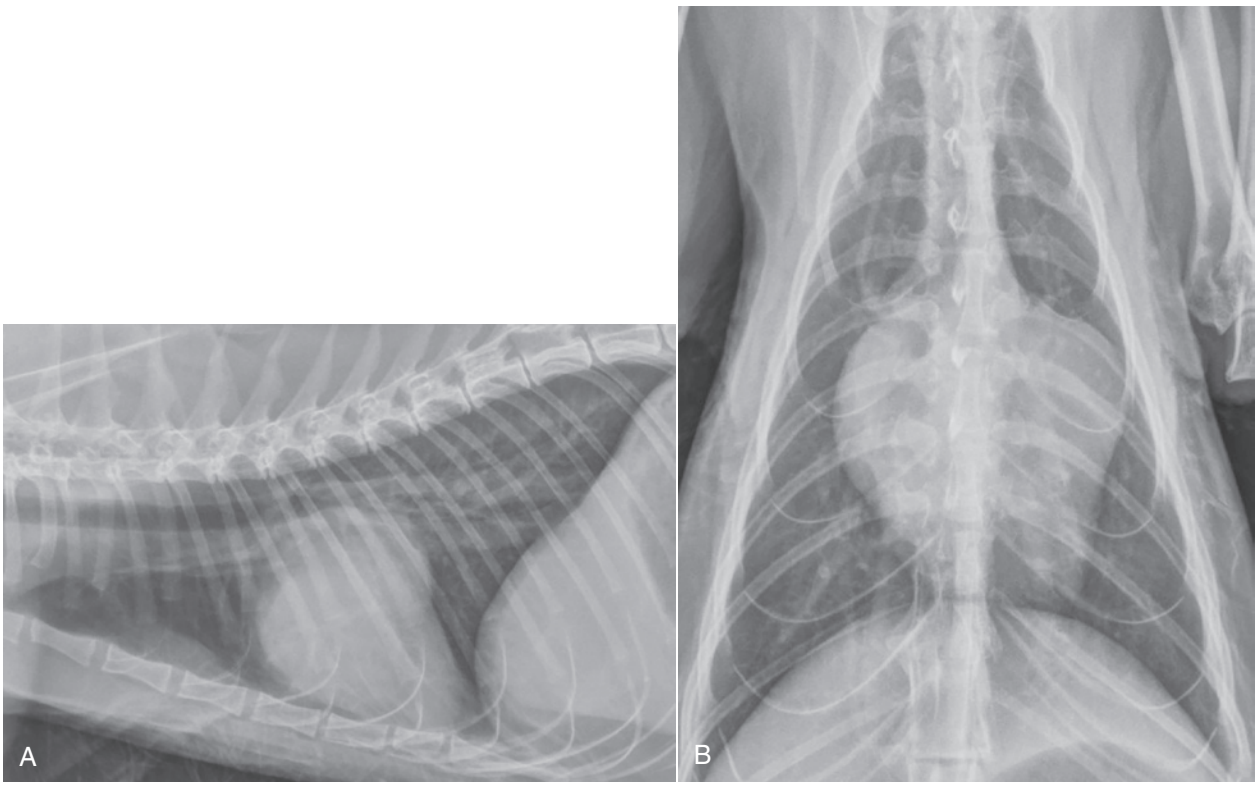

FIG 8.7
Lateral **(A)** and dorsoventral **(B)** radiographs from a domestic shorthair cat with restrictive cardiomyopathy show marked left atrial enlargement and prominent pulmonary vessels.

simple deficiency of this essential amino acid are likely to be involved in the pathogenesis, including genetic factors and a possible link with potassium depletion. Not all cats fed a taurine-deficient diet develop DCM, and taurine deficiency can occur even in cats fed a balanced commercial diet. Relatively few cases of DCM are identified now, and most of these cats are not taurine deficient. DCM in these cats could be idiopathic or represent the end stage of another myocardial metabolic abnormality, toxicity, or infection.

Doxorubicin can cause characteristic myocardial histopathologic lesions in cats as it does in dogs, and in rare instances echocardiographic changes consistent with DCM can occur after cumulative doses of 170 to 240 mg/m^2. However, clinically relevant doxorubicin-induced cardiomyopathy is not an issue in the cat; anecdotally, total cumulative doses of up to about 600 mg/m^2 (23 mg/kg) have been administered without evidence of cardiotoxicity.

Pathophysiology

DCM in cats has a similar pathophysiology to that in dogs (see p. 141). Poor myocardial contractility is the characteristic feature. Usually, all cardiac chambers become dilated. AV valve insufficiency occurs secondary to chamber enlargement and papillary muscle atrophy. As cardiac output decreases, compensatory neurohormonal mechanisms are activated, leading eventually to signs of CHF and low cardiac output. Pulmonary edema, pleural effusion, and arrhythmias are common in cats with DCM.

Clinical Features

DCM can occur at any age, although most affected cats are late-middle aged to geriatric. There is no breed or sex predilection. Clinical signs of CHF often include anorexia, lethargy, and increased respiratory effort or dyspnea. Evidence of poor cardiac output is usually found in conjunction with congestive signs (right-sided, left-sided, or biventricular CHF). Hypothermia, jugular venous distention, an attenuated precordial impulse, weak femoral pulses, a gallop sound (usually S_3), and a left or right apical systolic murmur (of mitral or tricuspid regurgitation) are common. Bradycardia and arrhythmias can be present, although many affected cats have normal sinus rhythm. Increased lung sounds and pulmonary crackles may be auscultated, but pleural effusion often muffles the lung sounds. Some cats have signs of arterial thromboembolism (see p. 224).

Diagnosis

Generalized cardiomegaly with rounding of the cardiac apex is often seen on radiographs. Pleural effusion is quite common and may obscure the heart shadow and coexisting evidence of pulmonary edema or venous congestion. Hepatomegaly and ascites also might be detected. Normal sinus rhythm predominates; variable ECG findings can include ventricular or supraventricular tachyarrhythmias (although AF is rare), AV conduction disturbance, and an LV enlargement pattern.

Echocardiography is an important tool to differentiate DCM from other myocardial pathophysiology. Findings are analogous to those in dogs with DCM (see p. 144). Poor FS (<26%), increased LV end-systolic (e.g., >1.1 cm) and end-diastolic (e.g., >1.8 cm) diameters, and wide mitral E point–septal separation (>0.4 cm) have been described as diagnostic criteria for DCM in cats. Cats with only focal hypokinesis (for example, of only the LV wall or septum) may actually have UCM or end-stage remodeled HCM, particularly if focal areas of hypertrophy are present. In DCM, ventricular wall thickness is normal or decreased. An intracardiac thrombus is identified in some cats, usually within the LA.

As with other feline heart diseases, routine clinicopathologic testing is generally nonspecific. Prerenal azotemia, mildly increased liver enzyme activity, and a stress leukogram are common. Elevated NT-proBNP and cardiac troponin concentrations are expected, particularly in cats with CHF.

Plasma or whole blood taurine concentration measurement is recommended to detect possible deficiency, even in cats fed commercial diets. Specific instructions for sample collection and mailing should be obtained from the laboratory used. Plasma taurine concentrations are influenced by the amount of taurine in the diet, the type of diet, and the time of sampling in relation to eating; an 8-hour fast is recommended. A plasma taurine concentration of less than 40 nmol/mL in a cat with DCM is diagnostic for taurine deficiency. Nonanorexic cats with a plasma taurine concentration of less than 60 nmol/mL probably should receive taurine supplementation or a different diet. Whole blood samples produce more consistent results than plasma samples. Normal whole blood taurine concentrations exceed 200 nmol/mL; < 150 nmol/L is diagnostic for taurine deficiency.

Treatment and Prognosis

The goals of acute and chronic CHF treatment are similar to those for cats with other cardiomyopathies (see p. 164) and analogous to those for dogs with DCM. Emphasis is placed on inotropic support; pimobendan is indicated in all cases and should be instituted as soon as oral medication can safely be given. Dobutamine (or dopamine) is administered by CRI for critical cases (see p. 62 and Box 3.1). Frequent ventricular tachyarrhythmias might respond to lidocaine, mexiletine, conservative doses of sotalol, or combination antiarrhythmic therapy (see Table 4.2). However, β-blockers (including sotalol) must be used cautiously (if at all) in cats with DCM and CHF because of their negative inotropic effect. Hemodynamically significant supraventricular tachyarrhythmias are treated with diltiazem, again with caution because of the drug's negative inotropic effect. Management of thromboembolism is described in Chapter 12, p. 227. Hypothermia is common in cats with decompensated DCM; external warming is provided as needed.

Supplemental taurine is recommended for taurine-deficient patients. Taurine (250-500 mg orally q12h) is instituted as soon as practical in cases where plasma taurine

concentration is low or cannot be measured. Clinical improvement, if it occurs, generally is not apparent until after a few weeks of taurine supplementation. Improved systolic function is seen echocardiographically within 6 weeks of starting taurine supplementation in most taurine-deficient cats. In some taurine-responsive cats, cardiac medications might be tapered and discontinued after 6 to 12 weeks (with close monitoring for recurrence of CHF). For cats previously eating a taurine-deficient diet, it may even be possible to transition from taurine supplementation to a diet known to support adequate plasma taurine concentrations (e.g., most name-brand commercial foods). Dry diets with 1200 mg of taurine per kilogram of dry weight and canned diets with 2500 mg of taurine per kilogram of dry weight are thought to maintain normal plasma taurine concentrations in adult cats. Requirements could be higher for diets incorporating rice or rice bran. Reevaluation of the plasma taurine concentration 2 to 4 weeks after discontinuing the supplement is advised.

Taurine-deficient cats that survive a month after initial diagnosis appear to have approximately a 50% chance for 1-year survival. It might be possible to wean the cat off some or all cardiac medications long-term. The prognosis for cats with DCM that are not taurine deficient is guarded to poor, with median survival time of 49 days even with pimobendan treatment.

OTHER MYOCARDIAL DISEASES

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Arrhythmogenic RV cardiomyopathy (ARVC) is a rare idiopathic cardiomyopathy similar to ARVC in people. Characteristic features include moderate to severe RV chamber dilation, with either focal or diffuse RV wall thinning. RV wall aneurysm also can occur, as can dilation of the RA and, less commonly, the LA. Myocardial atrophy with fatty and/or fibrous replacement tissue, focal myocarditis, and evidence of apoptosis are typical histologic findings. These are most prominent in the RV wall. Fibrous tissue or fatty infiltration is sometimes found in the LV and atrial walls.

Signs of right-sided CHF are common, including jugular venous distention, ascites or hepatosplenomegaly, and labored respirations caused by pleural effusion. Syncope occurs occasionally. Lethargy and inappetence without overt heart failure are the presenting signs in some cases.

Thoracic radiographs indicate right heart and sometimes LA enlargement. Pleural effusion is common. Ascites, caudal vena caval distention, and evidence of pericardial effusion could also be evident. The ECG can document various arrhythmias in affected cats, including VPCs, ventricular tachycardia, AF, and supraventricular tachyarrhythmias. A right bundle branch block pattern appears to be common; some cats have first-degree AV block. Echocardiography shows severe RA and RV enlargement similar to that seen with congenital tricuspid valve dysplasia, except that the valve apparatus appears structurally normal. Other possible findings include abnormal muscular trabeculation, aneurysmal dilation, areas of dyskinesis, and paradoxical septal motion. Tricuspid regurgitation appears to be a consistent finding on Doppler examination. Some cats also have LA enlargement, if the LV myocardium is affected.

The prognosis is guarded once signs of heart failure appear. Recommended therapy is similar to that for other causes of CHF in cats, and includes diuretics as needed, an ACEI, pimobendan, and prophylaxis against thromboembolism. Additional antiarrhythmic therapy may be necessary (see Chapter 4). In people and Boxer dogs with ARVC, ventricular tachyarrhythmias are a prominent feature and sudden death is common. Right heart dysfunction and right-sided CHF are a more consistent feature of ARVC in cats compared with Boxer dogs.

UNCLASSIFIED CARDIOMYOPATHY

UCM is a term used in people to describe cases of myocardial disease that do not fit within other defined categories (HCM, RCM, DCM, or ARVC). In cats, this label is most often applied to cases with severe LA or biatrial dilation despite normal LV size, wall thickness, and systolic function, and without obvious evidence of endomyocardial fibrosis (which would otherwise denote RCM). It is unclear whether UCM represents a distinct disease entity in cats; more likely, UCM includes end-stage or "remodeled" phenotypes of other cardiomyopathies, particularly HCM. Prevalence of UCM varies significantly among reports, likely owing to differences in diagnostic criteria. Most commonly it is estimated that UCM comprises approximately 10% of feline cardiomyopathy cases.

Clinical features of UCM are similar to those for other feline cardiomyopathies. The median age at diagnosis in one small study (8.8 years) is higher than for HCM or RCM, again supporting the notion that UCM may represent a common end-stage disease phenotype. Heart murmurs and arrhythmias are common on physical examination. The ECG may show ventricular or supraventricular tachyarrhythmias, and/or evidence of LA or LV enlargement. Radiographs indicate cardiomegaly with LA or biatrial enlargement; pleural effusion is more common than pulmonary edema. Echocardiography confirms atrial enlargement, with characteristics of ventricular structure and function inconsistent with other cardiomyopathy categories.

Treatment of UCM is identical to treatment for RCM. Patients in CHF receive furosemide, pimobendan, and ACEI, and thromboprophylaxis with clopidogrel, as well as dietary and lifestyle management. Prognosis is variable and probably similar to that for other cardiomyopathies.

CORTICOSTEROID-ASSOCIATED HEART FAILURE

CHF has been reported in cats approximately 3 to 7 days after receiving injectable long-acting corticosteroids (such as Depo-Medrol). The proposed mechanism is the diabetogenic effect of glucocorticoids causing a transient hyperglycemia

and subsequent intravascular fluid shift, precipitating volume overload and acute CHF. Presumably, preexisting structural heart disease (i.e., occult cardiomyopathy) could play a role in making certain cats more susceptible to corticosteroid-induced CHF.

An acute onset of lethargy, anorexia, tachypnea, and respiratory distress is described in affected cats. Most cats have normal auscultatory findings without tachycardia. Moderate cardiomegaly, with diffuse pulmonary infiltrates and mild or moderate pleural effusion, appears to be typical on radiographic examination. Possible ECG findings include sinus bradycardia, intraventricular conduction abnormalities, atrial standstill, atrial fibrillation, and VPCs. On echocardiogram, most affected cats have some degree of LV wall or septal hypertrophy and LA enlargement. Some have AV valve insufficiency or SAM.

CHF is treated as for other feline cardiomyopathies; in addition, corticosteroids should be discontinued. Resolution of abnormal cardiac findings and successful weaning from cardiac medications have been reported in some cats.

MYOCARDITIS

Inflammation of the myocardium and adjacent structures can occur in cats, as it does in other species (see p. 153). Severe, widespread myocarditis could cause CHF or fatal arrhythmias. Cats with focal myocardial inflammation could be asymptomatic. Acute and chronic viral myocarditis have been suspected, though a viral cause is rarely documented. Feline coronavirus has been identified as a cause of pericarditis-epicarditis. In one study, myocarditis was histologically identified in samples from more than half of cardiomyopathic cats but none from cats in the control group; viral deoxyribonucleic acid (panleukopenia) was found in about one third of the cats with myocarditis. However, the possible role of viral myocarditis in the pathogenesis of cardiomyopathy is not clear.

Endomyocarditis has been documented, mostly in young cats. Acute death, with or without preceding signs of pulmonary edema for 1 to 2 days, is the most common presentation. Histopathologic characteristics of acute endomyocarditis include focal or diffuse lymphocytic, plasmacytic, and histiocytic infiltrates with few neutrophils. Myocardial degeneration and lysis are seen adjacent to the infiltrates. Chronic endomyocarditis may have a minimal inflammatory response but significant myocardial degeneration and fibrosis. RCM or UCM could represent the end stage of nonfatal endomyocarditis. Therapy involves managing CHF signs and arrhythmias.

Bacterial myocarditis may develop in association with sepsis or as a result of bacterial endocarditis or pericarditis. Experimental *Bartonella* sp. infection can cause subclinical lymphoplasmacytic myocarditis, but it is unclear whether natural infection plays a role in the development of cardiomyopathy in cats. *Toxoplasma gondii* has occasionally been associated with myocarditis, usually in immunosuppressed cats as part of a generalized disease process. Traumatic myocarditis is recognized infrequently in cats.

CHAPTER 9

Pericardial Disease and Cardiac Tumors

Diseases of the pericardium and intrapericardial space can disrupt cardiac function. Although these comprise a fairly small proportion of cases presented for clinical signs of cardiac disease, it is important to recognize them because the approach to their management differs from other cardiac disorders. The normal pericardium forms a closed, double-layered sac around the heart and is attached to the great vessels at the heart base. Directly adhered to the heart is the visceral pericardium, or epicardium, which is composed of a thin layer of mesothelial cells. This layer reflects back over itself at the base of the heart to line the outer, fibrous layer (parietal pericardium). A small volume (~0.25 mL/kg) of serous fluid between these layers serves as a lubricant. The pericardium anchors the heart in place, provides a barrier to infection or inflammation from adjacent tissues, helps balance the output of the right and left ventricles, and limits acute distention of the heart. Despite these functions, there usually are no overt clinical consequences to its removal. Excess or abnormal fluid accumulation in the pericardial sac is the most common pericardial disorder. It occurs most often in dogs, and causes clinical signs from development of cardiac tamponade (see later in this chapter). Other acquired and congenital pericardial diseases are seen sporadically. Acquired pericardial disease that causes clinical signs is uncommon in cats.

CONGENITAL PERICARDIAL DISORDERS

PERITONEOPERICARDIAL DIAPHRAGMATIC HERNIA

Peritoneopericardial diaphragmatic hernia (PPDH) is the most common congenital malformation of the pericardium in dogs and cats. It occurs when abnormal embryonic development (probably of the septum transversum) allows persistent communication between the pericardial and peritoneal cavities at the ventral midline. The pleural space is not involved. Other congenital defects such as umbilical hernia, sternal malformations, and cardiac anomalies may coexist with PPDH. Abdominal contents herniate into the pericardial space to a variable degree and cause associated clinical signs. Although the peritoneal-pericardial communication is not trauma induced in dogs and cats, trauma can facilitate movement of abdominal contents through a preexisting defect.

Clinical Features

The initial onset of clinical signs associated with PPDH can occur at any age (ages between 4 weeks and 15 years have been reported). The majority of cases are diagnosed during the first 4 years of life, usually within the first year. In some animals, clinical signs never develop. Males appear to be affected more frequently than females, and Weimaraners may be predisposed. The malformation is common in cats as well; Persians, Himalayans, and domestic longhair cats may be predisposed.

Clinical signs usually relate to the gastrointestinal (GI) or respiratory system. Vomiting, diarrhea, anorexia, weight loss, abdominal pain, cough, dyspnea, and wheezing are most often reported; shock and collapse can occur also. Physical examination findings may include muffled heart sounds on one or both sides of the chest; displacement or attenuation of the apical precordial impulse; an "empty" feel on abdominal palpation (with herniation of many organs); and, rarely, signs of cardiac tamponade (see later in this chapter).

Diagnosis

Thoracic radiographs can be diagnostic or highly suggestive for PPDH. Enlargement of the cardiac silhouette, dorsal tracheal displacement, overlap of the diaphragmatic and caudal heart borders, and abnormal fat and/or gas densities within the cardiac silhouette are characteristic findings (Fig. 9.1, *A* and *B*). Especially in cats, a pleural fold (dorsal peritoneopericardial mesothelial remnant) extending between the caudal heart shadow and the diaphragm ventral to the caudal vena cava on lateral view might be evident. Gas-filled loops of bowel crossing the diaphragm into the pericardial sac, a small liver, and few organs within the abdominal cavity also may be seen. Pectus excavatum or other thoracic skeletal

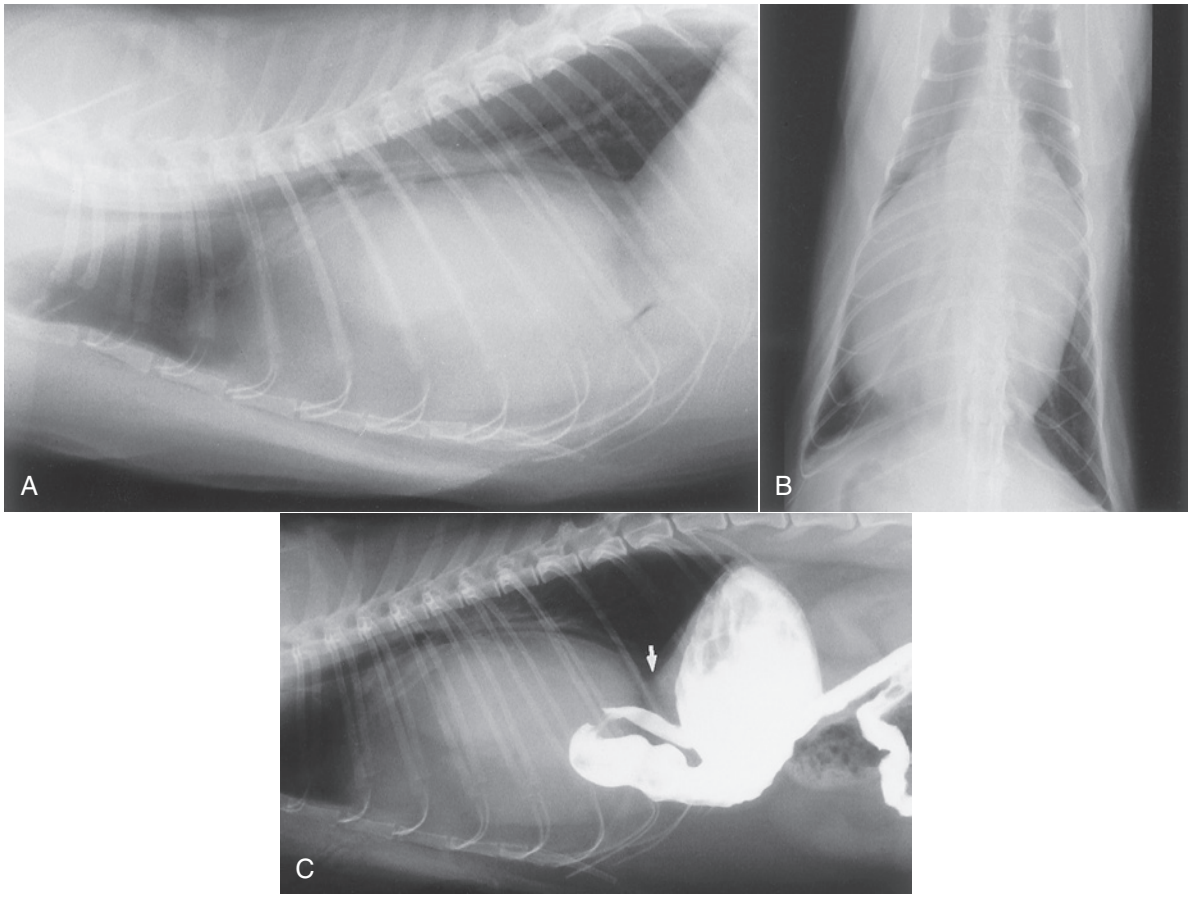

FIG 9.1
Lateral **(A)** and dorsoventral **(B)** radiographs from a 5-year-old male Persian cat with a congenital peritoneopericardial diaphragmatic hernia (PPDH). The cardiac silhouette is greatly enlarged and contains fat, soft tissue, and gas densities; the trachea has been displaced dorsally. There is overlap between the cardiac and diaphragmatic borders on both views. After barium administration, it is evident that a portion of the stomach and duodenum lie within the pericardial space **(C);** omental fat and liver also are within the pericardial sac. In **C,** the dorsal pleural fold between pericardium and diaphragm is best appreciated *(arrow)*.

deformity occasionally is present as well. Echocardiography (or abdominothoracic ultrasonography) helps confirm the diagnosis when radiographic findings are equivocal (Fig. 9.2). A GI barium series is diagnostic if the stomach and/or intestines are in the pericardial cavity (Fig. 9.1, *C*). Fluoroscopy, nonselective angiography (especially if only falciform fat or liver has herniated), positive contrast peritoneography, computed tomography (CT), magnetic resonance imaging (MRI), or pneumopericardiography also can be used for diagnosis. Electrocardiographic (ECG) changes are inconsistent; decreased amplitude complexes and axis deviations caused by cardiac position changes sometimes occur.

Treatment

Surgical closure of the peritoneal-pericardial defect can be done after viable organs are returned to their normal location. The patient's clinical signs and presence of other congenital abnormalities influence the decision to operate. The prognosis in uncomplicated cases is excellent. However, perioperative complications are common and, although usually mild, can include death. Animals without clinical signs, and some with mild signs, may do well without surgery. Trauma to organs chronically adhered to the heart or pericardium is of concern during attempted repositioning. Rare sequelae of surgery for PPDH have included pericardial cyst formation, arrhythmias, and constrictive pericardial disease. Overall, long-term survival appears similar between dogs and cats treated surgically compared with those not operated on.

OTHER PERICARDIAL ANOMALIES

Pericardial cysts are rare anomalies that could originate from abnormal fetal mesenchymal tissue or from incarcerated omental or falciform fat associated with a small PPDH. The pathophysiologic signs and clinical presentation can mimic those seen with pericardial effusion. Radiographically, the

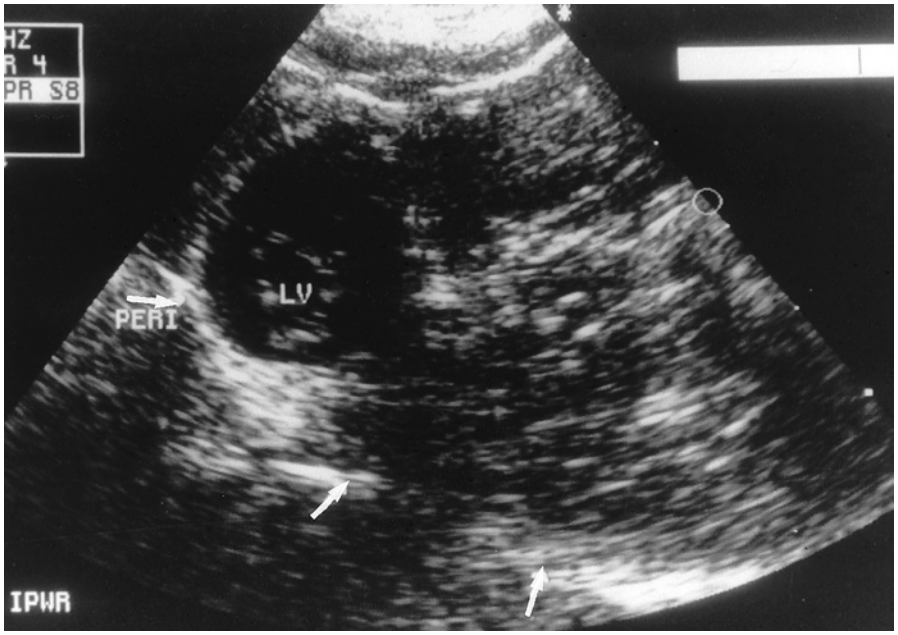

FIG 9.2

cardiac silhouette can appear enlarged and deformed. Echocardiography, CT, or MRI can reveal the diagnosis. Surgical cyst removal, combined with partial pericardiectomy, usually resolves the clinical signs.

Congenital defects of the pericardium itself are extremely rare in dogs and cats; most are incidental postmortem findings. Sporadic cases of partial (usually left-sided) or complete absence of the pericardium are reported. A possible complication of partial absence of the pericardium is herniation of a portion of the heart; this could cause syncope, embolic disease, or sudden death. Echocardiography, angiocardiography, CT, or MRI should allow antemortem diagnosis.

PERICARDIAL EFFUSION

Etiology and Types of Fluid

In dogs, most pericardial effusions are serosanguineous or hemorrhagic and are of neoplastic or idiopathic origin. Transudates, modified transudates, and exudates are found occasionally in both dogs and cats; the effusion rarely is chylous. In cats, pericardial effusion most often is associated with congestive heart failure (CHF) from cardiomyopathy, but this rarely causes cardiac tamponade. A minority of cats with pericardial effusion has neoplasia, feline infectious peritonitis (FIP), PPDH, pericarditis, or other infectious or inflammatory disease for an underlying cause.

HEMORRHAGE

Hemorrhagic effusions are most common in dogs. The fluid usually appears dark red, with a packed cell volume (PCV) greater than 7%, a specific gravity greater than 1.015, and a protein concentration greater than 3 g/dL. Cytologic analysis shows mainly red blood cells, but reactive mesothelial, neoplastic, or other cells can be seen. The fluid does not clot unless hemorrhage was recent. Neoplastic hemorrhagic effusions are more likely in dogs older than 7 years. Middle-aged, large-breed dogs are most likely to have idiopathic "benign" hemorrhagic effusion.

Hemangiosarcoma (HSA) is by far the most common neoplasm causing hemorrhagic pericardial effusion in dogs; it is rare in cats. Hemorrhagic pericardial effusion also occurs in association with various heart base tumors, pericardial mesothelioma, malignant histiocytosis, some cases of lymphoma and, rarely, metastatic carcinoma. HSAs (see p. 185) usually arise within the right heart, especially in the right auricle. Chemodectoma is the most common heart base tumor; it arises from chemoreceptor cells at the base of the aorta. Thyroid, parathyroid, lymphoid, and connective tissue neoplasms also occur at the heart base. Pericardial mesothelioma sometimes causes mass lesions at the heart base or elsewhere but often has a diffuse distribution and may mimic idiopathic disease. Lymphoma involving various parts of the heart is seen more often in cats than in dogs (and often causes a modified transudative effusion). Dogs with malignant histiocytosis and pericardial effusion usually have pleural effusion and ascites ("tricavitary effusion") despite the fact that they do not have cardiac tamponade.

Idiopathic (benign) pericardial effusion is the second-most common cause of canine hemorrhagic pericardial effusion. Its cause still is unclear. Although several viruses are associated with pericarditis in people, there is little evidence

to support an infectious cause in dogs. Idiopathic pericardial effusion is reported most frequently in medium- to large-breed dogs. Golden Retrievers, Labrador Retrievers, and Saint Bernards may be predisposed. Although dogs of any age can be affected, the median age is 6 to 7 years. More cases have been reported in males than females. Mild pericardial inflammation, with diffuse or perivascular fibrosis and focal hemorrhage, is common on histopathologic examination. Layers of fibrosis suggest a recurrent process in some cases. Constrictive pericardial disease is a potential complication.

Other, less common causes of intrapericardial hemorrhage include left atrial (LA) rupture secondary to severe mitral insufficiency (see Chapter 6, p. 130), coagulopathy (mainly rodenticide toxicity or disseminated intravascular coagulation), penetrating trauma (including iatrogenic laceration of a coronary artery during pericardiocentesis), and, possibly, uremic pericarditis.

TRANSUDATES

Pure transudates are clear, with a low cell count (usually <1000 cells/μL), specific gravity (<1.012), and protein content (<2.5 g/dL). Modified transudates might appear slightly cloudy or pink tinged. Their cellularity (≈1000-8000 cells/μL) is still low, but total protein concentration (≈2.5-5.0 g/dL) and specific gravity (1.015-1.030) are higher than those of a pure transudate. Transudative effusions occur in some dogs and cats with CHF, hypoalbuminemia, PPDH, pericardial cysts, or toxemias that increase vascular permeability (including uremia). These conditions usually are associated with relatively small-volume pericardial effusion; cardiac tamponade is rare.

EXUDATES

Exudative effusions are cloudy to opaque or serofibrinous to serosanguineous. They typically have a high nucleated cell count (usually much higher than 3000 cells/μL), protein content (often much above 3 g/dL), and specific gravity (>1.015). Cytologic findings are related to the etiology. Exudative pericardial effusions are rare in small animals, except in cats with FIP.

Infectious pericarditis usually is related to plant awn or porcupine quill migration, extension of a pleural or mediastinal infection, bite or other penetrating wounds, or possibly bacteremia. Various bacteria (aerobic and anaerobic), actinomycosis, coccidioidomycosis, aspergillosis, disseminated tuberculosis, and, rarely, systemic protozoal infections have been identified. Sterile exudative effusions have been reported in association with leptospirosis, canine distemper, and idiopathic pericardial effusion in dogs, and with FIP and toxoplasmosis in cats. FIP is the most important cause of symptomatic pericardial effusion in cats. Chronic uremia occasionally causes a sterile, serofibrinous, or hemorrhagic effusion.

Pathophysiology

Fluid accumulation within the pericardial space causes clinical signs when it raises intrapericardial pressure to or above normal cardiac filling pressure. This accumulation impedes venous return and cardiac filling. As long as intrapericardial pressure remains low, cardiac filling and output remain relatively normal. If fluid accumulates slowly, the pericardium may distend enough to accommodate the increased pericardial fluid volume at relatively low pressure. However, pericardial tissue is relatively noncompliant. Rapid fluid accumulation or a large effusion causes a steep rise in intrapericardial pressure, leading to cardiac tamponade. Pericardial fibrosis and thickening further limit the compliance of this tissue.

A pericardial effusion of extremely large volume can cause clinical signs by virtue of its size, even without overt cardiac tamponade. Lung and/or tracheal compression can compromise ventilation and stimulate cough; esophageal compression can cause dysphagia or regurgitation.

CARDIAC TAMPONADE

Cardiac tamponade develops when pericardial fluid accumulation raises intrapericardial pressure to or above the normal cardiac diastolic pressure. This external compression of the heart progressively limits filling, initially of the more compliant right heart, then the left. Cardiac output subsequently falls while systemic venous pressure rises. Pressure in all cardiac chambers and the great veins eventually becomes equilibrated during diastole. Neurohormonal compensatory mechanisms are activated as tamponade develops. Gradual pericardial fluid accumulation results in signs of CHF because of compensatory volume retention and the direct effects of impaired cardiac filling. Manifestations of systemic venous congestion and right-sided CHF (ascites and pleural effusion) usually predominate because of the right heart's thinner wall and lower pressures. Pericardial effusion does not typically affect cardiac contractility directly, but reduced coronary perfusion during tamponade can impair both systolic and diastolic function. Low cardiac output, arterial hypotension, and poor organ perfusion can ultimately lead to cardiogenic shock and death.

The rate of pericardial fluid accumulation and the distensibility of the pericardial sac determine whether and how quickly cardiac tamponade develops. Rapid accumulation of even a relatively small volume can raise intrapericardial pressure sharply. A gradual process is implied when the pericardial fluid volume is large. Cardiac tamponade is relatively common in dogs but rare in cats.

Pulsus paradoxus is the term used to describe the exaggerated variation in arterial blood pressure that occurs during the respiratory cycle because of cardiac tamponade. During inspiration intrapericardial and right atrial (RA) pressures fall, which facilitates right heart filling and pulmonary blood flow. At the same time, left heart filling is reduced as more blood is held in the pulmonary vasculature and the interventricular septum bulges leftward from the inspiratory increase in right ventricular (RV) filling; consequently, left heart output and systemic arterial pressure decrease during inspiration. The variation in systolic arterial pressure between

inspiration and expiration is usually greater than 10 mm Hg in patients with cardiac tamponade and pulsus paradoxus. Pulsus paradoxus is not always discernible by femoral pulse palpation.

Clinical Features

Clinical findings in patients with cardiac tamponade usually reflect right-sided CHF and poor cardiac output. Before obvious ascites develop, nonspecific signs might include lethargy, weakness, poor exercise tolerance, and inappetence or other GI signs. In many cases, the client history describes complaints of exercise intolerance, abdominal enlargement, tachypnea or difficulty breathing, collapse, and sometimes cough or vomiting. However, rapid pericardial fluid accumulation can cause acute tamponade, shock, and death without signs of ascites, pleural effusion, or marked radiographic cardiomegaly. Pulmonary edema, jugular venous distension, and hypotension might be evident in such cases, though. A history of collapse could be more common in dogs with neoplastic disease. Some cases with long-standing disease develop marked loss of lean body mass (cachexia; Fig. 9.3).

Jugular vein distention or a positive hepatojugular reflux, hepatomegaly, ascites, labored respirations, and weak femoral pulses are common physical examination findings. Pleural effusion and ascites also occur in both cats and dogs with cardiac tamponade. Ascites may be more prevalent in dogs without an identifiable mass lesion, reflecting a more gradual worsening or progression of tamponade. A palpable decrease in arterial pulse strength during inspiration (pulsus paradoxus) might be discernible in some dogs with tamponade. Sinus tachycardia, pale mucous membranes, and prolonged capillary refill time are common, as manifestations of high sympathetic tone. The precordial impulse is weak when the pericardial fluid volume is large. Heart sounds are muffled in patients with moderate to large pericardial effusions. Lung sounds are muffled over the ventral thorax in those with pleural effusion. Although pericardial effusion does not cause a murmur, concurrent cardiac disease may do so. Infectious pericarditis may be accompanied by fever; rarely, a pericardial friction rub may be heard.

FIG 9.3
Older male Boxer with chronic right-sided congestive heart failure signs secondary to cardiac tamponade caused by a chemodectoma. The abdomen is greatly distended with ascites. Chronic loss of lean body mass (cachexia) is evident along the spine, pelvis, and rib cage.

Diagnosis

Clinicopathologic findings

Hematologic and biochemical test results generally are nonspecific. The complete blood count (CBC) might indicate mild nonregenerative anemia, especially in patients with neoplastic disease, or may suggest inflammation or infection. Cardiac HSA can be associated with a regenerative anemia, increased numbers of nucleated red blood cells and schistocytes (with or without acanthocytes), and thrombocytopenia. Mild hypoproteinemia is seen in some patients. Mild increases in liver enzyme activities and prerenal azotemia can occur secondary to hepatic congestion and poor cardiac output. More pronounced liver enzyme elevation sometimes occurs with neoplastic effusions. Other biochemical abnormalities that have been reported in dogs with pericardial effusion include hyperlactatemia, hyponatremia, hyperglycemia, and hypermagnesemia. Pleural and peritoneal fluids in dogs and cats with cardiac tamponade are usually modified transudates.

Circulating cardiac troponin (cTnI) concentration can increase as a result of ischemia or myocardial invasion. An elevated cTnI helps differentiate pericardial effusion caused by HSA from other causes, especially in cases where a mass lesion is not obvious on echocardiogram. HSA that does not affect the heart does not increase cTnI concentration. Although pericardial fluid also can be used for cTnI measurement, this does not provide improved sensitivity. Serum NT-proBNP concentration is likely to be low in patients with pericardial effusion, in contrast to other cardiac diseases.

RADIOGRAPHY

Pericardial effusion enlarges the cardiac silhouette (Fig. 9.4). A massive amount of pericardial fluid causes the classic globoid-shaped heart shadow on both radiographic views. Nevertheless, radiographic vertebral heart score (VHS) or measures of sphericity are only moderately accurate for differentiating pericardial effusion from other cardiac disorders. These indices are not sensitive or specific enough to reliably identify dogs with pericardial effusion and cardiac tamponade from other causes of right-sided CHF signs. Smaller fluid volumes allow various cardiac contours to be identified, especially dorsally. Other findings associated with tamponade (as well as other causes of right-sided CHF) include pleural effusion, a distended caudal vena cava, hepatomegaly, and ascites. Pulmonary infiltrates of edema and distended pulmonary veins are noted only rarely. Some heart-base tumors cause tracheal deviation or a soft tissue mass effect. Metastatic lung lesions are common in dogs with HSA. CT and MRI provide greater

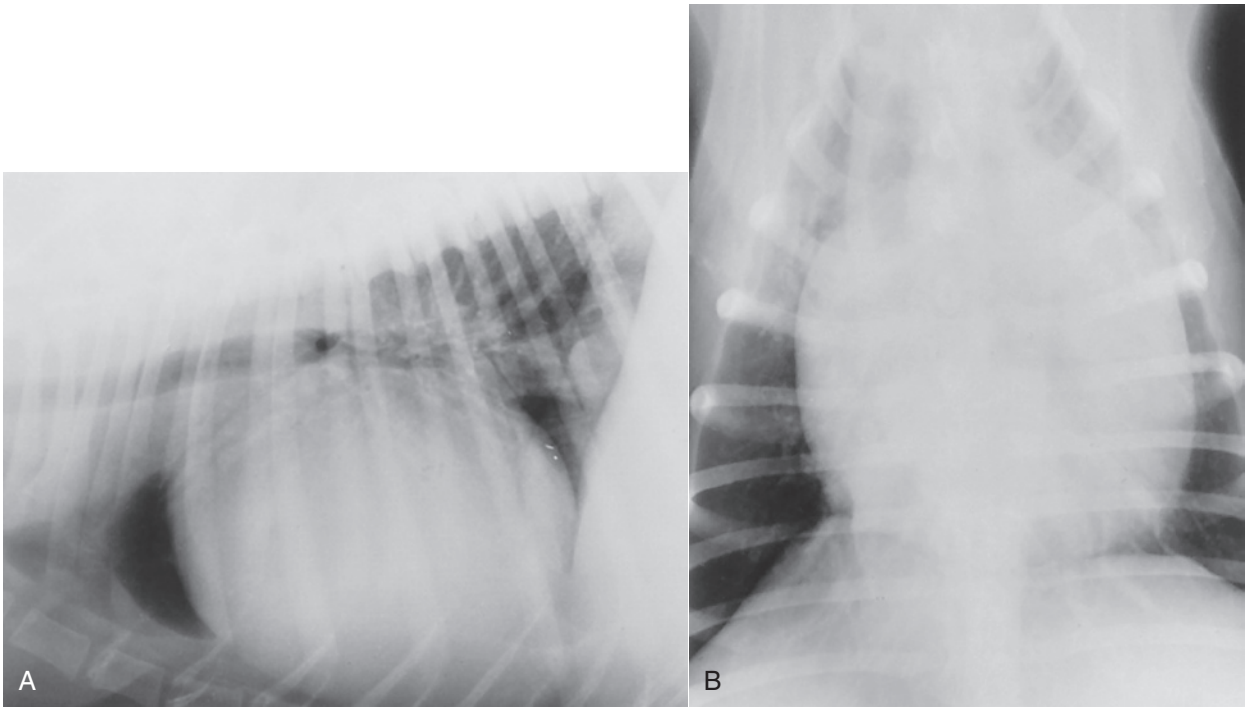

FIG 9.4
Lateral **(A)** and dorsoventral **(B)** radiographs from a mixed-breed dog with large-volume pericardial effusion. The cardiac silhouette has a globoid shape, and the caudal vena cava is distended in **A.**

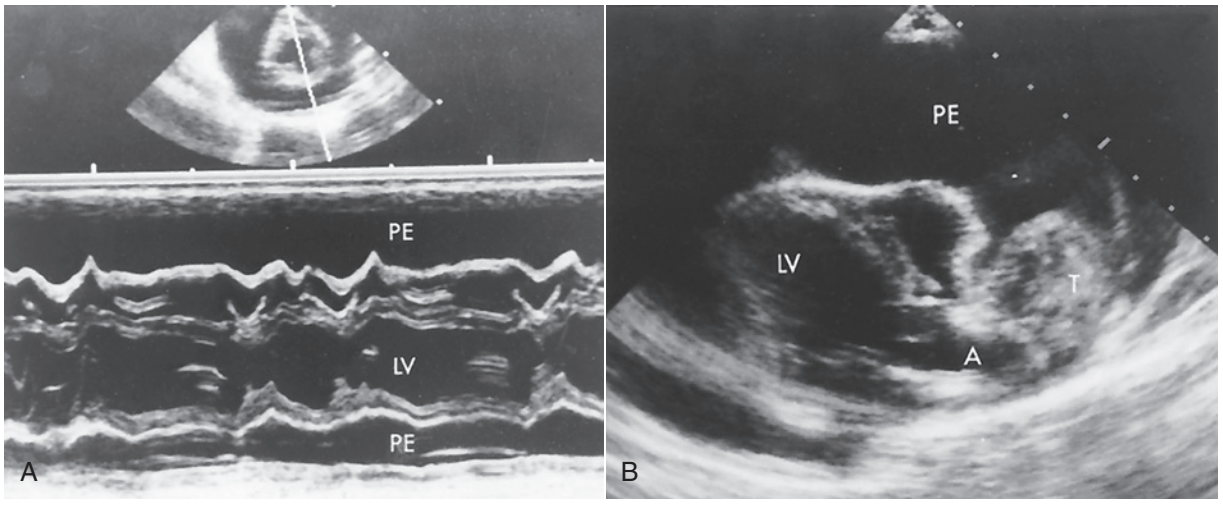

FIG 9.5
Echocardiographic examples of pericardial effusion. **(A)** Short-axis M-mode view at mitral valve (left side) and chordal levels. Large echo-free (fluid) spaces are seen on either side of the heart; the right ventricular wall is clearly visualized. The small two-dimensional image above the M-mode shows the heart (transected by the M-mode cursor line) surrounded by pericardial fluid (which appears black on the image). **(B)** Long-axis two-dimensional view from left parasternal position depicting a large heart base tumor and pericardial effusion in a Schnauzer. *A,* Aorta; *LV,* left ventricle; *PE,* pericardial effusion; *T,* tumor.

detail than plain radiographs, and can reveal some pulmonary metastases and other extracardiac lesions better. Yet they are not necessarily more accurate than echocardiography for identifying pericardial effusion and associated mass lesions.

ECHOCARDIOGRAPHY

Echocardiography is highly sensitive for detecting even small volumes of pericardial fluid. Because fluid is sonolucent, pericardial effusion appears as an echo-free space between the bright parietal pericardium and the epicardium (Fig. 9.5).

Large-volume pericardial effusions allow the heart to swing back and forth within the pericardial sac. Echocardiography also can identify intrapericardial and intracardiac mass lesions, as well as abnormal cardiac wall motion, chamber shape, and other cardiac abnormalities. Clinicians with basic training in echocardiography or just the "thoracic focused assessment with sonography for trauma" (TFAST) ultrasound examination should be able to identify pericardial and pleural effusions. Especially important in patients with collapse or respiratory distress, a TFAST examination can reveal pericardial effusion and tamponade quickly, even before radiographs are obtained. Nevertheless, after the patient has been stabilized, a more detailed echocardiographic examination is warranted to identify and define any mass lesions or other cardiac disease.

Cardiac tamponade is manifested by variable collapse of the RA and sometimes the RV (Fig. 9.6) through the cardiac cycle. Initially, the RA wall collapses transiently during ventricular systole. As tamponade worsens, the RA wall collapse intensifies and extends into diastole. Diastolic RV compression and collapse occur with advancing cardiac tamponade, and suggest that intrapericardial and intracardiac pressures have equalized. Further rise in intrapericardial pressure worsens the diastolic RV collapse and compresses the LV. These are signs of severe tamponade; immediate pericardiocentesis is especially urgent in these patients. It is important to remember that the volume of effusion is not the main determinant of hemodynamic compromise but rather the intrapericardial pressure. The RV and RA walls are often well visualized and may appear hyperechoic because of the surrounding fluid. Better visualization of the heart base and mass lesions generally is obtained before pericardiocentesis is performed. Therefore, if the patient is stable enough, it is helpful to do the echocardiographic examination just before pericardiocentesis. Careful evaluation of all portions of the RA and right auricle, RV, ascending aorta, and pericardium itself is important to screen for neoplasia. The left cranial parasternal transducer views are especially useful. Some mass lesions are difficult to visualize. Idiopathic pericardial effusion is diagnosed only after infectious and neoplastic causes have been excluded. Unfortunately, some mass lesions are not easily visualized, and mesothelioma without a discrete mass lesion cannot be reliably distinguished by noninvasive tests.

Sometimes pleural effusion, severe LA enlargement, a dilated coronary sinus, or persistent left cranial vena cava can be confused with pericardial effusion. Careful scanning from several positions helps in differentiating these conditions. Identification of the parietal pericardium in relation to the echo-free fluid helps differentiate pleural from pericardial effusion. Because the pericardium is a relatively strong ultrasound reflector, by progressively dampening the returning echo signals, pericardial echoes are usually the last to disappear. Most pericardial fluid accumulates near the cardiac apex because the pericardium adheres more tightly to the heart base; there is usually little fluid behind the LA.

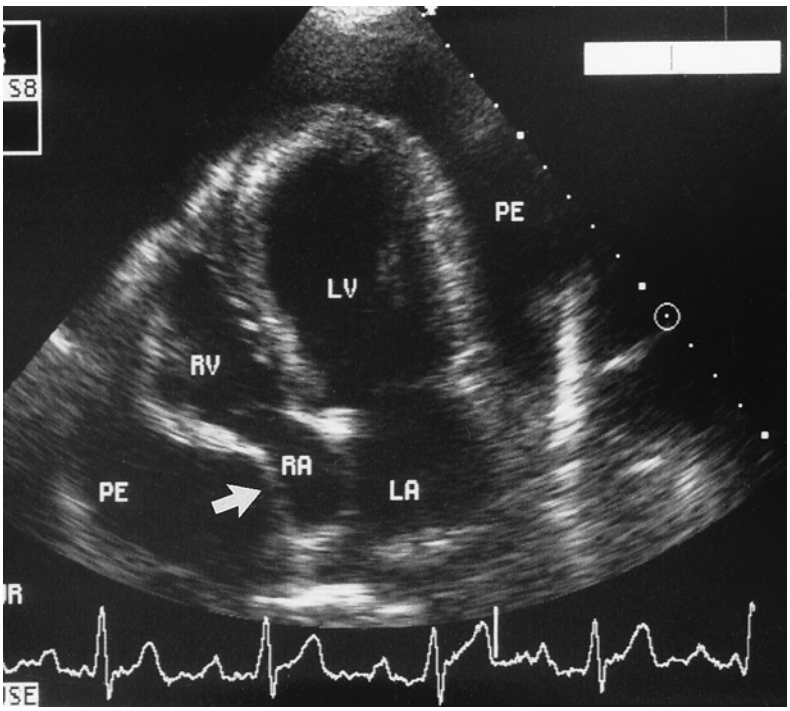

FIG 9.6
Diastolic collapse of the right atrial wall *(arrow)* is evident in this left apical four-chamber echocardiographic image from a 3-year-old female Saint Bernard with cardiac tamponade. *LA,* Left atrium; *LV,* left ventricle; *PE,* pericardial effusion; *RA,* right atrium; *RV,* right ventricle.

Furthermore, evidence of collapsed lung lobes or pleural folds often can be seen within pleural effusion.

ELECTROCARDIOGRAPHY

Although there are no pathognomonic ECG findings, the following abnormalities suggest pericardial effusion but are not seen consistently: small amplitude QRS complexes (<1 mV in dogs), electrical alternans, and ST segment elevation (epicardial injury current). Electrical alternans is a recurring alteration in the size of the QRS complex (or sometimes the T wave) with every other beat (Fig. 9.7). It results from the back-and-forth swinging motion of the heart within the pericardium and is more commonly seen in patients with large-volume pericardial effusion. Electrical alternans may be most evident at heart rates between 90 and 140/min and/or in the standing position. Sinus tachycardia is common with cardiac tamponade. Ventricular, or less often atrial, tachyarrhythmias can occur as well.

Central venous pressure

A central venous pressure (CVP) above 10 to 12 cm H_2O is common; normally, CVP is less than 8 cm H_2O. CVP measurement is helpful when the jugular veins are difficult to assess or it is unclear whether right heart filling pressure is elevated. Moderate- to large-volume pleural effusion should be drained before CVP measurement, not only to stabilize the patient but also to minimize artifactual CVP elevation.

Pericardial fluid evaluation

Cytologic evaluation helps characterize the pericardial fluid. Samples also should be saved for possible bacterial (or fungal) culture, pending cytology results. However, differentiating hemorrhagic neoplastic effusions from benign hemorrhagic pericarditis usually is not possible based on cytology alone. Reactive mesothelial cells within the effusion can closely resemble neoplastic cells; furthermore, chemodectomas and HSAs may not shed cells into the effusion. Therefore identifying a mass lesion with echocardiography is helpful for diagnosis. Depending on the accessibility and size of a visualized mass, cytologic diagnosis might be obtained by fine-needle aspiration. Patients with lymphoma typically have effusion consistent with a modified transudate, and neoplastic cells usually are identified easily. Many neoplastic (and other noninflammatory) effusions have a pH of 7.0 or greater, whereas inflammatory effusions generally have lower pH. However, there is too much overlap for pericardial effusion pH to be a reliable discriminator. Pericardial fluid culture is done if cytology and pH suggest an infectious or inflammatory cause. In some patients, fungal titers (for example, for coccidioidomycosis) or other serologic tests are helpful. Elevated cTnI, either in serum of pericardial fluid, suggests cardiac HSA or other cause of myocardial injury.

Treatment and Prognosis

It is important to differentiate cardiac tamponade from other causes of right-sided CHF signs because the treatment is very different. Positive inotropic drugs do not ameliorate the signs of tamponade; diuretics and vasodilators can further reduce cardiac output and exacerbate hypotension and shock. Immediate pericardiocentesis (discussed in the next section) is the initial therapeutic procedure for cardiac tamponade, and it also can provide diagnostic information. Most signs of CHF resolve soon after pericardial fluid is removed, although a dose or two of a diuretic may be useful after pericardiocentesis in some animals. Pericardial effusion secondary to other diseases that cause CHF, congenital malformations, or hypoalbuminemia do not usually cause tamponade and often resolve with management of the underlying condition.

Idiopathic Pericardial Effusion

Dogs with idiopathic pericardial effusion initially are treated conservatively with pericardiocentesis. Sometimes a glucocorticoid (e.g., prednisone, 1 mg/kg/day PO tapering over 2-4 weeks) is given after ruling out infectious causes by pericardial fluid analysis; however, the efficacy of glucocorticoid therapy in preventing recurrent idiopathic pericardial effusion is not known. Alternatively, a nonsteroidal antiinflammatory drug might help reduce inflammation associated with idiopathic pericardial disease; however, efficacy in preventing recurrence likewise is unknown. Some clinicians have used a course of broad-spectrum antibiotic concurrently,

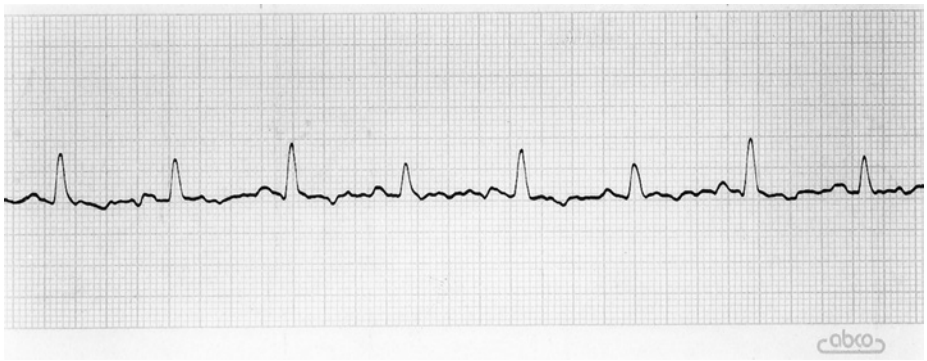

FIG 9.7
Electrical alternans is seen on this lead II electrocardiogram from a 10-year-old male Bulldog with a large pericardial effusion. Also note the small voltage QRS complexes and sinus tachycardia (heart rate ≈ 170 beats/min). 50 mm/sec, 1 cm = 1 mV.

although this should be unnecessary if sterile technique was used and the effusion shows no signs of infection. Periodic reevaluation of these dogs by radiography or echocardiography is recommended to detect recurrence. Apparent recovery occurs after one to three pericardial taps in about half of affected dogs. Cardiac tamponade can recur after a variable time span (days to years). Nevertheless, extended survival times are possible in dogs with idiopathic pericardial effusion, even in those requiring more than three pericardiocenteses. However, recurrent effusions that were thought to be idiopathic can be caused by mesothelioma or other neoplasia. Sometimes this becomes evident on repeated echocardiographic examination. Recurrent effusion that does not respond to repeated pericardiocenteses and antiinflammatory therapy (e.g., after two or three pericardial taps) usually is treated by pericardiotomy (pericardial window) or subtotal pericardiectomy (removing the pericardium ventral to the phrenic nerves), which allows drainage to the larger absorptive surface of the pleural space.

Neoplastic Pericardial Effusion

These also are drained to relieve cardiac tamponade. Recurrence of effusion is expected. Depending on tumor size, location, and histologic diagnosis, management might involve surgical biopsy or perhaps even resection, pericardiotomy or partial pericardiectomy, chemotherapy, or repeated pericardiocenteses. Surgical resection of most HSA and heart base tumors is not possible because of the tumor's invasiveness, although small tumors involving only the tip of the right auricle have been successfully removed. Surgery can be associated with significant morbidity and mortality, and is only palliative in most cases. Thoracoscopic pericardiotomy provides a less invasive option compared with partial pericardiectomy by open thoracotomy but might not be as effective as pericardiectomy. Biopsy samples for histopathologic evaluation can be obtained by both techniques. The thoracoscopic pericardial window procedure generally requires shorter procedure and hospitalization times than open thoracotomy and has low morbidity. Partial pericardiectomy also is possible using thoracoscopy in some animals. Percutaneous balloon pericardiotomy (see Suggested Readings for more information) is another minimally invasive means of providing long-term continuous pericardial drainage that might be useful if thoracoscopy is unavailable and thoracotomy is declined. These procedures can be effective for preventing recurrence of tamponade in idiopathic as well as some cases of neoplastic pericardial effusion, especially from a heart base tumor. The increased potential for tumor dissemination throughout the thoracic cavity does not appear to affect survival time, compared with pericardiocentesis alone, in dogs with HSA or mesothelioma. Chemotherapy, based on biopsy or clinicopathologic findings, may slow neoplastic progression, although most cardiac tumors are fairly resistant. Radiation therapy might provide some palliation for selected cases, as well. Consultation with a veterinary oncologist is recommended for dogs whose owner wishes to try chemo- or radiation therapy. Alternatively, many owners choose conservative therapy (repeated pericardiocentesis) until episodes of cardiac tamponade become unmanageable. Therapy with epsilon aminocaproic acid, an antifibrolytic agent that prevents activation of plasminogen to plasmin, anecdotally has been helpful in reducing hemorrhagic pericardial effusion associated with RA HSA. Conversely, a small retrospective study of dogs with a RA mass and pericardial effusion found no difference in time to recurrence of clinical signs from cardiac tamponade between dogs that had been treated with Yunnan Baiyao, a Chinese herbal remedy that can decrease clotting time and bleeding, either given alone or with epsilon aminocaproic acid compared with untreated dogs.

The prognosis in dogs with RA HSA with or without surgery alone is poor (median survival of 2-3 weeks). Multiagent chemotherapy reportedly has allowed survival times of 4 to 8 months in some dogs with atrial HSA. Survival time in dogs with mesothelioma might be slightly longer than in those with HSA, but the overall prognosis is poor. Therapy with IV doxorubicin and intracavitary cisplatin might extend survival time in some dogs. Heart base tumors (chemodectoma) tend to be slow-growing and locally invasive, although some do metastasize; pericardiotomy or partial pericardiectomy may prolong survival for years. More information about cardiac tumors is found later in this chapter (p. 185).

Infectious Pericarditis

Infection involving the pericardium should be treated aggressively with appropriate antimicrobial drugs (ideally determined by microbial culture and sensitivity testing) and pericardiocentesis as needed. Infusion of appropriate antimicrobial agent directly into the pericardium after pericardiocentesis can be helpful. Continuous drainage with an indwelling pericardial catheter or surgical debridement should be pursued if a foreign body is suspected or intermittent pericardiocentesis is ineffective. Surgery can remove a penetrating foreign body, provide more complete flushing of exudates, and manage pericardial constrictive disease. The prognosis with infective pericarditis is guarded. Even with successful elimination of infection, epicardial and pericardial fibrin deposition may lead to constrictive pericardial disease.

Intrapericardial Hemorrhage

Pure hemorrhage into the pericardial space, whether from trauma, LA rupture associated with advanced mitral valve disease, or a systemic coagulopathy, warrants pericardiocentesis if signs of cardiac tamponade exist. Only enough volume to control signs of tamponade should be removed, because continued pericardial drainage could predispose to further bleeding. The remaining blood usually is resorbed through the pericardium (autotransfusion). Surgery might be necessary to stop continued bleeding or remove large clots. Dogs that survive an initial episode of intrapericardial bleeding from LA rupture still have a guarded to poor prognosis because risk of recurrent LA tearing is high. Animals with intrapericardial hemorrhage of unclear cause should be

evaluated for a coagulation disorder. When trauma-induced intrapericardial hemorrhage persists in an animal with normal hemostasis, surgical exploration is indicated.

PERICARDIOCENTESIS

Pericardiocentesis should be done right away in animals with cardiac tamponade. As noted earlier, diuretic or vasodilator use is not indicated and can exacerbate hypotension and cause cardiogenic shock. When possible, a peripheral IV catheter should be placed before pericardiocentesis. This allows for IV fluid administration to support cardiac output during preparations for the pericardial tap procedure, and provides access for sedative, antiarrhythmic, or other drug administration as needed. Continuous ECG monitoring during the procedure is important because needle or catheter contact with the heart commonly causes ventricular arrhythmias.

Pericardiocentesis is a relatively safe procedure when performed carefully. Removal of even a small volume of pericardial fluid can markedly decrease intrapericardial pressure in animals with tamponade. Pericardiocentesis is usually approached from the right chest wall to minimize the risk of trauma to the lung (via the cardiac notch) and major coronary vessels (located mostly on the left). The need for sedation depends on the clinical status and temperament of the patient. The animal usually is placed in left lateral or sternal recumbency for more secure restraint, especially if the animal is weak or excitable. Although, in some cases, needle pericardiocentesis can be performed successfully on the standing animal, the risk of injury increases with sudden movement. An alternative approach is to use an elevated echocardiography table with a large cutout, if available; the animal is placed in right lateral recumbency, and the tap is performed from underneath. An advantage to this method is that fluid moves to the right (dependent) side with gravity; however, if adequate space is not available for wide sterile skin preparation or needle/catheter manipulation, this approach is not advised. Echocardiographic guidance can be used but generally is not necessary unless the effusion is of small volume or appears compartmentalized.

A variety of equipment can be used for pericardiocentesis. A butterfly needle/catheter (19- to 21-gauge) or appropriately long hypodermic or spinal needle attached to extension tubing is adequate in emergency situations. However, an over-the-needle catheter system can be a safer alternative because it reduces the risk of cardiopulmonary laceration during fluid aspiration. The catheter is chosen according to patient size. For example, a 12 to 16 gauge, 10 to 15 cm (4- to 6-in) long catheter system, or a commercially available over-the-wire pericardial drainage catheter allows for faster fluid removal in large dogs. For small dogs, an 18 to 20 gauge, 3.75 to 5.0 cm (1.5-2.0 in) long catheter could be adequate. Additional equipment to assemble before the procedure includes sterile extension tubing (except if using a butterfly needle), a three-way stopcock, a 20 to 60 mL collection syringe, a 3-mL syringe and small-gauge needle for local block, lidocaine, small surgical blade (for stab incision when using a larger catheter), sterile ethylenediaminetetraacetic acid (EDTA) and clot (red-top) tubes for fluid samples, and a large fluid collection receptacle. Personnel able to help restrain the animal and assist with fluid aspiration also are essential.

The skin is shaved and surgically prepared over the right precordium, from about the third to seventh intercostal spaces and from sternum to well above the costochondral junction. Before the final scrub, locate and mark the point of strongest precordial impulse; this usually is between the fourth and sixth rib near the costochondral junction. Usually this is the best site for needle entry. Ultrasound also can be used to locate an optimal puncture site. Infiltrate a small volume of 2% lidocaine (0.5-1 mL) into the skin and underlying intercostal muscle to the pleura at the puncture site (alternatively, some clinicians prefer to do this later using sterile technique). Local anesthesia is necessary when using a larger catheter and also recommended for needle pericardiocentesis.

After sterile skin preparation is complete, don sterile gloves and prepare the drainage catheter assembly. When using a large-gauge catheter, a couple of tiny (~1 mm) side holes can be cut (smoothly) with a sterile sharp blade or iris scissors near the catheter tip to facilitate fluid drainage. Care must be taken to offset these holes from each other and avoid making them too large, so that the catheter tip is not excessively weakened, lest it break off within the pericardium or pleural space. Carefully replace the catheter over the needle/stylet and attach the extension tubing to this. Then attach the three-way stopcock to the other end of the tubing, and the collection syringe to the stopcock. The stopcock should be set "off" to air. If not done previously, infiltrate lidocaine (with sterile technique) at the puncture site. When using a large-gauge catheter system, make a small stab incision into the skin to facilitate catheter entry. The puncture should be just cranial to the closest rib; when entering the chest, care should be taken to avoid the intercostal vessels that run caudal to each rib.

Before inserting the needle/catheter into the chest, pass the attached collection syringe to an assistant. Although a perpendicular orientation of needle/catheter to the skin initially may help avoid intercostal vessels, it often is helpful to "aim" the needle tip toward the point of the patient's opposite (left) shoulder as the chest is entered. Once the needle has penetrated the skin, the assistant should gently apply negative pressure to the attached syringe as the operator slowly advances the needle toward the heart. This way, any fluid will be detected as soon as it is encountered. Pleural fluid, usually straw-colored, may enter the tubing first. It is important to hold the needle/catheter steady during insertion to avoid extraneous motion of the sharp tip within the chest. When contacted, the pericardium creates increased resistance to needle advancement and may produce a subtle scratching sensation. With gentle pressure, slowly advance the needle through the pericardium. A loss of resistance may be felt with needle penetration, and pericardial fluid (usually dark red) will appear in the tubing. During initial insertion, the

extension tubing is attached to the needle stylet. The needle/catheter unit must be advanced far enough into the pericardial space so that the catheter is not deflected out of the pericardium as the needle stylet is removed; advance the catheter before pulling back on the stylet. After advancing the catheter into the pericardial space and removing the needle, attach the extension tubing directly to the catheter. Initial pericardial fluid samples should be saved into the sterile EDTA and serum clot tubes for evaluation. Then aspirate as much pericardial fluid as possible. When fluid drainage becomes difficult or stops, adjusting the catheter position slightly or tilting the patient more sternally may allow additional fluid retrieval. A small backflush into the catheter also may help.

If the needle contacts the heart, a prominent scratching or tapping sensation usually is felt, the needle may move with the heartbeat, and ventricular premature complexes are often provoked. The needle should be retracted slightly if cardiac contact occurs. It is important to avoid excessive needle motion within the chest.

When no additional pericardial fluid can be aspirated, the catheter is slowly withdrawn under continued but gentle negative pressure. A quick echocardiographic recheck should verify whether tamponade is resolved, cardiac filling is improved, and if any pericardial fluid remains. If substantial pericardial effusion remains, pericardiocentesis is repeated using a fresh catheter system and slight adjustment in the patient's position, if needed. A sample of the effusion should be submitted for fluid analysis and cytologic evaluation, and additional fluid reserved in the sterile clot tube for possible culture, pending cytology results. Further echocardiographic monitoring of the patient for acute recurrence of pericardial effusion before hospital discharge is wise, especially with suspected HSA.

Verifying Catheter Location

Pericardial effusion usually appears quite hemorrhagic. It can be distressing to see dark, bloody fluid being aspirated from near the heart, but pericardial fluid can be differentiated from intracardiac blood in several ways. Unless the fluid is caused by recent pericardial hemorrhage, it will not clot. A few drops can be placed on the table or into a serum tube to check this. The PCV of pericardial fluid usually is much lower than that of peripheral blood (except in some dogs with HSA); also, the supernatant is xanthochromic (yellow tinged). As the pericardial fluid is drained, the animal's ECG complexes usually increase in amplitude, tachycardia diminishes, and some dogs take a deep breath and appear to be more comfortable. On the other hand, if intracardiac blood is being aspirated, the patient is likely to become more tachycardic and hypotensive. Another method to verify catheter location, if an echo/ultrasound transducer is available, is to rapidly inject a small bolus of sterile, agitated saline through the pericardiocentesis catheter (via the three-way stopcock) to create an echocontrast ("bubble") study. If the catheter tip is within the pericardial space, small bright microbubbles will appear within the pericardial fluid around the heart. If the catheter tip has penetrated a cardiac chamber, the bubbles will appear within the heart.

Complications of Pericardiocentesis

Complications can include cardiac injury or puncture causing arrhythmias (the most common complication, although usually self-limiting when the needle is withdrawn); lung laceration causing pneumothorax and/or hemorrhage; coronary artery laceration with myocardial infarction or further bleeding into the pericardial space; dissemination of infection or neoplastic cells into the pleural space; and, occasionally, death.

CONSTRICTIVE PERICARDIAL DISEASE

Etiology and Pathophysiology

Constrictive pericardial disease is diagnosed occasionally in dogs but only rarely in cats. This condition occurs when thickening and scarring of the visceral, parietal, or both pericardial layers restrict ventricular diastolic expansion and prevent normal cardiac filling. Both ventricles are affected. Usually the entire pericardium is involved symmetrically. Fusion of parietal and visceral pericardial layers obliterates the pericardial space in some cases. In others, the visceral layer (epicardium) alone is involved. A small amount of pericardial effusion (constrictive-effusive pericarditis) may be present.

Although the etiology of constrictive pericardial disease often is unknown, acute inflammation with fibrin deposition and possibly varying degrees of pericardial effusion are thought to precede its development. Some cases in dogs were attributed to recurrent idiopathic hemorrhagic effusion, infectious pericarditis (especially from coccidioidomycosis but potentially also from actinomycosis, mycobacteriosis, blastomycosis, or bacteria), a metallic foreign body in the pericardium, tumors, prior PPDH surgery, and idiopathic pericardial osseous metaplasia and fibrosis.

Increased fibrous connective tissue and variable amounts of inflammatory and reactive pericardial infiltrates are seen on histopathologic examination. Pericardial fibrosis creates a stiff shell around the heart and increases ventricular interdependence. Ventricular filling is limited to early diastole, after which ventricular expansion is abruptly curtailed, in cases of advanced constrictive pericardial disease. Any further ventricular filling is accomplished only at high venous pressures. Compromised filling reduces cardiac output. Compensatory neurohormonal activation causes fluid retention with congestive signs of pleural effusion and ascites, as well as tachycardia and vasoconstriction.

Clinical Features

Middle-aged, large- to medium-breed dogs are affected most often. Males and German Shepherd Dogs may be at higher risk. Some dogs have a history of pericardial effusion. Clinical signs of right-sided CHF predominate. Abdominal distention (ascites), tachypnea or labored breathing, tiring,

syncope, weakness, and weight loss are common complaints. These signs may develop over weeks to months. Ascites and jugular venous distention are the most consistent clinical findings, as in dogs with cardiac tamponade. Weakened femoral pulses and muffled heart sounds are also typical. A diastolic pericardial "knock" sound, resulting from abrupt deceleration of ventricular filling in early diastole, has been described but usually is not identified in dogs. A systolic murmur or click, probably caused by valvular disease rather than the pericardial pathology, or a diastolic gallop sound may be heard.

Diagnosis

The diagnosis of constrictive pericardial disease can be challenging. Typical radiographic findings include mild to moderate cardiomegaly, pleural effusion, and caudal vena cava distention. Reduced cardiac motion may be evident on fluoroscopy (as with cases of pericardial effusion). Echocardiographic changes in dogs with constrictive pericardial disease can be subtle. Suggestive findings on M-mode and 2-D examination include diastolic flattening of the LV free wall and abnormal diastolic septal motion. During inspiration, leftward deviation of the interventricular and atrial septa reflects the relative increase in right heart filling at the expense of left heart filling during this phase of respiration. During exhalation, the septa shift rightward. The pericardium may appear thickened and intensely echogenic, but differentiating this from normal pericardial echogenicity may be impossible. Mild pericardial effusion is seen in some cases. RA collapse is not expected with constrictive disease, in contrast to effusion with cardiac tamponade. Other observations include vena cava and hepatic vein dilation, as well as pleural and abdominal effusions. Doppler mitral and tricuspid inflow velocities show increased variability with respiration. The transtricuspid early filling (E-wave) peak velocity is greatest in early inspiration, whereas the maximum peak transmitral E-wave velocity occurs with the onset of expiration. ECG abnormalities described with constrictive pericardial disease include sinus tachycardia, P-wave prolongation, and reduced-voltage QRS complexes.

A CVP greater than 15 mm Hg is common. Intracardiac hemodynamic measurements are diagnostic. In addition to high mean atrial and diastolic ventricular pressures, the atrial pressure waveform shows a prominent y descent (during ventricular relaxation). In contrast, with cardiac tamponade, the y descent is diminished because ventricular diastolic expansion immediately raises intrapericardial pressure and impairs caval flow into the RA (preventing the normal early diastolic decrease in CVP and y descent). With constrictive pericardial disease, filling pressure is low only in early diastole (during the time of y descent). Another classic finding with constrictive pericardial disease is an early diastolic dip in ventricular pressure, followed by a mid-diastolic plateau as filling is curtailed; however, this is not seen consistently in dogs. Angiocardiography could be unremarkable or might show vena caval and mild atrial enlargement with increased endocardial-pericardial distance.

Treatment and Prognosis

Pericardiectomy is necessary to improve ventricular filling. This is more likely to be successful when only the parietal pericardium is involved. Constrictive pericardial disease involving the visceral layer requires epicardial stripping. This procedure increases the surgical difficulty and associated complications. Pulmonary thrombosis reportedly is a common postoperative complication and can be life-threatening. Tachyarrhythmias are another complication of surgery. In the postoperative period, modest diuretic doses, and possibly an angiotensin-converting enzyme inhibitor, may be helpful. Positive inotropic and vasodilating drugs are not indicated. Constrictive pericardial disease is progressive and, without successful surgical intervention, ultimately fatal. Serologic testing for *Coccidioides* (or other fungal agent) is advisable in endemic regions. Adjunctive antifungal therapy has improved prognosis of affected dogs that survive pericardiectomy.

CARDIAC TUMORS

Etiology and Pathophysiology

Echocardiography has made the antemortem diagnosis of cardiac tumors more common, although the overall prevalence of such neoplasms is low. Some cardiac tumors cause severe clinical signs, whereas others are diagnosed fortuitously. By far, the most common cardiac tumor in dogs is HSA. The RA, especially the right auricle, most frequently is the site of origin. Some HSAs also infiltrate the ventricular wall extensively. Occasionally, this tumor is found within the LV, interventricular septum, or at the heart base. HSAs usually are associated with hemorrhagic pericardial effusion and cardiac tamponade (see p. 176). Primary cardiac HSA is likely to metastasize to other organs, including the lung and spleen. Primary splenic HSA only occasionally metastasizes to the heart. Golden Retrievers, German Shepherds, Afghan Hounds, Cocker Spaniels, English Setters, and Labrador Retrievers, among others, are at higher risk for this tumor.

Masses involving the heart base and ascending aortic region usually are aortic body tumors (also known as chemodectomas or nonchromaffin paragangliomas). This is the second-most-common cardiac tumor type in dogs. These are neoplasms of the chemoreceptor aortic bodies. However, ectopic thyroid or parathyroid or mixed-cell–type tumors also can occur at the heart base. Heart base tumors mainly tend to be locally invasive around the root of the aorta and surrounding structures, although metastases to other organs can occur and could be more common than previously appreciated. Unless they cause symptomatic pericardial effusion or dysfunction of surrounding structures, heart base tumors can be an incidental finding. Chemodectomas are reported more frequently in brachycephalic dogs (specifically Boxers, Boston Terriers, and Bulldogs) but affect individuals of other breeds as well. Clinical signs associated with heart base tumors most often are related to pericardial effusion and cardiac tamponade.

Mesothelioma occurs sporadically but may be more prevalent in some geographic regions. There appears to be no gender or breed predisposition in dogs, although in Golden Retrievers with mesothelioma, chronic inflammation associated with prior idiopathic pericardial disease is a postulated predisposing factor. Mesothelioma is rare in cats. This neoplasm can appear in variable forms and can be difficult to identify echocardiographically. Other primary tumors involving the heart are rare in dogs but include myxoma, various types of sarcoma, and other neoplasms. Most cases involve right-heart structures. Metastatic or systemic tumors, especially lymphoma, but also other sarcomas (including HSA), malignant histiocytosis, and various carcinomas, may involve the heart or pericardium as well. Most breeds affected with malignant histiocytosis are Golden Retrievers, Labrador Retrievers, Rottweilers, or Greyhounds; mild pericardial effusion, without overt signs of cardiac tamponade, coexists with pleural and abdominal effusion. Rarely, nonneoplastic mass lesions can affect the heart or pericardium, including fungal granuloma or pyogranuloma (as with coccidioidomycosis or blastomycosis), other granulomatous or cystic inflammatory lesions, and auricular aneurysm.

Lymphoma is the most common cardiac tumor in cats. Various (mostly metastatic) carcinomas occur less frequently. HSA is rare; other tumors (such as aortic body tumor, fibrosarcoma, rhabdomyosarcoma) also have been reported sporadically in cats.

Cardiac tumors can cause several pathophysiologic abnormalities, depending on their location and size. Many tumors impede cardiac filling by causing pericardial effusion and cardiac tamponade (discussed earlier). An intrapericardial mass can itself externally compress the heart, as well as cause pericardial effusion. Alternatively, a tumor that grows into the lumen of a cardiac chamber or great vessel can physically obstruct blood inflow or outflow and lead to low cardiac output signs. Myocardial tumor infiltration or secondary ischemia can disrupt the cardiac rhythm and impair contractility. Ultimately, the patient's clinical signs relate to one or a combination of these disturbances. If the tumor is small or has not yet markedly impaired cardiac function, clinical signs may be absent.

Clinical Features

Dogs with cardiac tumors tend to be middle-aged and older. More than 85% of affected dogs are between 7 and 15 years of age; however, very old dogs (>15 years) have a surprisingly low prevalence. Reproductive status influences the relative risk for cardiac tumors in dogs, despite a similar frequency of occurrence in males and females overall. Gonadectomized dogs have a greater relative risk, especially spayed females, which have a risk that is four to five times greater compared with that of intact females. Intact and neutered males also have greater risk than intact females. Certain breeds of dog have a higher prevalence of cardiac tumor compared with the general population (Table 9.1). The age distribution of cats with cardiac tumors is different from that of dogs; about 28% are 7 years old or younger. It is unknown whether reproductive status affects relative risk for cardiac tumors in cats.

Signs of right-sided CHF result from cardiac tamponade or from blood flow obstruction within the RA or RV. Syncope, weakness associated with exertion, and other low output signs also result from cardiac tamponade, blood flow obstruction, arrhythmias, or impaired myocardial function secondary to cardiac tumors. Tachyarrhythmias of any type can also occur; intracardiac conduction disturbances sometimes result from tumor infiltration. Lethargy or collapse might

TABLE 9.1

Dog Breeds with High Prevalence of Cardiac Tumors

BREED	# WITH TUMOR	# IN DATABASE	RELATIVE RISK	95% CI
Saluki	6	401	7.75	3.92-15.38
French Bulldog	3	215	7.19	2.72-19.23

relate to bleeding tumors (e.g., HSA) present in extracardiac locations as well.

Auscultatory findings vary. Arrhythmias or muffled heart sounds (if large pericardial effusion is present) are common. Sometimes a murmur is caused by partial obstruction of intracardiac blood flow caused by the tumor mass, but murmurs associated with unrelated disease (for example, chronic mitral valve disease) are more common. Conversely, auscultatory findings can be normal.

Diagnosis

Hematologic and serum biochemical tests generally are nonspecific in dogs and cats with cardiac tumors; with flow cytometry based hematology analyzers, neoplastic cells are frequently detected in the graphics of dogs with lymphoma or malignant histiocytosis. Plasma cTnI concentrations are likely to be elevated (>0.25 ng/mL) in dogs with cardiac HSA, compared with dogs with noncardiac HSA, other neoplasms, or pericardial effusion not caused by HSA. Mild increases in serum alanine aminotransferase activity and azotemia might occur in dogs with CHF signs. HSA can be associated with a regenerative anemia, increased number of nucleated red blood cells and schistocytes (with or without acanthocytes), leukocytosis, and thrombocytopenia. Pleural and peritoneal fluids, if present, are usually modified transudates.

Radiographic findings are quite variable. The cardiac silhouette may be normal or show an unusual bulge, a mass effect adjacent to the heart, or a globoid cardiac silhouette compatible with pericardial effusion. Intrapericardial masses usually are obscured by pericardial effusion. Caudal vena caval distension, pleural effusion, and/or ascites commonly occur with RV inflow or outflow obstruction. Dorsal deviation of the trachea and increased perihilar opacity are seen in some dogs with heart base tumors. Evidence of pulmonary metastases is found with some primary or secondary (metastatic) cardiac neoplasms; however, radiographic sensitivity for detecting small pulmonary metastases is low. CT, MRI, or other imaging techniques also can help in identifying and defining the extent of cardiac tumors.

The ECG might suggest pericardial effusion (see p. 181). Myocardial infiltration can provoke atrial or ventricular premature complexes or paroxysmal tachycardias. Likewise, varying degrees of AV or intraventricular conduction block and symptomatic bradycardia can develop from conduction system infiltration. Intracardiac tumors that obstruct RV outflow, causing RV systolic pressure overload and compensatory myocardial hypertrophy, can produce a right axis shift and RV hypertrophy pattern on the ECG. Other chamber enlargement or abnormal conduction patterns could result, depending on tumor location and hemodynamic sequelae.

Echocardiography can depict cardiac masses and determine the presence or absence of pericardial effusion, as well as secondary changes in cardiac chamber size, shape, and ventricular function. Doppler techniques allow assessment of associated blood flow abnormalities. Heart base tumors that extend into the pericardial space are easier to see when surrounded by pericardial effusion, just as intracardiac masses are accentuated by the echolucent intracardiac blood surrounding them (Fig. 9.8). The left cranial parasternal transducer position is especially useful for evaluating the ascending aorta, right auricle, and surrounding structures. The location and echocardiographic characteristics of a mass lesion can suggest the type of tumor, although cytologic or histopathologic evaluation is necessary for definitive diagnosis. HSA typically has variable echogenicity, with areas that appear cystic (hypoechoic). Chemodectoma and other heart base masses tend to have a more uniform soft tissue echogenicity. Myocardial lymphoma also can have a mottled appearance with areas of varying echogenicity. Echocardiographic assessment of the tumor's location, size, attachment (pedunculated or broad based), and extent (superficial or deeply invading adjacent myocardium) may help in determining whether surgical resection or biopsy is possible. Visualizing a suspected mass lesion in more than one echocardiographic plane helps verify it and prevent the misinterpretation of artifacts. Fine-needle aspirates for cytologic evaluation can be done under echocardiographic guidance in some cases. A discrete mass lesion often is not found with mesothelioma.

Pericardial fluid analysis is recommended, although definitive diagnosis of neoplasia usually cannot be made based on cytologic findings alone (see p. 181). Cardiac lymphoma or malignant histiocytosis is more likely to be diagnosed on pericardial fluid cytology. Nevertheless, visualization

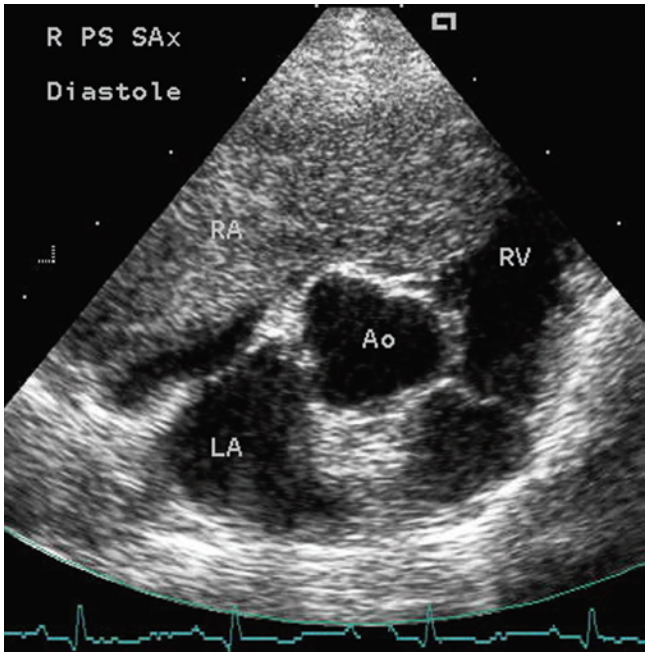

FIG 9.8

of a cardiac mass using echocardiography, CT, or another modality usually is necessary for tumor identification. Ultrasound-guided transthoracic fine-needle aspiration of some cardiac mass lesions might be possible depending on their location and can yield cytologic diagnosis. Anesthesia or sedation alone may be adequate in some cases.

Treatment and Prognosis

Unfortunately, for most patients with a heart tumor, there are few good long-term options. This is especially so for HSA, mesothelioma, and other masses that cause recurrent tamponade or obstruct blood flow. Pericardiocentesis is indicated immediately for cardiac tamponade (see p. 183). Conservative management, with pericardiocentesis as needed, is used in some patients until episodes of cardiac tamponade become unmanageable. Whether antiinflammatory doses of a glucocorticoid are of benefit is unclear. Surgical pericardiotomy or subtotal pericardiectomy can help prevent recurrent tamponade. Heart base tumors (e.g., chemodectoma) tend to be slow-growing; some never cause clinical signs and are found incidentally on echocardiogram or necropsy. For those that cause cardiac tamponade, partial pericardiectomy or pericardiotomy potentially could prolong survival for months or possibly even years.

Complete surgical resection rarely is possible because heart base, as well as many other tumors, are so locally invasive. Nevertheless, an occasional mass might be amenable to surgical resection depending on its location and extent; an example would be a small tumor localized to the tip of the right auricle. However, surgical biopsy of a nonresectable mass could be helpful if chemotherapy is contemplated.

Many, if not most, cardiac tumors are fairly unresponsive to chemotherapy, although some are treated with short-term success. Doxorubicin or carboplatin have been used in dogs with HSA for temporary palliation, with or without surgical mass resection. Lymphoma and malignant histiocytosis are treated using standard protocols. In regions where available, radiation therapy might provide another palliative option for dogs with chemodectoma or other masses. Early experience in dogs presumed to have HSA suggests that radiation therapy can slow the recurrence rate of cardiac tamponade, and therefore provide increased time before repeated pericardiocentesis is required. Current sources for antineoplastic drug protocols, radiation therapy, or other tumor treatment modalities should be consulted as needed. Overall, the long-term prognosis for animals that have shown clinical signs because of a cardiac tumor generally is guarded to poor.

CHAPTER 10

Pulmonary Hypertension and Heartworm Disease

PULMONARY HYPERTENSION

Etiology and Pathophysiology

In adult animals, the pulmonary circulation is a low pressure, low resistance, high capacitance system compared with the systemic circulation. Cardiac output from the right ventricle (RV) is equal to that of the left ventricle (in the absence of systemic-pulmonary shunts), but pulmonary vascular resistance is much lower than systemic vascular resistance. As a result, pulmonary arterial pressures are much lower than systemic arterial pressures (Pressure = Cardiac Output × Resistance). Normal pulmonary arterial pressures are approximately 20 to 25 mm Hg (systolic), 15 mm Hg (mean), and 10 mm Hg (end-diastolic).

Pulmonary arterial hypertension (PAH) is generally defined as systolic pulmonary arterial pressures greater than 35 mm Hg or mean pulmonary arterial pressures greater than 25 mm Hg. PAH severity is graded based on pulmonary arterial systolic pressure as follows: mild PAH (35-55 mm Hg), moderate PAH (55-80 mm Hg), and severe PAH (>80 mm Hg). PAH can occur secondary to a number of disease processes that increase pulmonary vascular resistance through various mechanisms. Common histopathologic changes in affected pulmonary arteries and arterioles include medial hypertrophy, intimal proliferation and fibrosis, luminal thrombosis, and eventually arterial necrosis.

The World Health Organization (WHO) classifies pulmonary hypertension using a five-group system that can be modified for application to veterinary patients. Group I PAH includes idiopathic (primary) pulmonary hypertension, congenital retention of fetal pulmonary vascular resistance, and pulmonary overcirculation from congenital left-to-right cardiac shunts causing vascular injury and pulmonary arterial remodeling. In the context of a congenital shunt, if PAH becomes severe enough that pulmonary arterial pressure exceeds systemic arterial pressure, shunt reversal occurs (Eisenmenger's physiology; see p. 114). Group II refers to PAH occurring secondary to pressure buildup across the pulmonary capillary bed due to chronically elevated pulmonary venous pressures, as seen in mitral regurgitation and other left-sided cardiac diseases. In such cases, pulmonary arterial pressure increases to maintain pulmonary blood flow in the face of resistance to pulmonary venous drainage. Typically, such "postcapillary" PAH is only mild to moderate, because pulmonary venous pressure can increase to only a certain limit before pulmonary edema develops; a disproportionate elevation in pulmonary arterial pressure suggests an element of precapillary reactive vasoconstriction in addition to pulmonary venous hypertension (see Chapter 6, p. 130). Group III PAH includes hypoxic pulmonary disease (such as pulmonary fibrosis or other chronic bronchopulmonary disease) leading to reactive vasoconstriction, reduced vascular area, and vascular remodeling. Group IV PAH refers to pulmonary thromboembolic disease. Thrombotic vascular obstruction reduces total cross-sectional pulmonary vascular area by mechanically obstructing vessels and provoking local hypoxic pulmonary vasoconstriction, as well as other reactive changes. Underlying causes of thrombotic disease and hypercoagulability are discussed in Chapter 12. Heartworm disease (HWD) is one of the most clinically important causes of PAH in dogs. The pathophysiology of PAH in HWD is multifactorial, including elements of direct pulmonary arteritis, hypoxic pulmonary disease causing reactive vasoconstriction (Group III), and pulmonary thromboembolic disease (Group IV). HWD is therefore sometimes classified separately as a "miscellaneous" cause of PAH (Group V). Retrospective studies report the most common causes of PAH in dogs to be pulmonary venous hypertension from left-sided heart disease (Group II, ~40%) and hypoxic pulmonary disease (Group III, 20%-40%), although this distribution is heavily influenced by the incidence of HWD in the region of study.

In addition to the WHO classification system, mechanisms of PAH can also be categorized as "precapillary" (primarily affecting pulmonary arteries and arterioles, before blood reaches the pulmonary capillary bed) or "postcapillary" (primarily affecting pulmonary veins, with secondary buildup of pressure across the capillary bed back to the pulmonary arterial tree). Group II PAH (pulmonary venous hypertension secondary to left-sided heart disease) is thus

an example of postcapillary PAH; all other causes of PAH are precapillary.

Clinical Findings

Clinical signs of moderate to severe PAH include reduced exercise tolerance, fatigue, persistent respiratory difficulty, cough, and syncope. As these clinical signs overlap with common clinical signs of many primary respiratory diseases, it often is challenging to determine whether clinical signs are directly attributable to PAH or to the underlying disease. Severe PAH also can lead to right heart remodeling (cor pulmonale) and eventual right-sided congestive heart failure (CHF), usually manifesting as ascites. Physical examination findings could include cyanotic mucous membranes (at rest or with exertion), a split S_2 heart sound, right-sided systolic heart murmur (of tricuspid regurgitation [TR]), and possibly jugular venous distension and/or pulsation. Heart rate and rhythm are usually normal; sinus arrhythmia and relative sinus bradycardia may reflect presence of underlying pulmonary pathology causing elevated vagal tone.

The clinical presentation of a dog with severe precapillary PAH (respiratory distress, cough, syncope) closely mimics presentation of a dog with pulmonary edema secondary to left-sided CHF. An additional confounding auscultatory finding is pulmonary crackles, which are common in dogs with pulmonary edema but can also be present in dogs with PAH secondary to pulmonary fibrosis or chronic pneumonia. Aspects of the physical examination can help differentiate these two presentations before obtaining a more definitive diagnosis with diagnostic imaging (thoracic radiographs and echocardiography). Dogs with left-sided CHF almost always have loud systolic heart murmurs (grade IV/VI or louder) with point of maximal intensity on the left hemithorax. Softer or right-sided heart murmurs raise index of suspicion for PAH. Dogs with left-sided CHF typically have sinus tachycardia with heart rates of 150 to 160 beats per minute because of sympathetic nervous system stimulation or may have tachyarrhythmias such as ventricular premature complexes or atrial fibrillation. Dogs with PAH generally have a sinus arrhythmia and/or relative sinus bradycardia related to elevated parasympathetic tone from underlying respiratory disease.

Diagnosis

RADIOGRAPHY

Radiographic findings in patients with moderate to severe PAH can include RV enlargement; main pulmonary artery dilation ("bulge" of the pulmonary trunk); and enlargement, tortuosity, and blunting of lobar pulmonary arteries (Fig. 10.1) Caudal lobar arteries can be considered enlarged if their width on dorsoventral (DV) or ventrodorsal (VD) views is greater than the width of the proximal third rib. Occasionally, dogs with severe PAH have patchy alveolar infiltrates that resolve rapidly with sildenafil administration. These infiltrates are thought to represent a variant of noncardiogenic pulmonary edema caused by regional nonuniformity in pulmonary capillary perfusion. Variable reactive pulmonary arterial vasoconstriction causes some areas of lung to be overperfused compared with others, leading to focally high hydrostatic pressure and edema formation. These alveolar infiltrates must be differentiated from cardiogenic pulmonary edema (caused by left-sided CHF), because sildenafil is the preferred treatment.

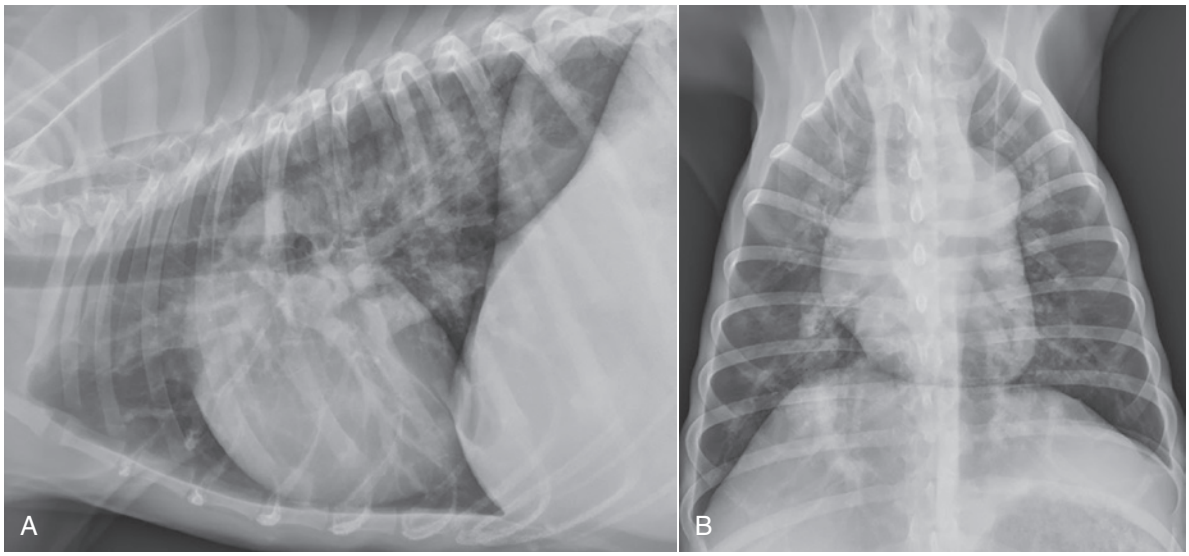

FIG 10.1
Lateral **(A)** and dorsoventral **(B)** radiographs from a young male Pit Bull with advanced heartworm disease. Note enlargement of the main pulmonary artery (particularly on dorsoventral view) and branch pulmonary arteries, as well as mild patchy interstitial pattern consistent with pneumonitis.

ELECTROCARDIOGRAPHY

Electrocardiographic (ECG) findings often are normal, although severe PAH can cause a right axis deviation from RV enlargement. Tall P waves suggestive of right atrial enlargement might also be found. Arrhythmias, such as ventricular premature complexes (originating from the RV) or atrial fibrillation, can occur with advanced cor pulmonale.

ECHOCARDIOGRAPHY

Echocardiographic findings in dogs with severe PAH include RV and RA dilation, RV hypertrophy, flattening of the interventricular septum with paradoxical septal motion, a small left heart, and pulmonary artery dilation (larger than the aorta) (Fig. 10.2). Secondary TR or pulmonic insufficiency (PI) are common, and their maximal velocity can be used to assess severity of the pulmonary hypertension by estimating pulmonary arterial systolic and diastolic pressures, respectively (see Chapter 2, p. 30). More advanced echocardiographic indices suggestive of PAH include transpulmonic flow profile, RV systolic time intervals, tissue Doppler indices of tricuspid annulus motion, tricuspid annular plane systolic excursion, and pulmonary artery distensibility index.

ADVANCED IMAGING

The gold standard diagnosis of PAH is right heart catheterization to measure pulmonary arterial pressures directly; however, this is rarely performed in clinical practice. Computed tomography with contrast can confirm size and tortuosity of pulmonary arteries, and may be useful in diagnosing underlying causes of PAH including pulmonary thromboemboli and pulmonary fibrosis.

Clinicopathologic Findings

Increased red blood cell distribution width (RDW) often is seen in dogs with severe PAH. Arterial blood gas evaluation may show hypoxemia and hypercapnia. Other routine laboratory test results (complete blood count [CBC], chemistry panel, urinalysis) will vary depending on the underlying cause of PAH. Cardiac biomarkers (NT-proBNP and cardiac troponin I) can be elevated in dogs with either precapillary or postcapillary PAH.

Diagnosis of Underlying Disease

Heartworm (HW) antigen testing should be performed in any dog diagnosed with PAH. If HWD is ruled out and echocardiography does not identify significant left-sided heart disease as a postcapillary cause for PAH, other potential etiologies of PAH should be considered. This diagnostic workup should be prioritized based on signalment and clinical presentation but may include airway imaging (bronchoscopy, fluoroscopy), airway sampling (bronchoalveolar lavage or tracheal wash), thoracic computed tomography, assessment of hypercoagulability (D-dimers or thromboelastography), or, potentially, lung biopsy.

Treatment and Prognosis

The only drugs currently available in veterinary medicine for directed therapy of precapillary PAH are the

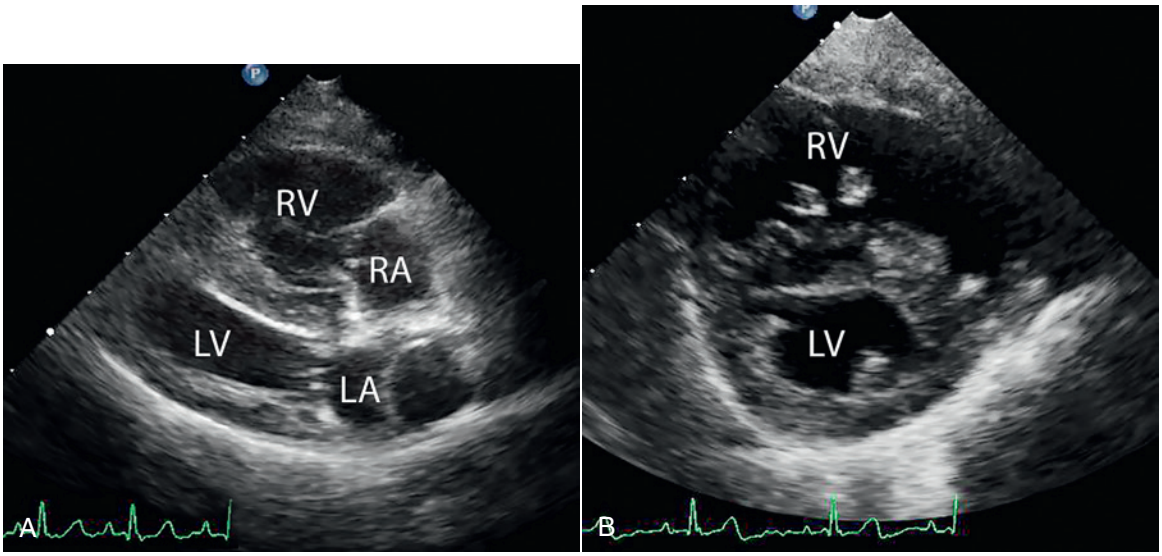

FIG 10.2
Right parasternal echocardiographic images from an older male Chihuahua with severe pulmonary arterial hypertension secondary to chronic bronchopulmonary disease. Views from the right parasternal **(A)** four-chamber long-axis and **(B)** short-axis at the level of the left ventricular papillary muscles are provided. Note the severe right ventricular hypertrophy and enlargement, right atrial enlargement, small left heart, and flattening of the interventricular septum. *RA,* Right atrium; *RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle.

phosphodiesterase-5 inhibitors (sildenafil and tadalafil). These drugs decrease the inactivation of cyclic guanosine monophosphate (GMP), a second messenger of the nitric oxide pathway, leading to vasodilation. Phosphodiesterase-5 inhibitors are relatively specific for the pulmonary vasculature and thus act as selective pulmonary vasodilators. Treatment with sildenafil can improve clinical signs and quality of life in dogs with severe PAH, although effects on echocardiographically estimated pulmonary arterial pressures are variable. Dose adjustments typically are made based on clinical status. Adverse effects are uncommon but can include cutaneous flushing, hypotension, and nasal congestion. Other therapies used in people with PAH (endothelin receptor antagonists, prostacyclin analogs, and nitric oxide substrates) usually are cost-prohibitive for veterinary patients, and many require delivery via inhalation or continuous intravenous (IV) infusion.

Management of patients with PAH also involves exercise restriction and treatment of the underlying disease (if identified). Treatment of HWD is discussed later in this chapter; treatment of pulmonary thromboembolic disease is discussed in Chapter 12; and treatment of chronic bronchopulmonary disease is discussed in Chapter 21.

For dogs with postcapillary PAH secondary to left-sided heart disease, treatment focuses on decreasing left atrial (and thus pulmonary venous) pressures. This generally involves balanced systemic vasodilation with pimobendan (a phosphodiesterase-III inhibitor) and an angiotensin-converting enzyme inhibitor (ACEI), as well as preload reduction with diuretics (furosemide). Further systemic arterial vasodilation (afterload reduction) with amlodipine also can be considered; amlodipine has some vasodilatory activity in pulmonary arterioles as well. If clinically relevant PAH persists despite therapy for pulmonary venous hypertension and CHF, sildenafil can be used as adjunctive therapy. Dogs with right-sided CHF secondary to PAH (cor pulmonale) are managed similarly to those with other causes of CHF (furosemide, pimobendan, ACEI, dietary sodium restriction) with the addition of sildenafil.

Prognosis for dogs with PAH varies with underlying disease. Other than HWD, most causes of PAH are advanced and incurable, and pulmonary vascular remodeling is irreversible. The prognosis for dogs with severe PAH generally is poor, with median survival times between 3 and 6 months; treatment with sildenafil improves survival, with one study reporting nearly 75% survival at 1 year postdiagnosis.

HEARTWORM DISEASE

HWD is an important cause of PAH in regions where the disease is endemic. HW infection is widespread throughout the United States, especially along the Eastern and Gulf coasts and in the Mississippi River Valley. The infection rate in unprotected dogs can be up to 45% or higher in some areas. Sporadic cases occur in other areas of the country and Canada; the disease is prevalent in other regions of the world as well. Infection with *Dirofilaria immitis* causes a spectrum of disease ranging from mild, subclinical changes to severe pulmonary disease and secondary right-sided CHF. Dogs and other canids are the preferred host species. Although cats also are affected by HWD, they are more resistant to infection than dogs. The overall prevalence of mature HW infection in cats in the United States is 0.4%, and regionally is thought to be 5% to 15% of that in dogs in the same geographic area. However, exposure to and subsequent clearance of larvae by host reactions is estimated to be much more common.

HEARTWORM LIFE CYCLE

The HW *(D. immitis)* is transmitted by various species of mosquitoes, which act as its obligate intermediate host. A mosquito initially ingests the microfilariae, or first-stage larvae (L_1), which circulate in the blood of an infected host animal. The L_1 develops into an L_2 and then enters the infective L_3 stage within the mosquito over a period of approximately 2 to 2.5 weeks. Symbiotic bacteria of the genus *Wolbachia* are important for larval development within the mosquito. Infective larvae enter the new host when the mosquito takes another blood meal. L_3 larvae migrate subcutaneously within the new host, molting into an L_4 stage within 9 to 12 days, and then entering the L_5 (final) stage by 2 to 3 months postinfection. The juvenile L_5 worms enter the vasculature within about 100 days of infection, where they migrate preferentially to the peripheral pulmonary arteries of the caudal lung lobes. It takes at least 5 to 6 and usually between 7 and 9 months before these worms develop into mature adults; after mating, gravid females release microfilariae (L_1) and the infection becomes patent. Mature male worms grow to approximately 15 to 18 cm, whereas adult females can reach 25 to 30 cm in length. Adult worms can survive for 5 to 7 years in dogs. HW transmission is limited by climate. An average daily temperature of greater than 64° F for about a month is necessary for the L_1 larvae to mature within a mosquito to the infective stage. HW transmission peaks during July and August in temperate regions of the Northern Hemisphere.

Microfilariae passed to another animal by blood transfusion or across the placenta do not develop into adult worms because the mosquito host is required to complete the parasite's life cycle. Therefore puppies younger than 6 months of age that have circulating microfilariae most likely received them transplacentally and do not have patent HWD. Survival of microfilaria for up to 30 months has been reported.

HW development proceeds more slowly in the cat, which is not the natural host, and infection does not become patent (mature) until at least 7 to 8 months postinfection. Adult worms can live for 3 to 4 years in cats. Microfilariae are evident only in a minority of cats. Nevertheless, infection with L_3 through immature L_5 can cause substantial pulmonary disease as the host attempts to reject the parasites.

HEARTWORM DISEASE IN DOGS

Pathophysiology

The presence of adult worms in the pulmonary arteries provokes reactive vascular lesions that reduce vascular compliance and lumen size. Disease severity depends on several factors, including the number of worms, how long they have been present, and the animal's reaction to the parasites. Pathologic vessel changes begin within days after young HWs enter the pulmonary arteries. The host-parasite interaction may be more important than the worm number alone in the development of clinical signs, although a large worm burden is generally associated with severe disease. The pathogenesis of HWD is modulated by the obligate intracellular bacterium *Wolbachia,* which is harbored by *D. immitis* and is integral to its growth and development. This may involve bacterial endotoxins and the host immune response to a major *Wolbachia* surface protein (WSP), which is thought to contribute to pulmonary and renal inflammation. The increase in pulmonary blood flow associated with exercise can exacerbate the pulmonary vascular pathology. A low worm burden can produce serious lung injury and a greater rise in pulmonary vascular resistance if cardiac output is high.

Villous myointimal proliferation of the pulmonary arteries containing HWs is the characteristic lesion. The HW-induced changes begin with endothelial cell swelling, widening of intercellular junctions, increased endothelial permeability, and periarterial edema. Endothelial sloughing leads to the adhesion of activated white blood cells and platelets. Various trophic factors stimulate smooth muscle cell migration and proliferation within the media and into the intima. Villous proliferations consist of smooth muscle and collagen with an endothelium-like covering. These proliferative changes of the intima occur 3 to 4 weeks after adult worms arrive; they cause luminal narrowing of the smaller pulmonary arteries and also induce further endothelial damage and more proliferative lesions. Endothelial damage promotes thrombosis, as well as a perivascular tissue reaction and periarterial edema. However, pulmonary infarction is unusual because collateral circulation within the lung is extensive.

Hypersensitivity (eosinophilic) pneumonitis may contribute to parenchymal lung lesions, and inflammation may organize into eosinophilic granulomas. Interstitial and alveolar infiltrates may become radiographically apparent; partial lung consolidation develops in some animals. Hypoxic vasoconstriction can also play a role in the vascular changes that increase pulmonary vascular resistance and consequently cause PAH. Hypoxia can occur in lung regions where pulmonary infiltrates and/or pulmonary thromboembolism (PTE) cause ventilation/perfusion mismatch. Pulmonary vasoconstriction may be exacerbated by increased endothelin-1 production or vasoconstrictive substances elaborated by HWs. Dead worms stimulate greater host response and worsen the pulmonary disease. Worm fragments and thrombi cause embolization and a more intense inflammatory reaction, which eventually leads to fibrosis.

The worm distribution and accompanying villous proliferation are most severe in the caudal and accessory lobar arteries. Affected pulmonary arteries lose their normal tapered peripheral branching appearance and appear blunted or pruned. Aneurysmal dilation and peripheral occlusion may occur. The vessels become tortuous and proximally dilated as the increased pulmonary vascular resistance demands higher perfusion pressures.

RV dilation and concentric hypertrophy develop in response to the chronic requirement for increased systolic pressure generation. Severe PAH eventually can lead to RV myocardial failure, increased RV diastolic pressure, and signs of right-sided CHF, especially in conjunction with secondary tricuspid insufficiency. Cardiac output progressively declines as the RV fails. When cardiac output becomes inadequate during exercise, exertional dyspnea, fatigue, and syncope can occur. PTE, either postadulticide or spontaneous, can exacerbate PAH and signs of CHF.

HWD can also have systemic complications. Circulating immune complexes or possibly microfilarial antigens result in glomerulonephritis. Renal amyloidosis has been associated rarely with HWD in dogs. Chronic hepatic congestion secondary to HWD may lead to permanent liver damage and cirrhosis. Although the caudal pulmonary arteries are the preferred site, worm migration "upstream" into the right heart and even to vena cavae is associated with heavy worm burdens. A massive number of worms can cause mechanical occlusion of the RV outflow tract, pulmonary arteries, tricuspid valve region, or venae cavae; this is known as the *caval syndrome.* Caval syndrome results in not only cardiovascular instability but also intravascular hemolysis due to physical shearing of red blood cells flowing past the mass of worms, resulting in anemia and hemoglobinuria. Systemic inflammation and thrombotic complications can lead to disseminated intravascular coagulation (DIC) or systemic inflammatory response system (SIRS). Aberrant systemic arterial worm migration causing embolization of the brain, eye, or other systemic arteries occasionally occurs. Cases of hindlimb lameness, with paresthesia and ischemic necrosis, have been described sporadically.

HEARTWORM DISEASE TESTING

Serologic (Antigen) Tests

Adult HW antigen (Ag) tests are recommended as the main screening test for HWD in dogs. Although controversy exists as to whether yearly testing is necessary, for several reasons the American Heartworm Society recommends yearly testing to ensure that prophylaxis is achieved and maintained. Currently available Ag test kits are highly accurate. Circulating Ag is usually detectable by about 6.5 to 7 months after infection but not sooner than 5 months. There is no reason to test puppies younger than 6 months of age. Ideally, testing of adults is recommended at about 6 to 7 months after the preceding transmission season.

Commercially available test kits are immunoassays that detect circulating HW Ag from the adult female reproductive

tract. Most are enzyme-linked immunosorbent assays (ELISAs), although immunochromatographic test methods are also used. These tests are generally specific and have a good sensitivity. Positive results are generally obtained when at least four (and usually fewer) female worms 7 to 8 months or older are present. Most HW Ag tests do not detect infections less than 5 months old, and male worms are not detected. A weak positive or ambiguous test result may be rechecked using a different test kit or repeated after a short time with the same type of kit; microfilaria testing and thoracic radiographs can also increase or decrease index of suspicion for infection. Colorimetric intensity of an Ag test is not a reliable estimate of worm count. A false-positive Ag test result can usually be traced to a technical error. False-negative results may occur with a low worm burden, immature female worms only, male unisex infection, or inaccurate adherence to test kit instructions. False-negative Ag tests have also been reported in some dogs due to formation of HW antigen-antibody complexes in the blood, effectively preventing free Ag to react with the serologic test. Heating the blood sample test tube to 104° C for 10 minutes before Ag testing can separate Ag-Ab complexes and cause a previously negative Ag result to turn positive. Heating the sample is only recommended in cases where false-negative testing due to Ag-Ab complexation is suspected (e.g., a dog that is HW Ag-negative but microfilaria-positive). Routine heating of samples before Ag testing is not currently recommended. For these reasons, the American Heartworm Society recommends that HW antigen test results be interpreted and recorded as either "positive" or "no antigen detected" (NAD), rather than "negative."

Microfilaria identification

The American Heartworm Society recommends that all dogs screened with HW Ag testing be concurrently screened for presence of circulating microfilaria. Microfilaria testing can identify HW Ag-positive patients that are reservoirs of infection, can assess whether high numbers of microfilariae are present before a monthly preventive drug is administered, and can identify HW-positive dogs who have false negative Ag testing (due to Ag-Ab complexation).

The vast majority (~90%) of HW-positive dogs that are not treated with a monthly preventative have circulating microfilariae. The remaining so-called occult infections, in which there are no circulating microfilariae, can result from an immune response that destroys the microfilariae within the lung (true occult infection), unisex infection, sterile adult HWs, or the presence of only immature worms (prepatent infection). Low numbers of microfilariae and diurnal variations in the number of circulating microfilariae in peripheral blood can also cause false-negative microfilaria test results. Occult (microfilaria-negative) infections can still cause severe disease.

Microfilaria concentration tests that use at least 1 mL of blood are recommended for detecting circulating microfilariae. The nonconcentration tests are more likely to miss low numbers of microfilariae, although they do allow observation of microfilarial motility. *Dirofilaria* have a stationary rather than a migratory movement pattern. Nonconcentration tests include examination of a fresh wet blood smear or adjacent to the buffy coat of a spun hematocrit tube.

Concentration tests are done using either a millipore filter or the modified Knott's centrifugation technique. Both techniques lyse the red blood cells and fix any existing microfilariae. The modified Knott test, which involves formalin fixation, centrifugation, and staining with methylene blue, is preferred for measuring larval body size and differentiating *D. immitis* from nonpathogenic filarial larvae such as *Acanthocheilonema* (formerly *Dipetalonema*) *reconditum* (Table 10.1). An occasional false-positive microfilaria test result occurs in animals with microfilariae but no live adult HWs, either due to transplacental transmission of microfilaria to a young puppy or due to recent adult female worm die-off after producing microfilariae.

The macrocyclic lactone preventive drugs, administered monthly, reduce and eliminate microfilaremia by impairing the reproductive function of female and possibly also male worms. Most dogs become amicrofilaremic by 6 to 8 months after initiating treatment with these drugs. Preventive drugs that kill microfilaria very rapidly may cause life-threatening inflammatory reactions during microfilaria die-off. Therefore microfilaria testing was historically mandatory when diethylcarbamazine (DEC) was routinely used as a HW preventive and is also currently recommended if milbemycin is used (the most potent microfilaricide among the macrocyclic lactones).

Clinical Features

There is no specific age or breed predilection for HWD in dogs. Although most affected dogs are between 4 and 8 years

TABLE 10.1

Morphologic Differentiation of Microfilaria

SMEAR	*DIROFILARIA IMMITIS*	*ACANTHOCHEILONEMA RECONDITUM*
Fresh smear	Few to large numbers	Usually small numbers
	Undulate in one place	Move across field
Stained smear*	Straight body	Curved body
	Straight tail	Posterior extremity hook ("button hook" tail); inconsistent finding
	Tapered head	Blunt head
	>295-325 µm long	<275-288 µm long
	>6 µm wide	<6 µm wide

*Size criteria given for lysate prepared using the modified Knott's test (1 mL blood mixed with 9 mL of 2% formalin, then centrifuged for 5 minutes; sediment stained with methylene blue); microfilariae tend to be smaller with lysate of filter tests. Width and morphology are the best discriminating factors.

old, HWD is also diagnosed in dogs younger than 1 year (but older than 6 months) of age, as well as in geriatric animals. Males are affected two to four times as often as females. Large-breed dogs and those living mainly outdoors are at much greater risk of infection than small-breed and indoor dogs. The length of the haircoat does not appear to affect infection risk.

Dogs diagnosed by a positive routine screening test often are asymptomatic. Dogs with occult disease and those not routinely tested are more likely to have advanced pulmonary arterial changes and clinical signs associated with pulmonary hypertension, eosinophilic pneumonitis, and secondary right-sided cardiac remodeling. Dogs with clinical disease generally have a history of poor exercise tolerance, cough, respiratory difficulty, syncope, weight loss, or abdominal distension with fluid. Overall severity of HWD is classified based on severity of clinical signs, radiographic signs, and clinicopathologic abnormalities (Table 10.2). Of all dogs diagnosed with HWD, the majority (70%) are asymptomatic (Class 1), approximately 25% have exercise intolerance or respiratory signs secondary to pneumonitis or pulmonary hypertension (Class 2), and less than 5% present with right-sided CHF or caval syndrome (Class 3 or 4).

Physical examination findings are often normal in dogs with early or mild disease. However, severe disease is associated with poor body condition, tachypnea or dyspnea, clinical signs of severe PAH (see p. 191), or evidence of right-sided CHF (see p. 201). Increased or abnormal lung sounds (wheezes and crackles) can accompany pulmonary parenchymal involvement as seen with eosinophilic pneumonitis. As with other causes of PAH, a loud and often split-second heart sound (S_2) and a murmur of TR are commonly heard on auscultation. Severe pulmonary arteritis and thromboembolism (see p. 224) can lead to marked dyspnea with cyanosis, hemoptysis, fever, DIC, thrombocytopenia, and epistaxis. These signs, as well as anemia and hemoglobinuria, also are associated with caval syndrome (see p. 202). Aberrant worm migration to the central nervous system, eye, femoral arteries, subcutis, peritoneal cavity, and other sites causes signs related to the organ involved.

Diagnosis

RADIOGRAPHY

Radiographic findings can be normal early in the disease process or with only a few worms. However, marked changes develop rapidly in dogs with heavy worm burdens. Characteristic findings are those suggestive of severe PAH, including RV enlargement, a pulmonary trunk bulge, and centrally enlarged and tortuous lobar pulmonary arteries with peripheral blunting (Fig. 10.1 and p. 191). Patchy pulmonary interstitial or alveolar infiltrates suggestive of pneumonitis, PTE, or fibrosis are also common, especially in the caudal lobes. These pulmonary opacities may be mainly perivascular. Occasionally eosinophilic granulomatosis occurs, with more organized interstitial nodules, enlarged bronchial lymph nodes, and sometimes pleural effusion. In severe cases where PAH has progressed to cause right-sided CHF, caudal vena cava enlargement, hepatosplenomegaly, and abdominal or pleural effusion may be seen.

TABLE 10.2

Classification of Heartworm Disease Severity in Dogs

CLASS	CLINICAL SIGNS	RADIOGRAPHIC SIGNS	CLINICOPATHOLOGIC ABNORMALITIES
1 (mild)	None or occasional cough, fatigue on exercise, or mild loss of condition	None	None
2 (moderate)	None or occasional cough, fatigue on exercise, or mild to moderate loss of condition	Right ventricular enlargement and/or some pulmonary artery enlargement; ±perivascular and mixed alveolar/interstitial opacities (pneumonitis)	±Mild anemia (PCV to 30%); ±proteinuria (2+ on dipstick)
3 (severe)	General loss of condition or cachexia; fatigue on exercise or mild activity; occasional or persistent cough; ±dyspnea; ±right-sided heart failure	Right ventricular ±atrial enlargement; moderate to severe pulmonary artery enlargement; perivascular or diffuse mixed alveolar/interstitial opacities (pneumonitis); ±evidence of thromboembolism	Anemia (PCV < 30%); proteinuria (≥2+ on dipstick)
4 (severe) caval syndrome	See p. 202		

PCV, Packed cell volume.

ELECTROCARDIOGRAPHY

ECG findings are usually normal, although advanced disease can cause a right axis deviation or arrhythmias, as with other causes of severe PAH (see p. 192).

ECHOCARDIOGRAPHY

Echocardiographic findings in dogs with advanced HWD are as for other causes of severe PAH, with the additional possibility of visualizing HWs in the right heart. Although HWs located in peripheral pulmonary arteries cannot be seen echocardiographically, worms within the main pulmonary artery and its bifurcation, RV, RA, or vena cavae appear as small, bright parallel echoes (Fig. 10.3). Suspected caval syndrome can be quickly confirmed by echocardiography. Ascites or pleural or pericardial effusion accompanies secondary right-sided CHF. Color-flow Doppler imaging can often reveal TR even when an audible murmur is absent. Spectral Doppler measurement of maximum tricuspid (or pulmonary) regurgitant jet velocity allows estimation of PAH severity (see p. 30).

Clinicopathologic Findings

Eosinophilia, basophilia, neutrophilia, and monocytosis are common but inconsistent hematologic findings. Mild regenerative anemia of inflammatory disease might be noted. More severe anemia secondary to intravascular hemolysis occurs in caval syndrome. Thrombocytopenia can result from platelet consumption in the pulmonary arterial system, especially after adulticide treatment. DIC also develops in some dogs with advanced disease. The immune response to HWs produces a polyclonal gammopathy. Mild to moderate elevations in liver enzyme activity may be seen, especially in cases of right-sided CHF (passive congestion of the liver). Azotemia, either prerenal or secondary to immune-complex glomerulonephritis, occasionally occurs. Proteinuria is found in 10% to 30% of affected dogs and is more likely with advanced disease; hypoalbuminemia can develop in severely affected dogs. If hypoalbuminemia or proteinuria is detected, a urine protein-creatinine ratio (UPC) is advised. Tracheal washings from coughing HW-infected dogs usually indicate eosinophilic inflammation.

Treatment of Dogs With Heartworm Disease

PREADULTICIDE EVALUATION AND TREATMENT

As a general rule, adulticide treatment is recommended for dogs infected with HWs. Dogs who test positive for HW Ag should have a thorough history and physical examination. Pretreatment thoracic radiographs provide the best overall assessment of pulmonary arterial and parenchymal disease status. The risk of postadulticide PTE is increased in dogs with preexisting clinical and radiographic signs

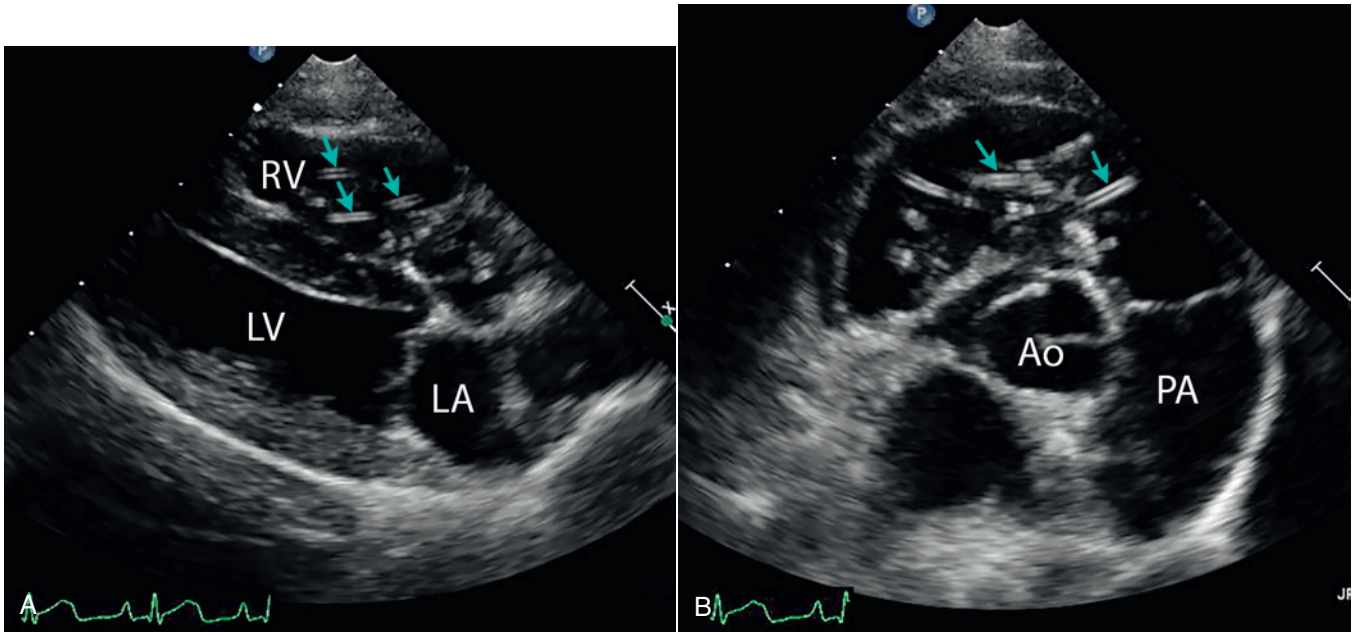

FIG 10.3
Echocardiographic images from a 4-year-old female spayed Beagle with caval syndrome. Views from the right parasternal **(A)** four-chamber long-axis and **(B)** short-axis at the level of the heart base are shown. There is enlargement of the right ventricle and main pulmonary artery, with right ventricular hypertrophy. Many small, bright parallel echoes are apparent in the body of the right ventricle *(arrows)*, caused by a clump of heartworms entangled in the tricuspid valve apparatus. *Ao,* Aortic root; *LA,* left atrium; *LV,* left ventricle; *PA,* main pulmonary artery; *RV,* right ventricle.

of severe pulmonary vascular disease, especially in those with right-sided CHF or a high worm burden. Whenever possible, other pretreatment tests should include a CBC, serum biochemical profile, urinalysis, and a microfilaria test. A platelet count is important for risk assessment in animals with severe pulmonary arterial disease. Mildly to moderately increased liver enzyme activity may be associated with hepatic congestion but does not preclude therapy with melarsomine. Liver enzyme activities usually normalize within 1 to 2 months of HW treatment in dogs without preexisting liver disease. As previously discussed, some dogs with HWD develop azotemia and/or severe proteinuria. Prerenal azotemia is treated with fluid therapy before adulticide is given. Severe glomerular disease can increase the risk for thromboembolism from loss of anticoagulant proteins (see p. 222); dogs with high UPC could benefit from ACEI treatment before adulticide therapy. Echocardiography aids in confirming and estimating severity of PAH and secondary right-sided cardiac remodeling, as well as confirming presence of caval syndrome if suspected, but is not required in most routine cases of HWD before treatment. In circumstances of shelter or owner financial limitations, adulticide treatment has frequently been undertaken with minimal pretreatment evaluation (positive Ag test only). Melarsomine injections were associated with <1% mortality rate in a high-volume shelter rescue situation after Hurricane Katrina. The risk-benefit and cost-benefit of pretreatment diagnostic testing should therefore be discussed with owners of HW-positive dogs.

Monthly HW prophylaxis with a macrocyclic lactone should begin immediately after diagnosis of HWD (if not already started). The American Heartworm Society recommends use of monthly HW preventative for 2 months before the administration of an adulticide in dogs diagnosed with HWD. This strategy can reduce HW Ag mass by decreasing or eliminating circulating microfilariae and tissue-migrating larvae, stunting immature worm growth, and damaging the adult female reproductive system. Delaying melarsomine for a few months also allows any late-stage larvae to mature further, which should increase susceptibility to the adulticidal effect. This 2-month window effectively narrows the so-called "susceptibility gap" between parasite life stages targeted by macrocyclic lactones (L_3-L_4) and adulticides (mature adult HWs). Microfilaria-positive dogs should be observed in the hospital after the first dose of macrocyclic lactone in case of adverse reaction, particularly if milbemycin oxime is used (the most microfilaricidal among macrocyclic lactones). Dogs with high numbers of microfilariae or those receiving milbemycin oxime might also benefit from administration of an antiinflammatory dose of glucocorticoid, with or without an antihistamine (e.g., diphenhydramine), an hour before the first macrolide preventive dose.

Exercise restriction should be enforced as soon as HWD is diagnosed and maintained until 1 to 2 months after final melarsomine treatment. Activity level is highly associated with progression of pulmonary arterial disease and risk of pre- or posttreatment complications, particularly PTE. More severely affected dogs warrant more strict exercise restriction (cage rest).

Use of doxycycline as therapy against *Wolbachia* contributes to reducing HW fertility and viability. Doxycycline (10 mg/kg PO q12h) is recommended in dogs for 4 weeks after diagnosis of HWD, before adulticide therapy. Doxycycline aids in reducing microfilaria, weakens and reduces reproductive ability of adult worms, kills developing larvae, and reduces pathologic immune reactions to dead and dying worms. The combination of a single preventative dose of ivermectin and doxycycline at 10 mg/kg PO q12h effectively eliminates microfilaria within 2 to 3 weeks, a rate that is appropriately rapid for reducing infectivity to other dogs but gradual enough to minimize risk of immune reaction to dying microfilaria. When the recommended combination of monthly preventative and doxycycline is used, no adjunct treatment specifically targeting microfilaria is needed (either before or after adulticide therapy). Although not specifically evaluated in HWD, the related drug minocycline has similar efficacy against *Wolbachia* and is a reasonable substitute if doxycycline is unavailable; the same dosing protocol is used for minocycline.

Antiplatelet therapy with aspirin or clopidogrel currently is not recommended as an adjunct to routine HW treatment because there is no convincing evidence for reduction in vascular lesion severity or risk of PTE. However, antiplatelet therapy should be considered in cases of documented proteinuria or PTE. Corticosteroid therapy (e.g., prednisone or dexamethasone) is reserved for treatment of eosinophilic pneumonitis or granulomatosis (see p. 201), PTE (see p. 201), treatment or prevention of microfilaricide reactions, or to mitigate tissue reaction to melarsomine injection. Otherwise corticosteroids are avoided because of their potential to cause fluid retention, reduced pulmonary blood flow, and hypercoagulability. Sildenafil is used in cases of severe PAH, PTE, and right-sided CHF secondary to PAH (see p. 201). Cardiac medications, including furosemide, pimobendan, and ACEIs, are reserved for cases of right-sided CHF secondary to PAH; ACEIs can also be considered in cases of proteinuria secondary to immune-complex glomerulonephritis. Herbal or other "natural" products have not shown efficacy in treatment or prevention of HWD and are not recommended.

The withholding of adulticide treatment in some asymptomatic HWD cases remains controversial and is not recommended. Although continuous monthly treatment with prophylactic ivermectin does eventually kill young adult worms, this effect occurs over a prolonged time period (over 1-2 years). Older worms are more resistant to ivermectin and can still cause clinical disease. Furthermore, progression of pulmonary arterial changes, pulmonary disease, and other HW-induced effects (e.g., glomerulonephritis) could increase the risks associated with adulticide treatment should this be undertaken in the future. Other macrocyclic lactones have variable adulticidal activity, with milbemycin showing the least efficacy against adult HWs at the preventative dose. It also is possible that use of HW preventive medication alone in HW-infected dogs could increase the potential for

resistant infections. The American Heartworm Society does not recommend the use of macrocyclic lactones alone (the so-called "slow kill" method) as an adulticide strategy. However, in selected cases where adulticide therapy cannot be given for one reason or another (such as during melarsomine drug shortages), dogs should be treated continuously (for at least 2 years) with ivermectin or possibly selamectin. Recent availability of a generic melarsomine product (Diroban) should reduce concerns about shortages of the brand-name product (Immiticide). If the "slow kill" method is used, doxycycline (10 mg/kg PO q12h) still should be used for a 4-week period after diagnosis, and exercise restriction should be maintained throughout the entire duration of the treatment process. HW Ag testing is recommended every 6 months. The HW infection is considered cleared when two consecutive negative test results are obtained. Lifelong HW prophylaxis is then used to prevent reinfection and disease transmission to other animals.

ADULTICIDE THERAPY IN DOGS

Melarsomine dihydrochloride (Immiticide, Diroban) is the adulticide of choice. It is effective against both immature and mature HWs; male worms are more susceptible than females. The American Heartworm Society recommends the three-dose "split" protocol for all HW-infected dogs in Classes 1 to 3 (see Box 10.1). Compared with the previously employed two-dose protocol, the three-dose protocol promotes a more gradual worm kill. It involves one initial dose, followed a month (or longer) later with two doses 24 hours apart. The first dose leads to death of approximately half of the worms, resulting in less chance for severe PTE or immune reactions associated with massive worm die-off. After the subsequent two doses, the worm kill is about 98%. This protocol does entail greater expense, higher arsenic exposure, and a requirement for more prolonged exercise restriction (from initial dose to at least a month after the final dose) compared with the two-dose protocol. The two-dose protocol remains an alternative option, especially for shelter situations, minimally affected dogs when owner financial constraints are an issue, or when marked renal or liver disease is present (because of the greater potential for arsenic toxicity). The two-dose protocol reportedly kills about 90% of adult worms. Dogs with caval syndrome (Class 4) should not be given adulticide treatment until after worms are surgically removed (see p. 202).

Melarsomine is absorbed rapidly from the intramuscular (IM) injection site. Unchanged drug and a major metabolite are rapidly eliminated in the feces; a minor metabolite is excreted in urine. The drug should be given by deep IM injection into the epaxial lumbar muscles (L_3 to L_5 region), exactly as recommended by the manufacturer. The lumbar muscle site provides good vascularity and lymphatic drainage with minimal fascial planes. Furthermore, gravity may help prevent the drug from leaking into subcutaneous tissues, where it can cause more irritation. The drug does cause a local reaction at the injection site; this is clinically noticeable in about a third of treated dogs. A tapering course of antiinflammatory prednisone beginning at the time of each melarsomine injection can help reduce local soreness, inflammatory reaction to dying worms, and clinical effects of pneumonitis (if present). Melarsomine is available as a sterile lyophilized powder in 50-mg vials. The rehydrated product is fully stable for 24 hours if kept refrigerated in the dark.

BOX 10.1

Heartworm Disease Management Protocol for Dogs*

Day 0: Dog diagnosed and verified as heartworm-positive
- Positive antigen (Ag) test verified with microfilaria (MF) test
- If no microfilariae are detected, confirm with second Ag test from a different manufacturer
- Begin exercise restriction
- The more pronounced the signs, the stricter the exercise restriction

If the dog is symptomatic:
- Stabilize with appropriate therapy and nursing care
- Prednisone prescribed at 0.5 mg/kg PO q12h first week, 0.5 mg/kg q24h second week, 0.5 mg/kg q48h third and fourth weeks

Day 1: Administer heartworm preventive
- If microfilariae are present, pretreat with antihistamine and glucocorticoid (if not already on prednisone) to reduce risk of anaphylaxis
- Observe for at least 8 hours for signs of reaction

Days 1-28: Administer doxycycline 10 mg/kg PO q12h for 4 weeks
- Reduces pathology associated with dead heartworms
- Disrupts heartworm transmission

Day 30: Administer heartworm preventive

Day 60: Administer heartworm preventive and first melarsomine injection, 2.5 mg/kg intramuscularly (IM)†
- Prescribe prednisone 0.5 mg/kg q12h first week, 0.5 mg/kg q24h second week, 0.5 mg/kg q48h third and fourth weeks

Decrease activity level even further
- Cage restriction/on leash when using yard

Day 90: Administer heartworm preventive, and second melarsomine injection, 2.5 mg/kg IM

Day 91: Third melarsomine injection, 2.5 mg/kg IM
- Prescribe prednisone 0.5 mg/kg q12h first week, 0.5 mg/kg q24h second week, 0.5 mg/kg q48h third and fourth weeks
- Continue exercise restriction for 6 to 8 weeks after last melarsomine injections

Day 120: Test for presence of microfilariae
- If positive, treat for microfilariae with additional 30-day regimen of doxycycline and retest in 4 weeks
- Establish year-round heartworm prevention

Day 271: Antigen test 6 months after completion; screen for microfilariae

*2014 American Heartworm Society Recommendations (www.heartwormsociety.org).
†Follow manufacturer's instructions closely for all melarsomine injections.

Coughing or (less often) dyspnea after treatment can be related to the HWD itself (pneumonitis), inflammatory reaction in the lungs and pulmonary vasculature secondary to worm die-off, or dead worm fragments causing PTE. In general, these reactions are steroid responsive and can be mitigated by administration of antiinflammatory prednisone course concurrently with melarsomine. Most clinical signs noted in dogs treated with melarsomine have been behavioral (e.g., tremors, lethargy, unsteadiness and ataxia, restlessness); respiratory (e.g., panting, shallow breathing, labored respirations, crackles); or injection-site related (e.g., edema, redness, tenderness, vocalization, increased aspartate aminotransferase and creatine kinase activities). Injection site reactions are generally mild to moderate and resolve within 4 (to 12) weeks. Occasionally these reactions are severe. The manufacturer reports that firm nodules might persist indefinitely at the sites. General signs of lethargy, depression, and anorexia occur in about 15% or fewer dogs; other adverse effects, including fever, vomiting, and diarrhea, occur occasionally. Adverse effects generally are mild at recommended doses. Hepatic and renal changes have not proved clinically relevant in animals receiving recommended doses of melarsomine. Overall, melarsomine causes less systemic toxicity than its predecessor, thiacetarsamide. Nevertheless, melarsomine has a low margin of safety. Overdose may cause collapse, severe salivation, vomiting, respiratory distress resulting from pulmonary inflammation and edema, stupor, and death.

Strict exercise restriction should be enforced for 4 to 6 weeks after each dose of adulticide therapy to reduce the effects of adult worm death and PTE. The rest period for working dogs should probably be longer because increased pulmonary blood flow in response to exercise exacerbates pulmonary capillary bed damage and subsequent fibrosis.

HW Ag testing (with concurrent microfilaria testing) is recommended 6 months after the final adulticide injection; results should be negative with successful treatment. Many dogs are HW Ag-negative by 3 to 4 months after adulticide therapy. Persistent antigenemia 6 months after three-dose melarsomine protocol may occur due to latent worm die-off, persistence of a small number of live worms postadulticide, or reinfection if monthly preventative was not given consistently. The Ag test should be repeated again 6 months later. A positive Ag test 12 months posttreatment despite adherence to a monthly preventative schedule suggests persistent infection. Because the three-dose melarsomine protocol kills 98% of worms, some dogs will remain Ag positive after treatment due to presence of a small number of residual worms. The decision to repeat adulticide therapy is guided by the patient's overall health, performance expectations, and age. Complete worm kill is probably not necessary; even if a few adult HWs survive, pulmonary arterial disease improves considerably after adulticide therapy.

Thiacetarsamide is an older arsenical agent that previously was the only adulticide available. It had no advantages and greater toxicity potential compared with melarsomine and is no longer used. Likewise, the use of other drugs such as levamisole or stibophen as adulticides is not recommended. Levamisole does not consistently kill adult HWs, although it is somewhat effective against male worms and may sterilize adult female worms.

The use of a flexible alligator forceps with fluoroscopic or transesophageal echocardiographic guidance has been advocated as a way to reduce the worm burden in accessible segments of the main or branch pulmonary arteries before adulticide therapy, even in dogs without caval syndrome. Removing as many worms as feasible reduces the risk for postadulticide PTE in heavily infected dogs. However, this procedure is not routinely performed due to requirements for imaging equipment and technical expertise, the need for sedation or anesthesia, and the potential for worm breakage with exacerbated pulmonary reaction.

POSTADULTICIDE PULMONARY THROMBOEMBOLIC COMPLICATIONS

Pulmonary arterial disease worsens from 5 to 30 days after adulticide therapy and can be especially severe in previously symptomatic dogs. Dead and dying worms promote thrombosis and pulmonary artery obstruction, with exacerbation of platelet adhesion, myointimal proliferation, villous hypertrophy, granulomatous arteritis, perivascular edema, and hemorrhage. Severe ventilation-perfusion mismatch may result from pulmonary hypoperfusion, hypoxic vasoconstriction and bronchoconstriction, pulmonary inflammation, and fluid accumulation. PTE is most likely to occur 7 to 10 days after adulticide therapy but can occur up to 4 weeks later. As expected, the caudal and accessory lung lobes are most commonly and severely affected. Pulmonary blood flow obstruction and increased vascular resistance further strain the RV and increase oxygen demand. Poor cardiac output and hypotension can result.

Depression, fever, tachycardia, tachypnea or dyspnea, and cough are common clinical signs. Hemoptysis, right-sided CHF, collapse, or death can also occur. Interstitial and alveolar pulmonary inflammation and fluid accumulation cause pulmonary crackles on auscultation. Focal lung consolidation can cause areas of muffled lung sounds. Thoracic radiographs show patchy alveolar infiltrates with air bronchograms, especially near the caudal lobar arteries. Thrombocytopenia or neutrophilia with a left shift may be seen on CBC.

Treatment of PTE (whether it occurs before or after adulticide therapy) includes strict rest (i.e., cage confinement) and glucocorticoid therapy to reduce pulmonary inflammation (e.g., prednisone, 0.5 mg/kg PO q12h for a week, then decreasing to 0.5 mg/kg q24h for a week, then decreasing again to 0.5 mg/kg q48h for 1 to 2 additional weeks). Supplemental oxygen therapy is recommended to reduce hypoxia-mediated pulmonary vasoconstriction, and sildenafil (1-3 mg/kg PO q8-12h) is indicated to decrease pulmonary vascular resistance. Antiplatelet therapy (clopidogrel or aspirin), as well as anticoagulant therapy (unfractionated heparin or low-molecular-weight heparin), may be considered for severe cases of thromboembolism. A bronchodilator (e.g., oral theophylline, 10 mg/kg q12h); judicious fluid

therapy (if there is evidence of cardiovascular shock); and cough suppressants could be useful. Antibiotics are of questionable benefit unless there is evidence of concurrent bacterial infection. Endothelial changes in survivors regress within 4 to 6 weeks after an adulticide. Pulmonary hypertension and arterial disease, along with radiographic changes, diminish over the next several months. Eventually, pulmonary arterial pressure and the contour of the proximal pulmonary arteries normalize, although some fibrosis may remain.

Treatment of Dogs With Complicated Heartworm Disease

PULMONARY COMPLICATIONS

Allergic or eosinophilic pneumonitis develops in a minority of dogs with HWD. It tends to develop early in the disease process and is thought to involve an immune-mediated reaction to dying larvae in the pulmonary microvasculature. Clinical manifestations of HW pneumonitis include a progressively worsening cough, crackles heard on auscultation, tachypnea or dyspnea, and sometimes cyanosis, weight loss, and anorexia. Eosinophilia, basophilia, and hyperglobulinemia are inconsistent findings. HW Ag tests are usually positive, but many cases do not have circulating microfilaria. Diffuse interstitial and alveolar infiltrates, especially in the caudal lobes, are common on radiographs; these can be similar to those in dogs with pulmonary edema, PTE, blastomycosis, or metastatic hemangiosarcoma. There is often no clinically relevant cardiomegaly or pulmonary lobar artery enlargement. Tracheal wash cytology usually reveals a sterile eosinophilic exudate with variable numbers of well-preserved neutrophils and macrophages. Therapy with a glucocorticoid (e.g., prednisone, 0.5 mg/kg PO q12h) usually results in rapid and marked improvement. Prednisone may be continued as needed, in gradually tapered doses (to 0.5 mg/kg every other day) and does not appear to adversely affect the adulticide efficacy of melarsomine.

Pulmonary eosinophilic granulomatosis is an uncommon syndrome that has been associated with HWD, although some affected dogs have negative HW tests. Its pathogenesis is thought to involve a hypersensitivity reaction to HW Ag or immune complexes, or both. Pulmonary granulomas are composed of a mixed cell population, with predominantly eosinophils and macrophages. A proliferation of bronchial smooth muscle within granulomas and an abundance of alveolar cells in the surrounding area are typical. Lymphocytic and eosinophilic perivascular infiltrates may also occur. Eosinophilic granulomas involving the lymph nodes, trachea, tonsils, spleen, gastrointestinal (GI) tract, and the liver or kidneys may occur concurrently. The clinical signs of pulmonary eosinophilic granulomatosis are similar to those of eosinophilic pneumonitis. Clinicopathologic findings variably include leukocytosis, neutrophilia, eosinophilia, basophilia, monocytosis, and hyperglobulinemia. In some cases, an exudative, primarily eosinophilic pleural effusion develops. Radiographic findings include multiple pulmonary nodules of varying size and location with mixed alveolar and interstitial pulmonary infiltrates; hilar and mediastinal lymphadenopathy may also be present. Eosinophilic granulomatosis is treated initially with prednisone (1-2 mg/kg PO q12h); however, additional cytotoxic therapy (e.g., cyclophosphamide or azathioprine) may be necessary as well. Not all dogs respond completely, and relapses are common, especially when therapy is reduced or discontinued. The response to immunosuppressive drugs after relapse may be poor. Surgical removal of a severely affected lung lobe is a strategy sometimes used. Therapy for adult HWs is given when pulmonary disease improves.

Severe pulmonary arterial disease, including PAH and PTE, is more common in dogs with long-standing HW infection, in those with many adult worms, and in active dogs. Severe cough, exercise intolerance, tachypnea or dyspnea, episodic weakness, syncope, weight loss, fever, and pallor are common clinical signs; sudden death sometimes occurs. Typical radiographic findings include markedly enlarged, tortuous, and blunted pulmonary arteries with or without pulmonary interstitial and alveolar infiltrates; signs usually are more severe in the caudal lobes. Marked hypoxemia occurs in some cases. Thrombocytopenia and sometimes hemolysis can occur in dogs with severe pulmonary arterial disease and thromboembolism; DIC develops in some dogs. As for postadulticide PTE, treatment with oxygen, sildenafil, prednisone, strict cage rest, and sometimes a bronchodilator (e.g., theophylline) is indicated to improve oxygenation and reduce pulmonary artery pressures. Caution is indicated to avoid systemic hypotension. Antiplatelet therapy (clopidogrel or aspirin) or anticoagulant therapy (unfractionated heparin or low-molecular-weight heparin) could be considered, although benefit of anticoagulation must be weighed against risk of bleeding, particularly in patients with thrombocytopenia or hemoptysis.

After the animal's condition is stabilized, the typical HW treatment protocol can commence as recommended by the American Heartworm Society (macrocyclic lactone and doxycycline; 3-injection melarsomine protocol after 2 months).

RIGHT-SIDED CONGESTIVE HEART FAILURE

Severe pulmonary arterial disease and PAH can cause right-sided CHF. Jugular venous distention or pulsation, ascites, syncope, exercise intolerance, and arrhythmias are typical signs; other physical and auscultatory signs secondary to severe PAH might also occur (see p. 191). Although ascites is the most common manifestation of right-sided CHF in dogs, pleural or pericardial effusion can occur as well. Cardiogenic pulmonary edema is not expected. Treatment is the same as for dogs with severe PAH (sildenafil 1-3 mg/kg PO q8-12h), with the addition of abdominocentesis or thoracocentesis as needed, furosemide (e.g., 1-2 mg/kg PO q12h or as needed), pimobendan (0.2-0.3 mg/kg PO q12h), an ACEI (e.g., enalapril or benazepril 0.5 mg/kg PO q12h), and moderate dietary salt restriction. Clopidogrel or aspirin could be considered, because PTE is one of the major mechanisms of

PAH in HWD. An additional diuretic (spironolactone or hydrochlorothiazide) could be helpful in refractory cases, if renal function is adequate. Dogs that develop right-sided CHF before adulticide therapy should be treated for heart failure while beginning initial American Heartworm Society treatment guidelines (macrocyclic lactone and doxycycline). If dogs respond well to heart failure treatment and remain clinically stable, they may receive the three-dose melarsomine protocol after the typical 2-month waiting period.

CAVAL SYNDROME

The (vena) caval syndrome occurs when venous inflow to the heart is obstructed by a mass of worms, leading to low-output cardiovascular shock. Other terms for this condition include *postcaval syndrome, acute hepatic syndrome, liver failure syndrome, dirofilarial hemoglobinuria,* and *vena cava embolism.* It is an uncommon but devastating complication in heavily infected animals. As the HW burden increases, adult worms migrate from their preferred location in the distal pulmonary arteries "backward" or "upstream" into the RV, right atrium (RA), and caudal vena cava. Dogs with more than 40 worms or with more severe PAH have increased risk for developing caval syndrome. Caval syndrome occurs more often in geographic areas where HWD is enzootic.

Most dogs that develop caval syndrome are males. Often no history of HW-related signs exists. Acute collapse is common, often accompanied by anorexia, weakness, tachypnea or dyspnea, pallor, and hemoglobinuria. Dogs with caval syndrome invariably have severe PAH and concurrent right-sided CHF, so additional clinical signs and findings typical of these syndromes can occur as well (see p. 201).

Intravascular hemolysis (from red blood cell trauma) results in Coombs-negative fragmentation hemolytic anemia, hemoglobinemia, and hemoglobinuria. Hemoglobinuria is considered a hallmark sign of caval syndrome. Other clinicopathologic findings are similar to other presentations of severe HWD (see p. 197)

Thoracic radiographs indicate right heart and pulmonary artery enlargement, consistent with severe HWD. The ECG usually suggests RV enlargement. Ventricular or supraventricular premature complexes are common. Echocardiography reveals a mass of worms entangled at the tricuspid valve and in the RA and/or venae cavae (see Fig. 10.3). Characteristic echocardiographic changes associated with severe PAH (RV dilation and hypertrophy, paradoxical septal motion, tricuspid insufficiency, and a small LV) are also seen.

Without aggressive treatment, most dogs die within between 24 and 72 hours as a result of cardiogenic shock complicated by metabolic acidosis, DIC, and anemia. Worms must be surgically removed from the vena cava and RA as soon as possible. The dog is sedated (preferred) or anesthetized. A right jugular venotomy, with the dog restrained in left lateral recumbency, is the usual approach. Local anesthesia is used after the right jugular region is shaved and surgically prepped. The jugular vein is isolated, and loops of moist umbilical tape or suture material are used to control bleeding once the vein is incised. Long alligator forceps (or another endoscopic retrieval instrument) are used to grasp and withdraw the HWs through the jugular vein incision. The instrument is gently passed down the vein through the cranial vena cava into the RA; repositioning of the animal's head and neck may be necessary to pass the instrument beyond the thoracic inlet. Fluoroscopic or echocardiographic guidance is helpful. The goal is to retrieve as many worms as possible without causing worm breakage; generally, five to six unsuccessful attempts in sequence is the end point. Resistance to instrument withdrawal from the vein may occur if too many worms are grasped at once or a cardiovascular structure is grabbed by forceps. The jugular vein is ligated proximally and distally, and then the subcutis and skin are closed routinely. Survival rates of 50% to 80% have been reported for dogs undergoing this procedure.

Other supportive care given during and after surgical worm removal might include IV fluid therapy, particularly in cases presenting with cardiovascular shock; however, most dogs with caval syndrome concurrently have right-sided CHF, and fluid therapy will exacerbate venous congestion. A hypotonic crystalloid solution (such as half-strength saline) is preferred, with fluid rate determined by the individual case. Depending on the degree of anemia, blood transfusion (fresh whole blood or packed red blood cells) might be required. Adjunctive therapy after HW extraction is similar to recommendations for the other complications of severe HWD. Treatment includes prednisone, sildenafil, and clopidogrel or aspirin (for pulmonary inflammation, PAH, and PTE); pimobendan (for right-sided congestive heart failure [R-CHF]); and initiation of doxycycline and macrocyclic lactone (as with any other HW-positive dog). Additional treatments for R-CHF, including furosemide and ACEIs, generally are delayed until the dog's clinical condition stabilizes and may not be required if venous congestion improves dramatically after worm removal. In the acute setting, monitoring for anemia, thrombocytopenia, DIC, and organ dysfunction is important; treatment is given as indicated. Severe PTE and renal or hepatic failure are associated with poor outcome. Assuming clinical stabilization after worm extraction, adulticide therapy can be started after the typical 2-month period to eliminate remaining worms.

Heartworm Prevention

HW prophylaxis is indicated for all dogs living in endemic areas. The American Heartworm Society recommends year-round administration of an HW preventive drug to prevent HWD, increase compliance, and control pathogenic and/or zoonotic parasites. The time of year in which infection can occur is limited in many geographic areas because sustained warm and moist conditions are necessary for transmission of the disease. Transmission usually occurs only during a few months in the most northern parts of the United States and Canada, and generally in fewer than 6 months per year north of the Virginia–North Carolina border; however, local microclimates may allow larval development in mosquitoes for a much longer period. Year-round transmission is likely in the southern continental United States. Although

monthly preventive therapy may be most important only during June through November in the majority of the United States, continuous chemoprophylaxis throughout the year may be more practical, not only for animals living in locations where transmission is likely during more than half the year but also for those that travel to warmer regions. If seasonal prophylaxis is elected for financial or other reasons, prevention should begin 1 month before the anticipated HW transmission season and continue for 6 months after the season's end. Puppies should begin HW prevention as early as feasible after weaning, by 8 weeks of age at the latest. HW Ag and microfilaria testing is recommended before the initial dose of preventive medication in dogs 6 months of age and older. For all age dogs, if accidental lapse in HW preventive drug administration occurs, continuous prophylaxis should be restarted as soon as possible and Ag test repeated 6 months and 12 months after the lapse. Owner education about the potential seriousness of HW infection and need for consistent administration of preventive medication as directed is important.

Several macrocyclic lactone (macrolide) drugs are currently available for HWD prevention, including the avermectins (ivermectin, selamectin) and the milbemycins (milbemycin oxime, moxidectin). DEC is no longer commercially available; this HW preventative required daily dosing and could be given only to amicrofilaremic dogs. Macrocyclic lactones induce neuromuscular paralysis and death in nematode (and arthropod) parasites by interacting with membrane chloride channels. They are effective against third- and fourth-stage larvae during the 2 months after infection, as well as microfilariae and in some cases adult worms. Ivermectin, used continuously for more than 30 months, is effective against adult *D. immitis;* selamectin also has adulticidal effect with chronic administration. Retroactive preventive efficacy ("reachback") with these agents lasts at least 1 and possibly more than 2 months after a single dose. These agents are quite safe in mammals when used as directed; all commercially available macrocyclic lactones at preventive doses are safe in sensitive Collies and other P-glycoprotein-deficient dogs. Cases of clinical toxicity usually have been related to dosage miscalculation using a concentrated livestock preparation.

Macrocyclic lactones available for monthly oral administration include ivermectin (6-12 μg/kg; Heartgard, Iverhart, Tri-Heart) and milbemycin oxime (0.5-1 mg/kg; Interceptor, Sentinel, Trifexis). Products available for monthly topical administration (applied to the skin between the shoulder blades, at dose ranges of 6-12 mg/kg) include selamectin (Revolution) and moxidectin/imidacloprid (Advantage Multi); efficacy is not affected if bathing or swimming is delayed at least 2 hours after application. A slow-release formulation of moxidectin in a liposomal formulation (ProHeart 6) is given by SC injection; its effect lasts 6 months. Some of these agents are effective against other parasites at the doses used for HW prevention (e.g., hookworms with milbemycin; fleas, ear mites, and ticks with selamectin). These drugs are sometimes marketed in combination with other antiparasitic agents for broader protection against endoparasites and ectoparasites.

Lack of efficacy (LOE) of HW preventives has been reported, particularly in the Mississippi Delta. Reasons for LOE include owner noncompliance (failure to administer HW prevention as directed), patient factors (failure of ingestion or absorption of HW preventative), or true parasite resistance. In the vast majority of cases, LOE of macrocyclic lactones can be attributed to owner noncompliance, highlighting the importance of client education and monthly reminder systems. However, in a few cases, genetic polymorphisms have been documented that suggest true resistance of HW microfilariae or adult worms to various macrocyclic lactones. Despite these rare and isolated instances of HW resistance, efficacy of HW preventatives remains extremely high, and veterinarian efforts should be directed toward educating clients of the importance of monthly year-round prevention. Reports of LOE have not altered the American Heartworm Society's guidelines for diagnosis, prevention, or treatment of HWD.

Effective HW prevention, particularly in heavily endemic areas, also involves limiting mosquito exposure. This includes removal or treatment of standing water sources, use of mosquito repellants or traps, and keeping pets indoors during peak mosquito hours.

HEARTWORM DISEASE IN CATS

Cats are an atypical host of HWD. HWs mature more slowly, fewer numbers of infective larvae mature to adults, and the adult life span is shorter in cats. However, live worms can persist for 2 to 4 years. HW-infected cats generally have fewer than six adult worms in the RV and pulmonary arteries, and most cats with mature HW infection have only one or two worms. Nevertheless, in terms of host versus parasite biomass, a cat infected with two or three worms is still considered heavily infected, and even one adult worm can cause death. Unisex infection is common. Most cats with both male and female worms have no or only a brief period of microfilaremia, so cats rarely serve as important reservoirs of infection. Aberrant worm migration is also more common in cats than dogs and complicates necropsy confirmation of infection. Aberrant sites have included the brain, subcutaneous nodules, body cavities, and occasionally a systemic artery.

HW infection where the parasites never reach maturity because of the host's inflammatory response is thought to be much more common than mature HWD in cats. This HW "exposure" with early parasite destruction has been called "pulmonary larval dirofilariasis" or "heartworm-associated respiratory disease" (HARD).

Pathophysiology

The pathophysiologic changes associated with HW infection in cats can be considered to occur in two stages, with most infections only reaching the first. Approximately 3 to 4 months after infection, immature worms arrive in the

pulmonary arteries, and most die from an acute host inflammatory reaction involving pulmonary intravascular macrophage activation. These specialized phagocytic cells are located in the pulmonary capillary beds of cats but not dogs. Activation of these macrophages by the presence of the parasites leads to acute eosinophilic and neutrophilic inflammation, and proliferative lesions in the pulmonary arteries, as well as in lung tissue and bronchioles. Increased pulmonary vascular permeability can promote edema formation, and the more extensive alveolar type 2 (surfactant-producing) cell hyperplasia seen in cats (compared with dogs) also can interfere with alveolar O_2 exchange. This initial HARD phase can mimic signs of feline allergic airway disease (asthma) and can lead to acute respiratory distress in cats 3 to 9 months after infection. Although many cats recover, this phase is fatal in others. Sudden death can occur.

In cats that survive, the acute inflammation subsides and any remaining worms continue to mature. Vascular injury leads to myointimal proliferation, muscular hypertrophy, luminal narrowing, tortuosity, and thrombosis in affected pulmonary arteries. Because HWD in cats usually involves only a few worms and worm life span is relatively short, pulmonary arterial lesions tend to be localized; as a result, clinically relevant pulmonary hypertension, secondary RV hypertrophy, and right-sided CHF are uncommon in cats. In cats that do develop CHF, pleural effusion (modified transudate or chylous), ascites, or both can develop. As in dogs, the bronchopulmonary collateral circulation helps protect against pulmonary infarction.

The host often tolerates mature HWs, but dying and degenerating worms cause recrudescence of pulmonary inflammation and thromboembolism that can be fatal. Disease is most severe in the caudal lung lobes. Caudal lobar arterial obstruction can be caused by villous proliferation, thrombi, or dead HWs. Adult worms are more likely to obstruct the pulmonary arteries of cats (compared with dogs) by virtue of their relative size.

Vomiting is common in cats with HWD. The mechanism for this may involve central stimulation (of the chemoreceptor trigger zone) by inflammatory mediators. Antiinflammatory doses of a glucocorticoid often control this sign.

Clinical Features

Most reported cases have occurred in cats 3 to 6 years of age, although cats of any age are susceptible. Although outdoor lifestyle is a risk factor for HW exposure in cats, those living strictly indoors account for approximately 25% of feline HW infections. Unlike in dogs, haircoat length does appear to affect HW prevalence in cats; longhaired cats are infected less frequently than shorthaired cats. Many exposed cats could clear the infection without ever showing clinical signs. Some clinicians have noted an increase in feline HWD diagnosis during fall and winter, presumably after infection in the spring, but others have found fewer cases in the latter part of the year.

Clinical signs are variable and can be transient or nonspecific. Respiratory signs mimicking feline asthma occur in more than half of symptomatic cats, including tachypnea, paroxysmal cough, and/or increased respiratory effort. Other client complaints include lethargy, anorexia, weight loss, vomiting (including hemoptysis), syncope, neurologic signs, or sudden death. Vomiting, usually unrelated to eating, is common and may be the only sign in some infected cats. Severe clinical signs usually are associated with the arrival of immature worms in the pulmonary arteries (HARD) or with the death of one or more adult worms. The sudden onset of neurologic signs, with or without anorexia and lethargy, is common during aberrant worm migration. Such signs include seizures, dementia, apparent blindness, ataxia, circling, mydriasis, and hypersalivation. Only rarely do cardiopulmonary and neurologic signs coexist. Although HWs can cause marked pulmonary disease, some cats have no clinical signs.

Auscultation might reveal pulmonary wheezes or crackles, muffled lung sounds (either from pulmonary consolidation or pleural effusion), tachycardia, and sometimes a cardiac gallop sound or murmur. Pleural effusion or ascites caused by right-sided CHF, as well as syncope, are less common in cats than in dogs with HWD. Pneumothorax occurs rarely. There are sporadic reports of caval syndrome in cats.

Diagnosis

Definitive diagnosis is more difficult in cats than dogs. A combination of serologic testing, thoracic radiographs, and echocardiography is used. Microfilaria testing is only occasionally helpful.

TESTS FOR HEARTWORM DISEASE IN CATS

Serologic tests

Antigen tests. The HW Ag tests are highly specific in detecting adult (female) HW infection, but their sensitivity depends on the sex, age, and number of worms; therefore Ag tests often are negative in cats. Ag test results are negative during the first 5 months of infection, the time period when clinical signs from HARD are common. Ag tests can be variably positive at 6 to 7 months; infections with mature female worms should be detected after 7 months. Feline-specific Ag tests are reported to have increased sensitivity for detecting HWD in cats compared with canine tests. False-negative HW Ag test results are more likely in cats because worm burden is typically low; also, a longer time is required for cats to become Ag-positive. Up to 50% of cats with mature HWs could have a negative Ag test, and acute death and severe clinical signs can occur in Ag-negative cats. False-negative tests can occur because of Ag-Ab complexation, similar to dogs; heating the samples before testing can improve test accuracy in cases with a high index of suspicion for HWD. Occasionally, a positive Ag test result occurs, but no worms are found on postmortem examination. Spontaneous worm death, worms overlooked during pulmonary evaluation, and ectopic infection are likely reasons for this finding. Postmortem diagnosis is difficult if the worms are located in distal pulmonary arteries or aberrant sites.

Antibody tests. HW antibody (Ab) tests are used to screen for feline HW exposure. They are relatively sensitive but not specific for adult HWs. The Ab tests detect circulating Abs against a surface protein of male or female L_4 larvae. These Ab tests have minimal to no cross-reactivity with GI parasitic infections. Ab tests provide greater sensitivity than Ag tests because larvae of either sex can provoke a host immune response, and Ab tests become positive during the time frame when cats typically experience clinical signs of HARD. Serum Ab is detected as early as 60 days after infection, although different Ab tests vary in sensitivity to different larval stages. A positive Ab test indicates exposure to migrating larvae and adults, not necessarily the presence of adult HWs. It is estimated that approximately 50% of Ab-positive but Ag-negative cats develop HARD, whereas only 10% to 20% develop a mature HW infection. When an Ab test is positive, other evidence should be sought to support a diagnosis of mature HW infection (and thus true HWD). This can include a positive HW Ag test or findings consistent with HWD on thoracic radiography or echocardiography. The concentration of Ab does not appear to correlate well with an individual cat's worm burden nor with the severity of clinical disease or radiographic signs, although high Ab titers are associated with HW death. Antibodies persist for 6 to 12 months and decrease as HWs mature, such that a cat with an adult HW that has persisted over 12 months may be Ag-positive and Ab-negative. HW Abs are not protective against future HW infection.

False-negative Ab tests also occur fairly frequently (up to 10%-15% of cases). Therefore a negative HW Ab test suggests one of the following: (1) the cat has not been exposed to HWs, (2) the cat has a HW infection less than 60 days old, or (3) the cat produced a concentration of IgG Ab against the Ag used in making the test that is too low to be detected. When clinical findings suggest HWD or HARD but the Ab test is negative, serologic testing should be repeated using a different Ab test and an HW Ag test. Thoracic radiographs and an echocardiogram also are recommended. The Ab test could be repeated in a few months, as well.

Radiography

Radiographic findings that suggest HWD are similar to those seen in dogs, including pulmonary artery enlargement with or without visible tortuosity and pruning, RV or generalized cardiac enlargement, and diffuse or focal pulmonary bronchointerstitial infiltrates (Fig. 10.4). Pulmonary hyperinflation sometimes is evident, similar to cats with asthma. The pulmonary artery and right heart changes typically are more subtle in cats than in dogs. Radiographic abnormalities occur in approximately 50% of cats with HWD, and may not correlate with severity of clinical signs or results of serologic tests. Pulmonary artery distention may be greatest within the first 7 months of infection. Caudal lobar arteries are most frequently abnormal, and are seen best on the DV view. The right caudal lobar artery can be more prominent; however, a left caudal pulmonary artery greater than or equal to 1.6 times the width of the ninth rib at the ninth intercostal space reportedly is the most discriminating radiographic finding for separating HW-infected from noninfected cats. The main pulmonary artery segment is not usually visible on DV or ventrodorsal views in cats because its location is more medial than it is in dogs. Marked right heart enlargement is more likely when signs of right-sided CHF (e.g., pleural effusion) exist. Ascites, which is a rare manifestation of CHF secondary to the common feline cardiomyopathies, occurs in some cats with HWD.

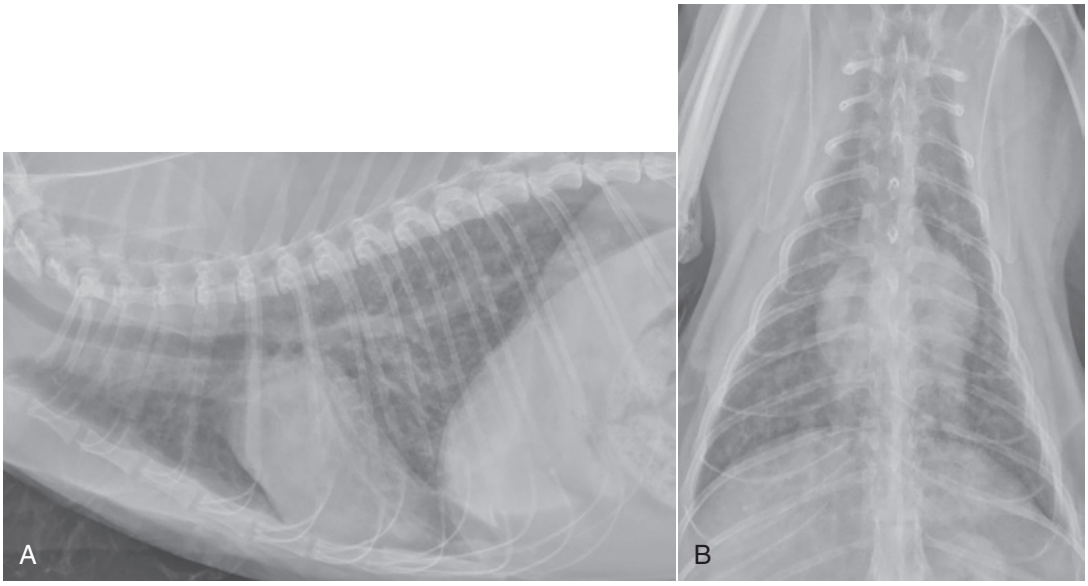

FIG 10.4
Lateral **(A)** and dorsoventral **(B)** radiographs from a cat with heartworm disease. There are interstitial infiltrates throughout the lung fields and enlarged pulmonary arteries seen on both views.

HW-associated pneumonitis and PTE result in pulmonary infiltrates. Focal perivascular and interstitial opacities are more common than diffuse infiltrates but are nonspecific. Radiographs tend to be normal in cats without clinical signs.

ECHOCARDIOGRAPHY

Echocardiographic findings can be normal unless worms are located in the heart, main pulmonary artery segment, or proximal left and right pulmonary arteries. Echocardiography is more sensitive for HW screening in cats versus dogs because worms are physically larger compared with the cat's body size; worms are therefore more likely to extend into the main PA or RV from their preferred location in the distal PAs. On two-dimensional echocardiograms, HWs appear as bright, double-line (parallel) echodensities; they are visible in up to 75% of infected cats. Higher numbers of worms increase the likelihood of identification with echocardiography. Because worms are seen more often in the pulmonary arteries than in right heart chambers, an index of suspicion and careful interrogation of these structures are important.

ELECTROCARDIOGRAPHY

ECG findings are often normal. Severely affected cats with HW-induced CHF can have changes suggesting RV enlargement and axis deviation. Arrhythmias appear to be uncommon, although advanced pulmonary arterial disease and CHF are more likely to cause ventricular tachyarrhythmias.

OTHER TESTS

Between one and two thirds of infected cats have peripheral eosinophilia, usually from 4 to 7 months after infection. Otherwise the eosinophil count often is normal; basophilia is uncommon. About one third of the cases have mild nonregenerative anemia. Advanced pulmonary arterial disease and thromboembolism might be accompanied by neutrophilia (sometimes with a left shift), monocytosis, thrombocytopenia, or DIC. Hyperglobulinemia, the most common biochemical abnormality, occurs inconsistently. The prevalence of glomerulopathies in cats with HWD is unknown, but it does not appear to be high.

Tracheal wash or bronchoalveolar lavage specimens can show an eosinophilic exudate that suggests allergic or parasitic disease, similar to that found with feline asthma or pulmonary parasites. This finding usually occurs between 4 and 8 months after infection. Later in the disease, tracheal wash findings can be unremarkable or indicate nonspecific chronic inflammation. Pleural effusion resulting from HW-induced CHF generally is a modified transudate, although chylothorax occasionally develops.

At around 6.5 to 7 months after infection, a transient (1-2 months in duration), low-grade microfilaremia occurs in about half of cats with mature infections. Therefore microfilaria concentration tests usually are negative. Nevertheless, a concentration test could still prove valuable in some individual cats. Between 3 and 5 mL, rather than 1 mL, of blood should be used to increase the probability of detecting microfilariae.

Treatment of Cats With Heartworm Disease

MEDICAL THERAPY AND COMPLICATIONS

Adulticide therapy is not recommended in most cases because the likelihood of severe complications in this species is high. Also, spontaneous cure can occur in cats because of the shorter HW life span, and cats do not act as reservoirs for HWD transmission to other animals.

The recommended approach for infected cats is to initiate monthly HW preventative (if not already begun) and to use prednisone as needed for respiratory signs and radiographically evident pulmonary interstitial infiltrates. Clinical utility of doxycycline in cats with HWD is not yet established; however, given the effects of doxycycline on HW viability and reproductive capacity in dogs, it is reasonable to treat cats with doxycycline in the same manner (10 mg/kg PO q12h for 4 weeks beginning at time of diagnosis). If cats develop GI adverse effects at this dose, the dose can be lowered to 5 mg/kg q12h. Serologic tests (for HW Ab and Ag in tandem) are obtained every 6 to 12 months to monitor infection status. Ag-positive cats usually become negative within 4 to 5 months of worm death; Ab tests can remain positive at least 6 to 12 months. Serial thoracic radiographs and echocardiograms also can be useful for monitoring cats that have had abnormal findings. Interstitial pulmonary infiltrates usually respond to prednisone (e.g., 1-2 mg/kg PO q24h, reduced gradually over 2 weeks to 0.5 mg/kg q48h, then discontinued after 2 more weeks). Prednisone therapy could be repeated periodically if respiratory signs recur.

The possibility of severe respiratory distress and death is always present, especially after worm death. PTE is more likely to produce a fatal outcome in cats than dogs. Clinical findings with PTE include fever, cough, dyspnea, hemoptysis, pallor, pulmonary crackles, tachycardia, and hypotension. Radiographic signs include poorly defined, rounded or wedge-shaped interstitial opacities that obscure associated pulmonary vessels. Alveolar infiltrates are seen in some cases. Cats with acute disease are given supportive care, including supplemental oxygen, a glucocorticoid (dexamethasone at 0.2 mg/kg IM or IV), a bronchodilator (such as terbutaline), and fluid support as needed. Sildenafil (1-2 mg/kg PO q8-12h) is indicated if severe PAH is documented. Antiplatelet drugs (clopidogrel or aspirin) or anticoagulants (heparins) can be considered in cats with PTE. Diuretics are not indicated unless right-sided CHF is present.

Right-sided CHF develops occasionally in cats with severe pulmonary arterial disease and PAH. Dyspnea (caused by pleural effusion) and jugular venous distention or pulsation are common. Radiographic and ECG findings usually suggest RV enlargement. Therapy is directed at decreasing pulmonary arterial pressure and controlling the signs of heart failure. This includes thoracocentesis as needed, cage rest, sildenafil, furosemide, an ACEI, and pimobendan. The cat's clinical progress and clinicopathologic abnormalities are used to guide supportive therapy.

SURGICAL THERAPY

Caval syndrome occurs rarely in cats. Successful removal of adult worms through a jugular venotomy is possible, as in dogs. Prior echocardiographic confirmation of worm location is important. A right jugular venotomy can be used to reach worms in the RA, vena cava, and possibly the RV with small alligator forceps, endoscopic grasping or basket retrieval forceps, or another device. Worm removal via thoracotomy and right atriotomy, ventriculotomy, or pulmonary arteriotomy also has been done successfully. A potentially fatal anaphylactic reaction associated with worm breakage could occur during such procedures. Presurgical treatment with a glucocorticoid and antihistamine has been suggested.

MICROFILARICIDE THERAPY

Microfilaricide therapy is rarely necessary because microfilaremia is brief. The combination of monthly HW preventative and doxycycline are sufficient to kill any microfilaria present.

HEARTWORM PREVENTION

HW prophylaxis is recommended for cats in endemic areas, including those living "indoors" only. Monthly preventative should be initiated 1 month before the beginning of regional HW transmission season and continued until at least 1 month after the season has ended. However, year-round prevention has advantages, including improved compliance, retroactive activity ("reachback") in case of missed doses, and activity against GI parasites. Oral HW prevention products for cats include ivermectin (Heartgard for Cats) and milbemycin oxime (Interceptor Flavor Tabs for Cats); topical options include selamectin (Revolution) and a moxidectin/imidacloprid combination (Advantage Multi for Cats). Selamectin is used at the same dose as for dogs (6 mg/kg, topically); it is also useful for controlling fleas and ear mites, as well as hookworm and roundworm infections in cats. Ivermectin is administered orally at 24 μg/kg monthly (four times the dose used in dogs). The minimum recommended dose for oral milbemycin is 2 mg/kg (about twice the dose used in dogs). Moxidectin is used at 1 mg/kg, applied topically. All these agents are safe in kittens 6 weeks or older, and all preventative agents are safe for use in seropositive cats. Serologic testing before preventive use can be useful for purposes of identifying local HW prevalence, as well as individual cat risk for HARD or adult HWD. However, the usefulness of serologic testing for individual cats before initiating monthly preventative is less than dogs.

ANGIOSTRONGYLOSIS

Infection with metastrongylid nematode *Angiostrongylus vasorum* in dogs, also known as the "French heartworm," can cause pulmonary vascular disease similar to dirofilariasis. Angiostrongylosis is regionally endemic in parts of Western and Northern Europe and the United Kingdom, as well as in Turkey, Brazil, Colombia, Uganda, and the maritime provinces of Canada. The natural definitive host of *Angiostrongylus vasorum* is the wild fox. Similar to dirofilariasis, domestic dogs can serve as a definitive host and shed L_1 larvae in feces; worms can mature in experimentally infected cats, but no larvae are produced. The life cycle requires a gastropod intermediate host (marine or freshwater snail or slug). L_1 larvae are ingested by the gastropod host during feeding on fox or dog feces and undergo two molting stages within the snail or slug to develop into infective L_3 larvae. Dogs become infected by eating either the gastropod or a paratenic host (frog). Once ingested, L_3 larvae penetrate through the intestinal mucosa and migrate to abdominal lymph nodes. Immature worms then travel via the portal circulation to the pulmonary arteries, where they mature, mate, and produce eggs. Immature worms reach the pulmonary arteries by approximately 30 to 35 days postinfection. Eggs lodge and develop in pulmonary capillaries; when L_1 larvae hatch, they break into airspaces and are coughed up and swallowed to pass in the feces of infected hosts. The overall prepatent period for *A. vasorum* is approximately 5 to 8 weeks. Life span of the adult worms is at least 2 years and can last the lifetime of the canine host, leading to lifelong intermittent shedding of larvae in feces.

Pathophysiologic consequences of angiostrongylosis are similar to HWD in dogs. Worms cause an inflammatory response in the pulmonary arteries that can cause pneumonitis, interstitial pneumonia, or pulmonary granulomatosis. Pulmonary vascular lesions include villous arteritis and intimal proliferation. Incidence of PTE and PAH appear to be less than in canine HWD, possibly due to recruitment of pulmonary arteriovenous shunts. Only approximately 15% of dogs diagnosed with *A. vasorum* in the United Kingdom have moderate to severe PAH; right-sided CHF is therefore a rare complication. Coagulopathies such as thrombocytopenia and DIC can occur, and hemorrhage is a relatively frequent complication compared with HWD. Aberrant migration of adult worms has been reported, including to sites such as the eye, left heart, and femoral artery. Aberrant migration of L_1 larvae is common, including to the brain, spinal cord, eye, kidney, liver, or other abdominal organs.

Clinical presentation of dogs with angiostrongylosis is variable and based on disease severity but generally mimics HWD. Dogs could present for cough, dyspnea, anorexia, exercise intolerance, or syncope. Sudden death has been reported. Coagulopathic (hemorrhagic) presentations are common as well, including mucosal or subcutaneous hemorrhage, melena, or hemoptysis. Common clinicopathologic findings are similar to those in dogs with HWD, and include eosinophilia, neutrophilia, thrombocytopenia, mild anemia, and hyperglobulinemia. Prothrombin time (PT) and activated partial thromboplastin time (APTT) are often prolonged. Thoracic radiographs typically reveal a patchy alveolar-interstitial pattern in peripheral lung areas and, occasionally, mild pleural effusion; pulmonary vascular lesions (enlarged and tortuous pulmonary arteries) are less

common. Echocardiography can be used to identify right heart remodeling and quantify PAH, if present.

Definitive diagnosis of *A. vasorum* infection involves visualization of L_1 larvae in feces of an infected dog. The Baermann technique is more sensitive than direct fecal smear. However, fecal shedding can be intermittent; serial examination is recommended, and negative fecal examinations do not rule out angiostrongylosis. Larvae also can be identified by airway cytology, such as with bronchoalveolar lavage. *A. vasorum* larvae can be differentiated from other nematode larvae by tail morphology.

Recently, serologic testing has become available for *A. vasorum*. An ELISA is available for detection of an Ag produced by adult female worms, similar to the HW Ag test. The test becomes positive approximately 5 to 9 weeks postinfection, and has high sensitivity and specificity (minimal cross-reaction with other parasites, including *D. immitis*). A cage-side test also is available (Angio Detect, IDEXX Laboratories). This test is highly specific (100%) although less sensitive (85%) and becomes positive later in the disease process (9-11 weeks).

Treatment options for adult worm infections include fenbendazole (25-50 mg/kg PO q24h for 7-21 days), milbemycin oxime (0.5 mg/kg PO once weekly for 4 weeks), or moxidectin (single topical dose of 2.5 mg/kg). Additional supportive care could include glucocorticoids for pulmonary inflammation, exercise restriction, oxygen therapy, and blood product transfusions in cases of coagulopathy and hemorrhage. Several macrolide anthelmintics have shown efficacy in prevention of *A. vasorum* infections, although to date none are currently licensed for this practice. Imidocloprid/moxidectin (Advantage Multi, Advocate); spinosad/milbemycin oxime (Trifexis, Milbemax); or afoxolaner/milbemycin oxime (NexGard) can be considered as monthly preventatives in endemic regions. Additional prevention strategies include prompt disposal of dog feces, and reducing contact with intermediate hosts (snails and slugs) when possible. Standard practices for screening, treatment, and prevention of this emerging parasite have yet to be established.

CHAPTER 11

Systemic Arterial Hypertension

GENERAL CONSIDERATIONS

Systemic hypertension refers to the sustained elevation of systemic arterial blood pressure (BP). Over time, marked increase in arterial BP can cause serious clinical consequences. Multiple studies have attempted to define BP levels in normal dogs and cats; the largest studies suggest average systolic BP of approximately 130 mm Hg in dogs and 120 mm Hg in cats. However, various factors influence values obtained for systolic, diastolic, and mean arterial BP in healthy, as well as diseased, animals. Variations related to age, sex, reproductive status, and other factors might contribute minimally, whereas breed differences in normal values can be more pronounced. For example, BP can be 10 to 20 mm Hg higher in normal Greyhounds and some other sighthounds compared with mixed-breed dogs, although this could reflect an increased and sustained level of anxiety in the hospital setting ("white-coat" effect). Lesser differences in normal BPs have been reported for some other dog breeds as well. Variation in measured BP could be related to technique (direct and various noninvasive methods) and patient anxiety. Use of a consistent protocol for BP measurement in the clinic can help reduce variability related to environmental factors and technique. The demarcation between acceptable and "abnormally high" arterial BP is not clear-cut. Furthermore, although some dogs and cats clearly have clinical disease caused by hypertension, many with "abnormally high" BP have no evidence of related pathology. In addition, systolic BP can exceed 180 mm Hg in some stressed normal animals. Repeated BP measurements over time along with careful clinical evaluation are indicated when considering a diagnosis of hypertension.

Classification of abnormal BP in dogs and cats is based on risk for damage to so-called *target organs* (see p. 212). Animals with BP less than 150/95 mm Hg (systolic/diastolic) have minimal risk (Risk Category I). In general, this level is the therapeutic goal for patients receiving antihypertensive medications. Repeatable BP measurements of 150 to 159 mm Hg systolic and 95 to 99 mm Hg diastolic constitute mild hypertension, as well as mild risk for future target organ disease (Category II). Moderate hypertension (Category III) is associated with BPs between 160 and 179 mm Hg systolic and 100 and 119 mm Hg diastolic. Arterial pressures greater than 180/120 mm Hg indicate severe hypertension, with severe risk for target organ damage (Category IV). An additional 20 mm Hg is allowed for specific breed differences (e.g., for sighthounds).

Animals with mild hypertension (Category II) usually are not given antihypertensive therapy, although any underlying disease should be addressed. Some surveys of normal animals show BPs in this range, and it is likely that anxiety ("white-coat" hypertension) plays a role in mild BP elevation. Animals with moderate hypertension (Category III) could benefit from specific antihypertensive therapy, especially if there is evidence for target organ damage or treatment for underlying disease does not normalize BP. However, animals with BP closer to 160 mm Hg or where the white-coat effect is thought likely usually are not treated unless the clinician's assessment of the case dictates otherwise. Patients with severe hypertension (Category IV) should be treated to prevent or reduce target-organ damage. When possible, BP measurement is repeated to confirm presence of severe hypertension. On occasion, marked patient anxiety or technical error in BP recording can produce this degree of BP elevation, although this is uncommon. Some animals require urgent antihypertensive therapy because of rapidly progressing signs (see p. 213). When antihypertensive therapy is used, close monitoring for efficacy, adverse effects, and deterioration of underlying conditions is warranted. In all cases, predisposing disease should be treated, as possible.

Etiology

Hypertension in dogs and cats usually is associated with other diseases (Box 11.1) rather than being a primary condition (idiopathic or essential hypertension). The most common associations in cats are chronic kidney disease (CKD) and hyperthyroidism. Reported prevalence of hypertension in these disease conditions ranges from 25% to 75%. In dogs, the most common conditions associated with hypertension are renal disease (especially glomerular disease) and hyperadrenocorticism, with prevalence of hypertension reported to be up to 30% to 80% for each disease. Diabetes

BOX 11.1

Diseases Associated With Hypertension

Documented or Suspected Causes in Dogs and Cats

Renal disease (especially glomerular)
Hyperadrenocorticism
Hyperthyroidism
Pheochromocytoma
Diabetes mellitus
Hyperaldosteronism
Intracranial lesions (↑ intracranial pressure)
High-salt diet (?)
Obesity

Other Diseases Associated With Hypertension in People*

Acromegaly
Inappropriate antidiuretic hormone secretion
Hyperviscosity/erythrocytosis
Renin-secreting tumors
Hypercalcemia
Hypothyroidism with atherosclerosis
Hyperestrogenism
Coarctation of the aorta
Pregnancy
Central nervous system disease

*Essential (idiopathic) hypertension is often associated with family history, high salt intake, smoking, or obesity.

mellitus also can be associated with higher BP in dogs. Other less common diseases associated with high prevalence of systemic hypertension include pheochromocytoma and primary hyperaldosteronism (Conn's syndrome). Because of the increased risk for hypertension in patients with such conditions, BP should be measured when the disease is diagnosed and periodically thereafter. Similarly, hypertension discovered during a routine examination could be an early marker of underlying diseases associated with hypertension, so additional testing is indicated. Certain drugs such as glucocorticoids, mineralocorticoids, nonsteroidal antiinflammatory agents, phenylpropanolamine, sodium chloride, and even topical ocular phenylephrine can increase BP. Inherited idiopathic (essential) hypertension has been documented in dogs and cats, although it is uncommon. Idiopathic hypertension is considered a diagnosis of exclusion. Primary cardiac disease is not a recognized cause of systemic hypertension in dogs and cats.

Pathophysiology

BP is the product of cardiac output and systemic vascular resistance. BP is increased by conditions that raise cardiac output (by increasing heart rate, stroke volume, and/or blood volume) or by those that increase peripheral vascular resistance. Arterial BP is normally maintained within narrow bounds by the actions of the autonomic nervous system (e.g., via arterial baroreceptors); various hormonal systems (e.g., the renin-angiotensin system [RAAS], aldosterone, vasopressin/antidiuretic hormone, and natriuretic peptides); blood volume regulation by the kidney; and other factors.

Modulation of these systems by various disease conditions can lead to chronic elevation of arterial BP. For example, hypertension can result from increased sympathetic activity or responsiveness (e.g., with hyperthyroidism or hyperadrenocorticism), increased catecholamine production (e.g., with pheochromocytoma), or volume expansion caused by increased sodium retention (e.g., decreased glomerular filtration and reduced sodium excretion in renal failure, hyperaldosteronism, or hyperadrenocorticism). RAAS activation, with subsequent salt and water retention and vasoconstriction, can result from intrarenal disease (e.g., glomerulonephritis, chronic interstitial nephritis), enhanced production of angiotensinogen (e.g., hyperadrenocorticism), or extrarenal diseases that increase sympathetic nervous activity or interfere with renal perfusion (e.g., hyperthyroidism, renal artery obstruction). Impaired production of vasodilator substances (e.g., prostaglandins, kallikreins) and effects related to secondary hyperparathyroidism could be involved in chronic renal failure.

High perfusion pressure can damage capillary beds. In most tissues, capillary pressure is regulated by vasoconstriction of arterioles that feed the capillaries, although this control could be inadequate because of underlying organ disease. The continued arteriolar constriction secondary to chronic hypertension leads to hypertrophy and other vascular remodeling changes that can further increase vascular resistance. These structural changes and vascular spasm can cause capillary hypoxia, tissue damage, hemorrhage, and infarction, which can lead to organ dysfunction (Box 11.2).

Organs that are particularly vulnerable to damage from chronic hypertension are the eye, kidney, heart, and brain. These structures often are referred to as *target organs* or *end organs* damaged by systemic hypertension. In the eye, hypertension often causes focal perivascular edema, hemorrhage, and ischemia, especially in the retina and choroid layers. Bullous or total retinal detachment is common. Hyphema, vitreal hemorrhage, and optic neuropathy also can occur. Renal glomerular hypertension occurs when afferent arteriolar autoregulation is disrupted. The resulting glomerular hyperfiltration can lead to glomerulosclerosis, renal tubular degeneration, and fibrosis. These changes contribute to deterioration of renal function and increases in vascular resistance, thus chronic hypertension tends to perpetuate itself. Proteinuria is an important manifestation of renal damage and has been associated experimentally with severity of hypertension in cats and dogs. Reduction in proteinuria can indicate that therapeutic benefit is being achieved, especially in cats. BP is not directly correlated with serum creatinine concentrations, and hypertension can develop before azotemia, particularly in glomerular disease. Increased systemic arterial pressure and vascular resistance increase the afterload stress on the heart and stimulate left ventricular (LV) hypertrophy and dilation of the ascending aorta. Increased cerebral vascular pressure can promote edema formation, raise intracranial pressure, and cause hemorrhage.

BOX 11.2

Complications of Hypertension

Ocular

Retinopathy (edema, vascular tortuosity, hemorrhage, focal ischemia, atrophy)
Choroidopathy (edema, vascular tortuosity, hemorrhage, focal ischemia)
Retinal detachment (bullous or total)
Hemorrhage (retinal, vitreal, hyphema)
Papilledema
Blindness
Glaucoma
Secondary corneal ulcers

Neurologic

Cerebral edema, ↑ intracranial pressure
Hypertensive encephalopathy (lethargy, behavioral changes)
Cerebrovascular accident (focal ischemia, hemorrhage)
Seizures
Other acute neurologic deficits

Renal

Glomerulosclerosis/proliferative glomerulitis
Renal tubular degeneration and fibrosis
Progression of chronic kidney disease
Worsening proteinuria
Polyuria/polydipsia

Cardiac

Left ventricular hypertrophy
Murmur or gallop sound
Aortic dilation
Aortic aneurysm or dissection (rare)
Left-sided congestive heart failure (rare)

Other

Epistaxis

Clinical Features

Clinically recognized systemic hypertension usually occurs in middle-aged to older dogs and cats, presumably because of the associated disease conditions. Cats with severe end-organ disease secondary to hypertension tend to be geriatric. Signs of hypertension relate either to underlying disease or end-organ damage caused by the hypertension itself.

Ocular signs are the most common presenting issue, especially sudden blindness, which usually results from acute retinal hemorrhage or detachment. Although the retina may reattach, sight often does not return. Ocular fundic changes associated with hypertension include bullous to complete effusive retinal detachment, intraretinal edema, and hemorrhage. Vascular tortuosity, hyperreflective scars, retinal atrophy, papilledema, and perivasculitis are other signs of hypertensive retinopathy. Hemorrhage in the anterior or posterior chamber or sclera, closed-angle glaucoma, and corneal ulceration can occur also. Ocular damage is more likely at systolic BPs greater than 180 mm Hg, although it can develop at lower pressures.

Another common complaint is polyuria and polydipsia, which can be associated with renal disease, hyperadrenocorticism (in dogs), or hyperthyroidism (in cats). Furthermore, hypertension itself causes a so-called pressure diuresis. Hypertensive encephalopathy can result from cerebral edema or hemorrhage and can cause lethargy, seizures, abnormal mentation, collapse, or other neurologic or nonspecific signs. Paresis and other focal defects can occur as a result of cerebrovascular accident (stroke) caused by hypertensive arteriolar spasm or hemorrhage. Epistaxis can result from vascular rupture in the nasal mucosa. A soft, systolic cardiac murmur is heard on auscultation in many animals with hypertension. A gallop sound might also be present, especially in cats. Clinical left-sided congestive heart failure is uncommon.

Diagnosis

BP measurements are indicated in the following patient populations: (1) patients with suspected target organ damage (such as retinal detachment or LV hypertrophy); (2) patients diagnosed with a disease known to be associated with systemic hypertension (such as hyperthyroidism, protein losing nephropathy, or CKD); or (3) as a screening test in older dogs and cats. BP measurement at age 5 to 7 can be useful to establish the patient's baseline values. Annual BP measurement is recommended in dogs and cats beginning at ~8 years of age given the increased prevalence of renal and other predisposing diseases with age. A diagnosis of systemic hypertension should be confirmed by measuring BP multiple times and (ideally) on different days. A fundic examination, as well as routine laboratory database (complete blood count [CBC]; serum biochemical profile; and urinalysis with a urine protein-to-creatinine ratio [UPC]), is indicated in all hypertensive patients. Not all hypertensive patients with underlying CKD are azotemic. Other tests are done as needed to rule out possible underlying diseases or complications. These might include various endocrine tests, thoracic and abdominal radiographs, echocardiography, abdominal ultrasound, and serologic tests.

Thoracic radiographs can show some degree of cardiomegaly in patients with chronic hypertension. Cats especially can have a prominent aortic arch and an undulating (wavy) appearance to the thoracic aorta, although these findings might be present in normal geriatric cats and are not exclusive to hypertension.

LV hypertrophy is the classic echocardiographic finding in animals with systemic hypertension. However, the degree of LV hypertrophy is generally mild. Mean LV wall thickness measurements in hypertensive cats are higher than in normal cats but often remain within reference range. LV wall and septal hypertrophy can be symmetric or asymmetric. Proximal aortic dilation is another echocardiographic finding in some animals with systemic hypertension. A ratio of proximal ascending aortic diameter–to–aortic valve annulus diameter of greater than or equal to 1.25 is a common finding in hypertensive cats. Other echocardiographic findings could

include mild LA enlargement and sometimes mild mitral or aortic regurgitation. Systolic BP could be estimated during an echocardiographic examination in animals with mitral valve insufficiency by measuring the peak velocity of the mitral regurgitation jet using continuous-wave Doppler imaging; the modified Bernoulli equation (see p. 30) then is used to estimate the pressure gradient between the LV and LA. However, this method can underestimate BP and correlates only moderately with indirect BP measurements.

BLOOD PRESSURE MEASUREMENT

Several methods can be used to measure systemic arterial BP in the clinic. High pressures should be confirmed by repeated measurement sessions before a diagnosis of hypertension is made. Anxiety related to the clinical setting can falsely increase BP in some animals (i.e., the white-coat effect), and BP measurements can decrease with acclimation. Using as little restraint as possible in a quiet environment and allowing time (e.g., 5-15 minutes) for acclimatization is best for awake animals. It is often helpful to have the owner present. Use of consistent technique and cuff sizing (for indirect methods) is important. The technical skill and experience of the individual who obtains the BP measurements are also highly relevant to achieving consistent results.

Direct Blood Pressure Measurement

Arterial pressure can be measured directly by a needle or catheter placed into an artery and connected to a pressure transducer. Direct arterial pressure measurement is considered the gold standard, but it requires greater technical skill; moreover, in awake animals the physical restraint and discomfort associated with arterial puncture may falsely increase BP. Direct arterial pressure measurement is more accurate than indirect methods in hypotensive animals.

For arterial pressure monitoring over a period of time, an indwelling arterial catheter is often the best approach. The dorsal metatarsal artery is commonly used for this technique. An electronic pressure monitor provides continuous measurement of systolic and diastolic pressures and calculated mean pressure. With fluid-filled systems, the pressure transducer must be placed at the level of the patient's right atrium (RA) to prevent a false increase or decrease of the measured pressure related to the effects of gravity on the fluid within the connecting tubing.

When occasional BP measurement is necessary, a small-gauge needle attached directly to a pressure transducer may be used to puncture the dorsal metatarsal or femoral artery. To prevent hematoma formation, direct pressure should be applied to the arterial puncture site for several minutes after removing the catheter or needle used for BP measurement.

Indirect Blood Pressure Measurement

Several noninvasive methods are available to measure BP indirectly. These techniques involve the use of an inflatable cuff placed around a limb to occlude blood flow, usually over the brachial, radial, or saphenous artery, or the median caudal artery of the tail. Controlled release of cuff pressure is monitored to detect the return of blood flow. A standardized protocol for noninvasive BP measurement in dogs and cats has been described. The patient is gently restrained in sternal or lateral recumbency, with the cuff's vertical position close to the level of the RA during BP measurement. In lateral recumbency, the nondependent limb is used for BP measurements. A sitting position is not recommended due to poor repeatability and systematic overestimation of BP.

Doppler ultrasonic flow detection and oscillometric methods are used most often. Both techniques produce measurements that correlate somewhat well with direct BP measurement but are not exactly predictive of it; falsely high or low values occur. Calculating the average of several measurements (generally five to seven) in succession is recommended to increase accuracy. Often the first reading, or the highest and lowest, is discarded. If there is more than 20% variability in systolic pressure readings among successive measurements, the cuff placement or limb may need to be changed to obtain more consistent readings. If the accuracy of the BP measurements is in doubt, the process should be repeated at a later time, when the patient (hopefully) is better acclimated and more relaxed. Indirect methods are most reliable in normotensive and hypertensive animals. The BP device used should be calibrated semiannually to maximize accuracy.

Other methods such as auscultation and arterial palpation are not recommended for estimating BP. The auscultatory method (used to detect Korotkoff sounds in people) is technically impractical because of the limb conformation of dogs and cats. Direct arterial palpation is not reliable for estimating BP because pulse strength depends on the pulse pressure (systolic minus diastolic arterial pressure), not the absolute level of systolic or mean pressure. Pulse strength is also influenced by body conformation and other factors.

Cuff size and placement. A wide selection of cuff sizes, including human pediatric- and infant-size cuffs, is available for indirect BP measurement in dogs and cats. The cuff must be the correct size for the patient. The width of the cuff should be about 40% of the circumference of the extremity it surrounds for dogs (30%-40% for cats). The length of the inflatable balloon (bladder) within the cuff should cover at least 60% of this circumference. Cuffs that are too large can cause falsely low BP readings, whereas cuffs that are too small can cause falsely high BP readings. Some of the cuff inflation pressure goes toward tissue compression. Cuffs that are too narrow are more affected by this phenomenon and produce falsely increased pressure readings; cuffs that are too wide may underestimate BP. Intra-individual differences in BP between forelimb and hindlimb measurement sites have been reported. For these reasons, the cuff size and specific placement site used should be noted in the animal's record for consistency when repeating BP measurements over time. The cuff bladder should be centered over the target artery. Common cuff locations are midway between the elbow and carpus, in the tibial region, or at the base of the tail; skeletal prominences are avoided. The cuff should encircle the limb snugly without being excessively tight. Tape (not just Velcro on the cuff) can be used to secure the cuff in position.

Oscillometric method. The indirect oscillometric method uses an automated system for detecting and processing cuff pressure oscillation signals. With these systems, the flow occlusion cuff is inflated to a pressure above the systolic pressure and then slowly deflated in small pressure decrements. The microprocessor measures and averages the resulting pressure oscillations characteristic of systolic, diastolic, and/or mean pressures (depending on the system). Accurate results with oscillometric methods depend on careful adherence to the directions for use and an immobile subject. Because muscle contraction can produce oscillations, the limb used should not be bearing weight. At least five readings should be obtained; the lowest and highest are discarded, and the remaining measurements are averaged. The oscillometric method may be difficult to use effectively in small dogs and cats; poor agreement in systolic BP values (specifically underestimation) compared with direct measurements has been reported with various oscillometric devices.

Doppler ultrasonic method. This method employs the frequency change between emitted ultrasound and returning echoes (from moving blood cells or vessel wall) to detect blood flow in a superficial artery. This frequency change, the so-called Doppler shift, is converted to an audible signal. One system commonly used in animals is designed to determine systolic pressure by detecting blood cell flow (Ultrasonic Doppler Flow Detector, Model 811, Parks Medical Electronics, Inc, Aloha, OR).

Effective locations for pressure measurement include the dorsal metatarsal, palmar common digital (forelimb), and median caudal (tail) arteries. The probe is placed distal to the occluding cuff. A small area of hair is clipped over the artery for probe placement. Ultrasonic coupling gel is applied to the flat Doppler flow probe to obtain air-free contact with the skin. The probe is positioned so that a clear flow signal is heard but not held so tightly that it occludes flow. The probe must remain still to minimize noise; it can be taped in place. A low-volume setting on the Doppler unit or a headset is used to minimize patient anxiety caused by loud audio signals.

The flow-occluding cuff is attached to a sphygmomanometer and inflated to about 20 to 30 mm Hg above the point at which arterial flow ceases and no audible signals are heard. The cuff is slowly deflated (by a few mm Hg per second). During deflation, characteristic pulsatile flow signals from blood cell (or arterial wall) motion return during systole. The systolic pressure is the pressure at which blood flow first recurs (indicated by brief swishing sounds). A change in the flow sound from short and pulsatile to a longer, more continuous swishing often can be detected as cuff pressure diminishes; the pressure at which this change occurs approximates the diastolic pressure. However, Doppler estimation of diastolic BP is less accurate because of its subjective nature. The change in flow sound is not always detectable, especially with small or stiff vessels. As with the oscillometric method, it may be difficult to obtain measurements in small or hypotensive animals with the Doppler method. Patient movement also interferes with measurement. Overall, Doppler is considered the preferred method for systolic BP measurement in cats and small dogs.

Treatment and Prognosis

Antihypertensive therapy definitely is indicated for animals with severe hypertension, animals with clinical signs presumed to be caused by hypertension, and animals with evidence of target-organ damage. It is unclear whether all asymptomatic dogs and cats with moderate hypertension (e.g., repeatable systolic pressures of 160-180 mm Hg) benefit from specific antihypertensive treatment. Nevertheless, patients with high BP that persists after treatment for the primary disease should generally be treated. The goal of therapy is to reduce the BP to below 150/95 mm Hg. The expense and time commitment required for long-term (usually life-long) antihypertensive therapy and monitoring, as well as the potential for adverse medication effects, are considerations and should be explained clearly to the owner. Although some cases constitute hypertensive emergencies that require immediate therapy and intensive monitoring (discussed in more detail later), most hypertensive animals can be managed more conservatively (Box 11.3). Gradual reduction in BP could be safer in patients with long-standing hypertension. Chronically high BP leads to vascular adaptations in the cerebral autoregulatory process; if BP is suddenly reduced, cerebral perfusion may be adversely affected.

Several drugs are used as antihypertensive agents in dogs and cats (Table 11.1). Usually one drug is administered initially, at a low to moderate dose, if there is not a hypertensive crisis; then the BP is rechecked in 7 to 10 days to assess efficacy. The dose of the initial agent can be increased within recommended guidelines, if needed; if this is not sufficiently effective a second antihypertensive agent can be added. The drugs used most often are angiotensin-converting enzyme inhibitors (ACEIs), the Ca^{++}-blocker amlodipine, and (less commonly) the β-adrenergic blocker atenolol. Therapy with a single agent is effective in some cases, but combination therapy may be necessary for adequate BP control in others. An ACEI is recommended as the antihypertensive drug of first choice for all dogs. If the ACEI does not provide adequate BP reduction even at maximum recommended dosage, amlodipine is added. Amlodipine is not recommended as the sole antihypertensive therapy in dogs, because amlodipine administration in dogs activates the RAAS (and thus requires concurrent ACEI). In cats, amlodipine often is recommended as the initial antihypertensive drug, unless hyperthyroidism is the underlying cause, in which case atenolol could be considered first or in combination with amlodipine. However, an ACEI also has been recommended as initial therapy for cats with renal disease and proteinuria as the suspected underlying cause of hypertension. Other strategies are indicated in certain other specific conditions, such as sympathetic antagonists for pheochromocytoma or an aldosterone antagonist (e.g., spironolactone) for hyperaldosteronism.

Ancillary strategies might be helpful in patients with hypertension, although alone they are unlikely to markedly

BOX 11.3

Approach to the Patient With Hypertension

Suspect Hypertension or Disease Associated With Hypertension (see Box 11.2, text)

- Measure BP (see text).
- Use quiet environment.
- Allow at least 5 to 10 minutes for patient to acclimate to environment (if animal is easily stressed, have owner present when possible).
- Measure limb circumference, and use appropriate-size cuff (use same cuff size for subsequent measurements as well).
- Use consistent measurement technique.
- Take at least five BP readings; discard highest and lowest, average the remaining readings.
- Repeat BP measurements at other (one to three) times, preferably on different days, to confirm diagnosis of hypertension, except:
- If acute, hypertension-induced clinical signs (e.g., ocular hemorrhage, retinal detachment, neurologic signs) are present, begin therapy immediately (see p. 217; Table 11.1).
- Screen for underlying disease(s) (see Box 11.1).
- Obtain CBC, serum biochemistry tests, urinalysis, urine protein-to-creatinine ratio.
- Obtain other data depending on individual presentation: endocrine testing, thoracic and abdominal radiographs, ocular examination, ECG, echocardiography, other tests as indicated.

If Hypertension Confirmed:

- Manage underlying disease(s).
- Avoid drugs that can increase BP, if possible.
- Consider mildly to moderately reduced-sodium diet.
- Use weight-reduction diet if patient is obese.
- Begin initial antihypertensive drug therapy (see Table 11.1).
- Dogs: ACEI
- Cats with proteinuric renal disease: ACEI
- Cats with hyperthyroidism: atenolol ± amlodipine
- Other cats: amlodipine
- If pheochromocytoma suspected, see p. 219
- If emergent therapy needed, see p. 218
- Provide client education about the patient's disease(s) and potential complications, medication and reevaluation schedules, potential adverse effects of medication(s), and dietary concerns.

Patient Reevaluation

- Recheck BP in 7 to 10 days for clinically stable patients.
- Earlier reevaluation is advised for unstable patients, but full effects of antihypertensive drugs might not yet be realized.
- Obtain other tests as individually indicated.
- If BP control is not achieved with initial agent, try combination therapy (add ACEI or amlodipine).
- Further control can be achieved with dose escalation of amlodipine.
- Continue weekly to biweekly BP monitoring and underlying disease management. When BP (and underlying disease) is controlled, gradually increase time between recheck examinations.
- Recheck at least every 3 to 4 months because medication requirements may change.
- Recheck baseline laboratory data every 6 months or as individually indicated.

ACEI, Angiotensin-converting enzyme inhibitor; *BP,* arterial blood pressure; *CBC,* complete blood count; *ECG,* electrocardiogram.

reduce BP. Dietary salt restriction is controversial. A high-salt diet could contribute to development of hypertension in some cats, although salt intake does not generally affect BP in normal animals (as is the case in people). Neurohormonal activation can occur in animals fed a very low-sodium diet; this can also increase potassium excretion, especially in cats with renal dysfunction. However, moderate dietary salt reduction (e.g., ≤0.22%-0.25% sodium on a dry matter basis) could be useful in some cases. Although not expected to normalize BP by itself, salt restriction might enhance antihypertensive drug effectiveness. Weight reduction usually is advised for obese animals. It is prudent to avoid prescribing drugs that can potentiate vasoconstriction (e.g., phenylpropanolamine and other α_1-adrenergic agonists). Glucocorticoids and progesterone derivatives should also be avoided when possible because steroid hormones can increase BP. A diuretic (thiazide or furosemide; see Chapter 3) might help by reducing blood volume in patients with volume expansion (this is a common approach to antihypertensive treatment in people); however, a diuretic alone rarely is effective in hypertensive animals. Diuretics should be avoided in animals with renal disease because they can cause dehydration and exacerbate azotemia.

The ability to monitor BP is important when antihypertensive drugs are prescribed. Serial measurements are necessary to assess treatment efficacy and prevent hypotension. Adverse effects of antihypertensive therapy usually relate to hypotension, manifested by lethargy or ataxia, or reduced appetite. Attaining initial BP control may take several weeks. Monitoring can be done every 7 to 10 days to assess the efficacy of antihypertensive treatment in nonurgent cases. The dosage of antihypertensive drug(s) can be increased if control has not been achieved or reduced if systolic BP is less than ~110 mm Hg. Once satisfactory regulation is achieved, BP should be measured every 1 to 4 months, depending on patient stability. Some animals become refractory to therapy that was initially effective. Increased antihypertensive dosage, adjunctive therapy, or a change of antihypertensive drug can

TABLE 11.1

Drugs Used to Treat Hypertension

DRUG	DOG	CAT
ACEIs (see Chapter 3)		
Enalapril	0.5 mg/kg PO q12h	0.5 mg/kg PO q24h
Benazepril	0.5 mg/kg PO q12h	Same
Ramipril	0.125-0.25 mg/kg PO q24h	0.125 mg/kg PO q24h
Captopril	0.5-2 mg/kg PO q8-12h	0.5-1.25 mg/kg PO q(8-)24h
Calcium Channel Blocker		
Amlodipine	0.1-0.3 (up to 0.5) mg/kg PO q24(-12)h	0.625 mg/cat (or 0.1-0.2 [up to 0.5] mg/kg) PO q(-12)24h
β-Adrenergic Blockers (see Chapter 4)		
Atenolol	0.2-1 mg/kg PO q12(-24)h (start low)	6.25-12.5 mg/cat PO q12(-24)h
Propranolol	0.1-1 mg/kg PO q8h (start low)	2.5-10 mg/cat PO q8-12h
α_1-Adrenergic Blockers		
Phenoxybenzamine	0.25 mg/kg PO q8-12h or 0.5 mg/kg q24h	2.5 mg/cat PO q8-12h or 0.5 mg/kg q12-24h
Prazosin	0.05-0.2 mg/kg PO q8-12h	0.25-0.5 mg/cat PO q12-24h
Drugs for Hypertensive Crisis		
Amlodipine	0.1-0.3 (up to 0.5) mg/kg PO q24(-12)h	0.625 mg/cat (or 0.1-0.2 [up to 0.5] mg/kg) PO q(-12)24h
Hydralazine (see Chapter 3)	0.5-2 mg/kg PO q12h (start low, titrate up to effect); or 0.1-0.2 mg/kg, IV or IM, repeat q2h as needed	Same (or 2.5 [up to 10] mg/cat PO q12h)
Nitroprusside (see Chapter 3)	0.5-1 mcg/kg/min CRI (initial) to 5-15 mcg/kg/min CRI	0.5-1 mcg/kg/min CRI (initial), to 5 mcg/kg/min CRI
Esmolol	25-75 (up to 200) mcg/kg/min CRI	Same
Propranolol	0.02 mg/kg (initial) to max of 0.1 mg/kg slow IV	Same
Acepromazine	0.05-0.1 mg/kg (up to 3 mg total) IV	0.01-0.05 mg/kg IV
Phentolamine	0.02-0.1 mg/kg IV bolus, followed by CRI to effect	Same

ACEI, Angiotensin-converting enzyme inhibitor; *CRI,* constant-rate infusion; *IV,* intravenous; *PO,* by mouth.

be tried. Continued attention to the underlying disease process is important. Routine CBC, serum biochemistry profile, and urinalysis (with UPC) are also recommended every 6 months. Other tests are done as indicated. Decreasing the magnitude of proteinuria associated with hypertension is a desired treatment outcome, as degree of proteinuria is a negative prognostic factor in cats with CKD.

The long-term prognosis for animals with hypertension reflects prognosis for the underlying disease, which may be chronic and progressive. Unfortunately, hypertension often persists even with adequate treatment or control of the underlying disease, particularly in dogs with hyperadrenocorticism and cats with hyperthyroidism. In addition, therapy for some primary diseases (such as fluid therapy, steroids, and erythropoietin) can exacerbate hypertension or complicate its control. Target-organ damage from systemic hypertension could improve or reverse once patients become normotensive. Retinal hemorrhage generally resolves and detached retinas may reattach, although prognosis for vision remains guarded. Reverse remodeling of LV hypertrophy can occur. Adequate control of BP also is thought to decrease the rate of progression of CKD.

ANTIHYPERTENSIVE DRUGS

The ACEIs (e.g., enalapril, benazepril) reduce angiotensin II production, thereby reducing vascular resistance and volume retention (see p. 67). These agents also selectively dilate the glomerular efferent arteriole and thus decrease

intraglomerular pressure and proteinuria. ACEI are relatively weak antihypertensive medications, leading to BP reduction in the realm of 10% to 20%, even at relatively high doses. The efficacy of these agents likely is greater in patients with glomerular hypertension (proteinuric renal disease) and in patients with significant RAAS activation. ACEIs are the recommended first-line treatment for systemic hypertension in dogs, as well as in cats with proteinuric renal disease. In dogs, q12h dosing is recommended for optimal RAAS suppression, whereas q24h dosing is adequate in cats. If BP remains elevated despite ACEI administration at a typical dose (0.5 mg/kg PO q12h for dogs, q24h for cats), it is unlikely that dose escalation will further reduce BP, and amlodipine is generally added. ACEI are generally very well tolerated, although GI upset, electrolyte disturbances, and hypotension are potential concerns. Worsening azotemia is possible in patients with CKD because efferent arteriolar dilation reduces glomerular filtration rate (GFR).

Angiotensin receptor blockers (ARBs), such as telmisartan, losartan, and irbesartan, inhibit the RAAS system "downstream" from ACEI by selectively antagonizing the AT_1 receptor to which angiotensin II binds. In experimental studies, ARBs appear to lower BP more effectively than ACEI, although reported BP reduction with ARBs is only in the realm of 20 to 25 mm Hg. As with ACEI, these agents are also used for treatment of proteinuria and are likely to be particularly useful for systemic hypertension associated with glomerular disease or in patients with RAAS activation. No studies have compared efficacy of ACEI to ARBs in clinical patients with systemic hypertension. Telmisartan appears to be the most effective ARB in dogs and cats, and has been studied at doses of 1 to 3 mg/kg PO q24h in both dogs and cats. Losartan is not recommended due to inferior BP control, likely due to failure of hepatic conversion to the active metabolite in dogs.

Amlodipine besylate is a long-acting dihydropyridine Ca^{++}-blocker that causes vasodilation without appreciable cardiac effects. It is a more effective antihypertensive agent than ACEIs or ARBs. The drug usually is dosed once daily, although q12h administration can be used in patients that do not respond sufficiently to the lower dose. Amlodipine dilates the glomerular afferent arterioles and can thereby act synergistically with ACEI to reduce glomerular hypertension. In dogs, amlodipine administration alone has been shown to activate the RAAS. In cats with CKD, amlodipine does not alter serum creatinine concentration, although RAAS activation specifically has not been studied.

Amlodipine is an effective antihypertensive in both dogs and cats. In cats, amlodipine monotherapy is effective in controlling hypertension secondary to various causes. Amlodipine is initially dosed in cats as 0.625 mg/cat (one quarter of a 2.5-mg tablet) q24h; this dose can be increased to q12h (or to 1.25 mg/cat) if needed, based on rechecked BP. Cats with higher BP at diagnosis (>200 mm Hg) often require a higher dose of amlodipine for eventual BP control. In hypertensive dogs, amlodipine is added to the treatment regimen when ACEI monotherapy fails to achieve adequate BP control; amlodipine should not be used as an antihypertensive monotherapy in dogs. A low dose is started initially and titrated upward as needed. Amlodipine's half-life is about 30 hours in dogs; maximal effects occur 4 to 7 days after initiating therapy. Oral bioavailability is high, and peak plasma concentrations are reached 3 to 8 hours after administration; plasma concentrations increase with chronic therapy. The drug undergoes hepatic metabolism, but there is not extensive first-pass elimination; caution is warranted when liver function is poor. The drug is excreted through the urine and feces. In both dogs and cats, combination therapy of amlodipine plus an ACEI can control BP while yielding a balanced effect on glomerular pressure and GFR through equal dilation of afferent and efferent arterioles.

β-adrenergic blockers potentially could reduce BP by decreasing heart rate, cardiac output, and renal renin release. Atenolol and propranolol have been used most often (see p. 94). A β-blocker can be considered for cats with hyperthyroid-induced hypertension, as increased activity of the sympathetic nervous system could underlie hypertension in this disease; furthermore, β-blockers can inhibit peripheral conversion of T_4 to active T_3. However, atenolol therapy causes no change in BP in normotensive cats and only decreases BP by ~15 mm Hg in hypertensive hyperthyroid cats. In general, β-blockers are ineffective as a sole antihypertensive agent in cats; adjunct amlodipine usually is required.

α_1-adrenergic antagonists oppose the vasoconstrictive effects of α-receptors. Their main use is for hypertension caused by pheochromocytoma. Phenoxybenzamine is a noncompetitive α_1- and α_2-blocker used most often for pheochromocytoma-induced hypertension. Treatment is initiated with a low dose titrated upward as needed. The selective α_1-blocker prazosin is another option. After α-blocker dosing is begun, adjunctive therapy with a β-blocker can help control reflex tachycardia or arrhythmias. In cases of pheochromocytoma, β-blockade should not be initiated before α-blockade, because use of a β-blocker as the sole agent in this setting leaves α_1-receptors unopposed and is likely to exacerbate hypertension.

Hypotension is a potential adverse effect of any antihypertensive drug. Hypotension usually is manifested as periods of lethargy or ataxia. Reduced appetite could be another adverse effect. Conversely, rebound hypertension can occur if antihypertensive therapy is suddenly discontinued. This especially is of concern when using β- or α_2-blockers. If therapy with such agents is to be terminated, the dosage should be gradually tapered down first.

HYPERTENSIVE EMERGENCY

Urgent antihypertensive therapy is indicated when new or progressive signs of severe hypertension are identified. Examples include acute retinal detachment and hemorrhage, encephalopathy, intracranial hemorrhage, acute renal failure, aortic aneurysm, or acute left-sided congestive heart failure. The animal should be hospitalized until BP and other acute signs are controlled.

Oral amlodipine can be effective in quickly decreasing BP, especially in cats, and has less risk of inducing hypotension than more potent vasodilators. Oral amlodipine is initiated at the typical dose of 0.625 mg/cat, and BP rechecked q2h. Maximal effect of amlodipine after a single oral dose in cats occurs at 4 to 6 hours. If BP is not adequately controlled in 4 to 6 hours, an additional 0.625 mg/cat PO can be given, and dose continued q12h.

Direct-acting vasodilator agents (e.g., nitroprusside, hydralazine) can produce faster reduction in BP; arterial pressure should be closely monitored to prevent hypotension. Nitroprusside is dosed to effect by constant intravenous (IV) infusion (see Table 11.1). Hydralazine (IV or PO) is an alternative, especially for dogs. An IV β-blocker (esmolol, propranolol) or acepromazine (see Table 11.1) can also be used. One of these agents can be added to oral amlodipine therapy if BP is not adequately reduced within 12 hours. BP rechecks within 1 to 3 days are recommended in patients with serious or rapidly progressive signs.

When a hypertensive crisis is related to pheochromocytoma or other cause of catecholamine excess, the α-blocker phentolamine can be used intravenously (see Table 11.1) and titrated to effect. Addition of a β-blocker can help mitigate pheochromocytoma-induced tachyarrhythmias, but it should not be administered alone or before an α-blocker is given, for reasons previously discussed. Antihypertensive treatment is recommended for 2 to 3 weeks before surgery for pheochromocytoma excision, if possible. For inoperable pheochromocytoma, therapy is continued orally to prevent hypertensive emergencies.

CHAPTER 12

Thromboembolic Disease

GENERAL CONSIDERATIONS

Thromboembolic (TE) disease involves either a locally formed (in situ) aggregation of platelets and other blood elements (thrombus), or a thrombus or other aggregate that breaks away from its origination site (embolus) and is carried downstream by blood flow. Both thrombi and emboli can partially or completely obstruct blood flow, either in a vessel or in the heart. TE disease can occur whenever normal hemostatic mechanisms are disturbed. Most clinically recognized TE events involve the distal aorta, pulmonary arteries, heart, or cranial vena cava. (For additional information on the pathogenesis of thromboembolism, see Chapter 87.)

The clinical sequelae of TE disease depend mainly on the size and location of the thrombus/thrombi. These factors determine how much functional compromise occurs and in which organs and tissues. Acute, profound clinical signs of pain and organ dysfunction result from some thromboemboli. Others cause subclinical tissue damage and varying degrees of pathology. TE disease is sometimes suspected antemortem; in other cases, it is discovered at necropsy (or not at all).

NORMAL HEMOSTATIC MECHANISMS

There is normally interplay among the different factors that promote coagulation, inhibit coagulation, and promote fibrinolysis. A proper balance of these factors maintains blood fluidity and minimizes loss when vessels are damaged. Platelets, the vascular endothelium, coagulation proteins, and the fibrinolytic system are all involved in normal hemostasis. Injury to the vascular endothelium quickly induces several reactions that cause vasoconstriction, hemostatic plug formation, and attempts at vascular repair to prevent blood loss.

Intact endothelium exerts anticoagulant properties via several mechanisms. First, the endothelium represents a physical barrier that is negatively charged, discouraging and repelling platelet adhesion. Second, the arrangement of phospholipids in healthy cell membranes inhibits coagulation. In normal endothelial cells and platelets, the outer membrane of the lipid bilayer contains neutral phospholipids; the more reactive phospholipids, phosphatidylserine (PTS) and phosphatidylethanolamine (PEA), are localized to the inner membrane. This asymmetry in the lipid bilayer is maintained by active transport of phospholipids by the ATP-dependent enzymes flippase and floppase. After cell injury, the enzyme scramblase shuffles phospholipids between the inner and outer membranes, resulting in PTS and PEA expression on the outer membrane. Membranes with exposed PTS provide a substrate that supports and catalyzes coagulation reactions, whereas such reactions occur very slowly on membranes lacking PTS. Finally, healthy endothelium actively produces substances that inhibit both platelet adhesion and coagulation. Antiplatelet substances produced by vascular endothelium include nitric oxide, prostacyclin, and adenosine diphosphatase (ADPase). Anticoagulant substances synthesized by intact endothelium include thrombomodulin, protein S, heparin sulfated proteoglycans (HSPGs), and tissue factor pathway inhibitor (TFPI).

Damaged endothelial cells promote thrombus formation. Although this reduces blood loss in the event of vascular damage, in other settings TE disease results. Endothelial damage contributes to thrombus formation in several ways. First, injured endothelial cells release endothelin, which promotes vasoconstriction and slows local blood flow, allowing more time for blood components to interact with the vessel wall. Second, as previously discussed, presence of PTS on the outer lipid membrane of damaged cells dramatically increases speed of coagulation reactions. Perhaps most importantly, damaged endothelium exposes cells expressing tissue factor (TF or thromboplastin), which is the key step to initiate thrombus formation.

Traditional models of hemostasis involve a temporal and functional division of thrombus formation into *primary hemostasis* (formation of the primary platelet plug), *secondary hemostasis* (coagulation proteins creating cross-linked fibrin), and *fibrinolysis* (thrombus breakdown). Secondary hemostasis has been further modeled as a "cascade" of coagulation proteins involving sequential cleavage of proenzymes, each step activating the next coagulation factor in the series. This cascade was historically divided into *extrinsic*

(outside the blood, TF-dependent) and *intrinsic* (within the blood, contact-dependent), considered to be two alternative pathways for eventual activation of factor Xa (FXa). FXa activation then initiates the final "common pathway": activation of prothrombin to thrombin, followed by cleavage of fibrinogen to fibrin. Although the cascade model historically explained many aspects of coagulation in vitro, more recent models have been proposed that highlight the role of cell membranes in the process of hemostasis in vivo.

The currently advocated *cell-based model* of hemostasis is divided into three sequential but overlapping phases: initiation, amplification, and propagation. During *initiation*, vascular injury exposes subendothelial cells expressing TF, which binds to factor VIIa (FVIIa) in circulating blood. The complex of TF-FVIIa activates FXa to produce small amounts of thrombin (FIIa), which attracts and activates nearby platelets. In the *amplification* phase, platelet activation by thrombin results in platelet shape change, platelet degranulation, and expression of platelet surface receptors. Platelet granules release substances that attract and activate other platelets (including thromboxane A_2, serotonin, adenosine diphosphate [ADP], calcium, and fibrinogen). Different types of platelet receptors bind to subendothelial von Willebrand factor (glycoprotein [GP] I_b-IX) or to other platelets via fibrinogen ($GP\alpha_{IIb}$ β_3, formerly known as $GPII_b$-III_a). This recruitment and aggregation creates a "plug" of fibrinogen-linked platelets. The platelet plug helps limit blood loss through small vessels; more importantly, however, the activated platelet membranes (with exposed PTS) create a substrate for the *propagation* phase of hemostasis. In the propagation phase, activated coagulation factors react on the activated platelet surface in a series of steps to generate more activated FXa, which along with its co-factor FVa cleaves prothrombin into thrombin (FIIa). Formation of large amounts of thrombin is the "final step" in the cell-based model of coagulation. Thrombin converts fibrinogen into fibrin monomers, which polymerize to soluble fibrin, which is then cross-linked by the action of thrombin-activated FXIII (or fibrin-stabilizing factor). This insoluble fibrin stabilizes the clot.

After a thrombus forms, several mechanisms limit its extent and promote its breakdown. Thrombolysis requires plasmin. Its inactive precursor, plasminogen, is converted to plasmin by tissue plasminogen activator (t-PA) when fibrin is present. During activation of the coagulation cascade, endothelial cells simultaneously release t-PA. Several other substances also can act as plasminogen activators. Plasmin degrades fibrinogen and soluble (noncross-linked) fibrin to yield fibrinogen/fibrin degradation products (FDPs). Plasmin also cleaves cross-linked fibrin in stabilized clots into large fragments (x-oligomers) that are further broken down into D-dimers and other fragments. D-dimers are produced only with active coagulation and subsequent fibrinolysis. There also are negative feedback constraints on fibrinolysis (e.g., plasminogen activator inhibitors [PAI], α_2-antiplasmin, thrombin-activated fibrinolytic factor). Defective fibrinolysis is thought to play a role in pathologic thrombosis.

There are multiple physiologic mechanisms that limit the extent of thrombus formation in addition to the fibrinolytic system. As previously discussed, inherent properties of healthy vascular endothelium effectively localize coagulation only to sites of injury. Antithrombin (AT), a small protein produced by the liver, is responsible for most of the anticoagulant effect of plasma. Along with its co-factor heparan sulfate, AT binds to and inactivates many coagulation proteins, including thrombin; FIXa, FXa, FXIa, and FXIIa; and kallikrein. Protein C (and its co-factor Protein S) are vitamin K–dependent glycoproteins that inactivate FVa and FVIIIa. Proteins C and S are stimulated by thrombin (via formation of the thrombin-thrombomodulin complex), thus acting as a negative feedback loop during the coagulation process. Endothelial-derived TFPI also limits hemostasis by inhibiting FVIIa and TF. Malfunction of one or more of these control systems promotes thrombosis.

Pathophysiology

TE disease is more likely when changes in normal hemostatic processes create conditions that favor clot formation or impair fibrinolysis. Three general situations (so-called "Virchow's triad") promote pathologic thrombosis: abnormal endothelial structure or function, slowed or static blood flow, and a hypercoagulable state (from either increased procoagulant substances or decreased anticoagulant or fibrinolytic substances). A number of common diseases produce such conditions (Box 12.1).

Diseases that induce severe or widespread endothelial injury promote thrombosis via loss of the antiplatelet, anticoagulant, and fibrinolytic functions of normal endothelium. Injured endothelium also releases TF and antifibrinolytic factors. Subendothelial tissue, exposed because of endothelial cell damage, promotes thrombosis by acting as a substrate for clot formation and stimulating platelet adherence and aggregation. Systemic release of inflammatory cytokines (e.g., tumor necrosis factor [TNF], various interleukins, platelet activating factor, nitric oxide) can cause widespread endothelial injury, induce TF expression, and inhibit anticoagulant mechanisms. This occurs in patients with sepsis and likely other systemic inflammatory conditions as well. Neoplastic invasion, vascular disruption resulting from other disease, and postischemic injury also induce endothelial damage. Microparticles, small membrane-bound vesicles derived from platelets or other cell types in certain disease states, can provide a procoagulant phospholipid membrane surface for pathologic thrombosis. Mechanical trauma to the vascular endothelium (as with catheterization) can also precipitate TE disease, especially when other predisposing conditions exist. Pulmonary artery endothelial injury resulting from heartworm disease (HWD) is well known (see Chapter 10). The inflammatory reaction to dead or dying worms and worm fragments exacerbates the endothelial damage and prothrombotic conditions.

Stagnant blood flow promotes thrombosis by impeding the dilution and clearance of coagulation factors, as well as increasing time for blood components to contact vessel

BOX 12.1

Diseases Potentially Associated With Thromboembolism

Endothelial Disruption

Sepsis
Systemic inflammatory disease
Heartworm disease
Neoplasia
Massive trauma
Shock
Intravenous catheterization
Injection of irritating substance
Atherosclerosis
Arteriosclerosis
Hyperhomocysteinemia

Abnormal Blood Flow

Vascular obstruction (e.g., mass lesion, adult heartworms, catheter or other device)
Heart disease (especially cardiomyopathy in cats)
Cardiovascular neoplasia
Endocarditis
Shock
Hypovolemia/dehydration
Prolonged recumbency
Hyperviscosity (e.g., polycythemia, leukemia, hyperglobulinemia)
Hypoviscosity (anemia)
Anatomic abnormality (e.g., aneurysm, AV fistula)

Increased Coagulability

Glomerular disease/protein-losing nephropathy
Hyperadrenocorticism
Immune-mediated hemolytic anemia (±thrombocytopenia)
Pancreatitis
Protein-losing enteropathy
Sepsis/infection
Neoplasia
Disseminated intravascular coagulation
Heart disease

walls. Poor flow also can promote local tissue hypoxia and endothelial injury. Abnormal turbulence has also been associated with thrombus formation because it can mechanically injure the endothelial surface.

Hypercoagulability can develop secondary to various systemic diseases in dogs and cats. Multiple mechanisms are thought to be involved. AT deficiency is a common cause of hypercoagulability. Excessive loss, increased consumption, or possibly inadequate hepatic synthesis all can lead to AT deficiency. Decreased protein C activity and other mechanisms (including hyperfibrinogenemia and increases in factors II, V, VII, VIII, IX, X, or XII) also can contribute to hypercoagulability. Increased platelet aggregability, another mechanism of hypercoagulability, has been associated with neoplasia, some heart diseases (including hypertrophic cardiomyopathy [HCM] in cats), diabetes mellitus, and nephrotic syndrome in some animals. Thrombocytosis alone, without an increase in platelet aggregability, is not thought to increase the risk for thrombosis. Defective fibrinolysis can promote pathologic thrombosis by preventing efficient breakdown of physiologic clots. This can result from either reduced levels of fibrinolytic substances (e.g., t-PA, plasminogen, urokinase) or increased production of PAIs; the latter is a major mechanism of TE disease in humans with hypertension. Finally, any severe systemic disease that progresses to the systemic inflammatory response syndrome (SIRS; e.g., pancreatitis, sepsis, neoplasia, heatstroke, immune-mediated disease) can lead to gross thrombosis, as well as disseminated intravascular coagulopathy (DIC). DIC involves massive activation of thrombin and plasmin, with generalized consumption of coagulation factors and platelets. DIC produces extensive thrombosis and hemorrhage in the microcirculation, resulting in widespread tissue ischemia and multiorgan failure (see p. 1400).

The most common, although not the only, cause of TE disease in cats is myocardial disease (see Chapter 8). Cats with cardiomyopathy are at risk for intracardiac thrombus formation and subsequent arterial embolization. Mechanisms involved include poor intracardiac blood flow and blood stasis, especially within an enlarged left atrium (LA). Cats with HCM have increased platelet expression of P-selectin and platelet-endothelial cell adhesion molecules, as well as increased plasma concentrations of fibrinogen, thrombin-antithrombin-complex, and D-dimers, suggesting a possible role for systemic hypercoagulability as well. Additionally, abnormal turbulence from mitral regurgitation or dynamic outflow tract obstruction could be a factor. Some cats with TE disease have decreased plasma arginine and vitamin B_6 and B_{12} concentrations; hyperhomocysteinemia might be a factor in some cases. Hyperhomocysteinemia and low plasma vitamin B concentrations are risk factors for thromboembolism in people. It is not known if hypercoagulability induced by a genetic abnormality exists in some cats, as it does in people.

Three common systemic diseases associated with TE disease in dogs are protein-losing nephropathy, immune-mediated hemolytic anemia (IMHA), and hyperadrenocorticism. Protein-losing nephropathy (resulting from glomerulonephritis, renal amyloid deposition, or hypertensive injury) can lead to marked AT deficiency. Because of its small size, AT is lost through damaged glomeruli more easily than most procoagulant proteins, which predisposes to thrombosis. Protein-losing enteropathies also cause AT deficiency, but concurrent loss of larger proteins tends to maintain a balance between procoagulant and anticoagulant factors. Other factors also could contribute to TE disease in animals with protein-losing nephropathies, such as increased platelet aggregation secondary to hypoalbuminemia.

Thrombosis associated with IMHA also is thought to be multifactorial, with the systemic inflammatory (immune-mediated) response playing a large role. Thrombocytopenia, hyperbilirubinemia, and hypoalbuminemia have been identified as risk factors for TE disease. The role of high-dose

corticosteroid therapy in pathologic thrombosis is unclear. However, TE disease is relatively common in animals receiving exogenous corticosteroids and in those with hyperadrenocorticism (see next paragraph). Other predisposing factors usually coexist in these cases as well.

TE disease occurs in some dogs with spontaneous hyperadrenocorticism. This endocrinopathy has been associated with decreased fibrinolysis (resulting from increased PAI activity) and high levels of several coagulation factors. Corticosteroids result in hypercoagulable thromboelastography (TEG) tracings in normal dogs. Diabetes mellitus is occasionally associated with TE disease in dogs. Platelet hyperaggregability and possibly hypofibrinolysis are thought to be involved. Greyhounds appear to be predisposed to TE disease despite lack of detectable hemostatic or cardiovascular abnormalities; one proposed mechanism is abnormalities of homocysteine metabolism (hyperhomocysteinemia). Occasionally, a patient with clinically relevant TE disease does not have any detectable abnormality that can result in hypercoagulability.

PULMONARY THROMBOEMBOLISM

Pulmonary thromboemboli (PTE) in dogs are associated with HWD, IMHA, neoplasia, DIC, sepsis, hyperadrenocorticism, protein-losing nephropathy, pancreatitis, trauma, hypothyroidism, and right atrial (RA) thrombi related to infection or neoplasia.

Pulmonary TE disease appears to be rare in cats compared with dogs, except in those with HWD (see Chapter 10). Nevertheless, PTE have been associated with a variety of systemic and inflammatory disorders in cats, including neoplasia, HWD, anemia (probably immune-mediated), pancreatitis, glomerulonephritis, encephalitis, pneumonia, heart disease, sepsis, glucocorticoid administration, protein-losing enteropathy, and hepatic lipidosis.

Pulmonary TE disease is an important cause of precapillary pulmonary hypertension, and can lead to right ventricular hypertrophy and even right-sided congestive heart failure (CHF). See Chapters 19 and 25 for further information about pulmonary thromboembolism and pulmonary hypertension.

SYSTEMIC ARTERIAL THROMBOEMBOLISM IN CATS

Cardiomyopathy, mainly HCM, is the most common underlying disease in cats with arterial thromboembolism (ATE) (see Chapter 8). Thrombi initially form in the left heart, usually in an enlarged LA or auricle, and can become quite large. Neoplastic and systemic inflammatory disease occasionally are associated with systemic thromboemboli in cats. Pulmonary carcinoma is the most common neoplasm to cause ATE, potentially because tumor emboli from the lungs have direct access to pulmonary veins and, thereby, the left heart. Hyperthyroidism could be a risk factor for ATE in cats independent of its cardiac effects. A rare cause of ATE could occur in cats with atrial septal defect, if a venous embolus crossed from RA to LA. In some cases of feline ATE, no predisposing condition is identified.

Systemic arterial emboli usually lodge at the aortic trifurcation (so-called "saddle thrombus" or, more correctly, "saddle embolus"; Fig. 12.1), but iliac, femoral, renal, brachial, and other arteries can be affected depending on embolus size and flow path. Besides obstructing flow in the affected artery, thromboemboli release vasoactive substances that induce vasoconstriction and compromise collateral blood flow around the obstructed vessel. Tissue ischemia results and causes further damage and inflammation, including ischemia-reperfusion injury after blood flow to the area is restored. An ischemic neuromyopathy occurs in the affected limb(s), with peripheral nerve dysfunction and degeneration, as well as pathologic changes in associated muscle tissue. Coronary thromboembolism with myocardial necrosis has occurred in cats with cardiac disease, especially severe HCM or infective endocarditis, as well as from carcinoma emboli.

Clinical Features

Arterial TE in cats usually causes acute and dramatic clinical signs secondary to tissue ischemia (Fig. 12.2). Male cats appear to be at higher risk for ATE, but this gender bias appears to be related to the prevalence of HCM. Common physical examination findings of cats with ATE can be summarized with the mnemonic "5 Ps": pain, pallor (pale coloration of affected pawpad[s]), paresis or plegia (of affected limb[s]), pulselessness (weak or absent pulse in affected limb[s]), and poikilothermia (decreased temperature of affected compared with unaffected limb[s]). Additional clinical abnormalities are summarized in Box 12.2.

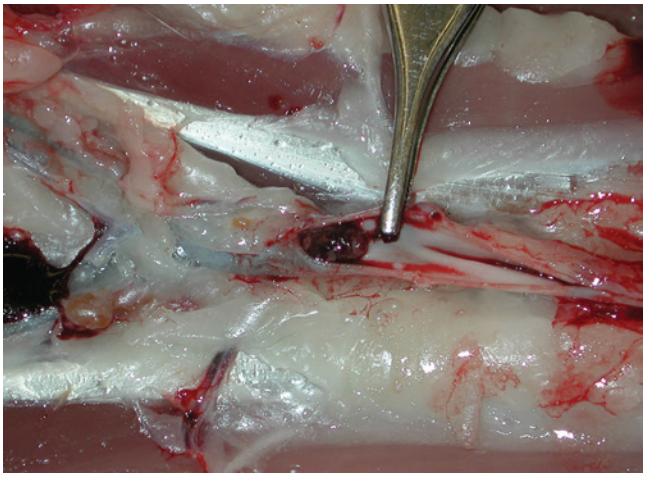

FIG 12.1
Postmortem image with opened distal aorta, from a cat with cardiomyopathy. A thromboembolus (just left of the forceps tip) is lodged at the aortic trifurcation. The rear limbs are to the left in the image; cranial is to the right.

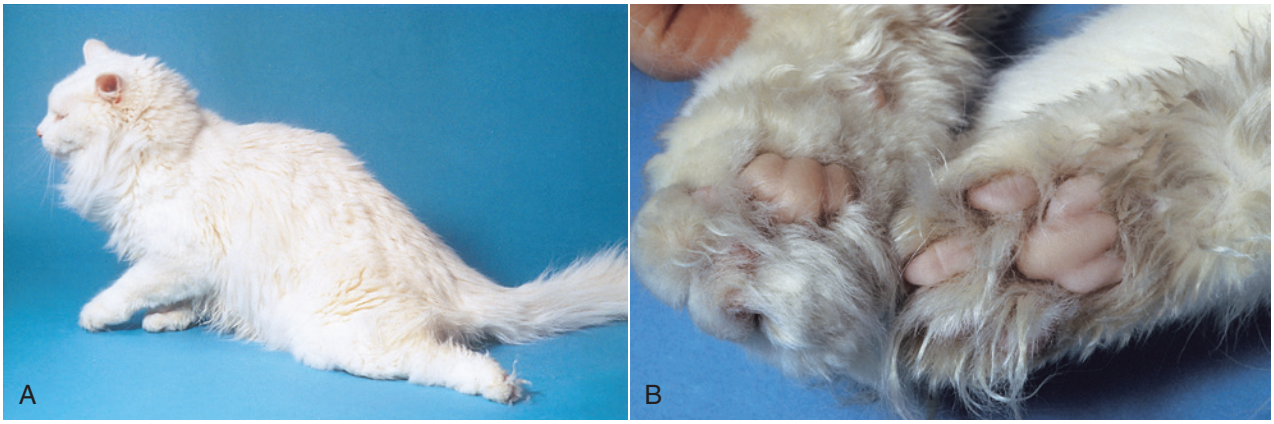

FIG 12.2
(A) Cat with thromboembolism to the distal aorta. The left rear limb was dragged behind as the cat tried to walk; there was slightly better function in the right rear limb. **(B)** The pads of the left rear paw (right side of image) in this cat were paler as well as cooler compared with the left forepaw (left side of image).

Signs of poor systemic perfusion usually are present. Hypothermia and azotemia are common. A heart murmur, gallop sound, or arrhythmia often is identified, but these signs are not always evident even with underlying heart disease. Clinical signs of heart disease before the ATE event are absent in many cases. Tachypnea and open-mouth breathing are common in cats with acute arterial embolization. Although these signs often relate to the onset of CHF, they also occur in cats without overt CHF. These respiratory signs could represent a pain response or result from increased pulmonary venous pressure. Thoracic radiographs should be obtained as soon as possible, because it is important to determine whether pulmonary edema underlies the respiratory signs.

Peripheral limb functional deficits depend on the area embolized, as well as the extent and duration of arterial blockage. However, distal aortic embolization occurs in most cases, so bilateral hindlimb deficits are most common. Acute hindlimb paresis without palpable femoral pulses is typical. Motor function in the rear limbs is minimal to absent in most cases, although the cat can usually flex and extend the hips. Sensation to the lower limbs is poor. Hindlimb deficits can be asymmetric. Emboli occasionally are small enough to lodge more distally in only one limb, which causes paresis of the lower limb alone. Embolization of an axillary or the more distal brachial artery produces (usually right) forelimb monoparesis. Intermittent claudication (see pp. 230–231) occurs rarely. Thromboemboli within the renal or mesenteric arterial circulation can result in failure of these organs and death. Emboli to the brain could induce seizures or various neurologic deficits. Clinical signs related to other predisposing disease may be evident in cats without cardiomyopathy.

Diagnosis

Feline ATE usually is diagnosed clinically based on a combination of acute onset paraparesis and absent femoral pulses on physical examination. If the diagnosis is not straightforward, obtaining a small amount of peripheral blood from an affected limb might be helpful. Blood glucose values are lower, whereas lactate values are higher, in blood from limbs affected by ATE compared with unaffected limbs or centrally obtained samples. Abdominal ultrasound can confirm the presence of a thrombus in the distal aorta.

Thoracic radiography is used to screen for evidence of cardiomyopathy, including cardiomegaly (and especially LA enlargement), and to determine whether CHF is present. Signs of CHF include pulmonary venous distension, pulmonary edema, and/or pleural effusion. Thoracic radiographs also could suggest the presence of other diseases potentially associated with ATE (e.g., pulmonary carcinoma, HWD). A few affected cats have no radiographic abnormalities.

Echocardiography depicts the type of myocardial disease, and sometimes the presence of an intracardiac thrombus as well (see Fig. 8.4). Echocardiography also can reveal cavitary effusions (pleural or pericardial effusion) suggestive of CHF. Some degree of LA enlargement is seen the majority (>90%) of cats with ATE. An LA dimension of greater than 20 mm (measured from the two-dimensional, long-axis, four-chamber view) may increase the risk for ATE, though only approximately half of cats with ATE have this degree of LA dilation.

Cats with ATE often have azotemia. This can be prerenal, resulting from poor systemic perfusion or dehydration; primary renal, resulting from embolization of the renal arteries or preexisting kidney disease; or a combination of both. Metabolic acidosis, DIC, electrolyte abnormalities (especially low serum sodium, calcium, potassium, and elevated phosphorus), and stress hyperglycemia are common. Hyperkalemia can develop secondary to ischemic muscle damage and reperfusion. Skeletal muscle damage and necrosis are accompanied by rapid elevation in CK; ALT and AST activities become elevated within 12 hours of the ATE event and peak by 36 hours. Myoglobinuria may also occur

BOX 12.2

Common Clinical Findings in Cats With Systemic Arterial Thromboembolism

- Acute limb paresis
  - Posterior paresis
  - Monoparesis
  - ±Intermittent claudication
- Characteristics of affected limb(s)
  - Painful
  - Cool distal limbs
  - Pale footpads
  - Cyanotic nailbeds
  - Absent arterial pulse
  - Contracture of affected muscles (especially gastrocnemius and cranial tibial)
- Tachypnea/dyspnea
  - Rule out congestive heart failure versus pain or other pulmonary disease
- Vocalization (pain and distress)
- Hypothermia
- Anorexia
- Lethargy/weakness
- Signs of heart disease (inconsistent)
  - Systolic murmur
  - Gallop sounds
  - Arrhythmias
  - Cardiomegaly
- Signs of congestive heart failure
  - Pulmonary edema
  - Cavitary effusions
- Hematologic and biochemical abnormalities
  - Azotemia
  - Increased creatine kinase activity
  - Increased aspartate aminotransferase activity
  - Increased alanine aminotransferase activity
  - Increased lactate dehydrogenase activity
  - Increased cardiac biomarkers (Troponin I, NT-proBNP)
  - Hyperglycemia (stress)
  - Lymphopenia (stress)
  - Disseminated intravascular coagulation

secondary to widespread muscle injury. Cats with ATE usually have normal coagulation parameters (PT and PTT), though fibrinogen and D-dimers might be elevated. Laboratory tests can reveal abnormalities associated with other underlying disease as well, such as eosinophilia from HWD. Thyroxine (T_4) levels should be measured in older cats to screen for hyperthyroidism.

Other causes of acute posterior paresis to be considered include intervertebral disk disease, spinal neoplasia (e.g., lymphoma), trauma, fibrocartilaginous infarction, diabetic neuropathy, and possibly myasthenia gravis.

Treatment and Prognosis

The goals of treatment are to prevent extension of the embolus and additional thrombus formation, promote collateral circulation, and manage concurrent CHF and arrhythmias (if present). Other supportive care is given to improve and maintain adequate tissue perfusion, minimize further endothelial damage and blood stasis, optimize organ function, and allow time for collateral circulation development. (Box 12.3). The treatment of CHF in cats is outlined in Chapter 8 and Box 8.1. General supportive care in acute ATE includes active external warming for hypothermia, rotation of position and recumbency (if nonambulatory), assistance with litter box posturing or bladder expression, and physical therapy once the patient is stable.

An analgesic is indicated for cats with ATE, especially for the first 24 to 36 hours after the embolic event, because this is a painful condition. For caudal arterial obstruction, analgesic administration into a more cranial site is recommended to improve absorption (e.g., IV into the cephalic vein or IM into the cranial lumbar area). Drugs that are most useful include μ-opioids such as fentanyl citrate (IV bolus followed by infusion), buprenorphine HCl, hydromorphone, methadone, oxymorphone, or morphine (see Box 12.3). A fentanyl patch (25 μg/h size) applied to a shaved area of skin can be used for pain relief for up to 3 days, but because this formulation takes about 12 hours to become effective, another analgesic is used simultaneously during this initial period. Respiratory depression and reduced gastrointestinal (GI) motility are potential adverse effects of opioids. Narcotics sometimes cause dysphoria in cats. Acepromazine is not recommended for animals with ATE, despite its vasodilatory α-adrenergic receptor–blocking effects. Improved collateral flow has not been documented, and hypotension and exacerbation of dynamic ventricular outflow obstruction (in cats with hypertrophic obstructive cardiomyopathy) are potential adverse effects.

Antiplatelet therapy is used to inhibit platelet aggregation and to reduce production of vasoconstrictive substances released from activated platelets. Platelet inhibitors are considered especially important for inhibiting thrombus formation within arteries, where blood flows under high shear rates and platelet adhesion via von Willebrand factor is critical for clot formation. Clopidogrel (Plavix) has replaced aspirin as the standard of care for antiplatelet therapy in cats with ATE. Clopidogrel is a second-generation thienopyridine with antiplatelet effects that are more potent than aspirin. A double-blind randomized controlled trial in 75 cats (Feline Arterial Thromboembolism: Clopidogrel versus Aspirin Trial; FATCAT) (Hogan, 2015) demonstrated that clopidogrel was superior to aspirin for secondary prevention of ATE and resulted in longer survival times post-ATE.

The thienopyridines inhibit ADP-binding at platelet receptors and subsequent ADP-mediated platelet aggregation. Clopidogrel irreversibly antagonizes platelet membrane ADP_{2Y12} receptors, which inhibit a conformational change of the $GP\alpha_{IIb}\ \beta_3$ complex, resulting in reduced binding to fibrinogen and von Willebrand factor. Clopidogrel also impairs platelet release of serotonin, ADP, and other vasoconstrictive and platelet-aggregating substances. Clopidogrel's antiplatelet effects occur after the drug is transformed in the liver to an active metabolite. Similar to humans, there

BOX 12.3

Therapy for Acute Thromboembolic Disease

Initial Diagnostic Tests

Complete physical examination and history
Thoracic radiographs (rule out signs of congestive heart failure, other infiltrates, pleural effusion)
CBC, serum biochemical profile, urinalysis
±Comparative blood glucose and blood lactate from affected vs. unaffected limbs
±Coagulation and D-dimer tests

Analgesia as Needed (Especially for Systemic Arterial Thromboembolism)

Fentanyl citrate
- Dog: 0.002-0.005 mg/kg IV bolus, followed by 0.002-0.005 mg/kg/h infusion
- Cat: 0.002-0.005 mg/kg IV bolus, followed by 0.002-0.005 mg/kg/h infusion

or Buprenorphine
- Dog: 0.01-0.03 mg/kg IM, IV, SC q6-8h
- Cat: 0.01-0.03 mg/kg IM, IV, SC q6-8h; can give PO for transmucosal absorption

or Hydromorphone
- Dog: 0.05-0.2 mg/kg IM, IV, SC q4-6h
- Cat: 0.05-0.2 IM, IV, SC q4-6h

or Oxymorphone
- Dog: 0.05-0.2 mg/kg IM, IV, SC q2-4h
- Cat: 0.05-0.2 mg/kg IM, IV, SC q2-4h

or Morphine
- Dog: 0.2-0.4 mg/kg IM, IV, SC q4-6h
- Cat: 0.1 mg/kg IM, IV, SC q4-6h

Supportive Care

Provide supplemental O_2 if respiratory signs exist.
Monitor for and correct azotemia and electrolyte abnormalities.
Manage congestive heart failure if present (see Chapters 3 and 8).
Provide external warming if hypothermia persists after rehydration.
Identify and manage underlying disease(s).
Administer intravenous fluid if indicated (and if not in congestive heart failure).
Provide nutritional support if anorexia persists.

Further Diagnostic Testing

Complete cardiac evaluation, including echocardiogram
±Abdominal ultrasound to confirm presence of thrombus/embolus in distal aorta
Other tests as indicated (based on initial findings and cardiac examination) to rule out predisposing conditions

Inhibit Extension of Existing Clot and New Thromboembolic Events

Antiplatelet therapy

Clopidogrel
- Dog: 2-4 mg/kg PO q24h
- Cat: loading dose of 75 mg PO once, then 18.75 mg/cat PO q24h

Aspirin (in cats, consider only if clopidogrel not tolerated or available)
- Dog: 0.5-1.0 mg/kg PO q24h
- Cat: 81 mg/cat q72h

Anticoagulant therapy

Sodium heparin (unfractionated)*
- Dog: 100-300 IU/kg IV, followed by 100-300 IU/kg SC q8h (or CRI of 600 IU/kg/day) for 2-4 days or as needed
- Cat: 100 IU/kg IV, followed by 200 IU/kg SC q8h (or CRI of 600-800 IU/kg/day) for 2-4 days or as needed

or Enoxaparin*
- Dog: 1.5 mg/kg SC q12-24h
- Cat: 1.5 mg/kg SC q12-24h

or Dalteparin sodium*
- Dog: 50-100 U/kg SC q12-24h
- Cat: 100 U/kg SC q12-24h

Thrombolytic therapy (pursue only with caution, see text)

rt-PA
- Dog: 1.4 mg/kg IV total as front-loaded 90-minute protocol:
  0.2 mg/kg IV bolus
  0.7 mg/kg IV over 30 minutes
  0.5 mg/kg IV over 1 hour
- Cat: 5 mg/cat IV total as front-loaded 90-minute protocol:
  0.75 mg IV bolus
  2.5 mg IV over 30 minutes
  1.75 mg over 1 hour

Cats: Draw blood samples for LMWH peak anti-Xa activity at 2-3 hours postdose.
Dogs: Draw blood samples for LMWH peak anti-Xa activity at 3-4 hours postdose.
IM, Intramuscularly; *IV,* intravenously; *PO,* by mouth; *rt-PA,* recombinant tissue plasminogen activator; *SC,* subcutaneously; *TE,* thromboembolic.
*Anti-Xa monitoring is recommended. One laboratory providing this service for cats and dogs is the Cornell Comparative Coagulation laboratory, http://ahdc.vet.cornell.edu/Sects/Coag/.

may be pharmacogenomic differences in individual cats' ability to biotransform clopidogrel, resulting in clopidogrel "nonresponders"; the clinical implications of this finding remain unclear. The recommended oral dose is 18.75 mg/cat once daily (or 2-4 mg/kg once daily); maximal antiplatelet effects occur within 72 hours and disappear about 7 days after drug discontinuation. A loading dose of 75 mg/cat given as soon as possible after an acute ATE event might also confer vasomodulating effects that improve collateral blood flow, and short-term administration of this dose appears to be well tolerated. Clopidogrel does not cause GI ulceration, as aspirin can; however, a single cat receiving clopidogrel in the FATCAT trial developed a reversible icterus. Vomiting does occur in some cats, and the tablets taste very bitter. This can be ameliorated by giving the drug with food or in a gelatin capsule.

Aspirin (acetylsalicylic acid) previously was employed to block platelet activation and aggregation in cats with, or at risk for, ATE. Aspirin irreversibly inhibits cyclooxygenase, which reduces prostaglandin and thromboxane A_2 synthesis and therefore could reduce subsequent platelet aggregation, serotonin release, and vasoconstriction. Because platelets cannot synthesize additional cyclooxygenase, this reduction of procoagulant prostaglandins and thromboxane persists for the platelet's life span (7-10 days). Endothelial production of prostacyclin (also via the cyclooxygenase pathway) is reduced by aspirin but only transiently as endothelial cells synthesize additional cyclooxygenase. Adverse effects of aspirin tend to be mild, unless overdosed, and usually relate to signs of GI upset or ulceration, mainly as anorexia and vomiting. The optimal dose is unclear. Cats lack an enzyme (glucuronyl transferase) necessary to metabolize aspirin, so less frequent dosing is required compared with dogs. Aspirin's efficacy at clinical doses in acute ATE is unknown. In cats with experimental aortic thrombosis, high-dose aspirin (100 mg/kg) inhibited platelet aggregation and improved collateral circulation, but this dose would be toxic in a clinical setting. The commonly used dose of 10 to 25 mg/kg (81 mg/cat) q72h does inhibit platelet aggregation in vitro, but the clinical benefit for treatment or prevention of ATE has not been established. In cats with ATE, there was no difference in outcome for cats receiving low-dose aspirin (5 mg/cat q72h) compared with more typical doses (40-81 mg/cat q48h), and fewer GI side effects were seen at the lower dose. However, given the superiority of clopidogrel (18.75 mg/cat q24h) compared with aspirin (81 mg/cat q72h) in the FATCAT trial, clopidogrel now should be the first-line antiplatelet for treatment or prevention of ATE in cats. Aspirin could be used for cats that fail to tolerate clopidogrel, or possibly as an adjunct antiplatelet in addition to clopidogrel.

Several new antiplatelet medications have been developed recently for use in people. These include later-generation P_{2Y12} platelet inhibitors, such as prasugrel (a third-generation thienopyridine) and ticagrelor (a nonthienopyridine), as well as the $GP\alpha_{IIb}\ \beta_3$ receptor antagonists abciximab and eptifibatide. Prasugrel and ticagrelor have yet to be evaluated in veterinary patients. Abciximab was shown to improve arterial flow in cats with experimentally induced arterial thrombosis but interestingly did not reduce platelet aggregation in vitro. Eptifibatide effectively reduced platelet aggregation in vitro but caused cardiovascular collapse and death when given systemically to cats. Further research is needed before these new drugs are added to the veterinary repertoire.

In addition to antiplatelet therapy, anticoagulation with heparin is used in treatment of acute ATE. Heparin is indicated to limit extension of existing thrombi and prevent additional thrombus formation; it does not promote thrombolysis. Unfractionated heparin and a number of low-molecular-weight heparin (LMWH) products are available. Heparin's main anticoagulant effect occurs through AT activation, which in turn inhibits FIXa, FXa, FXIa, FXIIa, and FIIa (thrombin). Unfractionated heparin binds thrombin and AT. Optimal dosing protocols for animals are not known. For acute ATE, unfractionated heparin is usually given as an initial IV bolus (often 100 U/kg) followed by either a continuous rate infusion or SC injections (see Box 12.3). Heparin is not given IM because of the risk for hemorrhage at the injection site. Unfractionated heparin treatment is continued until the patient is stable and has been on antiplatelet therapy for a few days.

Monitoring the patient's activated partial thromboplastin time (aPTT) has been recommended, although results may not accurately predict serum heparin concentrations; pretreatment coagulation testing is done for comparison, and the goal is to prolong the aPTT to 1.5 to 2.0 times baseline. Monitoring of anti-Xa activity could be a more accurate means of assessing heparin therapy. Hemorrhage is the major complication of heparin therapy. Protamine sulfate can be used to counteract heparin-induced bleeding; however, an overdose of protamine can paradoxically cause irreversible hemorrhage. Dosage guidelines for protamine sulfate are as follows: 1 mg/100 U of heparin is given slowly IV if the heparin was given within the previous 30 minutes; 0.5 mg/100 U of heparin is given if the heparin was given more than 30 but fewer than 60 minutes earlier; and 0.25 mg/100 U of heparin is given if more than 1 hour has elapsed since heparin was administered. Fresh-frozen plasma might be necessary to replenish AT in cases of heparin overdose.

For long-term treatment, LMWH is a safer and more practical alternative to unfractionated heparin. LMWH products are a diverse group of depolymerized heparin that vary in size, structure, and pharmacokinetics. Their smaller size prevents simultaneous binding to thrombin and AT. LMWH products have more specific effect against factor Xa and have minimal ability to inhibit thrombin, thus are less likely to cause bleeding. LMWH products have greater bioavailability and a longer half-life than unfractionated heparin when given subcutaneously because of lesser binding to plasma proteins, as well as endothelial cells and macrophages. However, LMWH products do not markedly affect coagulation times, so aPTT cannot be used to monitor LMWH. LMWH effect can be monitored indirectly

by anti-Xa activity (see Box 12.3). Optimal anti-Xa activity level in cats is not known; the target range in people is reported as 0.5 to 1 U/mL, although 0.3 to 0.6 U/mL has also been used.

The LMWH products have differences in biologic and clinical effects and are not interchangeable. The most effective dosage for the various LMWH products is not clearly established in dogs and cats. Commonly used dosages of dalteparin sodium and enoxaparin (see Box 12.3) have been extrapolated from human use. Although enoxaparin produces anti-Xa activity close to target range at 4 hours postdose in cats, activity is generally undetectable 8 hours later. This finding led to the presumption that higher and more frequent doses should be used to maintain anti-Xa levels closer to human target range. However, this rationale is disputed because it does not appear necessary to maintain peak or target anti-Xa levels throughout the dosing period. Indeed, an experimental study of enoxaparin in a modified venous stasis model in healthy cats showed no correlation between antithrombotic effect and anti-Xa levels; in this model, antithrombotic effect of enoxaparin lasted >12 hours. The optimal therapeutic range in cats and the most effective dosage in cats with ATE remain unknown. LMWHs are relatively expensive and require owner compliance to administer SC injections every 12 to 24 hours.

Warfarin was historically the most common long-term anticoagulant treatment for cats with ATE. However, due to serious risk of bleeding, requirement for frequent monitoring, and availability of alternative anticoagulants (including LMWH), warfarin is now rarely used in cats. Warfarin is still sometimes used in large dogs with systemic TE (see pg. 232) if other agents are cost-prohibitive.

A number of new anticoagulant drugs have been developed for human use and are becoming available for veterinary patients. In people, these drugs offer similar or improved antithrombotic efficacy compared with warfarin, with fewer side effects. Synthetic factor Xa inhibitors (e.g., rivaroxaban, apixiban, fondaparinux) potentiate effects of AT without affecting thrombin or platelet function. Their effect is monitored via anti-Xa activity measurement because they do not affect results of routine coagulation tests. Fondaparinux is given SC, whereas apixaban and rivaroxaban are both oral. Doses for rivaroxaban, apixaban, and fondaparinux in cats have been published based on pharmacokinetics and anti-Xa activity in healthy cats; however, clinical efficacy in cats with ATE has yet to be investigated. Dabigatran etexilate is an oral direct thrombin inhibitor; use of this medication has not been reported in veterinary medicine.

All treatments for ATE discussed thus far are supportive rather than directed therapy; the common approach is essentially to support the cat while the patient's own intrinsic fibrinolytic system breaks down the embolus, rather than pursuing treatment specifically aimed at dissolving the clot. However, thrombolytic drugs that directly promote clot lysis are available. These medications increase conversion of plasminogen to plasmin, thus facilitating fibrinolysis. The most commonly used thrombolytic agent in veterinary medicine is human recombinant tissue plasminogen activator (rt-PA). rt-PA is a single-chain polypeptide serine protease with a higher specificity for fibrin within thrombi and a low affinity for circulating plasminogen. The risk of hemorrhage is therefore less with rt-PA than with nonspecific plasminogen activators such as streptokinase and urokinase. However, there remains the potential for serious bleeding, reperfusion injury, and neurologic adverse effects. rt-PA also is potentially antigenic in animals because it is a human protein.

Veterinary experience with rt-PA is limited, it is relatively expensive, and the optimal dosage is not known; the most commonly used dose is 5 mg per cat, generally given as a front-loaded IV infusion over 1 to 2 hours (see Box 12.3). In a case series of 11 cats with ATE, rt-PA administration was associated with improved limb function and return of pulses; however, there was a high rate of adverse effects related to reperfusion injury (azotemia, hyperkalemia, and neurologic signs), and mortality was high. Thus although rt-PA can effectively break down clots, a clear survival advantage has not been shown. If used, this therapy is best instituted within 3 to 4 hours of vascular occlusion. An intensive care setting, including frequent monitoring of serum potassium concentration, acid-base status, and electrocardiogram (ECG), is important to detect reperfusion-induced hyperkalemia and metabolic acidosis. The risk-to-benefit profile of thrombolytic treatment may be more favorable in patients with brain, renal, or splanchnic thromboembolism. Other thrombolytics, including the nonspecific plasminogen activators streptokinase and urokinase, are associated with even more severe side effects and higher mortality, and are not currently recommended.

Surgical thromboembolus removal is typically not advised in cats. The surgical risk is high, and significant neuromuscular ischemic injury is likely to have already occurred by the time of surgery. Percutaneous clot removal using an embolectomy catheter has not been effective in cats.

In general, the prognosis for cats with ATE is poor. Many cats are euthanized on presentation (approximately ⅓ of cats in reports from tertiary care facilities, and nearly ⅔ of cats in a primary care setting). Of cats where treatment is attempted, approximately half survive the initial ATE episode regardless of therapy chosen (conservative or thrombolytic). Survival is better if only one limb is involved and/or if some motor function is preserved at presentation. Hypothermia and CHF at presentation are both associated with poor survival in cats. Other negative factors can include hyperphosphatemia, progressive hyperkalemia or azotemia, bradycardia, persistent lack of motor function, progressive limb injury (continued muscle contracture after 2-3 days, necrosis), severe LA enlargement, presence of intracardiac thrombi or spontaneous contrast ("swirling smoke") on echocardiogram, DIC, and history of previous ATE. Significant embolization of the kidneys, intestines, or other organs carries a grave prognosis.

Barring complications, limb function should begin to return within days to a week. Some cats become clinically normal within 1 to 2 months, although residual deficits can

persist for a variable time. Tissue necrosis might require wound management and skin grafting. Permanent limb deformity develops in some cats, and amputation is occasionally necessary. Repeated ATE events are common, as is progressive CHF. Overall, median long-term survival is approximately 6 to 9 months.

PROPHYLAXIS AGAINST ARTERIAL THROMBOEMBOLISM IN CATS

Prophylactic therapy with an antiplatelet or anticoagulant drug is commonly used in cats thought to be at increased risk for ATE. This includes cats with history of ATE, as well as cats with cardiomyopathy and moderate to severe LA enlargement, decreased LA or auricular function, or intracardiac spontaneous echo-contrast or thrombus on echocardiography, However, the efficacy of thromboprophylaxis is unknown, and a strategy that consistently prevents ATE has not been identified.

Drugs used for ATE prophylaxis include platelet inhibitors (clopidogrel or aspirin), LMWH, warfarin, and factor Xa antagonists. The antiplatelet drugs are prescribed most commonly, both because they target platelet adhesion (the most critical factor for thrombus formation in high-shear states), and because platelet inhibitors present a low risk for serious hemorrhage and require minimal monitoring. Clopidogrel is preferred over aspirin based on its superior clinical effect in prevention of secondary ATE in cats, although a comparison of clopidogrel versus aspirin for prevention of *primary* ATE has not been undertaken. Warfarin rarely is used because of increased bleeding risk, frequent monitoring required, and lack of demonstrated survival benefit. LMWH is expensive and must be given by SC injection, but some owners are motivated to do this. Platelet inhibitors can be used concurrently with LMWH in cats that are not thrombocytopenic. No studies have evaluated the efficacy of antiplatelet or anticoagulant drugs in prevention of ATE in cats. Therefore empiric decisions about thromboprophylaxis are clinician-dependent judgments based on risk stratification: cats with HCM and severe LA often receive clopidogrel alone, whereas cats with spontaneous echo-contrast, an intracardiac thrombus, or history of ATE might receive clopidogrel in combination with LMWH or a factor Xa inhibitor.

SYSTEMIC ARTERIAL THROMBOSIS IN DOGS

Arterial thrombotic disease in dogs is relatively uncommon compared with cats. However, the true prevalence is unknown and may be underrecognized in dogs because of differences in pathogenesis and clinical presentation. The distal aorta is the most commonly reported location, and in dogs usually results from primary (in situ) thrombus formation, rather than an acute distant embolic event as in cats. The development of clinical signs in these dogs is usually more vague and chronic. Aortic thrombosis in dogs has been associated with many conditions, including systemic and endocrine diseases leading to hypercoagulability, neoplasia, aortic disease, and some cardiovascular diseases. However, in many cases (up to half of dogs with aortic thrombosis in some reports) no predisposing abnormality can be found. Aortic thrombosis appears more prevalent in male compared with female dogs. It is unclear whether any true breed predisposition exists, although Greyhounds, Cavalier King Charles Spaniels, and Labradors might be overrepresented.

The most common cause of aortic thrombosis in dogs is protein-losing nephropathy, in which urinary loss of AT leads to a hypercoaguable state. Similarly, protein-losing enteropathy could predispose dogs to aortic thrombosis via alimentary loss of AT. Other procoagulant conditions commonly associated with aortic thrombosis in dogs include hyperadrenocorticism (or recent steroid administration), hypothyroidism, and diabetes mellitus. Neoplasia can result in TE disease either via tumor embolism or by inducing a paraneoplastic hypercoagulable state. Common neoplasms associated with aortic thrombosis include hemangiosarcoma, pulmonary carcinoma, osteosarcoma, intravascular lymphoma, and adrenal tumors. Diseases directly affecting the aorta, including aortitis, aortic intimal fibrosis, atherosclerosis, aortic dissection, or aortic tumors, can also cause aortic thrombosis.

Unlike in cats, common primary structural cardiac diseases of dogs (cardiomyopathy or degenerative valve disease) rarely cause thrombosis. The most common cardiac diseases associated with systemic thrombotic disease in dogs are vegetative endocarditis and cardiac neoplasia. Other cardiovascular conditions occasionally associated with canine thrombotic disease include patent ductus arteriosus (thrombosis at the surgical ligation site), arteritis, LA rupture, or granulomatous inflammatory erosion into the LA. In the presence of a right-to-left shunting atrial or ventricular septal defect, fragments originating from venous thrombosis could cross the defect to cause systemic arterial embolization.

Atherosclerosis is uncommon in dogs, but it has been associated with thrombotic disease in this species, as it has in people. Endothelial disruption in areas of atherosclerotic plaque, hypercholesterolemia, increased PAI-1, and possibly other mechanisms could be involved in thrombus formation. Atherosclerosis may develop with profound hypothyroidism, hypercholesterolemia, or hyperlipidemia. The aorta, coronary arteries, and other medium to large arteries are affected. Myocardial and cerebral infarctions occur in some cases, and there is a high rate of interstitial myocardial fibrosis in affected dogs. Vasculitis related to infectious, inflammatory, immune-mediated, neoplastic, or toxic disease can underlie thrombosis or embolic events. Arteritis of immune-mediated pathogenesis is described in some young Beagles and other dogs.

Clinical Features

The distal aorta is the most common location for clinically recognized TE disease in dogs. Affected dogs typically present for intermittent rear limb lameness or paresis

(claudication) and have weak femoral pulses on the affected side. In contrast to cats, most dogs have more chronic clinical signs (>2 weeks before presentation). Less than a quarter of dogs have peracute paralysis without prior signs of lameness. These species differences support the notion that aortic thrombi in dogs form in situ in the caudal aorta, rather than embolizing from a distant location as in cats. Clinical signs in dogs include unilateral or bilateral hindlimb lameness or paresis (which may be progressive or intermittent), exercise intolerance, pain, and self-trauma or hypersensitivity of the affected limb(s) or lumbar area. Most dogs are ambulatory on presentation. Intermittent claudication, common in people with peripheral occlusive vascular disease, can be a manifestation of distal aortic TE disease. This involves pain, weakness, and lameness that develop during exercise. Inadequate perfusion during exercise leads to lactic acid accumulation and cramping. These signs intensify until walking becomes impossible and they then disappear with rest.

Key physical examination findings in dogs with aortic thrombosis include absent or weak femoral pulses and hindlimb neuromuscular dysfunction. Cool extremities, hindlimb pain, loss of sensation in the digits, hyperesthesia, and cyanotic nailbeds are variably present. Occasionally, a brachial or other artery is embolized. TE disease involving an abdominal organ causes abdominal pain, with clinical and laboratory evidence of damage to the affected organ.

Coronary artery thromboembolism usually results in arrhythmias, as well as ST segment and T-wave changes on ECG. Ventricular (or other) tachyarrhythmias are common, although if the atrioventricular (AV) nodal area is injured, conduction block may result. Clinical signs of acute myocardial infarction/necrosis can mimic those of pulmonary TE disease; these include weakness, dyspnea, and collapse. Patients might have a heart murmur, tachycardia, and weak pulses. Respiratory difficulty can develop as a result of left-sided CHF (depending on degree of myocardial dysfunction) or concurrent pulmonary abnormalities, including pulmonary thromboembolism. Coronary artery thromboembolism also can cause sudden death; the associated acute ischemic myocardial injury might not be detectable on routine histopathology.

Diagnosis

Definitive diagnosis requires direct visualization of the thrombus. Typically, abdominal ultrasonography is used to identify an intraluminal or mural mass in the distal aorta (or other vessels). Doppler studies can demonstrate partial or complete obstruction to blood flow in some cases. Computed tomography (CT) with contrast or angiography can also demonstrate presence of the thrombus and vascular occlusion. Contrast imaging can be valuable in cases where ultrasound is inconclusive, to demonstrate collateral circulation, or if concurrent CT imaging of other body areas is desired.

Once the diagnosis of aortic thrombosis is confirmed, additional testing is indicated to look for an underlying cause. Thoracic radiography provides an initial screen for cardiac abnormalities. Evidence for CHF or pulmonary abnormalities associated with TE disease (e.g., neoplasia, HWD, other infections) may also be found. Echocardiography is indicated to identify and characterize heart disease (if present), particularly vegetative endocarditis or cardiac neoplasia. Thrombi within the left or right heart chambers and proximal great vessels can be readily seen with two-dimensional echocardiography. In dogs with coronary TE disease, the echocardiographic examination might indicate reduced myocardial contractility with or without regional dysfunction. Spontaneous echo-contrast ("swirling smoke") could be seen in one or both ventricles; similar to cats, this finding is thought to indicate increased risk for TE disease.

Routine laboratory test results depend largely on the disease process underlying the TE event(s). Azotemia and proteinuria are common, because protein-losing nephropathy is the most common disease causing aortic thrombosis. Systemic arterial TE disease also produces elevated muscle enzyme activities from skeletal muscle ischemia and necrosis, including CK, AST, and ALT.

Coagulation test results in dogs with thrombotic disease are variable. The concentration of FDPs or D-dimers may be increased, but this can occur in patients with inflammatory disease and is not specific for a TE event or DIC. Modestly increased D-dimer concentrations also can occur in diseases associated with procoagulant states, such as neoplasia, liver disease, and IMHA, as well as in body cavity hemorrhage (due to increased fibrin formation). Elevation of D-dimers is therefore a sensitive but nonspecific test for pathologic thromboembolism. It is important to interpret D-dimer results in the context of other clinical and test findings. Assays for circulating AT and proteins C and S are available for dogs and cats also. Deficiencies of these proteins are associated with increased risk of thrombosis.

TEG provides an easy point-of-care method of assessing global hemostasis and can be used to demonstrate hypercoagulability in patients with TE disease. However, in most Greyhounds and other sighthounds with aortic thrombosis, results of TEG are within normal limits for the breed.

Treatment and Prognosis

Although the clinical presentation often is more subtle and chronic in canine aortic thrombosis compared with feline ATE, the goals of therapy are the same: stabilize the patient by supportive treatment as indicated, prevent extension of the existing thrombus and additional TE events, and restore perfusion. Supportive care is given to improve and maintain adequate tissue perfusion, minimize further endothelial damage and blood stasis, and optimize organ function, as well as to allow time for collateral circulation development. Correcting or managing underlying disease(s), to the extent possible, is important. Antiplatelet and anticoagulant therapies are used to reduce platelet aggregation and growth of existing thrombi (see p. 232 and Box 12.3). Coagulation testing, including TEG if available, should be used to monitor response to anticoagulants in patients with TE disease.

Management strategies used for TE disease in dogs are outlined in Box 12.3. Although fibrinolytic therapy is available, its use is limited by dosage uncertainties, the need for intensive care, and the potential for serious complications. Systemic thrombolysis with rt-PA and streptokinase have been reported in dogs, with variable success. Locally directed thrombolysis (catheter delivery of rt-PA directly to the side of thrombosis) is feasible in dogs and may reduce systemic effects of thrombolytics. Interventional radiology techniques can also be used to break down or remove thrombi percutaneously via catheter-directed thrombectomy and embolectomy. These techniques have not been effective in cats with ATE but might hold promise in dogs of larger size. Arterial stenting has been used successfully in some dogs with aortic thromboembolism. The consequences of reperfusion injury and distal embolization of clot fragments remain serious concerns with any form of thrombolytic therapy.

Fluid therapy is used (in patients without CHF) to expand vascular volume, support blood pressure, and correct electrolyte and acid/base abnormalities depending on individual patient needs. Hypothermia that persists after circulating volume is restored can be addressed with external warming. Concurrent CHF is rarely a concern because cardiac disease is an uncommon cause of aortic thrombosis in dogs; acute respiratory signs are more likely to signal pain or pulmonary thromboembolism. In cases where heart disease is present, treatment for CHF or arrhythmias is provided as indicated (see Chapters 3 and 4 and other relevant chapters).

Analgesic therapy is important in cases of acute ATE, which is particularly painful especially for the first 24 to 36 hours (see Box 12.3). Chronic in situ aortic thrombosis is less painful, and analgesics may or may not be indicated. Loosely bandaging the affected limb(s) to prevent self-mutilation might be necessary. Renal function, serum electrolyte concentrations, and ECG rhythm are monitored frequently to help detect acute hyperkalemia associated with reperfusion (see Chapter 2, p. 47).

Antiplatelet and anticoagulant therapies are indicated to prevent growth of the existing clot and decrease additional thrombus formation. Drug options are the same as in cats, and no standard therapeutic protocol has been established. Given that aortic thrombi in dogs generally develop in situ in the distal aorta (an area of high-shear blood flow), platelet inhibitors are thought to be particularly important. As in cats, clopidogrel and aspirin are the most commonly used antiplatelet medications. There are few studies evaluating efficacy of antiplatelet drugs in dogs, and none specifically in dogs with aortic thrombosis. In dogs with IMHA, a disease known to predispose dogs to TE disease (though more commonly pulmonary thromboemboli), a retrospective study suggested that dogs that received ultra–low-dose aspirin (0.5 mg/kg PO q24h) in addition to other therapies had improved survival compared with dogs that did not receive aspirin. Although this study does not prove efficacy of aspirin in preventing TE disease, it did establish safety of ultra–low-dose aspirin in a patient population concurrently receiving immunosuppressive doses of glucocorticoids. Clopidogrel (at a dose of 2-4 mg/kg PO q24h) is more effective than aspirin for in vitro platelet inhibition. At this dose, effective levels of clopidogrel are achieved within 3 days; alternatively, an oral loading dose (10 mg/kg) can provide antithrombotic effect in dogs within 90 minutes. However, unlike in cats, there is no convincing evidence of clinical superiority of clopidogrel over aspirin. In a subsequent prospective study of dogs with IMHA, there was no difference in outcome between dogs given clopidogrel, ultra–low-dose aspirin, or both, although sample size was low. Both drugs are well-tolerated in dogs, with minimal GI effects of aspirin at such low doses; aspirin is less expensive than clopidogrel. Thus although many clinicians prefer clopidogrel based on its superior platelet inhibition in vitro, low-dose aspirin remains a reasonable, inexpensive alternative in dogs.

Anticoagulants are recommended in addition to antiplatelet drugs in dogs with aortic thrombosis. In the acute setting, unfractionated heparin remains the mainstay of treatment. A common initial dose is 100 IU/kg IV bolus followed by 600 to 800 IU/kg/day (as a CRI or divided into q8h intermittent boluses), although the ideal dose has not been established. Monitoring recommendations are similar to those for cats, with the goal of prolonging aPTT to 1.5-2.5× baseline value. However, recent evidence suggests that monitoring anti-FXa activity might better assess anticoagulant effects of unfractionated heparin and may improve survival. After initial stabilization, or for dogs with more chronic clinical signs, dogs are transitioned to more long-term anticoagulation with LMWH, warfarin, or a factor Xa inhibitor (see later).

In general, the prognosis for aortic thrombosis in dogs is guarded to poor, with 50% to 60% of dogs surviving to discharge. Rear limb function improvement could be seen within several days of initiating therapy; however, 2 or more weeks are required in most cases. Prognosis for dogs that are ambulatory on presentation, and those with chronic clinical signs, is much better than for dogs with acute-onset signs or that are nonambulatory on presentation.

PROPHYLAXIS AGAINST AORTIC THROMBOSIS

Strategies to prevent recurrence of ATE in dogs are similar to those used in cats. Generally, a combination of an antiplatelet (clopidogrel or aspirin) and anticoagulant is used. Options for long-term anticoagulants include LMWH, warfarin, and factor Xa inhibitors. LMWHs (such as dalteparin and enoxaparin) require SC administration, and their expense makes them cost-prohibitive for medium- to large-breed dogs. Therefore although LMWH has essentially replaced warfarin as the anticoagulant of choice in cats with ATE, warfarin remains a reasonable treatment option for dogs with aortic thrombosis because of their larger body size.

Warfarin inhibits the enzyme (vitamin K epoxide reductase) responsible for activating the vitamin K–dependent clotting factors (II, VII, IX, and X), as well as proteins C and S. Initial warfarin treatment causes transient hypercoagulability

because the anticoagulant proteins have a shorter half-life than most procoagulant factors. Therefore unfractionated heparin or LMWH is given concurrently for 2 to 4 days after warfarin is initiated. There is wide variability in dose response to warfarin and potential for serious bleeding. Warfarin is highly protein bound; concurrent use of other protein-bound drugs or change in serum protein concentration can markedly alter the anticoagulant effect. Intensive monitoring is required and frequent dose adjustments might be necessary initially. Uneven distribution of drug within the tablets is reported, so compounding rather than administering tablet fragments is recommended.

The initial recommended dose of warfarin is 0.05 to 0.2 mg/kg PO q24h. After initiation of treatment, the dose is adjusted based on PT and international normalization ratio (INR). INR is a more precise method of serial coagulation monitoring recommended to prevent problems related to variation in commercial PT assays. The INR is calculated by dividing the animal's PT by the control PT and raising the quotient to the power of the international sensitivity index (ISI) of the thromboplastin used in the assay, or INR = (animal PT/control PT)^{ISI}. The ISI is provided with each batch of thromboplastin made. Extrapolation from human data suggests that an INR of 2 to 3 provides therapeutic anticoagulation with less chance for bleeding. Heparin overlap until the INR is greater than 2 is recommended. A coagulation panel, INR, and platelet count are evaluated at baseline before warfarin administration. INR is then rechecked 1 to 3 days after initiation of warfarin and then at progressively increasing time intervals, with INR values guiding dose adjustments and time interval until the next recheck (see Table 12.1). Dose adjustments are small (5%-20%) and are made based on the total *weekly* dose, which may require some variation in day-to-day doses. Drug administration and blood sampling times should be consistent. If the INR increases excessively, warfarin is discontinued and vitamin K_1 administered (1-2 mg/kg/day administered orally or subcutaneously) until the PT is normal and the packed cell volume (PCV) is stable. Transfusion with fresh-frozen plasma, packed red blood cells, or whole fresh blood sometimes is necessary.

Direct factor Xa inhibitors are emerging as attractive alternatives to warfarin for long-term management of thrombotic disease in dogs. In people, these oral medications have equal or superior efficacy to warfarin with reduced risk of bleeding. The favorable adverse effect profile also means less monitoring and increased convenience. Fondaparinux (Arixtra) is a synthetic pentasaccharide that binds to both AT and factor Xa with high affinity, thus selectively inhibiting factor Xa. Rivaroxaban (Xarelto) and apixaban (Eliquis) directly bind to and inhibit factor Xa without involvement of AT. Although there are published doses in cats for all three factor Xa inhibitors, rivaroxaban is the only drug with clinical dosing information described in dogs. A dose of rivaroxaban 0.5 to 1.0 mg/kg PO q24h appears to be well tolerated and was associated with decreased thrombus size in a small number of dogs. Although further research will be required to establish efficacy and ideal dosing protocols, these drugs provide an exciting alternative to warfarin in dogs with aortic thrombosis.

TABLE 12.1

Guidelines for Adjusting Total Weekly Warfarin Dose*

INR	TOTAL WEEKLY WARFARIN DOSE ADJUSTMENT	RECHECK INR IN
1.0-1.4	Increase TWD by 10%-20%	1 week
1.5-1.9	Increase TWD by 5%-10%	2 weeks
2.0-3.0	No change in TWD	4-6 weeks
3.1-4.0	Decrease TWD by 5%-10%	2 weeks
4.1-5.0	Stop warfarin for 1 day Decrease TWD 10%-20%	1 week
>5.0	Stop warfarin until INR < 3.0 Decrease TWD 20%-40%	1 week

INR = (animal PT/control PT)^{ISI}
Control PT, Laboratory reference mean prothrombin time; *INR,* international normalized ratio; *ISI,* international sensitivity index (of the thromboplastin reagent); *TWD,* total weekly warfarin dose.
*See text for additional information.

VENOUS THROMBOSIS

Thrombosis in large veins is more likely to be clinically evident than thrombosis in small vessels. Cranial vena caval thrombosis in dogs has been associated with many disease processes causing hypercoagulability, including IMHA and/or immune-mediated thrombocytopenia, sepsis, neoplasia, protein-losing nephropathies, fungal disease, cardiac disease, and glucocorticoid therapy. Most cases have more than one predisposing factor. An indwelling jugular catheter or permanent pacemaker lead increases the risk for cranial caval thrombosis, probably by causing vascular endothelial damage or laminar flow disruption or by acting as a nidus for clot formation.

Portal vein thrombosis, along with DIC, has occurred in dogs with pancreatitis and pancreatic necrosis. Peritonitis, neoplasia, hepatitis, protein-losing nephropathy, IMHA, and vasculitis have also been diagnosed occasionally in dogs with portal thrombosis. A high proportion of dogs with incidental portal or splenic vein thrombosis were receiving corticosteroids.

Venous thrombosis produces signs related to increased venous pressure upstream from the obstruction. Portal vein thrombosis can result in ascites. Thrombosis of the cranial vena cava can lead to the cranial caval syndrome, characterized by bilaterally symmetric subcutaneous edema of the head, neck, and forelimbs. Another cause of this syndrome

is external compression of the cranial cava, usually by a mass. Pleural effusion occurs commonly; the effusion is often chylous because lymph flow from the thoracic duct into the cranial vena cava also is impaired. Thrombosis that extends into the jugular veins is palpable in some cases. Because vena caval obstruction reduces pulmonary blood flow and both left heart and right heart filling, signs of poor cardiac output are common.

Diagnosis of venous thrombosis is confirmed using ultrasound or contrast imaging (angiography or CT with contrast). Vena caval thrombosis might be visible on echocardiogram, especially when the clot extends into the RA. Thrombosis of the portal vein or caudal vena cava can be documented on abdominal ultrasound. Computer tomography with contrast can allow imaging of multiple body areas to demonstrate thrombosis (luminal masses within vessels with associated filling defects).

Clinicopathologic findings generally reflect underlying disease and tissue damage resulting from vascular obstruction. Cranial caval thrombosis has been associated with thrombocytopenia. Management is as discussed earlier for arterial thrombosis, with an emphasis on anticoagulants rather than antiplatelet drugs because of the low shear conditions in the venous system. Stenting of the affected vessel is another therapeutic option.

CHAPTER 13

Clinical Manifestations of Nasal Disease

GENERAL CONSIDERATIONS

The nasal cavity and paranasal sinuses have a complex anatomy and are lined by mucosa. Their rostral portion is inhabited by bacteria in health. Nasal disorders are frequently associated with mucosal edema, inflammation, and secondary bacterial infection. They are often focal or multifocal in distribution. These factors combine to make the accurate diagnosis of nasal disease a challenge that can be met only through a thorough, systematic approach.

Diseases of the nasal cavity and paranasal sinuses typically cause nasal discharge, congestion, sneezing, or stertor (i.e., snoring or snorting sounds). Less common signs include facial deformity, systemic signs of illness (e.g., lethargy, inappetence, weight loss), or, rarely, central nervous system signs. The general diagnostic approach to animals with nasal disease is included in the discussion of nasal discharge. Specific considerations related to sneezing, stertor, and facial deformity follow. Stenotic nares are discussed in the section on brachycephalic airway syndrome (see Chapter 18).

Nasal foreign bodies are mentioned throughout the discussion of nasal disease. Nasal foreign bodies most often enter the nasal cavity through the external nares, although nasal or pharyngeal signs can also be the result of foreign material taken into the mouth and subsequently coughed into the caudal nasopharynx. Plant material is most often the culprit. Blades of grass, grass seeds arranged in heads with stiff bristles (grass awns; Fig. 13.1), and thin, stiff leaves (such as those of juniper bushes and cedar trees) have a physical design that facilitates movement in one direction. Consider running a blade of grass between your fingertips. Usually the grass moves smoothly in one direction but resists movement in the other. Because of this property, attempts to expel the foreign material by coughing or sneezing often cause the material to travel more deeply into the body instead. Nasal foreign bodies are particularly common in the western United States, where "foxtail" grasses (those with awns) are widespread. Awns can enter the body through any orifice, even through intact skin; the external nares are one common route.

NASAL DISCHARGE

Classification and Etiology

Nasal discharge is most commonly associated with disease localized solely within the nasal cavity and paranasal sinuses, although it may also develop with disorders of the lower respiratory tract, such as bacterial pneumonia and infectious tracheobronchitis, or with systemic disorders, such as coagulopathies and systemic hypertension. Nasal discharge is characterized as serous, mucopurulent with or without hemorrhage, or purely hemorrhagic (epistaxis). Serous nasal discharge has a clear, watery consistency. Depending on the quantity and duration of the discharge, a serous discharge may be normal, may be indicative of viral upper respiratory infection, or may precede the development of a mucopurulent discharge. As such, many of the causes of mucopurulent discharge can initially cause serous discharge (Box 13.1).

Mucopurulent nasal discharge typically is characterized by a thick, ropey consistency and has a white, yellow, or green tint. A mucopurulent nasal discharge implies inflammation. Most intranasal diseases result in inflammation and secondary bacterial infection, making this nonspecific sign a common presentation for most nasal diseases. Potential etiologies include infectious agents, foreign bodies, neoplasia, polyps, and extension of disease from the oral cavity (see Box 13.1). If mucopurulent discharge is present in conjunction with signs of lower respiratory tract disease, such as cough, respiratory distress, or auscultable crackles, the diagnostic emphasis is initially on evaluation of the lower airways and pulmonary parenchyma. Hemorrhage may be associated with mucopurulent exudate from any etiology, but significant and prolonged bleeding in association with

FIG 13.1
Typical grass awn. Seed heads from "foxtail" grasses have stiff bristles that facilitate movement of the awns in one direction and make it difficult for the awns to be expelled from the body. (Courtesy Lynelle R. Johnson.)

mucopurulent discharge is usually associated with neoplasia or mycotic infections.

Persistent pure hemorrhage (epistaxis) can result from trauma, local aggressive disease processes (e.g., neoplasia, mycotic infections), systemic bleeding disorders, or systemic hypertension. Systemic hemostatic disorders that can cause epistaxis include thrombocytopenia, thrombocytopathies, von Willebrand disease, rodenticide toxicity, and vasculitides. Ehrlichiosis, Rocky Mountain spotted fever and, potentially, bartonellosis can cause epistaxis through several of these mechanisms. Nasal foreign bodies may cause hemorrhage after entry into the nasal cavity, but the bleeding tends to subside quickly. Bleeding can also occur after aggressive sneezing from any cause.

Diagnostic Approach

A complete history and physical examination can be used to prioritize the differential diagnoses for each type of nasal discharge (see Box 13.1). Acute and chronic diseases are defined by obtaining historical information regarding the onset of signs and by evaluating the overall condition of the animal. Acute processes, such as foreign bodies or acute feline viral infections, often result in a sudden onset of signs, including sneezing, although the animal's body condition is excellent. In chronic processes, such as mycotic infections or neoplasia, signs are present over a long period, and the overall body condition may be deleteriously affected. A history of gagging, retching, or reverse sneezing may indicate masses, foreign bodies, or exudate in the caudal nasopharynx.

Nasal discharge is characterized as unilateral or bilateral on the basis of both historical and physical examination findings. When nasal discharge is apparently unilateral, a cold microscope slide may be held close to the external nares to determine the patency of the side of the nasal cavity without discharge. Condensation will not be visible in front

BOX 13.1

Differential Diagnoses for Nasal Discharge in Dogs and Cats

Serous Discharge

Normal
Viral infection
Early sign of etiology of mucopurulent discharge

Mucopurulent Discharge with or without Hemorrhage

Viral infection
  Feline herpesvirus (rhinotracheitis virus)
  Feline calicivirus
  Canine influenza virus
Bacterial infection (usually secondary)
  Mycoplasma felis (possibly primary)
Fungal infection
  Aspergillus
  Cryptococcus
  Penicillium
  Rhinosporidium
Nasal parasites
  Pneumonyssoides
  Capillaria (Eucoleus)
Foreign body
Neoplasia
  Carcinoma
  Sarcoma
  Malignant lymphoma
Nasopharyngeal polyp
Extension of oral disease
  Tooth root abscess
  Oronasal fistula
  Deformed palate
Allergic rhinitis
Feline chronic rhinosinusitis
Canine chronic/lymphoplasmacytic rhinitis

Pure Hemorrhagic Discharge (Epistaxis)

Nasal disease
  Acute trauma
  Acute foreign body
  Neoplasia
  Fungal infection
  Less commonly, other etiologies as listed for mucopurulent discharge
Systemic disease
  Clotting disorders
  • Thrombocytopenia
  • Thrombocytopathy
  • Coagulation defect
  Vasculitis
  Hyperviscosity syndrome
  Polycythemia
  Systemic hypertension

of the naris if airflow is obstructed, which suggests that the disease is actually bilateral. Although any bilateral process can cause signs from one side only and unilateral disease can progress to involve the opposite side, some generalizations can be made. Systemic disorders and infectious diseases tend to involve both sides of the nasal cavity, whereas foreign bodies, polyps, and tooth root abscessation tend to cause unilateral discharge. Neoplasia initially may cause unilateral discharge that later becomes bilateral after destruction of the nasal septum.

Ulceration of the nasal plane is highly suggestive of a diagnosis of nasal aspergillosis (Fig. 13.2). Polypoid masses protruding from the external nares in the dog are typical of rhinosporidiosis, and in the cat they are typical of cryptococcosis.

A thorough assessment of the head, including facial symmetry, teeth, gingiva, hard and soft palate, mandibular lymph nodes, and eyes, should be performed. Mass lesions invading beyond the nasal cavity can cause deformity of facial bones or the hard palate, exophthalmos, or inability to retropulse the eye. Pain on palpation of the nasal bones is suggestive of aspergillosis. Gingivitis, dental calculi, loose teeth, or pus in the gingival sulcus should raise an index of suspicion for oronasal fistulae or tooth root abscess, especially if unilateral nasal discharge is present. Foci of inflammation and folds of hyperplastic gingiva in the dorsum of the mouth should be probed for oronasal fistulae. **A normal examination of the oral cavity does not rule out oronasal fistulae or tooth root abscess.** The hard and soft palates are examined for deformation, erosions, or congenital defects such as clefts or hypoplasia. Mandibular lymph node enlargement suggests active inflammation or neoplasia, and fine-needle aspirates of enlarged or firm nodes are evaluated for organisms, such as *Cryptococcus,* and neoplastic cells (Fig. 13.3). A fundic examination should always be performed because active chorioretinitis can occur with cryptococcosis, ehrlichiosis, and malignant lymphoma (Fig. 13.4). Retinal detachment can occur with systemic hypertension or mass lesions extending into the bony orbit. With epistaxis, identification of petechiae or hemorrhage in other mucous membranes, skin, ocular fundus, feces, or urine supports a systemic bleeding disorder. Note that melena may be present as a result of swallowing blood from the nasal cavity.

FIG 13.2
Depigmentation and ulceration of the planum nasale are suggestive of nasal aspergillosis. The visible lesions usually extend from one or both nares and are most severe ventrally. This dog has unilateral depigmentation and mild ulceration.

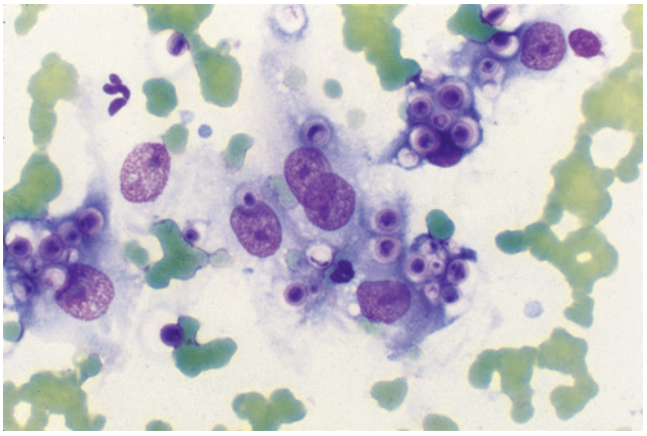

FIG 13.3
Photomicrograph of fine-needle aspirate of a cat with facial deformity. Identification of cryptococcal organisms provides a definitive diagnosis for cats with nasal discharge or facial deformity. Organisms can often be found in swabs of nasal discharge, fine-needle aspirates of facial masses, or fine-needle aspirates of enlarged mandibular lymph nodes. The organisms are variably sized, ranging from about 3 to 30 μm in diameter, with a wide capsule and narrow-based budding. They may be found intracellularly or extracellularly.

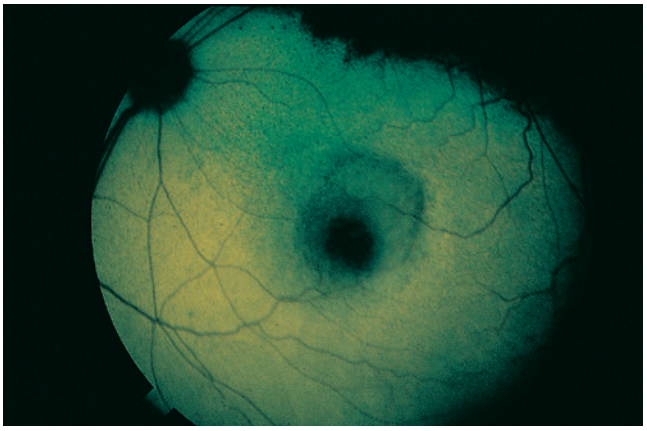

FIG 13.4
Fundic examination can provide useful information in animals with signs of respiratory tract disease. This fundus from a cat with chorioretinitis caused by cryptococcosis has a large, focal, hyporeflective lesion in the area centralis. Smaller regions of hyporeflectivity are also seen. The optic disk can be seen in the upper left-hand corner of the photograph. (Courtesy M. Davidson, North Carolina State University, Raleigh, NC.)

Diagnostic tests that should be considered for a dog or cat with nasal discharge are presented in Box 13.2. The signalment, history, and physical examination findings dictate in part which diagnostic tests are ultimately required to establish the diagnosis. As a general rule, less invasive diagnostic tests are performed initially. A complete blood count with platelet count, a coagulation panel (i.e., activated clotting time or prothrombin and partial thromboplastin times), buccal mucosal bleeding time, and arterial blood pressure should be evaluated in dogs and cats with epistaxis. Von Willebrand factor assays are performed in purebred dogs with epistaxis and in dogs with prolonged mucosal bleeding times. Determination of *Ehrlichia* spp. and Rocky Mountain spotted fever titers are indicated for dogs with epistaxis in regions of the country where potential exposure to these rickettsial agents exists. Testing for *Bartonella* spp. is also considered. Testing for feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV) should be performed in cats with chronic nasal discharge and potential exposure. Cats infected with FeLV may be predisposed to chronic infection with herpesvirus or calicivirus, whereas those with FIV may have chronic nasal discharge without concurrent infection with these upper respiratory viruses.

Most animals with intranasal disease have normal thoracic radiographs. However, thoracic radiographs may be useful in identifying primary bronchopulmonary disease, pulmonary involvement with cryptococcosis, and rare metastases from neoplastic disease. They may also serve as a useful preanesthetic screening test for animals that will require nasal imaging, rhinoscopy, and nasal biopsy.

Cytologic evaluation of superficial nasal swabs may identify cryptococcal organisms in cats (see Fig. 13.3). Nonspecific findings include proteinaceous background, moderate to severe inflammation, and bacteria. Mandibular lymph node aspirates may provide a diagnosis of cryptococcosis in cats or neoplasia in dogs or cats.

Tests to identify herpesvirus, calicivirus, and *Mycoplasma felis* infections may be performed in cats with acute and chronic rhinitis. These tests are most useful in evaluating cattery problems or cats with persistent clinical signs (see Chapter 15, Feline Upper Respiratory Infection).

Fungal titer determinations are available for aspergillosis in dogs and cryptococcosis in dogs and cats. The test for aspergillosis detects antibodies in the blood. A single positive test result strongly suggests active infection by the organism; however, a negative titer does not rule out the disease. In either case, the result of the test must be

BOX 13.2

General Diagnostic Approach to Dogs and Cats with Chronic Nasal Discharge

Phase I (Noninvasive Testing)

All Patients	Dogs	Cats	Dogs and Cats with Hemorrhage
History	*Aspergillus* titer	Nasal swab cytologic evaluation (cryptococcosis)	Complete blood count
Physical examination	Fecal flotation	Cryptococcal antigen titer	Platelet count
Funduscopic examination	*Capillaria/Eucoleus)*	Viral testing	Coagulation times
Thoracic radiographs		Feline leukemia virus	Buccal mucosal bleeding time
Mandibular lymph node cytology		Feline immunodeficiency virus	Tests for tick-borne diseases (dogs)
		Herpesvirus (PCR, virus isolation)	Arterial blood pressure
		±Calicivirus (PCR, virus isolation)	von Willebrand factor assay (dogs)
		Mycoplasma felis PCR or culture	

Phase II—All Patients (General Anesthesia Required)

Computed tomography (CT) or nasal radiography
Oral examination
Rhinoscopy: external nares and nasopharynx
Dental radiographs (if CT and rhinoscopy are not diagnostic)
Nasal biopsy/histologic examination
Deep nasal culture
- Fungal
- Bacterial (significance of growth is uncertain)

Phase III—All Patients (Referral Usually Required)

CT (if not previously performed) or magnetic resonance imaging (MRI)
Frontal sinus exploration (if involvement identified by CT, MRI, or radiography)

Phase IV—All Patients (Consider Referral)

Phase II repeated in several months using CT or MRI
Exploratory rhinotomy with turbinectomy

interpreted in conjunction with results of nasal imaging, rhinoscopy, and nasal histology and culture.

The blood test of choice for cryptococcosis is the latex agglutination capsular antigen test (LCAT). Because organism identification is usually possible in specimens from infected organs, organism identification is the method of choice for a definitive diagnosis. The LCAT is performed if cryptococcosis is suspected but an extensive search for the organism has failed. The LCAT is also performed in animals with a confirmed diagnosis as a means of monitoring therapeutic response (see Chapter 97).

Most often, computed tomography (CT) or nasal radiography, rhinoscopy, and biopsy are required to establish a diagnosis of intranasal disease in dogs and cats in which acute viral infection is not suspected. Dental radiographs should also be obtained if a diagnosis is not obvious from CT or rhinoscopy, as they can be more sensitive for detecting tooth root disease than CT. These diagnostic tests are performed with the dog or cat under general anesthesia. CT scans or nasal radiographs are obtained first, followed by oral examination and rhinoscopy, and then specimen collection. This order is recommended because results of CT or radiography and rhinoscopy are often useful in the selection of biopsy sites. In addition, hemorrhage from biopsy sites could obscure or alter radiographic and rhinoscopic detail if the specimen were collected first. However, in dogs and cats highly suspected of having acute foreign body inhalation, rhinoscopy is performed first in the hopes of identifying and removing the foreign material. (See Chapter 14 for more detail on nasal radiography, CT, and rhinoscopy.)

The combination of radiography, rhinoscopy, and nasal biopsy has been reported to have a diagnostic success rate of approximately 80% in dogs; however, a diagnosis of idiopathic disease was considered a diagnostic success in dogs without progressive signs. The success rate was closer to 50% if the diagnosis of idiopathic disease was excluded. It is more difficult to evaluate the success rate for cats. High proportions of cats with chronic nasal discharge suffer from feline chronic rhinosinusitis (idiopathic rhinitis) and are diagnosed only through exclusion. Dogs with persistent signs in which a diagnosis cannot be obtained after the assessment described earlier require further evaluation. Cats are evaluated further only if signs suggestive of another disease are found during any part of the evaluation, or if the clinical signs are progressive or intolerable to the owners.

Nasal CT is considered if not performed previously and if a diagnosis has not been made. CT provides excellent visualization of all of the nasal sinuses and may allow identification of small masses that are not visible on nasal radiography or rhinoscopy. CT is also more accurate than nasal radiography in determining the extent of nasal tumors. Magnetic resonance imaging (MRI) may be more accurate than CT in the assessment of soft tissues, such as nasal neoplasia. Dental radiographs should also be obtained if not previously performed. In the absence of a diagnosis, nasal imaging (preferably CT or MRI), dental radiographs, rhinoscopy, and biopsy can be repeated after a 1- to 2-month period.

Frontal sinus exploration should be considered in dogs with fluid or tissue opacity in the frontal sinus in the absence of a diagnosis. Aspergillosis, in particular, may be localized within the frontal sinus and may elude diagnosis through rhinoscopy.

Exploratory rhinotomy with turbinectomy is the most aggressive diagnostic test. Surgical exploration of the nose allows direct visualization of the nasal cavity for detecting the presence of foreign bodies, mass lesions, or fungal mats and for obtaining biopsy and culture specimens. The potential benefits of surgery, however, should be weighed against the potential complications associated with rhinotomy and turbinectomy. The Suggested Readings section offers surgical references.

SNEEZING

Etiology and Diagnostic Approach

A sneeze is an explosive release of air from the lungs through the nasal cavity and mouth. It is a protective reflex that expels irritants from the nasal cavity. Intermittent, occasional sneezing is considered normal. Persistent, paroxysmal sneezing should be considered abnormal. Disorders commonly associated with acute-onset, persistent sneezing include nasal foreign body and feline upper respiratory infection. The canine nasal mite, *Pneumonyssoides caninum,* and exposure to irritating aerosols are less common causes of sneezing. All nasal diseases considered as differential diagnoses for nasal discharge are also potential causes for sneezing; however, animals with these diseases more often present with nasal discharge as the primary complaint.

The owners should be questioned carefully concerning possible recent exposure of the pet to foreign bodies (e.g., rooting in the ground, running through grassy fields) or irritants (powders and aerosols) or, in cats, exposure to respiratory viruses through new cats or kittens. Sneezing is an acute phenomenon that often subsides with time. A foreign body should not be excluded from the differential diagnoses just because sneezing subsides. In the dog a history of acute sneezing followed by the development of a nasal discharge is suggestive of a foreign body or progressive disease.

Other findings may help narrow the list of differential diagnoses. Dogs with foreign bodies or nasal mites may paw at their nose. Foreign bodies are typically associated with unilateral, mucopurulent nasal discharge, although serous or serosanguineous discharge may be present initially. Foreign bodies in the caudal nasopharynx may cause gagging, retching, or reverse sneezing. The nasal discharge associated with reactions to aerosols, powders, or other inhaled irritants is usually bilateral and serous in nature. In cats other clinical signs supportive of a diagnosis of upper respiratory infection, such as conjunctivitis and fever, may be present as well as a history of exposure to other cats or kittens.

Dogs in which acute, paroxysmal sneezing develops should undergo prompt rhinoscopic examination (see Chapter 14). With time, foreign material may become covered with mucus

or may migrate more deeply into the nasal passages, and any delay in performing rhinoscopy may interfere with identification and removal of foreign bodies. Nasal mites are also identified rhinoscopically. In contrast, cats sneeze more often as a result of acute viral infection rather than a foreign body. Immediate rhinoscopic examination is not indicated unless there has been known exposure to a foreign body and the history and physical examination findings do not support a diagnosis of viral upper respiratory infection.

REVERSE SNEEZING

Reverse sneezing is a paroxysm of noisy, labored inspiration that can be initiated by nasopharyngeal irritation. Such irritation can be the result of a foreign body located dorsal to the soft palate, or it may be associated with nasopharyngeal inflammation. Foreign bodies usually originate from grass or plant material that is prehended into the oral cavity and that, presumably, is coughed up or migrates into the nasopharyx. Most cases are idiopathic. Small-breed dogs are usually affected, and signs may be associated with excitement or drinking. The paroxysms last only seconds and do not significantly interfere with oxygenation. Although these animals usually display this sign throughout their lifetime, the problem rarely progresses.

Clients may present a dog with reverse sneeze for respiratory distress if they are not familiar with this sign. Their ability to describe the events may be limited, and dogs will rarely exhibit reverse sneeze during an examination. A key historic feature of reverse sneezing is that the dog instantly returns to normal breathing and attitude as soon as the event is over. This immediate return to normal is not characteristic of more serious problems, such as upper airway obstructions. Confirmation that described events indicate reverse sneezing can be obtained by showing the client a video recording of a dog reverse sneezing (Video 13.1). This approach is usually more efficient than having the client try to capture the reverse sneeze by video, although the latter is ideal.

A thorough history and physical examination is indicated to identify signs of potential underlying nasal or pharyngeal disorders. Further evaluation is needed if syncope, exercise intolerance, stertor, or other signs of respiratory disease are reported, or if reverse sneezing is severe or progressive.

In the absence of an underlying disease, treatment is rarely needed for reverse sneezing itself, because episodes are nearly always self-limiting. Some owners report that massaging the neck shortens an ongoing episode, or that administration of antihistamines decreases the frequency and severity of episodes, but controlled studies are lacking.

STERTOR

Stertor refers to coarse, audible snoring or snorting sounds associated with breathing. It indicates upper airway obstruction. Stertor is most often the result of pharyngeal disease (see Chapter 16). Intranasal causes of stertor include obstruction caused by congenital deformities, masses, exudate, or blood clots. Evaluation for nasal disease proceeds as described for nasal discharge.

FACIAL DEFORMITY

Carnassial tooth root abscess in dogs can result in swelling, often with drainage, adjacent to the nasal cavity and beneath the eye. Excluding dental disease, the most common causes of facial deformity adjacent to the nasal cavity are neoplasia and, in cats, cryptococcosis (Fig. 13.5). Visible swellings can

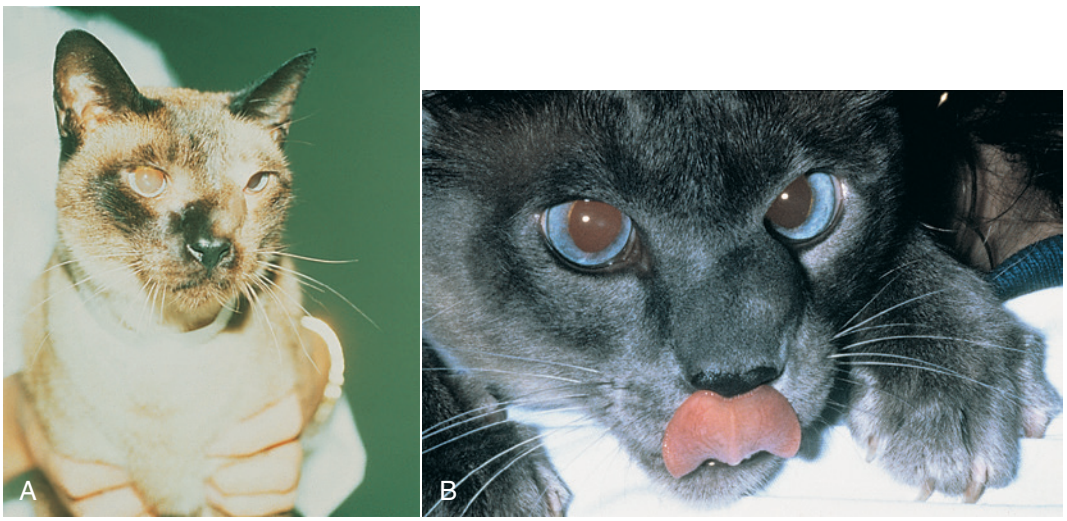

FIG 13.5
Facial deformity characterized by firm swelling over the maxilla in two cats. **(A)** Deformity in this cat was the result of carcinoma. Notice the ipsilateral blepharospasm. **(B)** Deformity in this cat was the result of cryptococcosis. A photomicrograph of the fine-needle aspirate of this swelling is provided in Fig. 13.3.

often be evaluated directly through fine-needle aspiration or punch biopsy (see Fig. 13.3). Further evaluation proceeds as for nasal discharge if such an approach is not possible or is unsuccessful.

CHAPTER 14

Diagnostic Tests for the Nasal Cavity and Paranasal Sinuses

NASAL IMAGING

Nasal imaging is a key component of the diagnostic assessment of animals with signs of intranasal disease, allowing assessment of bone and soft tissue structures that are not visible by physical examination or rhinoscopy. Nasal radiography, the type of imaging most readily available in general practice, is described in some detail. However, computed tomography (CT) provides images that are superior to radiographs in most cases and has widespread availability. The role of magnetic resonance imaging (MRI) in the evaluation of canine and feline nasal disease has not been well established, but it likely provides more accurate images of soft tissue than are provided by CT. MRI is not used routinely on account of its limited availability and relatively high expense. High-quality dental imaging is indicated for patients in which CT and rhinoscopy do not provide an obvious diagnosis. Dental radiographs can be more sensitive than CT for the diagnosis of tooth root disease.

Because nasal imaging rarely provides a definitive diagnosis, it is usually followed by rhinoscopy and nasal biopsy. All of these procedures require general anesthesia. Nasal imaging should be performed before, rather than after, these procedures for two reasons: (1) The results of nasal imaging help the clinician direct biopsy instruments to the most abnormal regions, and (2) rhinoscopy and biopsy cause hemorrhage, which obscures soft tissue detail.

RADIOGRAPHY

Nasal radiographs are useful for identifying the extent and severity of disease, localizing sites for biopsy within the nasal cavity, and prioritizing the differential diagnoses. The dog or cat must be anesthetized to prevent motion and facilitate positioning. Radiographic abnormalities are often subtle. At least four views should be taken: lateral, ventrodorsal, intraoral, and frontal sinus or skyline. The intraoral view is particularly helpful for detecting subtle asymmetry between the left and right nasal cavities. Radiographs of the tympanic bullae are obtained in cats to determinate extension of disease into the middle ear, particularly with nasopharyngeal polyps. High quality dental films are indicated in dogs and cats with possible tooth root abscess. Because nasal signs may be the only indication of tooth root disease, imaging is indicated for patients without an obvious diagnosis from CT and rhinoscopy.

The intraoral view is taken with the animal in sternal recumbency. The corner of a nonscreen film is placed above the tongue as far into the oral cavity as possible, and the radiographic beam is positioned directly above the nasal cavity (Figs. 14.1 and 14.2). The frontal sinus view is obtained with the animal in dorsal recumbency. Adhesive tape can be used to support the body and draw the forelimbs caudally, out of the field. The head is positioned perpendicular to the spine and the table by drawing the muzzle toward the sternum with adhesive tape. Endotracheal tube and anesthetic tubes are displaced lateral to the head to remove them from the field. A radiographic beam is positioned directly above the nasal cavity and frontal sinuses (Figs. 14.3 and 14.4). The frontal sinus view identifies disease involving the frontal sinuses, which in diseases such as aspergillosis or neoplasia may be the only area of disease involvement. The tympanic bullae are best seen with an open-mouth projection in which the beam is aimed at the base of the skull (Figs. 14.5 and 14.6). The bullae are also evaluated individually by lateral-oblique films, offsetting each bulla from the surrounding skull.

Nasal radiographs are evaluated for increased fluid density, loss of turbinates, lysis of facial bones, radiolucency at the tips of the tooth roots, and the presence of radiodense foreign bodies (Box 14.1). Increased fluid density can be caused by mucus, exudate, blood, or soft tissue masses such as polyps, tumors, or granulomas. Soft tissue masses may appear localized, but the surrounding fluid often obscures their borders. A thin rim of lysis surrounding a focal density may represent a foreign body. Fluid density within the frontal sinuses may represent normal mucus accumulation caused by obstruction of drainage into the nasal cavity, extension of disease into the frontal sinuses from the nasal cavity, or primary disease involving the frontal sinuses.

Loss of the normal fine turbinate pattern in combination with increased fluid density within the nasal cavity can occur

FIG 14.1
Positioning of a dog for intraoral radiographs.

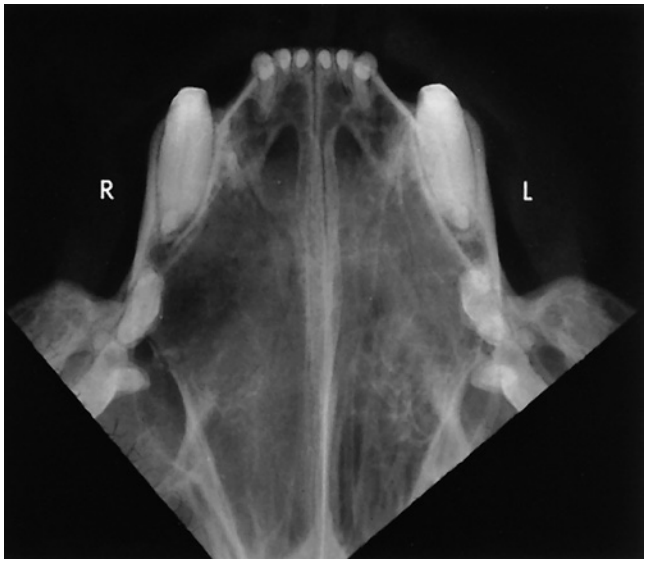

FIG 14.2
Intraoral radiograph of a cat with carcinoma. Normal fine turbinate pattern is visible on the left side *(L)* of the nasal cavity and provides a basis for comparison with the right side *(R)*. The turbinate pattern is less apparent on the right side, and an area of turbinate lysis can be seen adjacent to the first premolar.

with chronic inflammatory conditions of any etiology. Early neoplastic changes can also be associated with an increase in soft tissue density and destruction of the turbinates (see Figs. 14.2 and 14.4). More aggressive neoplastic changes may include marked lysis or deformation of the vomer and/or facial bones. Multiple, well-defined lytic zones within the nasal cavity and increased radiolucency in the rostral portion of the nasal cavity suggest aspergillosis (Fig. 14.7). The vomer bone may be roughened but is rarely destroyed. Previous traumatic fracture of the nasal bones and secondary osteomyelitis can also be detected radiographically.

FIG 14.3
Positioning of a dog for frontal sinus radiographs. The endotracheal and anesthetic tubes are displaced laterally in this instance by taping them to an upright metal cylinder.

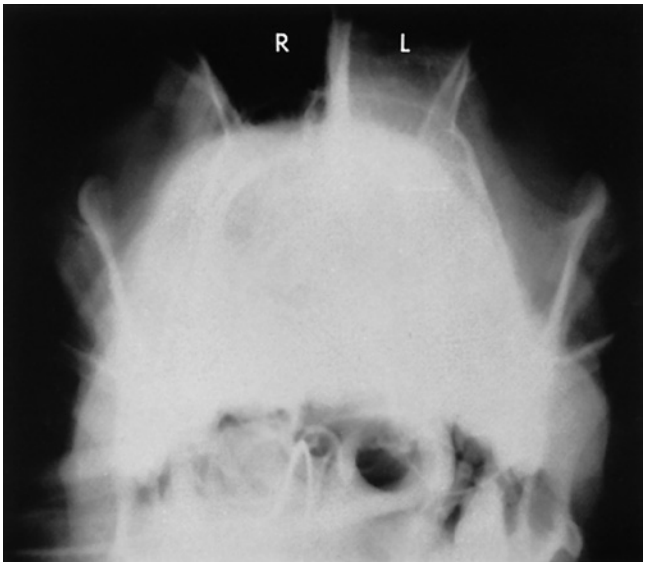

FIG 14.4
Frontal sinus view of a dog with a nasal tumor. The left frontal sinus *(L)* has increased soft tissue density compared with the air-filled sinus on the right side *(R)*.

FIG 14.5
Positioning of a cat for open-mouth projection of the tympanic bullae. The beam *(arrow)* is aimed through the mouth toward the base of the skull. Adhesive tape *(t)* is holding the head and mandible in position.

FIG 14.6
Radiograph obtained from a cat with nasopharyngeal polyp using the open-mouth projection demonstrated in Fig. 14.5. The left bulla has thickening of bone and increased fluid density, indicating bulla osteitis and probable extension of the polyp.

BOX 14.1

Radiographic Signs of Common Nasal Diseases*

Feline Chronic Rhinosinusitis

Soft tissue opacity within nasal cavity, possibly asymmetric
Mild turbinate lysis
Soft tissue opacity in frontal sinus(es)

Nasopharyngeal Polyp

Soft tissue opacity above soft palate
Soft tissue opacity within nasal cavity, usually unilateral
Mild turbinate lysis possible
Bulla osteitis: soft tissue opacity within bulla, thickening of bone

Nasal Neoplasia

Soft tissue opacity, possibly asymmetric
Turbinate destruction
Vomer bone and/or facial bone destruction
Soft tissue mass external to facial bones

Nasal Aspergillosis

Well-defined lucent areas within the nasal cavity
Increased radiolucency rostrally
Increased soft tissue opacity possibly also present
No destruction of vomer or facial bones, although signs often bilateral
Vomer bone sometimes roughened
Fluid density within the frontal sinus; frontal bones sometimes thickened or moth-eaten

Cryptococcosis

Soft tissue opacity, possibly asymmetric
Turbinate lysis
Facial bone destruction
Soft tissue mass external to facial bones

Canine Chronic/Lymphoplasmacytic Rhinitis

Soft tissue opacity
Lysis of nasal turbinates, especially rostrally

Allergic Rhinitis

Increased soft tissue opacity
Mild turbinate lysis possible

Tooth Root Abscesses

Radiolucency adjacent to tooth roots, commonly apically

Foreign Bodies

Mineral and metallic dense foreign bodies readily identified
Plant foreign bodies: focal, ill-defined, increased soft tissue opacity
Lucent rim around abnormal tissue (rare)

*Note that these descriptions represent typical cases and are not specific findings.

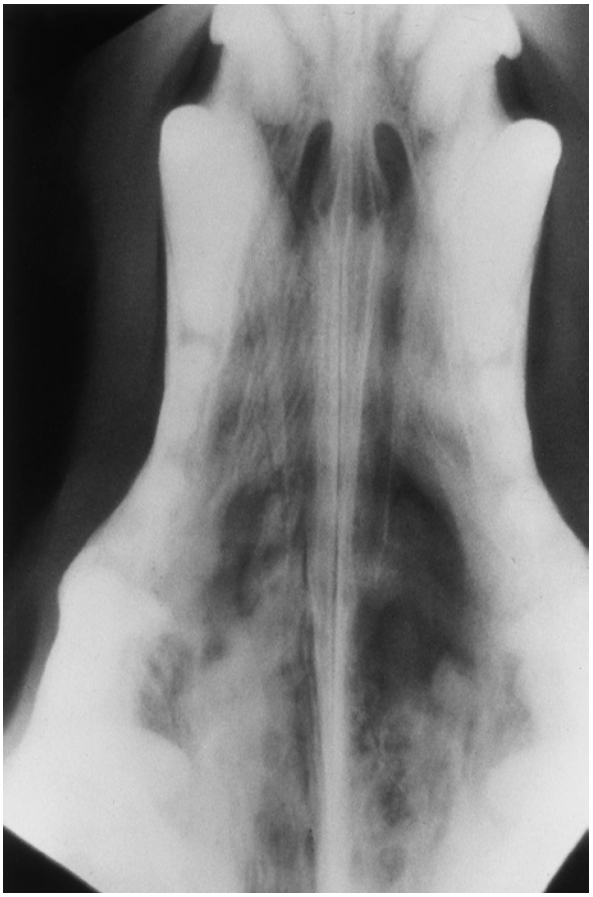

FIG 14.7
Intraoral radiograph of a dog with nasal aspergillosis. Focal areas of marked turbinate lysis are present on both sides of the nasal cavity. The vomer bone remains intact.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

CT provides excellent visualization of the nasal turbinates, nasal septum, hard palate, and cribriform plate (Fig. 14.8). In cats CT is also useful for determining middle ear involvement with nasopharyngeal polyps or other nasal disease. CT is more accurate than conventional radiography in assessing the extent of neoplastic disease insofar as it allows more accurate localization of mass lesions for subsequent biopsy than nasal radiography, and it is instrumental for radiotherapy treatment planning. Determination of the integrity of the cribriform plate is important in treatment planning for nasal aspergillosis. CT may also identify the presence of lesions in animals with undiagnosed nasal disease when other techniques have failed. Typical lesions are as described in Box 14.1. MRI may be more accurate than CT in the assessment of soft tissues, such as nasal neoplasia.

RHINOSCOPY

Rhinoscopy allows visual assessment of the nasal cavity through the use of a rigid or flexible endoscope or an otoscopic cone. Rhinoscopy is used to visualize and remove foreign bodies; to grossly assess the nasal mucosa for the presence of inflammation, turbinate erosion, mass lesions, fungal plaques, and parasites; and to aid in the collection of nasal specimens for histopathologic examination and culture. Complete rhinoscopy always includes a thorough examination of the oral cavity and caudal nasopharynx,

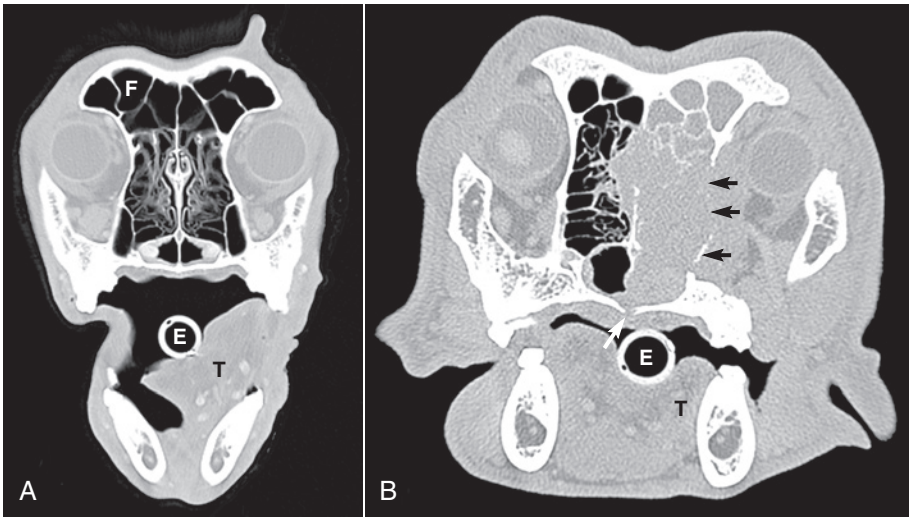

FIG 14.8
Computed tomography scans of the nasal cavity of two different dogs at the level of the eyes. **(A)** Normal nasal turbinates and intact nasal septum are present. **(B)** Neoplastic mass is present within the right cavity; it is eroding through the hard palate *(white arrow)*, the frontal bone into the retrobulbar space *(small black arrows)*, and the nasal septum. The tumor also extends into the right frontal sinus. *E,* Endotracheal tube; *F,* frontal sinus; *T,* tongue.

in addition to visualization of the nasal cavity through the external nares.

The extent of visualization depends on the quality of the equipment and the outside diameter of the rhinoscope. A narrow (2- to 3-mm diameter), rigid fiberoptic endoscope provides good visualization through the external nares in most patients. Endoscopes without biopsy or suction channels are preferable because of their small outside diameter. Some of these systems are relatively inexpensive. Scopes designed for arthroscopy, cystoscopy, and sexing of birds also work well. In medium-sized to large dogs, a flexible pediatric bronchoscope (e.g., 4-mm outer diameter) can be used. Flexible endoscopes are now available in smaller sizes, similar to small rigid scopes, although they are relatively more expensive and fragile. If an endoscope is not available, the rostral region of the nasal cavity can be examined with an otoscope. Human pediatric otoscopic cones (2- to 3-mm diameter) can be purchased for examining cats and small dogs.

General anesthesia is required for rhinoscopy. Rhinoscopy is usually performed immediately after nasal imaging unless a foreign body is strongly suspected. The oral cavity and caudal nasopharynx should be assessed first. During the oral examination, the hard and soft palates are visually examined and palpated for deformation, erosions, or defects, and the gingival sulci are probed for fistulae.

The caudal nasopharynx is evaluated for the presence of nasopharyngeal polyps, neoplasia, foreign bodies, and strictures (stenosis). Foreign bodies, particularly grass or plant material, are commonly found in this location in cats and occasionally in dogs. The caudal nasopharynx is best visualized with a flexible endoscope passed into the oral cavity and retroflexed around the soft palate (Figs. 14.9 through 14.11).

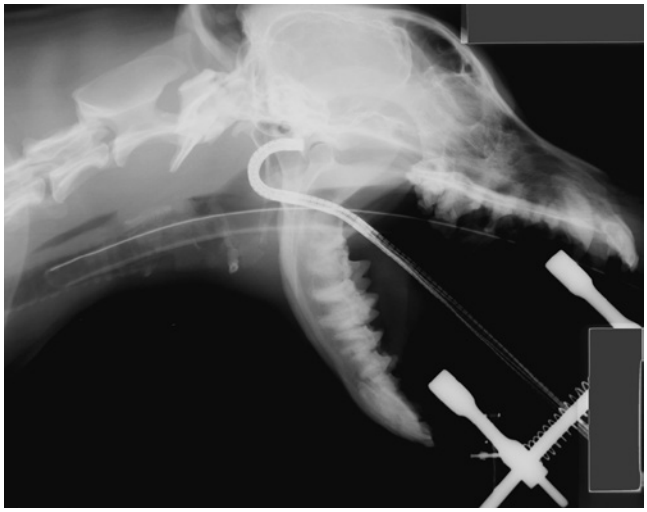

FIG 14.9
The caudal nasopharynx is best examined with a flexible endoscope that is passed into the oral cavity and retroflexed 180 degrees around the edge of the soft palate, as shown in this radiograph.

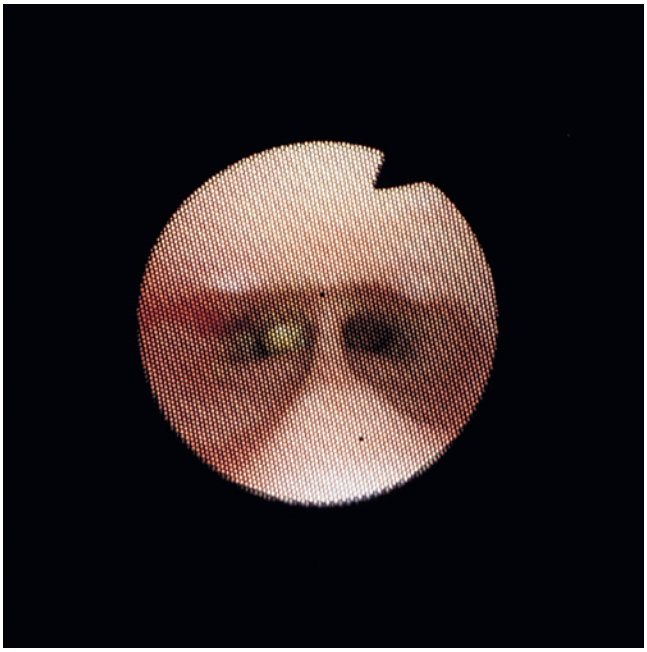

FIG 14.10
View of the internal nares obtained by passing a flexible bronchoscope around the edge of the soft palate in a dog with sneezing. A small white object is seen within the left nasal cavity adjacent to the septum. Note that the septum is narrow and the right internal naris is oval in shape and is not obstructed. On removal, the object was found to be a popcorn kernel. The dog had an abnormally short soft palate, and the kernel presumably entered the caudal nasal cavity from the oropharynx.

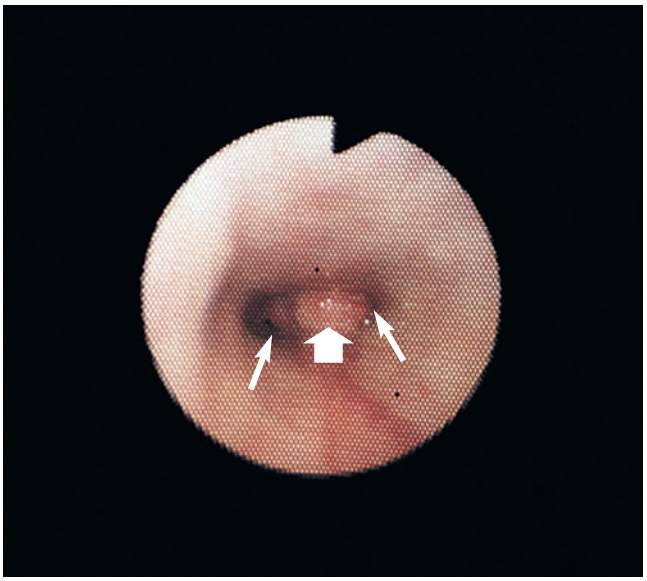

FIG 14.11
View of the internal nares *(thin arrows)* obtained by passing a flexible bronchoscope around the edge of the soft palate in a dog with nasal discharge. A soft tissue mass *(broad arrow)* is blocking the normally thin septum and is partially obstructing the airway lumens. Compare this view with the appearance of the normal septum and the right internal naris in Fig. 14.10.

Alternatively, the caudal nasopharynx can be evaluated with the aid of a dental mirror, penlight, and spay hook, which is attached to the caudal edge of the soft palate and pulled forward to improve visualization of the area. It may be possible to visualize nasal mites of infected dogs by observing the caudal nasopharynx while flushing anesthetic gases (e.g., isoflurane and oxygen) through the nares.

Rhinoscopy must be performed patiently, gently, and thoroughly to maximize the likelihood of identifying gross abnormalities and to minimize the risk of hemorrhage. The more normal side of the nasal cavity is examined first. The tip of the scope is passed through the naris with the tip pointed medially. Each nasal meatus is evaluated, beginning ventrally and working dorsally. Each nasal meatus should be examined as far caudally as the scope can be passed without trauma.

Although the rhinoscope can be used to evaluate the large chambers of the nose, many of the small recesses cannot be examined, even with the smallest endoscopes. Thus disease or a foreign body may be missed if only these small recesses are involved. Swollen and inflamed nasal mucosa, hemorrhage caused by the procedure, and the accumulation of exudate and mucus can also interfere with visualization of the nasal cavity. Foreign bodies and masses are frequently coated and effectively hidden by seemingly insignificant amounts of mucus, exudate, or blood. The tenacious material must be removed using a rubber catheter with the tip cut off attached to a suction unit. No catheter should ever be passed blindly into the nasal cavity beyond the level of the medial canthus of the eye to avoid entering the cranial vault through the cribriform plate.

If necessary, saline flushes can also be used, although resulting fluid bubbles may further interfere with visualization. Some clinicians prefer to maintain continuous saline infusion of the nasal cavity using a standard intravenous administration set attached to a catheter or, if available, the biopsy channel of the rhinoscope. The entire examination is done "underwater."

Particular care must be exercised to avoid aspiration of blood or saline into the lungs, particularly if saline is infused. The clinician must be sure the endotracheal tube cuff is fully inflated and the back of the pharynx is packed with gauze. The gauze should be checked frequently and replaced if saturated. The clinician must be careful not to overinflate the endotracheal tube cuff, which could result in a tracheal tear.

The nasal mucosa is normally smooth and pink, with a small amount of serous to mucoid fluid present along the mucosal surface. Potential abnormalities visualized with the rhinoscope include inflammation of the nasal mucosa; mass lesions; erosion of the turbinates (Fig. 14.12, *A*); mats of fungal hyphae (see Fig. 14.12, *B*); foreign bodies; and, rarely, nasal mites or *Capillaria* worms (Fig. 14.13). Differential diagnoses for gross rhinoscopic abnormalities are provided in Box 14.2.

The location of any abnormality should be noted, including the meatus involved (common, ventral, middle, dorsal), the medial-to-lateral orientation within the meatus, and the distance caudal from the naris. Exact localization is critical for directing instruments for the retrieval of foreign bodies or nasal biopsy specimens should visual guidance become impeded by hemorrhage or size of the cavity.

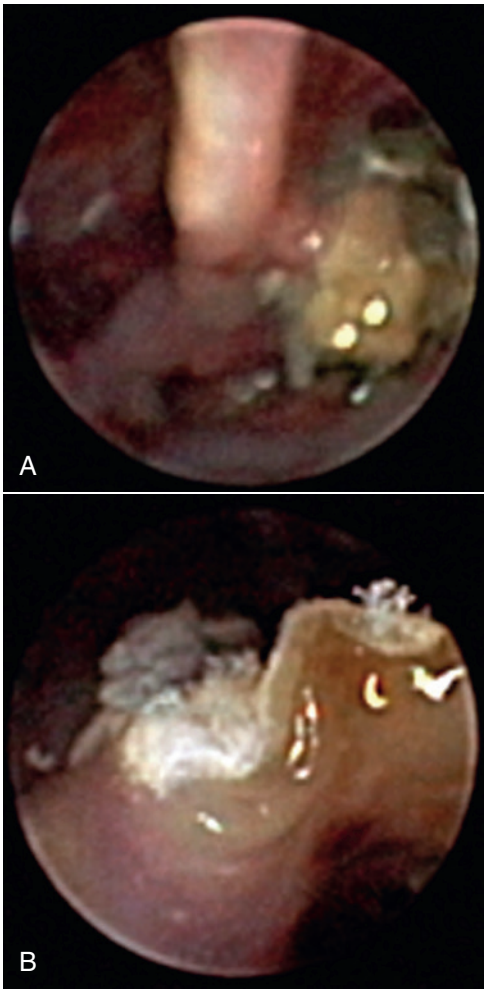

FIG 14.12
(A) Rhinoscopic view through the external naris of a dog with aspergillosis showing erosion of turbinates and a green-brown granulomatous mass. **(B)** A closer view of the fungal mat shows white, filamentous structures (hyphae).

FRONTAL SINUS EXPLORATION

Occasionally the primary site of disease is the frontal sinuses, most often in dogs with aspergillosis. Boney destruction may be sufficient to allow visualization and sampling by rhinoscopy through the external naris. However, in cases with evidence of frontal sinus involvement on imaging studies and the absence of a diagnosis through rhinoscopy and biopsy, surgical exploration of the frontal sinus may be necessary.

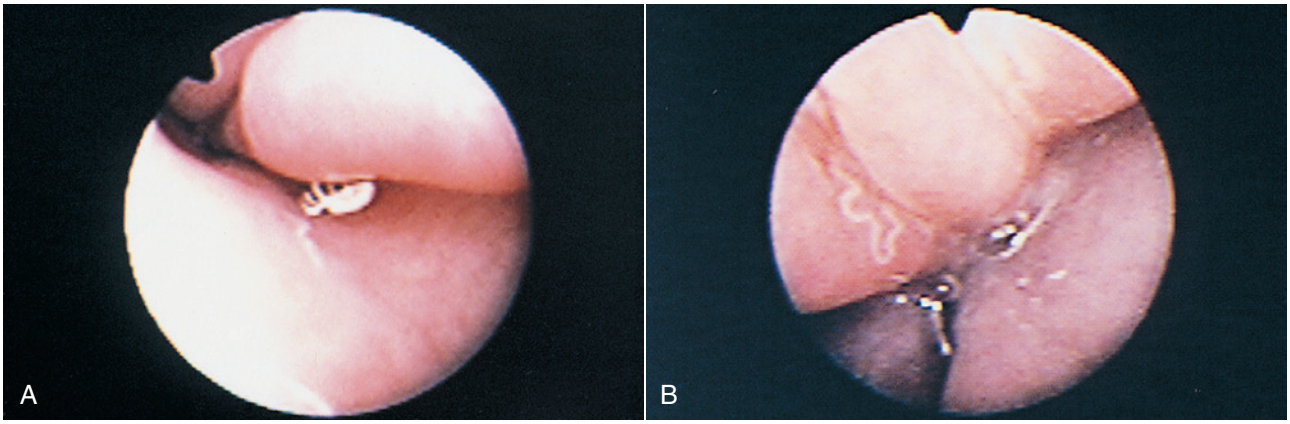

FIG 14.13
Rhinoscopic view through the external naris. **(A)** A single nasal mite is seen in this dog with *Pneumonyssoides caninum*. **(B)** A thin white worm is seen in this dog with *Capillaria (Eucoleus) boehmi*.

BOX 14.2

Differential Diagnoses for Gross Rhinoscopic Abnormalities in Dogs and Cats

- Inflammation (Mucosal Swelling, Hyperemia, Increased Mucus, Exudate)
  - Nonspecific finding; consider all differential diagnoses for mucopurulent nasal discharge (infectious, inflammatory, neoplastic)
- Mass
  - Neoplasia
  - Nasopharyngeal polyp
  - Cryptococcosis
  - Mat of fungal hyphae or fungal granuloma (aspergillosis, penicilliosis, rhinosporidiosis)
- Turbinate Erosion
  - Mild
    - Feline herpesvirus
    - Chronic inflammatory process
  - Marked
    - Aspergillosis
    - Neoplasia
    - Cryptococcosis
    - Penicilliosis
- Fungal Plaques
  - Aspergillosis
  - Penicilliosis
- Parasites
  - Mites: *Pneumonyssoides caninum*
  - Worms: *Capillaria (Eucoleus) boehmi*
- Foreign Bodies

NASAL BIOPSY: INDICATIONS AND TECHNIQUES

Visualization of a foreign body or nasal parasites during rhinoscopy establishes a diagnosis. For many dogs and cats, however, the diagnosis must be based on cytologic, histologic, and microbiologic evaluation of nasal biopsy specimens. Nasal biopsy specimens should be obtained immediately after nasal imaging and rhinoscopy while the animal is still anesthetized. These earlier procedures can help localize the lesion, maximizing the likelihood of obtaining material representative of the primary disease process.

Nasal biopsy techniques include nasal swab, nasal flush, pinch biopsy, and turbinectomy. Fine-needle aspirates can be obtained from mass lesions as described in Chapter 74. Pinch biopsy is the preferred nonsurgical method of specimen collection. It is more likely than nasal swabs or flushes to provide pieces of nasal tissue that extend beneath the superficial inflammation, which is common to many nasal disorders. In addition, the pieces of tissue obtained with this more aggressive method can be evaluated histologically, whereas the material obtained with the less traumatic techniques may be suitable only for cytologic analysis. Histopathologic examination is preferred over cytologic examination in most cases because the marked inflammation that accompanies many nasal diseases makes it difficult to cytologically differentiate primary from secondary inflammation and reactive from neoplastic epithelial cells. Carcinomas can also appear cytologically as lymphoma and vice versa.

Regardless of the technique used (except for nasal swab), the cuff of the endotracheal tube should be inflated (avoiding overinflation) and the caudal pharynx packed with gauze sponges to prevent the aspiration of fluid. Intravenous crystalloid fluids (10-20 mL/kg/h plus replacement of estimated blood loss) are recommended during the procedure to counter the hypotensive effects of prolonged anesthesia and blood loss from hemorrhage after biopsy. Blood-clotting capabilities should be assessed before the more aggressive biopsy techniques are performed if there is any history of hemorrhagic exudate or epistaxis or any other indication of coagulopathy.

NASAL SWAB

The least traumatic techniques are the nasal swab and nasal flush. Unlike the other collection techniques, nasal swabs can be collected from an awake animal. Nasal swabs are useful for identifying cryptococcal organisms cytologically and should be collected early in the evaluation of cats with chronic rhinitis. Other findings are generally nonspecific. Exudate immediately within the external nares or draining from the nares is collected using a cotton-tipped swab. Relatively small swabs are available that can facilitate specimen collection from cats with minimal discharge. The swab is then rolled on a microscope slide. Routine cytologic stains are generally used, although India ink can be applied to reveal cryptococcal organisms (see Chapter 97).

NASAL FLUSH

Nasal flush is a minimally invasive technique. A soft catheter is positioned in the caudal region of the nasal cavity via the oral cavity and internal nares, with the tip of the catheter pointing rostrally. With the animal in sternal recumbency and the nose pointed toward the floor, approximately 100 mL of sterile saline solution is forcibly injected in pulses by syringe. The fluid exiting the external nares is collected in a bowl and can be examined cytologically. Occasionally nasal mites can be identified in nasal flushings. Magnification or placement of dark paper behind the specimen for contrast may be needed to visualize the mites. A portion of fluid can also be filtered through a gauze sponge. Large particles trapped in the sponge can be retrieved and submitted for histopathologic analysis. These specimens are often insufficient for providing a definitive diagnosis.

PINCH BIOPSY

Pinch biopsy is the author's preferred method of nasal biopsy. In the pinch biopsy technique, alligator cup biopsy forceps (minimum size, 2 × 3 mm) are used to obtain pieces of nasal mucosa for histologic evaluation (Fig. 14.14). Full-thickness tissue specimens can be obtained, and guided specimen collection is more easily performed with this technique than with previously described methods. When possible, the biopsy forceps are passed adjacent to a rigid endoscope and directed to any gross lesions. If a flexible scope is used, biopsy instruments can be passed through the biopsy channel of the endoscope. The resulting specimens are extremely small and may not be of sufficient quality for diagnostic purposes. Larger alligator forceps are preferred. If lesions are not present grossly but are present radiographically or by CT, the biopsy instrument can be guided using the relationship of the lesion to the upper teeth.

After the first piece is taken, bleeding will prevent further visual guidance; therefore the forceps are passed blindly to the position identified during rhinoscopic examination (e.g., meatus involved and depth from external naris). If a mass is present, the forceps are passed in a closed position until just before the mass is reached. The forceps are then opened and passed a short distance farther until resistance is felt. Larger forceps, such as a mare uterine biopsy instrument, are useful for collecting large volumes of tissue from medium-sized to large dogs with nasal masses. *No forceps should ever be passed into the nasal cavity deeper than the level of the medial canthus of the eye without visual guidance to keep from penetrating the cribriform plate.*

A minimum of six tissue specimens (using 2 × 3-mm forceps or larger) should be obtained from any lesion. If no

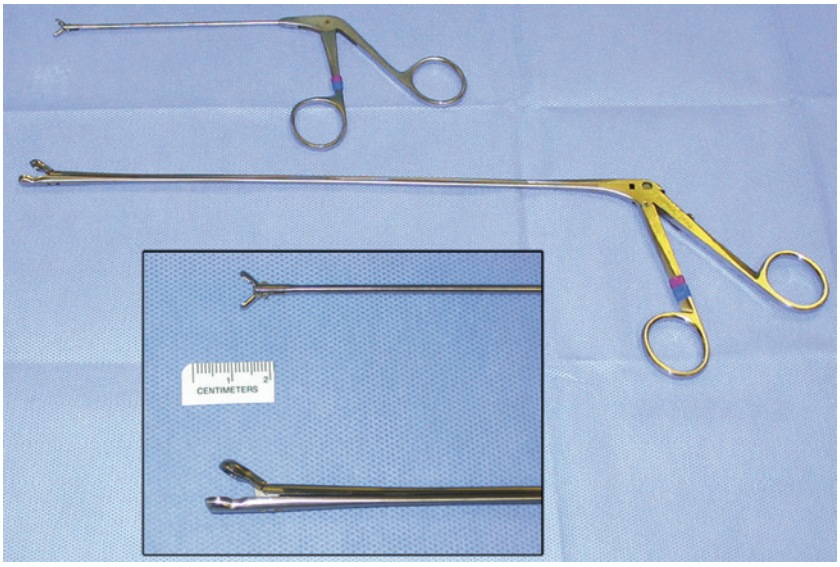

FIG 14.14
Cup biopsy forceps are available in different sizes. To obtain sufficient tissue, a minimum size of 2 × 3 mm is recommended. The larger forceps are particularly useful for obtaining biopsy specimens from nasal masses in dogs.

localizable lesion is identified radiographically or rhinoscopically, multiple biopsy specimens (usually 6-10) are obtained randomly from both sides of the nasal cavity.

TURBINECTOMY

Turbinectomy provides the best tissue specimens for histologic examination and allows the clinician to remove abnormal or poorly vascularized tissues, debulk fungal granulomas, and place drains for subsequent topical nasal therapy. Turbinectomy is performed through a rhinotomy incision and is a more invasive technique than those previously described. Turbinectomy is a reasonably difficult surgical procedure that should be considered only when other less invasive techniques have failed to establish the diagnosis. Potential operative and postoperative complications include pain, excessive hemorrhage, inadvertent entry into the cranial vault, and recurrent nasal infections. Cats may be anorectic postoperatively. Placement of an esophagostomy or gastrostomy tube (see Chapter 28) should be considered if necessary to provide a means for meeting nutritional requirements during the recovery period. (See Suggested Readings in Chapter 13 for information on the surgical procedure.)

Complications

The major complication associated with nasal biopsy is hemorrhage. The severity of hemorrhage depends on the method used to obtain the biopsy, but even with aggressive techniques the hemorrhage is rarely life-threatening. When any technique is used, the floor of the nasal cavity is avoided to prevent damage to major blood vessels. For minor hemorrhage, the rate of administration of intravenous fluids should be increased and manipulations within the nasal cavity should be stopped until the bleeding subsides. Cold saline solution with or without diluted epinephrine (1:100,000) can be gently infused into the nasal cavity. Persistent severe hemorrhage can be controlled by packing the nasal cavity with umbilical. The tape must be packed through the nasopharynx as well as through the external nares, or the blood will only be redirected. Similarly, placing swabs or gauze in the external nares serves only to redirect blood caudally. In the rare event of uncontrolled hemorrhage, the carotid artery on the involved side can be ligated without subsequent adverse effects. Rhinotomy should not be attempted. In the vast majority of animals, only time or cold saline infusions are required to control hemorrhage. The fear of severe hemorrhage should not prevent the collection of good-quality tissue specimens.

Trauma to the brain is prevented by never passing any object into the nasal cavity beyond the level of the medial canthus of the eye without visual guidance. The distance from the external nares to the medial canthus is noted by holding the instrument or catheter against the face, with the tip at the medial canthus. The level of the nares is marked on the instrument or catheter with a piece of tape or marking pen. The object should never be inserted beyond that mark.

Aspiration of blood, saline solution, or exudate into the lungs must be avoided. A cuffed endotracheal tube should be in place during the procedure, and the caudal pharynx should be packed with gauze after visual assessment of the oral cavity and nasopharynx. The cuff should be sufficiently inflated to prevent audible leakage of air during gentle compression of the reservoir bag of the anesthesia machine. Overinflation of the cuff may lead to tracheal trauma or tear. The nose is pointed toward the floor over the end of the examination table, allowing blood and fluid to drip out from the external nares after rhinoscopy and biopsy. Finally, the caudal pharynx is examined during gauze removal and before extubation for visualization of continued accumulation of fluid. Gauze sponges are counted during placement and then re-counted during removal so that none are inadvertently left behind.

NASAL CULTURES: SAMPLE COLLECTION AND INTERPRETATION

Microbiologic cultures of nasal specimens are often performed but can be difficult to interpret. Aerobic and anaerobic bacterial cultures, mycoplasmal cultures, and fungal cultures can be performed on material obtained by swab, nasal flush, or tissue biopsy. However, a wide range of organisms that may be pathogenic in some settings can be present in the proximal nasal cavity in healthy dogs and cats, including *Pseudomonas, Mycoplasma,* and *Aspergillus* organisms, along with a variety of other aerobic and anaerobic bacteria and fungi. Thus bacterial or fungal growth from nasal specimens does not necessarily confirm the presence of infection.

Cultures should be performed on specimens collected within the caudal nasal cavity of anesthetized patients. Bacterial growth from superficial specimens, such as nasal discharge or swabs inserted into the external nares of unanesthetized patients, is unlikely to be clinically significant. It is difficult for a culture swab to be passed into the caudal nasal cavity without its being contaminated with superficial (insignificant) organisms. Guarded specimen swabs can prevent contamination but are relatively expensive and may be too long to safely extrude into the nasal cavity of cats and small dogs. Alternatively, mucosal biopsies from the caudal nasal cavity can be obtained for culture using sterilized biopsy forceps; the results may be more indicative of true infection than those from swabs because, in theory, the organisms have invaded the tissues. Superficial contamination may still occur.

Regardless of the method used, the growth of many colonies of one or two types of bacteria rather than the growth of many different organisms more likely reflects infection. The microbiology laboratory should be asked to report all growth. Otherwise, the laboratory may report only one or two organisms that more often are pathogenic and provide misleading information about the relative purity of the culture. The presence of septic inflammation based on histologic examination of nasal specimens and a positive response to antibiotic therapy support a diagnosis of bacterial infection contributing to clinical signs. Although bacterial rhinitis is rarely a

primary disease entity, improvement in nasal discharge may be seen if the bacterial component of the problem is treated; however, the improvement is generally transient unless the underlying disease process can be corrected. Some animals in which a primary disease process is never identified or cannot be corrected (e.g., cats with chronic rhinosinusitis) respond well to long-term antibiotic therapy. Sensitivity data from bacterial cultures considered to represent significant infection may help in antibiotic selection. (See Chapter 15 for further therapeutic recommendations.)

The role of *Mycoplasma* spp. in respiratory tract infections of dogs and cats is still being elucidated, although a recent systematic review found a significant association between the isolation of *Mycoplasma felis* and upper respiratory tract signs in cats (LeBoedec, 2017). Cultures or polymerized chain reaction (PCR) for *Mycoplasma* spp. and treatment with appropriate antibiotics are a consideration for cats with chronic rhinosinusitis.

A diagnosis of nasal aspergillosis or penicilliosis requires the presence of several supportive signs, and fungal cultures are indicated whenever fungal disease is one of the differential diagnoses. The growth of *Aspergillus* or *Penicillium* organisms is considered along with other clinical data, such as radiographic and rhinoscopic findings, and serologic titers. Fungal growth supports a diagnosis of mycotic rhinitis only when other data also support the diagnosis. The fact that fungal infection occasionally occurs secondary to nasal tumors should not be overlooked during initial evaluation and monitoring of therapeutic response. The sensitivity of fungal culture can be greatly enhanced by collecting a swab or biopsy for culture directly from a fungal plaque or granuloma with rhinoscopic guidance.

CHAPTER 15

Disorders of the Nasal Cavity

FELINE UPPER RESPIRATORY INFECTION

Etiology

Upper respiratory infections (URIs) are common in cats. Feline herpesvirus (FHV), also known as *feline rhinotracheitis virus* and *feline calicivirus (FCV),* cause nearly 90% of these infections. *Bordetella bronchiseptica* and *Chlamydophila felis* (previously known as *Chlamydia psittaci*) are less commonly involved. Other viruses and *Mycoplasmas* (particularly *M. felis*) may play a primary or secondary role, whereas other bacteria are considered secondary pathogens.

Cats become infected through contact with actively infected cats, carrier cats, and fomites. Cats that are young, stressed, or immunosuppressed are most likely to develop clinical signs. Infected cats often become carriers of FHV or FCV after resolution of the clinical signs. The duration of the carrier state is not known, but it may last from weeks to years. *Bordetella* and *M. felis* can be isolated from asymptomatic cats, although the effectiveness of transmission of disease from such cats is not known.

Clinical Features

Clinical manifestations of feline URI can be acute, chronic and intermittent, or chronic and persistent. Acute disease is most common. The clinical signs of acute URI include fever, sneezing, serous or mucopurulent nasal discharge, conjunctivitis and ocular discharge, hypersalivation, anorexia, and dehydration. FHV can also cause corneal ulceration, abortion, and neonatal death, whereas FCV can cause oral ulcerations, interstitial pneumonia, or polyarthritis. Rare, short-lived outbreaks of highly virulent strains of calicivirus have been associated with severe upper respiratory disease, signs of systemic vasculitis (facial and limb edema progressing to focal necrosis), and high rates of mortality. *Bordetella* can cause cough and, in young kittens, pneumonia. *Chlamydophila* infections are commonly associated with conjunctivitis.

Some cats that recover from the acute disease have periodic recurrence of acute signs, usually in association with stressful or immunosuppressive events. Other cats may have chronic, persistent signs, most notably serous to mucopurulent nasal discharge with or without sneezing. Chronic nasal discharge can presumably result from persistence of an active viral infection or from irreversible damage to turbinates and mucosa by FHV; the latter predisposes the cat to an exaggerated response to irritants and secondary bacterial rhinitis. Unfortunately, correlation between tests to confirm exposure to or the presence of viruses and clinical signs is poor (Johnson et al., 2005). Because the role of viral infection in cats with chronic rhinosinusitis is not well understood, cats with chronic signs of nasal disease are discussed in the later section on feline chronic rhinosinusitis.

Diagnosis

Acute URI is usually diagnosed on the basis of history and physical examination findings. Specific tests that are available to identify FHV, FCV, *Bordetella, Mycoplasma,* and *Chlamydophila* organisms include polymerase chain reaction (PCR), and virus isolation procedures or bacterial cultures. PCR testing and virus isolation can be performed on pharyngeal, conjunctival, or nasal swabs (using sterile polyester swabs) or on tissue specimens such as tonsillar biopsy specimens or mucosal scrapings. Tissue specimens are usually preferred. Specimens are placed in appropriate transport media. Routine cytologic preparations of conjunctival smears can be examined for intracytoplasmic inclusion bodies suggestive of *Chlamydophila* infection, but these findings are nonspecific. Although routine bacterial cultures of the oropharynx can be used to identify *Bordetella,* the organism can be found in both healthy and infected cats. Regardless of the method used, close coordination with the diagnostic laboratory on specimen collection and handling is recommended for optimal results.

Tests to identify specific agents are particularly useful in cattery outbreaks in which the clinician is asked to recommend specific preventive measures. Multiple cats, both with and without clinical signs, should be tested when cattery surveys are performed. Test panels are commercially available to probe specimens for multiple respiratory pathogens by PCR. Specific diagnostic tests are less useful for testing

individual cats with acute disease because most cats recover uneventfully. It may be of value to test individual cats with severe or persistent signs because specific antimicrobial treatment for FHV, *Chlamydia,* or *Mycoplasma* can be prescribed. False-negative results may occur if signs are the result of permanent nasal damage or if the specimen does not contain the agent, and positive results may merely reflect a carrier cat that has a concurrent disease process causing the clinical signs.

Treatment

In most cats URI is a self-limiting disease, and treatment of cats with acute signs includes appropriate supportive care. Fluid therapy and nutritional supplementation should be provided when necessary. Dried mucus and exudate should be cleaned from the face and nares. The cat can be placed in a steamy bathroom or a small room with a vaporizer for 15 to 20 minutes two or three times daily to help clear excess secretions. Severe nasal congestion is treated with pediatric topical decongestants such as 0.25% phenylephrine or 0.025% oxymetazoline. A drop is gently placed in each nostril daily for a maximum of 3 days. If longer therapy is necessary, the decongestant is withheld for 3 days before another 3-day course is begun to prevent possible rebound congestion after withdrawal of the drug (based on problems with rebound congestion that occurs in people).

The Antimicrobial Guidelines Working Group of the International Society for Companion Animal Infectious Diseases recommends that antibiotic treatment be considered during the first 10 days of clinical signs only if fever, lethargy, or anorexia is present concurrently with mucopurulent nasal discharge (Lappin et al., 2017). This group recommends doxycycline (5 mg/kg, PO, q12h; or 10 mg/kg, PO, q24h; always followed by a bolus of water or food) as the first-line option because of its efficacy against *Chlamydia* and *Mycoplasma*. Amoxicillin (22 mg/kg, PO, q8-12h given orally) is considered an acceptable alternative when those organisms are not highly suspected. Doxycycline should be administered for 42 days in cats infected with *Chlamydophila felis* or *Mycoplasma* spp. to eliminate detectable organisms (Hartmann et al., 2008). Azithromycin (5-10 mg/kg q12h for 1 day, then every 3 days, orally) can be prescribed for cats that are difficult to medicate.

Cats with FHV infection may benefit from treatment with famcylovir. Several clinical trials have shown therapeutic benefit. In a placebo-controlled trial, 26 cats receiving a dosage of 90 mg/kg three times daily had significantly reduced clinical signs (Thomasy et al., 2016). In these cats, the time to clinical improvement was 3 to 28 days (median, 7 days). Side effects occurred in 15% of cats receiving this dosage and were primarily gastrointestinal, including diarrhea, vomiting, anorexia, and weight loss. Experience with a larger number of cats and chronic administration of drug is needed to fully understand the potential risks of treatment with this drug. Thomasy and Maggs (2016) recommend that cats should be closely monitored, and that CBC, serum biochemistry panel, and urinalysis be considered for those cats with known concurrent disease and for cats expected to receive famcyclovir for long periods. They also state that twice-daily dosing at 90 mg/kg is likely to be sufficient, based on pharmacokinetic studies.

It has been postulated that excessive concentrations of L-lysine may antagonize arginine, a promoter of herpesvirus replication. Lysine (500 mg/cat q12h), obtained from health food stores, is often added to food for the treatment or prevention of FHV. Its effectiveness is not certain (Thomasy and Maggs, 2016).

Chlamydophila infection should be suspected in cats with conjunctivitis as the primary problem and in cats from catteries in which the disease is endemic. Oral antibiotics are administered for a minimum of 42 days. In addition, chloramphenicol or tetracycline ophthalmic ointment should be applied at least three times daily and continued for a minimum of 14 days after signs have resolved.

Corneal ulcers resulting from FHV are treated with topical antiviral drugs, such as trifluridine, idoxuridine, or adenine arabinoside. One drop should be applied to each affected eye five to six times daily for no longer than 2 to 3 weeks. Routine ulcer management is also indicated. Tetracycline or chloramphenicol ophthalmic ointment is administered two to four times daily. Topical atropine is used for mydriasis as needed to control pain. Treatment is continued for 1 to 2 weeks after epithelialization has occurred.

Topical and systemic corticosteroids are contraindicated in cats with acute URI or ocular manifestations of FHV infection. They can prolong clinical signs and increase viral shedding.

Treatment of cats with chronic signs is discussed later with feline chronic rhinosinusitis.

Prevention in the Individual Pet Cat

Prevention of URI in all cats is based on avoiding exposure to the infectious agents (e.g., FHV, FCV, *Bordetella, Mycoplasma,* and *Chlamydophila* organisms) and strengthening immunity against infection. Most household cats are relatively resistant to prolonged problems associated with URIs, and routine health care with regular vaccination using a subcutaneous product is adequate. Vaccination decreases the severity of clinical signs resulting from URIs but does not prevent infection. Owners should be discouraged from allowing their cats to roam freely outdoors.

Subcutaneous modified-live virus vaccines for FHV and FCV are used for most cats and are available in combination with panleukopenia vaccine. These vaccines are convenient to administer, do not result in clinical signs when used correctly, and provide adequate protection for cats that are not heavily exposed to these viruses. These vaccines are not effective in kittens while maternal immunity persists. Kittens are usually vaccinated beginning at 6 to 10 weeks of age and again in 3 to 4 weeks. At least two vaccines must be given initially, with the final vaccine administered after the kitten is 16 weeks old. A booster vaccination is recommended 1 year after the final vaccine in the initial series. Subsequent booster vaccinations are recommended every 3 years, unless

the cat has increased risk of exposure to infection. Detection of FHV and FCV antibodies in the serum of cats is predictive of susceptibility to disease and therefore may be useful in determining the need for revaccination (Lappin et al., 2002). Queens should be vaccinated before breeding.

Subcutaneous modified-live vaccines for FHV and FCV are safe but can cause disease if introduced into the cat by the normal oronasal route of infection. The vaccine should not be aerosolized in front of the cat. Vaccine inadvertently left on the skin after injection should be washed off immediately before the cat licks the area.

Modified-live vaccines should not be used in pregnant queens. Killed products are available for FHV and FCV that can be used in pregnant queens. Killed vaccines have also been recommended for cats with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infection.

Modified-live vaccines for FHV and FCV are also available for intranasal administration. Signs of acute URI occasionally occur after vaccination. Attention should be paid to ensure that panleukopenia is included in the intranasal product or that a panleukopenia vaccine is administered subcutaneously.

Vaccines against *Bordetella* or *Chlamydophila* are recommended for use only in catteries or shelters where these infections are endemic. Infections with *Bordetella* or *Chlamydophila* are less common than FHV and FCV infection, and disease resulting from *Bordetella* infections occurs primarily in cats housed in crowded conditions. Furthermore, these diseases can be effectively treated with antibiotics.

Prognosis

The prognosis for cats with acute URI is good. Chronic disease does not develop in most pet cats.

BACTERIAL RHINITIS

Acute bacterial rhinitis caused by *Bordetella bronchiseptica* occurs occasionally in cats (see the section on feline URI) and rarely in dogs (see the section on canine infectious respiratory disease complex in Chapter 21). *Mycoplasma* spp. and *Streptococcus equi,* subsp. *zooepidemicus,* also may act as primary nasal pathogens. In the vast majority of cases, bacterial rhinitis is a *secondary* complication and not a primary disease process. Bacterial rhinitis occurs secondarily to almost all diseases of the nasal cavity. The bacteria that inhabit the nasal cavity in health are quick to overgrow when disease disrupts normal mucosal defenses. Antibiotic therapy often leads to clinical improvement, but the response is usually temporary. Therefore management of dogs and cats with suspected bacterial rhinitis should include a thorough diagnostic evaluation for an underlying disease process, particularly when signs are chronic.

Diagnosis

Most dogs and cats with bacterial rhinitis have mucopurulent nasal discharge. No clinical signs are pathognomonic for bacterial rhinitis, and it is difficult to make a definitive diagnosis because of the diverse flora in the normal nasal cavity. Microscopic evidence of neutrophilic inflammation and bacteria is a nonspecific finding and is found in the majority of animals with nasal signs (Fig. 15.1). Bacterial cultures of swabs or nasal mucosal biopsy specimens collected deep within the nasal cavity can be performed. The growth of many colonies of only one or two organisms may represent significant infection. Growth of many different organisms or small numbers of colonies probably represents normal flora. The microbiology laboratory should be requested to report all growth. Specimens for *Mycoplasma* cultures should be placed in appropriate transport media for culture using specific isolation methods. Beneficial response to antibiotic therapy is often used to support a diagnosis of bacterial involvement.

Treatment

The bacterial component of nasal disease is treated with antibiotic therapy. If growth obtained by bacterial culture is believed to be significant, sensitivity information can be used in selecting antibiotics. Anaerobic organisms may be involved. Broad-spectrum oral antibiotics that may be effective include amoxicillin (22 mg/kg q8-12h) or clindamycin (10 mg/kg q12h). Doxycycline (5 mg/kg q12h or 10 mg/kg q24h; always followed by a bolus of water) is often effective against *Bordetella* and *Mycoplasma* organisms.

For acute infection or in cases in which the primary etiology (e.g., foreign body, diseased tooth root) has been eliminated, antibiotics are administered for 7 to 10 days. Chronic infections require prolonged treatment. Antibiotics are

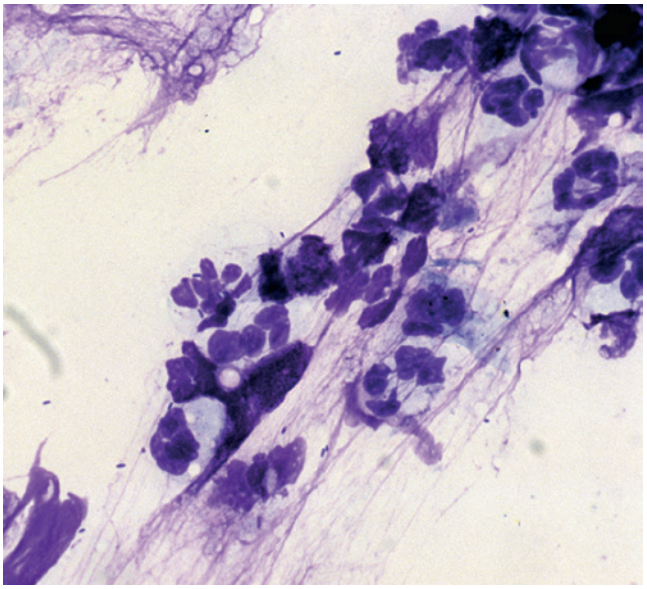

FIG 15.1

administered initially for 1 week. If a beneficial response is seen, the drug is continued for a minimum of 4 to 6 weeks. If signs recur after discontinuation of drug after 4 to 6 weeks, the same antibiotic is reinstituted for even longer periods.

If no response is seen after the initial week of treatment, the drug should be discontinued. Another antibiotic can be tried, although further evaluation for another, as yet unidentified, primary disorder should be pursued. Further diagnostic evaluation is particularly warranted in dogs because, compared with cats, they less frequently have idiopathic disease. Frequent stopping and starting of different antibiotics every 7 to 14 days is not recommended and may predispose the animal to the growth of resistant gram-negative infections.

Prognosis

Bacterial rhinitis is usually responsive to antibiotic therapy. However, long-term resolution of signs depends on the identification and correction of any underlying disease process.

NASAL MYCOSES

CRYPTOCOCCOSIS

Cryptococcus neoformans is a fungal agent that infects cats and, less commonly, dogs. It most likely enters the body through the respiratory tract and, in some animals, may disseminate to other organs. In cats clinical signs usually reflect infection of the nasal cavity, central nervous system (CNS), eyes, or skin and subcutaneous tissues. In dogs signs of CNS involvement are most common. The lungs are commonly infected in both species, but clinical signs of lung involvement (e.g., cough, dyspnea) are rare. Clinical features, diagnosis, and treatment of cryptococcosis are discussed in Chapter 97.

ASPERGILLOSIS

Aspergillus fumigatus is a normal inhabitant of the nasal cavity in many animals. In some dogs and, rarely, cats, it becomes a pathogen. The mold form of the organism can develop into visible fungal plaques that invade the nasal mucosa ("fungal mats") and fungal granulomas. An animal that develops aspergillosis will rarely have another nasal condition such as neoplasia, foreign body, prior trauma, or immune deficiency that predisposes the animal to secondary fungal infection. Most often no underlying disease is identified. Excessive exposure to *Aspergillus* organisms may explain the frequent occurrence of disease in otherwise healthy animals. Another type of fungus, *Penicillium,* can cause signs similar to those of aspergillosis.

Clinical Features

Aspergillosis can cause chronic nasal disease in dogs of any age or breed but is most common in young male dogs. Nasal infection is rare in cats. The discharge can be mucoid, mucopurulent with or without hemorrhage, or purely hemorrhagic. The discharge can be unilateral or bilateral. Sneezing may be reported. Features that are not common, but are highly suggestive of aspergillosis are sensitivity to palpation of the face or depigmentation and ulceration of the external nares (see Fig. 13.2). Lung involvement is not expected.

Systemic aspergillosis in dogs is generally caused by *Aspergillus terreus* and other *Aspergillus* spp. rather than *A. fumigatus*. It is an unusual, generally fatal disease that occurs primarily in German Shepherd Dogs. Nasal signs are not reported.

Diagnosis

No single test result is diagnostic for infection with aspergillosis. The diagnosis is based on the cumulative findings of a comprehensive evaluation of a dog with appropriate clinical signs. As aspergillosis can be an opportunistic infection, underlying nasal disease must also be considered.

Radiographic signs of aspergillosis include well-defined lucent areas within the nasal cavity and increased radiolucency rostrally (see Fig. 14.7). Typically no destruction of the vomer or facial bones occurs, although the bones may appear roughened. However, destruction of these bones or the cribriform plate may occur in dogs with advanced disease. Increased fluid opacity may be present. Fluid opacity within the frontal sinus can represent a site of infection or mucus accumulation from obstructed drainage. The bones surrounding the frontal sinus may be thickened or appear moth-eaten. In some patients the frontal sinus is the only site of infection.

Imaging by computed tomography (CT) is preferred over nasal radiography. The enhanced imaging allows for more accurate assessment of extent of disease. The presence or absence of plaques in the frontal sinuses (Fig. 15.2), integrity

FIG 15.2
Computed tomography scan of a dog with nasal aspergillosis. The right side is unaffected, providing comparison for the abnormalities on the left *(L)*. There is lysis of the nasal turbinates with increased soft-tissue density. Irregularly shaped soft tissue is apparent in the left frontal sinus *(*)*, which was confirmed to be a fungal plaque during frontal sinusotomy performed for debridement and infusion of clotrimazole cream. There is also mild osteitis of the bone surrounding the left frontal sinus.

of the cribriform plate, and extension of disease beyond the nasal cavity impact treatment decisions, as discussed later.

Rhinoscopic abnormalities include erosion of nasal turbinates and fungal plaques, which appear as white-to-green plaques of mold on the nasal mucosa (see Fig. 14.12). Failure to visualize these lesions does not rule out aspergillosis. Confirmation that presumed plaques are indeed fungal hyphae can be achieved by cytology (Fig. 15.3) and culture of material collected by biopsy or swab under visual guidance. During rhinoscopy, plaques are mechanically debulked by scraping or vigorous flushing to increase the efficacy of topical treatment. The frontal sinuses are included in examination and debriding whenever turbinate erosion allows.

Multiple biopsy specimens should be obtained because the mucosa is affected focally or multifocally rather than diffusely. Best results are obtained when mucosa with visible fungus is sampled. Invading *Aspergillus* organisms can generally be seen with routine staining techniques, although special staining can be performed to improve sensitivity. Neutrophilic, lymphoplasmacytic, or mixed inflammation is usually also present.

Results of fungal cultures are difficult to interpret, unless the specimen is obtained from a visualized plaque. The organism can be found in the nasal cavity of normal animals, and false-negative culture results can also occur. A positive culture, in conjunction with other appropriate clinical and diagnostic findings, supports the diagnosis.

Positive serum antibody titers also support a diagnosis of infection. Although titers provide indirect evidence of infection, animals with *Aspergillus* organisms as a normal nasal inhabitant do not usually develop measurable antibodies against the organism. Pomerantz et al. (2007) found that serum antibodies had a sensitivity of 67%, a specificity of 98%, a positive predictive value of 98%, and a negative predictive value of 84% for the diagnosis of nasal aspergillosis.

Treatment

Topical treatment is currently recommended for nasal aspergillosis, after aggressive debridement of fungal plaques. Oral itraconazole is recommended for patients with extension of disease beyond the nasal cavity and frontal sinuses. Oral therapy is simpler to administer than topical therapy but appears to be somewhat less successful, has potential systemic side effects, and requires prolonged treatment. Itraconazole is administered orally at a dose of 5 mg/kg q12h and must be continued for 60 to 90 days or longer. Some clinicians give terbinafine concurrently. In a recent study, dogs with nasal aspergillosis that had failed topical and oral treatment had resolution or significant improvement in clinical signs with oral posaconazole (5 mg/kg q12h), terbinafine (30 mg/kg q12h), and doxycycline (5 mg/kg q12h) (Stewart and Bianco, 2017). Prolonged treatment was necessary with an average duration of 9 months (range 6-18 months). (See Chapter 97 for a complete discussion of these drugs.)

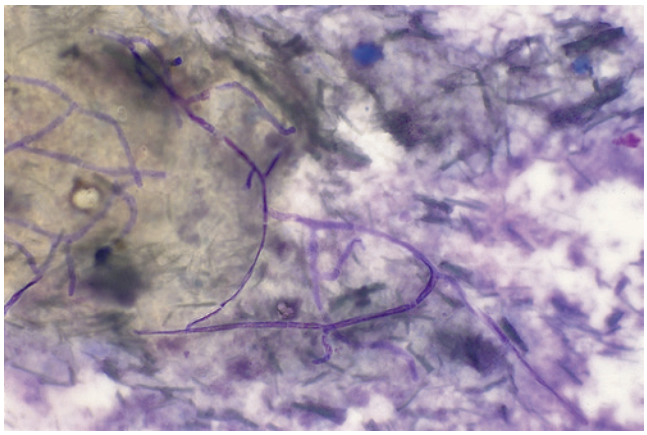

FIG 15.3
Branching hyphae of *Aspergillus fumigatus* from a swab of a visualized fungal plaque.

Successful topical treatment of aspergillosis was originally documented with enilconazole administered through tubes placed surgically into both frontal sinuses and both sides of the nasal cavity. The drug was administered through the tubes twice daily for 7 to 10 days. Subsequently, it was discovered that the over-the-counter drug clotrimazole was equally efficacious when infused through surgically placed tubes over a 1-hour period (70% success with a single treatment; Mathews et al., 1996). During 1-hour infusion, the dogs were kept under anesthesia and the caudal nasopharynx and external nares were packed to allow filling of the nasal cavity. It has since been demonstrated that good distribution of the drug can be achieved in some cases using a noninvasive technique (discussed in the next paragraphs).

Unfortunately, after a full review of the literature, success rate following a single topical treatment with enilconazole or clotrimazole was only 46% (Sharman et al., 2010). As a result, the following adjunctive treatments are currently recommended in addition to noninvasive clotrimazole soaks. Visible fungal plaques are aggressively debrided during rhinoscopy immediately before topical therapy. In dogs with frontal sinus involvement, surgical or endoscopic debridement is performed and clotrimazole cream is packed into the sinuses. All dogs are reevaluated 2 to 3 weeks after treatment. Rhinoscopy, debridement, and topical treatment are repeated if signs persist. In the previously mentioned report (Sharman et al., 2010), 70% of dogs recovered after receiving multiple treatments.

For noninvasive clotrimazole soaks (without the placement of tubes through the frontal sinuses), the animal is anesthetized and oxygenated through a cuffed endotracheal tube. The dog is positioned in dorsal recumbency with the nose pulled down parallel with the table (Figs. 15.4 and 15.5). For a large-breed dog, a 24F Foley catheter with a 5-mL balloon is passed through the oral cavity, around the soft palate, and into the caudal nasopharynx such that the bulb is at the junction of the hard and soft palates. The bulb is inflated with approximately 10 mL of air to ensure a snug fit. A laparotomy sponge is inserted within the oropharynx, caudal to the balloon and ventral to the soft palate, to help hold the balloon in position and to further obstruct the nasal pharynx. Additional laparotomy sponges are packed

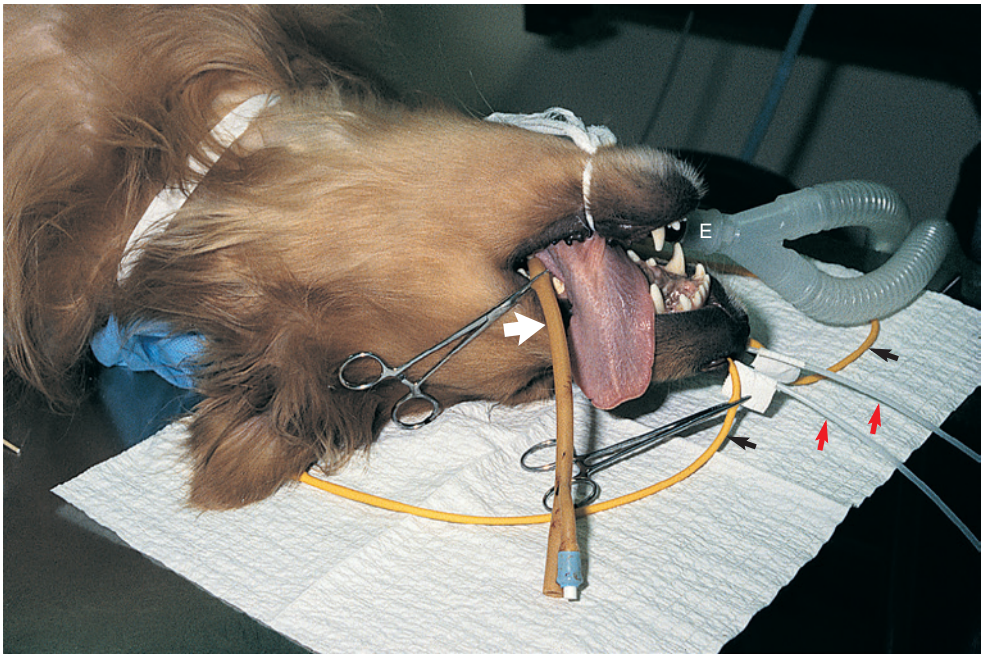

FIG 15.4

(Reprinted with permission from Mathews KG et al.: Computed tomographic assessment of noninvasive intranasal infusions in dogs with fungal rhinitis, *Vet Surg* 25:309, 1996.)

carefully into the back of the mouth around the tracheal tube to prevent any drug that might leak past the nasopharyngeal packing from reaching the lower airways.

A 10F polypropylene urinary catheter is passed into the dorsal meatus of each nasal cavity to a distance approximately midway between the external naris and the medial canthus of the eye. The correct distance is marked on the catheters with tape to prevent accidental insertion of the catheters too far during the procedure. A 12F Foley catheter with a 5-mL balloon is passed adjacent to the polypropylene catheter into each nasal cavity. The cuff is inflated and pulled snugly against the inside of the naris. A small suture is placed across each naris lateral to the catheter to prevent balloon migration. A gauze sponge is placed between the endotracheal tube and the incisive ducts behind the upper incisors to minimize leakage.

A solution of 1% clotrimazole is administered through the polypropylene catheters. Approximately 30 mL is used for each side in a typical retriever-size dog. Each Foley catheter is checked for filling during the initial infusion and is then clamped when clotrimazole begins to drip from the catheter. The solution is viscous, but excessive pressure is not required for infusion. Additional clotrimazole is administered during the next hour at a rate that results in approximately 1 drop every few seconds from each external naris. In dogs of the size described, a total of approximately 100 to 120 mL will be used.

After the initial 15 minutes, the head is tilted slightly to one side and then the other for 15 minutes each and then back into dorsal recumbency for 15 minutes. After this hour of contact time, the dog is rolled into sternal recumbency with the head hanging over the end of the table and the nose pointing toward the floor. The catheters are removed from the external nares, and the clotrimazole and resulting mucus are allowed to drain. Drainage will usually subside in 10 to 15 minutes. A flexible suction tip may be used to expedite this process. The laparotomy pads are then carefully removed from the nasopharynx and oral cavity and are counted to ensure that all are retrieved. The catheter in the nasopharynx is removed. Any drug within the oral cavity is swabbed or suctioned.

Two potential complications of clotrimazole treatment are aspiration pneumonia and meningoencephalitis. Meningoencephalitis is a risk when clotrimazole, polyethylene glycol carrier, and/or organisms and debris from the nasal cavity make contact with the brain through a compromised cribriform plate. It is difficult to determine the integrity of the cribriform plate before treatment without the aid of CT or magnetic resonance imaging (MRI), although marked radiographic changes in the caudal nasal cavity should increase concern. Fortunately, these complications are not common.

Some dogs have a persistent nasal discharge after treatment for aspergillosis. Most often the discharge indicates incomplete elimination of the fungal infection. However, some dogs may have secondary bacterial rhinitis or sensitivity to inhaled irritants because of the damaged nasal anatomy and mucosa. If recurrence of fungal infection cannot be found and signs persist despite repeated treatments, dogs are managed as described in the section on canine chronic/lymphoplasmacytic rhinitis in this chapter.

Prognosis

The prognosis for dogs with nasal aspergillosis has improved with debridement and repeated topical treatments. For most animals a fair to good prognosis is warranted. Reported success rates were provided in the treatment section.

NASAL PARASITES

NASAL MITES

Pneumonyssoides caninum is a small white mite approximately 1 mm in size (see Fig. 14.13, *A*). Most infestations are clinically silent, but some dogs may have moderate to severe clinical signs.

Clinical Features and Diagnosis

A common clinical feature of nasal mites is sneezing, which is often violent. Head shaking, pawing at the nose, reverse sneezing, chronic nasal discharge, and epistaxis can also occur. These signs are similar to those caused by nasal foreign bodies. The diagnosis is made by visualizing the mites during rhinoscopy or by retrograde nasal flushing, as described in Chapter 14. The mites can be easily overlooked in the retrieved saline solution; they should be specifically searched for with slight magnification or by placing dark material behind the specimen for contrast. Further, the mites are often located in the frontal sinuses and the caudal nasal cavity. Flushing the nasal cavities from the nares with an anesthetic gas in oxygen may cause the mites to migrate to the caudal nasopharynx. The mites can be visualized in the nasopharynx by endoscopy during the flushing procedure.

Treatment

Milbemycin oxime (0.5-1 mg/kg, orally, every 7-10 days for three treatments) and selemectin (6-24 mg/kg, topically over the shoulders, every 2 weeks for three treatments) have been used successfully for treating nasal mites. Ivermectin is also effective (0.2 mg/kg, administered subcutaneously and repeated in 3 weeks), but it is not safe for certain breeds. Any dogs in direct contact with the affected animal should also be treated.

Prognosis

The prognosis for dogs with nasal mites is excellent.

NASAL CAPILLARIASIS

Nasal capillariasis is caused by a nematode, *Capillaria (Eucoleus) boehmi,* originally identified as a worm of the frontal sinuses in foxes. The adult worm is small, thin, and white and lives on the mucosa of the nasal cavity and frontal sinuses of dogs (see Fig. 14.13, *B*). The adults shed eggs that

are swallowed and pass in the feces. Clinical signs include sneezing and mucopurulent nasal discharge, with or without hemorrhage. The diagnosis is made by identifying double operculated *Capillaria (Eucoleus)* eggs on routine fecal flotation (similar to the eggs of *Capillaria [Eucoleus] aerophila;* see Fig. 20.12, *C*) or by visualizing adult worms during rhinoscopy. Treatments include ivermectin (0.2 mg/kg, orally, once) or fenbendazole (25-50 mg/kg, orally, q12h for 10-14 days). Ivermectin is not safe for certain breeds. Success of treatment should be confirmed with repeated fecal examinations, in addition to resolution of clinical signs. Repeated treatments may be necessary, and reinfection is possible if exposure to contaminated soil continues.

FELINE NASOPHARYNGEAL POLYPS

Nasopharyngeal polyps are benign growths that occur most often in kittens and young adult cats, although they are occasionally found in older animals. Their origin is unknown, but they are often attached to the base of the eustachian tube. They can extend into the external ear canal, middle ear, pharynx, and nasal cavity. Grossly, they are pink, polypoid growths, often arising from a stalk (Fig. 15.6). Because of their gross appearance, they are sometimes mistaken for neoplasia.

Clinical Features

Respiratory signs caused by nasopharyngeal polyps include stertorous breathing, upper airway obstruction, and serous to mucopurulent nasal discharge. Signs of otitis externa or otitis media/interna, such as head tilt, nystagmus, or Horner syndrome, can also occur.

FIG 15.6
A nasopharyngeal polyp was visualized during rhinoscopy through the exterior naris of a cat with chronic nasal discharge. The polyp was excised by traction and has an obvious stalk.

Diagnosis

Identification of a soft tissue opacity above the soft palate radiographically and gross visualization of a mass in the nasopharynx, nasal cavity, or external ear canal support a tentative diagnosis of nasopharyngeal polyp. Complete evaluation of cats with polyps also includes a deep otoscopic examination and radiographs or CT scans of the osseous bullae to determine the extent of involvement. Most cats with polyps have otitis media, detectable radiographically as thickened bone or increased soft tissue opacity of the bulla (see Fig. 14.6). The definitive diagnosis is made by histopathologic analysis of tissue that is usually obtained during surgical excision. Nasopharyngeal polyps are composed of inflammatory tissue, fibrous connective tissue, and epithelium.

Treatment

The primary treatment of nasopharyngeal polyps is surgical excision by way of traction via the oral cavity. Recurrence is possible as a result of tissue being left behind. Cats with radiographic or CT evidence of involvement of the osseous bullae are at increased risk of recurrence, and bulla osteotomy for complete removal has been recommended for such cats. However, Anderson et al. (2000) reported successful treatment with traction alone, particularly when followed by a course of prednisolone. Prednisolone was administered orally at 1 to 2 mg/kg q24h for 2 weeks, then at half the original dose for 1 week, then every other day for 7 to 10 more days. A course of antibiotics (e.g., amoxicillin) was also administered. Therefore removal of the polyp by traction followed by a course of corticosteroids and antibiotics is generally recommended before exploration of the middle ear via bulla osteotomy. Rarely, rhinotomy is required for complete removal of a nasal polyp.

Prognosis

The prognosis is excellent, but treatment of recurrent disease may be necessary. Regrowth of a polyp can occur at the original site if abnormal tissue remains, with signs of recurrence typically appearing within 1 year. Bulla osteotomy, if not performed with initial treatment, should be considered in cats with recurrence and signs of otitis media.

CANINE NASAL POLYPS

Dogs rarely develop nasal polyps. These masses can result in chronic nasal discharge, with or without hemorrhage. They are often locally destructive to turbinates and bone, and as a result can be misdiagnosed as neoplasia. The diagnosis is made by histologic evaluation of biopsy specimens. Aggressive surgical removal is recommended. Complete excision may be impossible and signs may recur.

NASAL TUMORS

Most nasal tumors in the dog and cat are malignant. Adenocarcinoma, squamous cell carcinoma, and undifferentiated carcinoma are common nasal tumors in dogs. Lymphoma and adenocarcinoma are common in cats. Fibrosarcomas and other sarcomas also occur in both species. Benign tumors include adenomas, fibromas, papillomas, and transmissible venereal tumors (the latter only in dogs).

Clinical Features

Nasal tumors usually occur in older animals but cannot be excluded from the differential diagnosis of young dogs and cats. No breed predisposition has been consistently identified.

The clinical features of nasal tumors are usually chronic and reflect the locally invasive nature of these tumors. Nasal discharge is the most common complaint. The discharge can be serous, mucoid, mucopurulent, or hemorrhagic. One or both nostrils can be involved. With bilateral involvement, the discharge is often worse from one nostril than from the other. For many animals, the discharge is initially unilateral and progresses to bilateral. Sneezing may be reported and may be the only clinical sign early in the disease process. Obstruction of the nasal cavity by the tumor may cause decreased or absent air flow through one or both of the nares.

Deformation of the facial bones, hard palate, or maxillary dental arcade may be visible (see Fig. 13.5). Tumor growth extending into the cranial vault can result in neurologic signs. Growth into the orbit may cause exophthalmos or inability to retropulse the eye. Animals only rarely experience neurologic signs (e.g., seizures, behavior changes, abnormal mental status) or ocular abnormalities as the primary complaints (i.e., no signs of nasal discharge). Weight loss and anorexia are other rare complaints.

Diagnosis

A diagnosis of neoplasia is supported by typical abnormalities detected by imaging of the nasal cavity and frontal sinuses or rhinoscopy. Abnormalities can reflect soft tissue mass lesions; turbinate, vomer bone, or facial bone destruction; or diffuse infiltration of the mucosa with neoplastic and inflammatory cells (see Figs. 14.2, 14.4, and 14.8, *B*). Identification of neoplastic cells in fine-needle aspirates of nasal masses or affected mandibular lymph nodes may further support the diagnosis. Be aware that a cytologic diagnosis of neoplasia from a mass aspirate must be accepted cautiously, with consideration of concurrent inflammation and potentially marked hyperplastic and metaplastic change. Furthermore, in some cases the cytologic characteristics of lymphoma and carcinoma will mimic each other, which may lead to an erroneous classification of the neoplasia.

A definitive diagnosis requires histopathologic examination of a biopsy specimen. Biopsy specimens should always include tissue from deep within the lesion. Nasal neoplasms frequently cause a marked inflammatory response of the nasal mucosa and, in some patients, secondary infection. Superficial specimens are more likely to lead to a misdiagnosis.

Not all cases of neoplasia will be diagnosed on initial evaluation of the dog or cat. Imaging, rhinoscopy, and biopsy may need to be repeated in 1 to 3 months in animals with persistent signs in which a definitive diagnosis has not been made. CT and MRI are more sensitive techniques than routine radiography for imaging nasal tumors, and one of these should be performed when available (see Fig. 14.8, *B*). Surgical exploration is occasionally necessary to obtain a definitive diagnosis.

Once a definitive diagnosis has been made, determining the extent of disease can help in assessing the feasibility of surgical or radiation therapy versus chemotherapy. Some information can be obtained from high-quality nasal radiographs, but CT and MRI are more sensitive methods for evaluating the extent of abnormal tissue. Aspirates of mandibular lymph nodes should be examined cytologically for evidence of local spread. Thoracic radiographs are evaluated, although pulmonary metastases are uncommon at the time of initial diagnosis. Cytologic evaluation of bone marrow aspirates, as well as abdominal radiography or ultrasound, is indicated for patients with lymphoma. Cats with lymphoma are also tested for FeLV and FIV.

Treatment

Benign tumors, though rare, may be treatable with surgical excision. Radiation therapy is generally recommended for malignant tumors. Chemotherapy is considered for adjunctive therapy for patients with metastatic disease, or as a sole treatment for patients with lymphoma (Chapter 79). Chemotherapy can also be the sole treatment when radiation is not readily available. Carcinomas may be responsive to cisplatin, carboplatin, or multiagent chemotherapy. (See Chapter 76 for a discussion of general principles for the selection of chemotherapy.) Surgical excision alone is not successful for managing malignant nasal tumors, although some oncologists have recommended surgical excision following radiation therapy.

Palliation of clinical signs can often be achieved with radiation treatment at a reduced dose and frequency, avoiding many of the side effects of full dose radiation. Similarly, palliation can sometimes be achieved with piroxicam (DOSE) or corticosteroids at antiinflammatory dosages (prednisone or prednisolone, 0.5-1 mg/kg/day orally, gradually tapered to lowest effective dose). Note that these two drugs should not be given in combination.

Prognosis

The prognosis for dogs and cats with malignant nasal tumors is poor without treatment. Survival after diagnosis is usually only a few months. Euthanasia is often requested because of persistent epistaxis or discharge, and eventually, labored respirations, anorexia and weight loss, or neurologic signs. Epistaxis is a poor prognostic indicator. In a study of 132 dogs with untreated nasal carcinoma by Rassnick et al. (2006), the median survival time of dogs with epistaxis was

88 days (95% confidence interval [CI], 65-106 days) and of dogs without epistaxis was 224 days (95% CI, 54-467 days). The overall median survival time was 95 days (range, 7-1114 days).

Radiation therapy can prolong survival and improve quality of life in some animals and consultation with a radiation oncologist is recommended. The therapy is well tolerated by most animals, and in those that achieve remission the quality of life is usually excellent. The prognosis for a given patient is dependent upon a number of variables, including histopathologic classification, extent of the tumor, and the presence and location of metastatic disease. Early studies of dogs treated with megavoltage radiation, with or without prior surgical treatment, found median survival times of approximately 1 year. Less information is available concerning prognosis in cats. A study by Theon et al. (1994) of 16 cats with nonlymphoid neoplasia receiving radiation therapy showed a 1-year survival rate of 44% and a 2-year survival rate of 17%. Cats with nasal lymphoma treated with radiation and chemotherapy had a median survival time of 511 days, according to preliminary data from Arteaga et al. (2007).

ALLERGIC RHINITIS

Etiology

Allergic rhinitis has not been well characterized in dogs or cats. However, dermatologists provide anecdotal reports of atopic dogs rubbing the face (possibly indicating nasal pruritus) and experiencing serous nasal discharge, in addition to dermatologic signs. Allergic rhinitis is generally considered to be a hypersensitivity response within the nasal cavity and sinuses to airborne antigens. It is possible that food allergens play a role in some patients. Other antigens are capable of inducing a hypersensitivity response as well, and thus the differential diagnoses must include parasites, other infectious diseases, and neoplasia.

Clinical Features

Dogs or cats with allergic rhinitis experience sneezing and/or serous or mucopurulent nasal discharge. Signs may be acute or chronic. Careful questioning of the owner may reveal a relationship between signs and potential allergens. For instance, signs may be worse during certain seasons, or after the introduction of a new brand of kitty litter or new perfumes, cleaning agents, furniture, or fabric in the house. Note that worsening of signs may simply be a result of exposure to irritants, such as cigarette smoke, rather than an actual allergic response. Debilitation of the animal is not expected.

Diagnosis

Identifying a historical relationship between signs and a particular allergen and then achieving resolution of signs after removal of the suspected agent from the animal's environment support the diagnosis of allergic rhinitis. When this approach is not possible or successful, a thorough diagnostic evaluation of the nasal cavity is indicated (see Chapters 13 and 14). Nasal radiographs reveal increased soft tissue opacity with minimal or no turbinate destruction. Classically, nasal biopsy reveals eosinophilic inflammation. It is possible that with chronic disease, a mixed inflammatory response occurs, obscuring the diagnosis. There should be no indication in any of the diagnostic tests of an aggressive disease process, parasites or other active infection, or neoplasia.

Treatment

Removing the offending allergen from the animal's environment or diet is the ideal treatment for allergic rhinitis. When this is not possible, a beneficial response may be achieved with antihistamines. Chlorpheniramine can be administered orally at a dose of 4 to 8 mg/dog q12h or 2 mg/cat q12h. The second-generation antihistamine cetirizine may be more successful in cats. A pharmacokinetic study of this drug in healthy cats found a dosage of 1 mg/kg, administered orally every 24 hours, to maintain plasma concentrations similar to those reported in people (Papich et al., 2006). Glucocorticoids may be used if antihistamines are unsuccessful. Prednisone is initiated at a dose of 0.25 mg/kg, orally, q12h until signs resolve. The dose is then tapered to the lowest effective amount. If treatment is effective, signs will generally resolve within a few days. Drugs are continued only as long as needed to control signs. Administration of steroids via face mask using a metered dose inhaler, as described for the treatment of feline bronchitis (see Chapter 21), can also be tried. Although the inhalers are designed to deliver drug to the lower airways, some drug will also be deposited within the nasal cavity.

Prognosis

The prognosis for dogs and cats with allergic rhinitis is excellent if the allergen can be eliminated. Otherwise, the prognosis for control is good, but a cure is unlikely.

IDIOPATHIC RHINITIS

Idiopathic rhinitis is a more common diagnosis in cats compared with dogs. The diagnosis cannot be made without a thorough diagnostic evaluation to rule out specific diseases (see Chapters 13 and 14).

FELINE CHRONIC RHINOSINUSITIS

Etiology

Feline chronic rhinosinusitis has long been presumed to be a result of viral infection with FHV or FCV (see the earlier section on feline URI). Persistent viral infection has been implicated, but studies have failed to show an association between tests indicating exposure to or infection with these viruses and clinical signs. It is possible that infection with these viruses results in damaged mucosa that is more susceptible to bacterial infection or that mounts an excessive

inflammatory response to irritants or normal nasal flora. Preliminary studies have failed to show an association with feline chronic rhinosinusitis and *Bartonella* infection, based on serum antibody titers or PCR of nasal tissue (Berryessa et al., 2008). In the absence of a known cause, this disease will be denoted by the term *idiopathic feline chronic rhinosinusitis*.

Clinical Features and Diagnosis

Chronic mucoid or mucopurulent nasal discharge is the most common clinical sign of idiopathic feline chronic rhinosinusitis. The discharge is typically bilateral. Fresh blood may be seen in the discharge of some cats but is not usually a primary complaint. Sneezing may occur. Given that this is an idiopathic disease, the lack of specific findings is important. Cats should have no funduscopic lesions, no lymphadenopathy, no facial or palate deformities, and healthy teeth and gums. Anorexia and weight loss are rarely reported. Thorough diagnostic testing is indicated, as described in Chapters 13 and 14. Results of such testing do not support the diagnosis of a specific disease. Usual nonspecific findings include turbinate erosion, mucosal inflammation, and increased mucus accumulation as assessed by nasal imaging and rhinoscopy; neutrophilic or mixed inflammation with bacteria on cytology of nasal discharge; and neutrophilic and/or lymphoplasmacytic inflammation on nasal biopsy. Nonspecific abnormalities attributable to chronic inflammation, such as epithelial hyperplasia and fibrosis, may also be seen. Secondary bacterial rhinitis or *Mycoplasma* infection may be identified.

Treatment

Cats with idiopathic chronic rhinosinusitis often require management for years. Fortunately, most of these cats are healthy in all other respects. Treatment strategies include facilitating drainage of discharge; decreasing irritants in the environment; controlling secondary bacterial infections; treating possible *Mycoplasma* or FHV infection; reducing inflammation; and, as a last resort, performing a turbinectomy and frontal sinus ablation (Box 15.1).

Keeping secretions moist, performing intermittent nasal flushes, and judiciously using topical decongestants facilitate drainage. Keeping the cat in a room with a vaporizer, for instance, during the night can provide symptomatic relief by keeping secretions moist. Alternatively, drops of sterile saline can be placed into the nares. Some cats experience a marked improvement in clinical signs for weeks after flushing of the nasal cavity with copious amounts of saline. General anesthesia is required, and the lower airways must be protected with an endotracheal tube, gauze sponges, and positioning of the head to facilitate drainage from the external nares. Topical decongestants, as described for feline URI, may provide symptomatic relief during episodes of severe congestion.

Irritants in the environment can further exacerbate mucosal inflammation. Irritants such as smoke (from tobacco or fireplace) and perfumed products should be avoided. Motivated clients can take steps to improve the air quality in their homes, such as by cleaning carpet, furniture, drapery, and furnace; regularly replacing air filters; and using an air cleaner. The American Lung Association has a useful Web site with nonproprietary recommendations for improving indoor air quality (www.lung.org).

Long-term antibiotic therapy may be required to manage secondary bacterial infections. Broad-spectrum oral antibiotics such as amoxicillin (22 mg/kg q8-12h) are often successful. Doxycycline (5 mg/kg q12h or 10 mg/kg q24h, followed by a bolus of water) has activity against some bacteria and *Chlamydophila* and *Mycoplasma* organisms and can be effective in some cats when other drugs have failed. Azithromycin (5-10 mg/kg q12h for 1 day, then every 3 days) can be prescribed for cats that are difficult to medicate. This author reserves fluoroquinolones for cats with documented resistant gram-negative infections that have failed other treatment attempts. If a beneficial response to antibiotic therapy is seen within 1 week of its initiation, the antibiotic should be continued for at least 4 to 6 weeks. If a beneficial

BOX 15.1

Management Considerations for Cats With Idiopathic Chronic Rhinosinusitis

Facilitate Drainage of Discharge

Vaporizer treatments
Topical saline administration
Nasal cavity flushes under anesthesia
Topical decongestants

Decrease Irritants in the Environment

Improvement of indoor air quality

Control Secondary Bacterial Infections

Long-term antibiotic treatment

Treat Possible Mycoplasma Infection

Antibiotic treatment

Treat Possible Herpesvirus Infection

Lysine treatment

Reduce inflammation

Second-generation antihistamine treatment
Oral prednisolone treatment
Other unproven treatments with possible antiinflammatory effects
- Azithromycin
- Piroxicam
- Leukotriene inhibitors
- Omega-3 fatty acids

Provide Surgical Intervention

Turbinectomy
Frontal sinus ablation

response is not seen, the antibiotic is discontinued. Note that frequent stopping and starting of different antibiotics every 7 to 14 days is not recommended and may predispose the cat to resistant gram-negative infections. Cats that respond well during the prolonged course of antibiotics but that relapse shortly after discontinuation of the drug despite 4 to 6 weeks of relief are candidates for continuous long-term antibiotic therapy. Treatment with the previously used antibiotic often can be successfully reinstituted. Amoxicillin administered twice daily is often sufficient.

Treatment with famcyclovir may be effective in cats with active herpesvirus infection, as discussed in the section on feline URIs earlier in this chapter. Anecdotal success in occasional cats has been reported with treatment with the second-generation antihistamine cetirizine, as described previously for allergic rhinitis.

Cats with severe signs that persist despite the previously described methods of supportive care may benefit from glucocorticoids to reduce inflammation. However, certain risks are involved. Glucocorticoids may further predispose the cat to secondary infection, increase viral shedding, and mask signs of a more serious disease. Glucocorticoids should be prescribed only after a complete diagnostic evaluation has been performed to rule out other diseases. Prednisolone is administered orally at a dose of 0.5 mg/kg q12h If a beneficial response is seen within 1 week, the dose is gradually decreased to the lowest effective dose. A dose as low as 0.25 mg/kg every 2 to 3 days may be sufficient to control clinical signs. If a clinical response is not seen within 1 week, the drug should be discontinued. As discussed with allergic rhinitis, administration of glucocorticoids via metered dose inhaler may be effective in cats responsive to oral glucocorticoids.

Other drugs with potential antiinflammatory effects that may provide relief include azithromycin (described with antibiotics), piroxicam, and leukotriene inhibitors. Omega-3 fatty acid supplementation may also serve to dampen the inflammatory response. Effectiveness of these treatments in cats with chronic signs is based on anecdotal reports of success in individual cats. Remember that piroxicam should not be given concurrently with corticosteroids.

Cats with severe or deteriorating signs that persist despite conscientious care are candidates for turbinectomy and frontal sinus ablation, if a complete diagnostic evaluation to eliminate other causes of chronic nasal discharge has been performed (see Chapters 13 and 14). Turbinectomy and frontal sinus ablation are difficult surgical procedures. Major blood vessels and the cranial vault must be avoided, and tissue remnants must not be left behind. Anorexia can be a postoperative problem; placement of an esophagostomy or gastrostomy tube serves as an excellent means of meeting nutritional requirements if necessary after surgery. Complete elimination of respiratory signs is unlikely, but signs may be more easily managed. The reader is referred to surgical texts for a description of surgical techniques (e.g., see Fossum in Suggested Readings).

IDIOPATHIC CANINE CHRONIC (LYMPHOPLASMACYTIC) RHINITIS

Etiology

Idiopathic chronic rhinitis in dogs is sometimes characterized by the inflammatory infiltrates seen in nasal mucosal biopsy specimens; thus the disease *lymphoplasmacytic rhinitis* has been described. It was originally reported to be a steroid-responsive disorder, but a subsequent report by Windsor et al. (2004) and clinical experience suggest that corticosteroids are not always effective in the treatment of lymphoplasmacytic rhinitis. It is not uncommon for neutrophilic inflammation to be found, predominantly or along with lymphoplasmacytic infiltrates. For these reasons, the less specific term *idiopathic canine chronic rhinitis* will be used.

Many specific causes of nasal disease result in a concurrent inflammatory response because of the disease itself or as a response to the secondary effects of infection or as an enhanced response to irritants; this makes a thorough diagnostic evaluation of these cases imperative. Windsor et al. (2004) performed multiple PCR assays on paraffin-embedded nasal tissue from dogs with idiopathic chronic rhinitis and failed to find evidence for a role of bacteria (based on DNA load), canine adenovirus-2, parainfluenza virus, *Chlamydophila* spp., or *Bartonella* spp. in affected dogs. Large amounts of fungal DNA were found in affected dogs, suggesting a possible contribution to clinical signs. Alternatively, the result may simply reflect decreased clearance of fungal organisms from the diseased nasal cavity.

Although not supported in the previously quoted study, a potential role for *Bartonella* infection has been suggested on the basis of a study that found an association between seropositivity for *Bartonella* spp. and nasal discharge or epistaxis (Henn et al., 2005) and a report of three dogs with epistaxis and evidence of infection with *Bartonella* spp. (Breitschwerdt et al., 2005). A study conducted in our laboratory (Hawkins et al., 2008) failed to find an obvious association between bartonellosis and idiopathic rhinitis, in agreement with findings by Windsor et al. (2004).

Clinical Features and Diagnosis

The clinical features and diagnosis of idiopathic canine chronic rhinitis are similar to those described for idiopathic feline chronic rhinosinusitis. Chronic mucoid or mucopurulent nasal discharge is the most common clinical sign and is typically bilateral. Fresh blood may be seen in the discharge of some dogs, but it is not usually a primary complaint. Given that it is an idiopathic disease, the lack of specific findings is important. Dogs should have no funduscopic lesions, no lymphadenopathy, no facial or palate deformities, and healthy teeth and gums. Anorexia and weight loss are rarely reported. Thorough diagnostic testing is indicated, as described in Chapters 13 and 14.

Results of such testing do not support the diagnosis of a specific disease. Usual nonspecific findings include turbinate erosion, mucosal inflammation, and increased mucus accumulation as assessed by nasal imaging and rhinoscopy; neutrophilic or mixed inflammation with bacteria on cytology of nasal discharge; and lymphoplasmacytic and/or neutrophilic inflammation on nasal biopsy. Nonspecific abnormalities attributable to chronic inflammation, such as epithelial hyperplasia and fibrosis, can also be seen. Secondary bacterial rhinitis or *Mycoplasma* infection may be identified.

Treatment

Treatment of idiopathic canine chronic rhinitis is also similar to that described for idiopathic feline rhinosinusitis (see previous section and Box 15.1). Dogs are treated for secondary bacterial rhinitis (as described the earlier in this chapter), and efforts are made to decrease irritants in the environment (see feline chronic rhinosinusitis). As with cats, some dogs will benefit from efforts to facilitate the draining of nasal discharge by humidification of air or instillation of sterile saline into the nasal cavity.

Although antiinflammatory treatment as described previously for cats may be beneficial in some dogs, successful treatment was originally reported in dogs with lymphoplasmacytic rhinitis using immunosuppressive doses of prednisone (1 mg/kg, orally, q12h). A positive response is expected within 2 weeks, at which time the dose of prednisone is decreased gradually to the lowest effective amount. If no response to initial therapy occurs, other immunosuppressive drugs such as azathioprine can be added to the treatment regimen (see Chapter 72). Unfortunately, immunosuppressive treatment is not always effective. If clinical signs worsen during treatment with corticosteroids, the clinician should discontinue therapy and carefully reevaluate the dog for other diseases.

Dogs with severe or nonresponsive signs are candidates for rhinotomy and turbinectomy, as described for feline chronic rhinosinusitis.

Prognosis

The prognosis for idiopathic chronic rhinitis in dogs is generally good with respect to improvement of signs and quality of life. However, some degree of clinical signs persists in many dogs.

CHAPTER 16

Clinical Manifestations of Laryngeal and Pharyngeal Disease

CLINICAL SIGNS

LARYNX

Regardless of the cause, diseases of the larynx result in similar clinical signs, most notably respiratory distress and stridor. Gagging or coughing may also be reported. Voice change is specific for laryngeal disease, though not always present. Clients may volunteer that they have noticed a change in the dog's bark or the cat's meow, but specific questioning may be necessary to obtain this important information. Localization of disease to the larynx can generally be achieved with a good history and physical examination. A definitive diagnosis is made through a combination of laryngeal radiography, laryngoscopy, and laryngeal biopsy. Fluoroscopy and computed tomography (CT) can be useful for dynamic disease and improved imaging of mass lesions or anatomic abnormalities, respectively.

Respiratory distress resulting from laryngeal disease is due to airway obstruction. Although most laryngeal diseases are progressive over several weeks to months, animals frequently present in acute distress. Dogs and cats seem to be able to compensate for their disease initially through self-imposed exercise restriction. Often an exacerbating event occurs, such as exercise, excitement, or high ambient temperature, resulting in markedly increased respiratory efforts. These increased efforts lead to excess negative pressures on the diseased larynx, sucking the surrounding soft tissues into the lumen and causing laryngeal inflammation and edema. Obstruction to airflow becomes more severe, leading to even greater respiratory efforts (Fig. 16.1). The airway obstruction can ultimately be fatal.

A characteristic breathing pattern can often be identified on physical examination of patients in distress from extrathoracic (upper) airway obstruction, such as that resulting from laryngeal disease (see Chapter 25). The respiratory rate is normal to only slightly elevated (often 30-40 breaths/min), which is particularly remarkable in the presence of overt distress. Inspiratory efforts are prolonged and labored, relative to expiratory efforts. The larynx tends to be sucked into the airway lumen as a result of negative pressure within the extrathoracic airways that occurs during inspiration, making inhalation of air more difficult. During expiration, pressures are positive in the extrathoracic airways, "pushing" the soft tissues open. Nevertheless, expiration may not be effortless. Some obstruction to airflow may occur during expiration with fixed obstructions, such as laryngeal masses. Even with the dynamic obstruction that results from laryngeal paralysis, in which expiration should be possible without any blockage of flow, resultant laryngeal edema and inflammation can interfere with normal expiration. On auscultation, referred upper airway sounds are heard and lung sounds are normal to increased.

Stridor, a high-pitched wheezing sound, is typically heard predominantly during inspiration. It is audible without a stethoscope, although auscultation of the neck may aid in identifying mild disease. Stridor is produced by air turbulence through the narrowed laryngeal opening. Narrowing of the extrathoracic trachea less commonly produces stridor, more often producing a coarse stertorous sound.

When patients are not presented for respiratory distress (e.g., patients with exercise intolerance or voice change), it may be necessary to exercise the patient to identify the characteristic breathing pattern and stridor associated with laryngeal disease (Video 16.1).

Some patients with laryngeal disease, particularly those whose laryngeal paralysis is an early manifestation of more diffuse neuromuscular disease or those presenting with distortion of normal laryngeal anatomy, have subclinical aspiration or overt aspiration pneumonia resulting from the loss of normal protective mechanisms. Patients may show clinical signs reflecting aspiration, such as cough, lethargy, anorexia, fever, tachypnea, and abnormal lung sounds. (See Chapter 22 for a discussion of aspiration pneumonia.)

PHARYNX

Space-occupying lesions of the pharynx can cause signs of upper airway obstruction as described for the larynx, but overt respiratory distress occurs only with advanced disease. More typical presenting signs of pharyngeal disease include stertor, reverse sneezing, gagging, retching, and dysphagia. Stertor is a loud, coarse sound such as that produced by snoring or snorting. Stertor results when excessive soft tissue

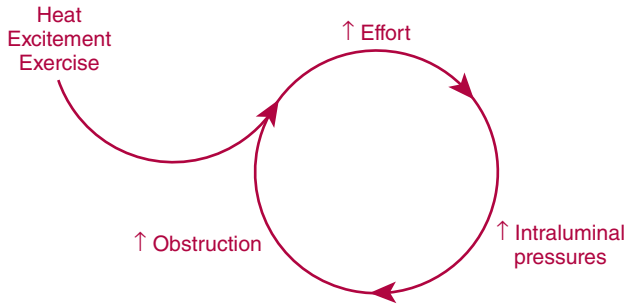

FIG 16.1
Patients with extrathoracic (upper) airway obstruction often present in respiratory distress as a result of progressive worsening of airway obstruction after an exacerbating event.

in the pharynx, such as an elongated soft palate or mass, causes turbulent airflow. Reverse sneezing (see Chapter 13), gagging, or retching may result from local stimulation from the tissue itself or from secondary secretions. Dysphagia results from physical obstruction, usually caused by a mass. As with laryngeal disorders, a definitive diagnosis is made through a combination of visual examination, radiography, and biopsy of abnormal tissue. Visual examination includes a thorough evaluation of the oral cavity, larynx, and caudal nasopharynx. In some cases, fluoroscopy or CT scan may be necessary to assess abnormalities visible only during the stress of labored breathing or to assess mass lesions resulting in external compression of the airway, respectively.

DIFFERENTIAL DIAGNOSES FOR LARYNGEAL SIGNS IN DOGS AND CATS

Differential considerations for dogs and cats with respiratory distress are discussed in Chapter 25.

Dogs are more commonly presented for laryngeal disease than cats and usually have laryngeal paralysis (Box 16.1). Laryngeal neoplasia can occur in dogs or cats. Obstructive laryngitis is a poorly characterized inflammatory disorder. Other possible diseases of the larynx include laryngeal collapse (see Laryngoscopy, Chapter 17), web formation (i.e., adhesions or fibrotic tissue across the laryngeal opening, usually as a complication of surgery), trauma, foreign body, and compression caused by an extraluminal mass. Acute laryngitis is not a well-characterized disease in dogs or cats but presumably could result from viral or other infectious agents, foreign bodies, or excessive barking. Gastroesophageal reflux, a cause of laryngitis in people, has recently been documented to cause laryngeal dysfunction in a dog (Lux, 2012).

DIFFERENTIAL DIAGNOSES FOR PHARYNGEAL SIGNS IN DOGS AND CATS

The most common pharyngeal disorders in dogs are brachycephalic airway syndrome and elongated soft palate (Box 16.2). Elongated soft palate is a component of brachycephalic airway syndrome, which is discussed in Chapter 18, but it can also occur in nonbrachycephalic dogs. Nasophparyngeal polyps are the most common pharyngeal disease in cats, followed by neoplasia. Nasopharyngeal polyps, nasal tumors, and foreign bodies are discussed in the chapters on nasal diseases (see Chapters 13 to 15). Other differential diagnoses are abscess or granuloma and compression caused by an extraluminal mass. Nasopharyngeal stenosis can occur as a complication of chronic inflammation (rhinitis or pharyngitis), vomiting, or gastroesophageal reflux in dogs or cats. Dogs with tracheobronchomalacia (see Chapter 21) who are presented for signs of upper airway obstruction resulting from extrathoracic tracheal collapse can have loud, stertorous breathing similar to that heard in dogs with brachycephalic airway syndrome. The difference in breed predisposition for these two conditions assists in prioritizing the differential diagnoses.

CHAPTER 17

Diagnostic Tests for the Larynx and Pharynx

RADIOGRAPHY

Radiographs of the pharynx and larynx should be evaluated in animals with suspected upper airway disease (Figs. 17.1 and 17.2). Radiographs are particularly useful in identifying radiodense foreign bodies such as needles, which can be embedded in tissues, external compression of the airways, and adjacent bony changes. It may not be possible to identify or characterize these types of lesions with laryngoscopy alone. Intraluminal soft tissue masses and soft palate abnormalities may also be seen.

A lateral view of the larynx, caudal nasopharynx, and cranial cervical trachea is usually obtained. The vertebral column interferes with airway evaluation on dorsoventral or ventrodorsal projections. Care must be taken to assure excellent positioning of the head. Normal structures can appear to be abnormal (e.g., masses, palate abnormalities) if there is any rotation of the head and neck. The head should be held with the neck slightly extended. Padding under the neck and around the head may be needed to avoid rotation, but it should not distort the anatomic structures. Good positioning of radiographs can be assessed by the superimposition of the left and right osseous bullae, mandibles, and frontal sinuses. Regardless, abnormal soft tissue opacities or narrowing of the airway lumen identified radiographically must be confirmed with laryngoscopy, endoscopy and/or computed tomography, and biopsy. Laryngeal paralysis cannot be detected radiographically.

ULTRASONOGRAPHY

Ultrasonography provides another noninvasive imaging modality for evaluating the pharynx and larynx. Reportedly laryngeal motion can be assessed (Rudorf et al., 2001). Because air interferes with sound waves, accurate assessment of this area can be difficult. Experience is necessary to avoid misdiagnosis, particularly with respect to laryngeal motion as it can be the result of passive, paradoxical movement rather than active muscle contraction (see Laryngoscopy and Pharyngoscopy later in this chapter). Localization of mass lesions and guidance of needle aspiration of abnormal tissue or enlarged regional lymph nodes can provide a diagnosis in some cases.

FLUOROSCOPY

In some patients, signs of upper airway obstruction occur only during labored breathing. A diagnosis may be missed if adequate breathing efforts do not occur during routine radiography or during visual examination under anesthesia. In these cases, fluoroscopic evaluation during signs of airway obstruction, or audible sounds (stertor or stridor), can be invaluable. Unusual diagnoses, such as epiglottic retroversion and collapse of the dorsal pharyngeal wall, may not be possible by other means. Extrathoracic tracheal collapse, a differential diagnosis for upper airway obstruction due to pharyngeal or laryngeal disease, can often be diagnosed as well.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Computed tomography and magnetic resonance imaging are sensitive modalities for identifying masses that result in external compression of the larynx or pharynx. Extent of involvement and size of local lymph nodes can be assessed for patients with mass lesions external to or within the airway.

LARYNGOSCOPY AND PHARYNGOSCOPY

Laryngoscopy and pharyngoscopy allow visualization of the larynx and pharynx for assessment of structural

FIG 17.1
Lateral radiograph of the neck, larynx, and pharynx showing normal anatomy. Note that the patient's head and neck are not rotated. The left and right osseous bullae, mandibles, and frontal sinuses are all superimposed. Excellent visualization of the soft palate and epiglottis is possible. Images obtained from poorly positioned patients often result in the appearance of "lesions" such as masses or abnormal soft palate because normal structures are captured at an oblique angle or are superimposed on one another.

abnormalities and laryngeal function. These procedures are indicated in any dog or cat with clinical signs that suggest upper airway obstruction or laryngeal or pharyngeal disease. It should be noted that patients with increased respiratory efforts resulting from upper airway obstruction might have difficulty during recovery from anesthesia. For a period between removal of the endotracheal tube and full recovery of neuromuscular function, the patient may be unable to maintain an open airway. *Therefore laryngoscopy should not be undertaken in these patients unless the clinician is prepared to perform whatever surgical treatments may be indicated during the same anesthetic period.*

The animal is placed in sternal recumbency. Anesthesia is induced and maintained with a short-acting injectable agent without prior sedation. Propofol is commonly used. Depth of anesthesia is carefully titrated, with just enough drug administered to allow visualization of the laryngeal cartilages; some jaw tone is maintained, and spontaneous deep respirations occur. Gauze is passed under the maxilla behind the canine teeth, and the head is elevated by hand (preferred) or by tying the gauze to a stand (Fig. 17.3). This positioning avoids external compression of the neck.

Gentle retraction of the tongue with a gauze sponge should allow visualization of the caudal pharynx and larynx. Avoid distorting the normal anatomy with excessive retraction. A laryngoscope is used for proper illumination of this

FIG 17.2

region. A tongue depressor for elevating the soft palate and a head lamp or well-positioned surgical lamp facilitate the examination.

The motion of the arytenoid cartilages is evaluated while the patient takes several deep breaths. An assistant is needed to verbally report the onset of each inspiration by observing chest wall movements. Normally the arytenoid cartilages abduct symmetrically and widely with each inspiration and close on expiration (Fig. 17.4). Laryngeal paralysis resulting in signs of upper airway obstruction is usually bilateral. The cartilages are not abducted during inspiration. In fact, they may be passively forced outward during expiration and/or sucked inward during inspiration, resulting in paradoxical motion.

If the patient fails to take deep breaths, doxapram hydrochloride (1.1-2.2 mg/kg, administered intravenously) can be given to stimulate breathing. In a study by Tobias et al. (2004), none of the potential systemic side effects of the drug were noted following the 1.1 mg/kg dosage, but some dogs required intubation when increased breathing efforts resulted in significant obstruction to airflow at the larynx.

If no laryngeal motion is observed, examination of the arytenoid cartilages should be continued as long as possible while the animal recovers from anesthesia. Effects of anesthesia and shallow breathing are the most common causes of an erroneous diagnosis of laryngeal paralysis.

After evaluation of laryngeal function, the plane of anesthesia is deepened and the caudal pharynx and larynx are

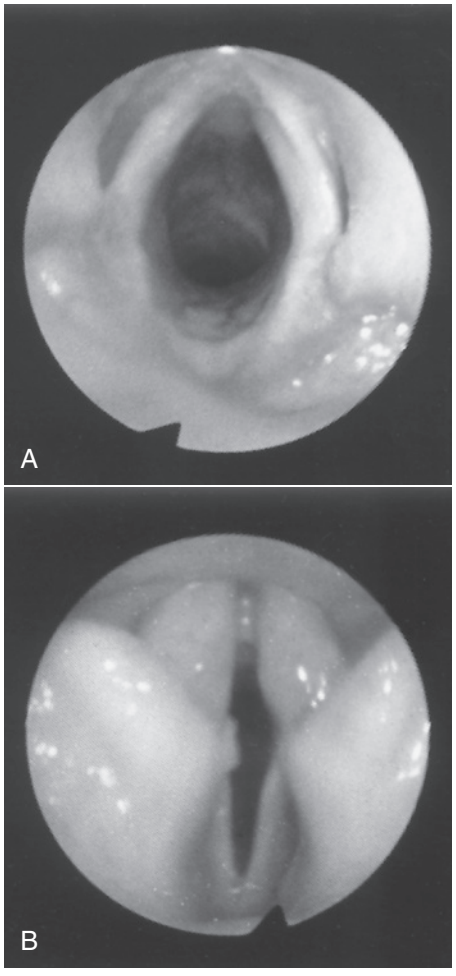

FIG 17.4
Canine larynx. **(A)** During inspiration, arytenoid cartilages and vocal folds are abducted, resulting in wide symmetric opening to the trachea. **(B)** During expiration, cartilages and vocal folds nearly close the glottis.

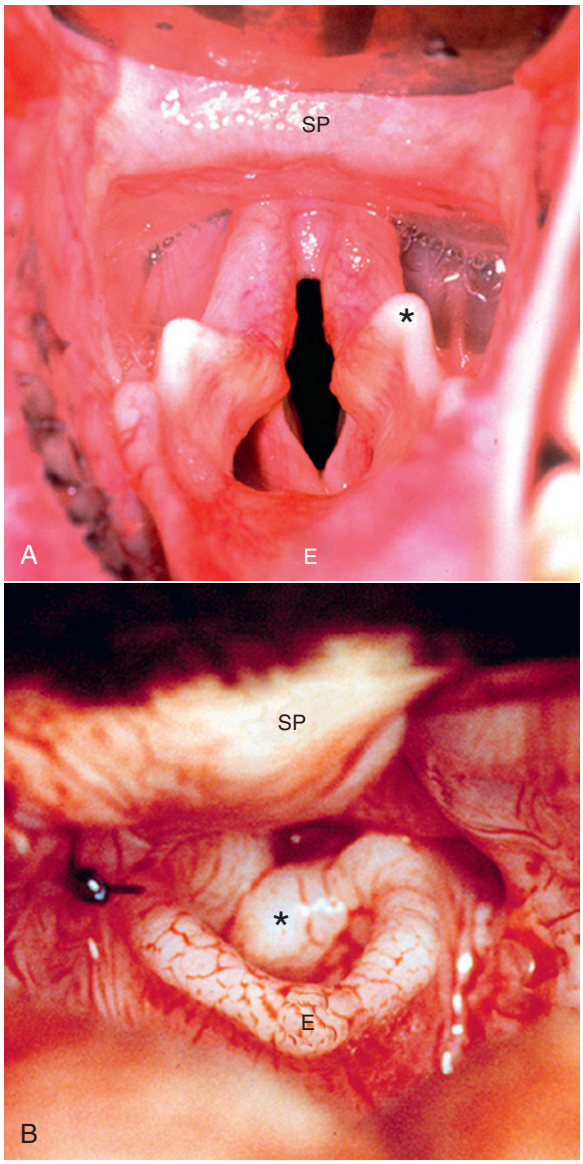

FIG 17.5
The laryngeal anatomy from a healthy dog **(A)** is contrasted with that of a dog with laryngeal collapse **(B).** In the collapsed larynx, the cuneiform process *(*)* of the arytenoid process has folded medially and obstructs most of the airway. Also labeled are the soft palate *(SP)* and the epiglottis *(E)*. thoroughly evaluated for structural abnormalities, foreign bodies, or mass lesions. The length of the soft palate should be assessed. The soft palate normally extends to the tip of the epiglottis during inhalation. An elongated soft palate can contribute to signs of upper airway obstruction.

As described in Chapter 14, the caudal nasopharynx should be evaluated for nasopharyngeal polyps, mass lesions, foreign bodies, and nasopharyngeal stenosis. Needles or other sharp objects may be buried in tissue, and careful visual examination and palpation are required for detection. Brachycephalic patients are evaluated for obstruction of the internal nares by abnormal turbinate anatomy.

The trachea should be examined with a rigid or flexible endoscope if abnormalities are not identified on laryngoscopy in the dog or cat with signs of upper airway obstruction. If no endoscope is available, the laryngeal cartilages can be held open with an endotracheal tube for a cursory examination of the proximal trachea.

Neoplasia, granulomas, abscesses, or other masses can occur within or external to the larynx or pharynx, causing compression or deviation of normal structures or both. Severe, diffuse thickening of the laryngeal mucosa can be caused by infiltrative neoplasia or obstructive laryngitis. Biopsy specimens for histologic examination should be obtained from any lesions to establish an accurate diagnosis because the prognoses for these diseases are quite different. The normal diverse flora of the pharynx makes culture results difficult or impossible to interpret. Bacterial growth from abscess fluid or tissue obtained from granulomatous lesions may represent infection.

Obliteration of most of the airway lumen by collapse of the normal laryngeal structure is known as *laryngeal collapse* (Fig. 17.5). With prolonged upper airway obstruction, the soft tissues are sucked into the lumen by the increased negative pressure created as the dog or cat struggles to get air into its lungs. Eversion of the laryngeal saccules, thickening and elongation of the soft palate, and inflammation with thickening of the pharyngeal mucosa can occur. The laryngeal cartilages can become soft and deformed, unable to support the soft tissues of the pharynx. It is unclear whether this chondromalacia is a concurrent or secondary component of laryngeal collapse. Collapse most often occurs in dogs with brachycephalic airway syndrome but can also occur with any chronic obstructive disorder.

CHAPTER 18

Disorders of the Larynx and Pharynx

LARYNGEAL PARALYSIS

Laryngeal paralysis refers to failure of the arytenoid cartilages to abduct during inspiration, creating extrathoracic (upper) airway obstruction. The abductor muscles are innervated by the left and right recurrent laryngeal nerves. If clinical signs develop, both arytenoid cartilages are usually affected. The disease can affect dogs and cats, but dogs are more often presented with clinical signs.

Etiology

Potential causes of laryngeal paralysis are listed in Box 18.1, with the cause remaining idiopathic in most cases. Historically, dogs with idiopathic laryngeal paralysis were considered to have dysfunction limited to the laryngeal nerve. It is now believed that idiopathic laryngeal paralysis is part of a generalized neuromuscular disorder. A study by Stanley et al. (2010) demonstrated that dogs with idiopathic laryngeal paralysis have esophageal dysfunction detected by swallowing studies. This study further showed that, on the basis of neurologic examination, these dogs will demonstrate signs of generalized neuromuscular disease within a year. Abnormal electrodiagnostic testing and histologic changes in peripheral nerves have also been reported (Thieman et al., 2010). Dogs with overt polyneuropathy-polymyopathy also may present with laryngeal paralysis as the predominant clinical sign. Polyneuropathies in turn have been associated with immune-mediated diseases, endocrinopathies, or other systemic disorders (see Chapter 66).

Congenital laryngeal paralysis has been documented in the Bouvier des Flandres and is suspected in Siberian Huskies and Bull Terriers. A laryngeal paralysis-polyneuropathy complex has been described in young Dalmatians, Rottweilers, and Great Pyrenees. The possibility that a genetic predisposition exists in Labrador Retrievers, even though signs appear later in life, has been proposed on the basis of their overrepresentation in reports of laryngeal paralysis (Shelton, 2010).

Direct damage to the laryngeal nerves or the larynx can also result in paralysis. Trauma or neoplasia involving the ventral neck can damage the recurrent laryngeal nerves directly or through inflammation and scarring. Masses or trauma involving the anterior thoracic cavity can also cause damage to the recurrent laryngeal nerves as they course around the subclavian artery (right side) or the ligamentum arteriosum (left side). These causes are less commonly encountered.

Clinical Features

Laryngeal paralysis can occur at any age and in any breed, although it is most commonly seen in older large-breed dogs. Labrador Retrievers are overrepresented. The disease is uncommon in cats. Clinical signs of respiratory distress and stridor are a direct result of narrowing of the airway at the arytenoid cartilages and vocal folds. The owner may also note a change in voice (i.e., bark or meow). Many patients are presented for acute respiratory distress, in spite of the chronic, progressive nature of this disease. Decompensation occurs as a result of exercise, excitement, or high environmental temperatures, resulting in a cycle of increased respiratory efforts; increased negative airway pressures, which suck the soft tissue into the airway; and pharyngeal edema and inflammation, which lead to further increased respiratory efforts. Cyanosis, syncope, and death can occur. Dogs in respiratory distress require immediate emergency therapy.

Some dogs with laryngeal paralysis exhibit gagging or coughing, often noted particularly with eating or drinking. These signs could be a result of secondary laryngitis, concurrent pharyngeal or esophageal dysfunction, and/or esophageal reflux secondary to upper airway obstruction. Signs of aspiration pneumonia may also be present but are rarely the presenting complaint.

Diagnosis

A definitive diagnosis of laryngeal paralysis is made through laryngoscopy (see Chapter 17). Movement of the arytenoid cartilages is observed during a light plane of anesthesia while the patient is taking deep breaths. In laryngeal paralysis, the arytenoid cartilages and the vocal folds remain in a midline position or are sucked inward (paradoxically)

during inspiration and may open slightly during expiration. The larynx does not exhibit the normal coordinated movement associated with breathing, opening on inspiration and closing on expiration. Additional laryngoscopic findings may include laryngeal edema and inflammation. The larynx and the pharynx are also examined for neoplasia, foreign bodies, or other disorders that might interfere with normal function and for laryngeal collapse (see Chapter 17).

Once a diagnosis of laryngeal paralysis has been established, additional diagnostic tests should be considered to identify underlying or associated diseases (particularly if the patient is an atypical breed), to identify concurrent aspiration pneumonia, and identify concurrent pharyngeal and esophageal motility problems (Box 18.2).

Treatment

In animals with respiratory distress, emergency medical therapy to relieve upper airway obstruction is indicated (see Chapter 25). Following stabilization and a thorough diagnostic evaluation, surgery is usually the treatment of choice. Even when specific therapy can be directed at an associated disease (e.g., hypothyroidism), complete resolution of clinical signs of laryngeal paralysis is rarely seen.

Various laryngoplasty techniques have been described, including arytenoid lateralization (tie-back) procedures, partial laryngectomy, and castellated laryngoplasty. The goal of surgery is to provide an adequate opening for the flow of air but not one so large that the animal is predisposed to aspiration and the development of pneumonia. Several operations to gradually enlarge the glottis may be necessary to minimize the chance of subsequent aspiration. The recommended initial procedure for most dogs and cats is unilateral arytenoid lateralization.

If surgery is not an option, medical management consisting of antiinflammatory doses of short-acting glucocorticoids (e.g., prednisone, 0.5 mg/kg given orally q12h initially) and cage rest may reduce secondary inflammation and edema of the pharynx and larynx and enhance airflow. For long-term management, situations resulting in prolonged or increased breathing efforts, such as heavy exercise, and high ambient temperatures are avoided. Exercise may need to be limited to leash walks or other routines where the intensity of activity is controlled. Trazadone can be considered for highly excitable dogs.

Prognosis

The overall prognosis for dogs with laryngeal paralysis treated surgically is fair to good, despite evidence for progressive, generalized disease, esophageal dysfunction, or aspiration pneumonia. Wilson et al. (2016) showed that

outcome following surgical intervention was not related to presurgical esophageal dysfunction. In this study, 232 dogs that underwent unilateral lateralization procedures had 1-, 2-, 3-, and 4-year survival rates of 94%, 89%, 84%, and 75%, respectively. These numbers are quite positive, particularly considering the median age and body weights of these dogs were 10.6 years and 35 kg. At 1-, 3-, and 4-year follow-up, aspiration pneumonia occurred in 19%, 32%, and 32% of dogs. Risk factors for aspiration pneumonia were postoperative megaesophagus and postoperative administration of opioid analgesics before discharge. In contrast to previously held conventional wisdom, preoperative aspiration pneumonia was not a negative prognostic indicator. A good prognosis was reported for a small number of cats undergoing unilateral arytenoid lateralization (Thunberg et al., 2010).

BRACHYCEPHALIC AIRWAY SYNDROME

The term *brachycephalic airway syndrome,* or *brachycephalic airway obstruction syndrome (BOAS),* refers to the multiple anatomic abnormalities commonly found in brachycephalic dogs and, to a lesser extent, in short-faced cats such as Himalayans. The predominant, readily identified, anatomic abnormalities include stenotic nares, elongated soft palate, and, in Bulldogs, hypoplastic trachea. However, with the common use of computed tomography and rhinoscopy, it is now known that abnormal, obstructing nasal turbinates contribute significantly to the breathing abnormalities of dogs with this conformation (Oechtering, 2010; Oechtering et al., 2016). Prolonged upper airway obstruction resulting in increased inspiratory efforts may lead to eversion of the laryngeal saccules and, ultimately, to laryngeal collapse (see Fig. 17.5). The severity of these abnormalities varies, and one or any combination of these abnormalities may be present in any given brachycephalic dog or short-faced cat (Fig. 18.1).

Concurrent gastrointestinal signs such as ptyalism, regurgitation, and vomiting are common in dogs with brachycephalic airway syndrome (Poncet et al., 2005) Underlying gastrointestinal disease may be a concurrent problem in these breeds of dogs or may result from or may be exacerbated by increased intrathoracic pressures generated in response to the upper airway obstruction.

Clinical Features

Abnormalities associated with the brachycephalic airway syndrome impair the flow of air through the extrathoracic (upper) airways and cause clinical signs of upper airway obstruction, including loud breathing sounds, stertor, increased inspiratory efforts, cyanosis, and syncope. Clinical signs are exacerbated by exercise, excitement, and high environmental temperatures. The increased inspiratory effort commonly associated with this syndrome may cause secondary edema and inflammation of the laryngeal and pharyngeal mucosae and may enhance eversion of the laryngeal saccules or laryngeal collapse, further narrowing the glottis, exacerbating the clinical signs, and creating a vicious cycle.

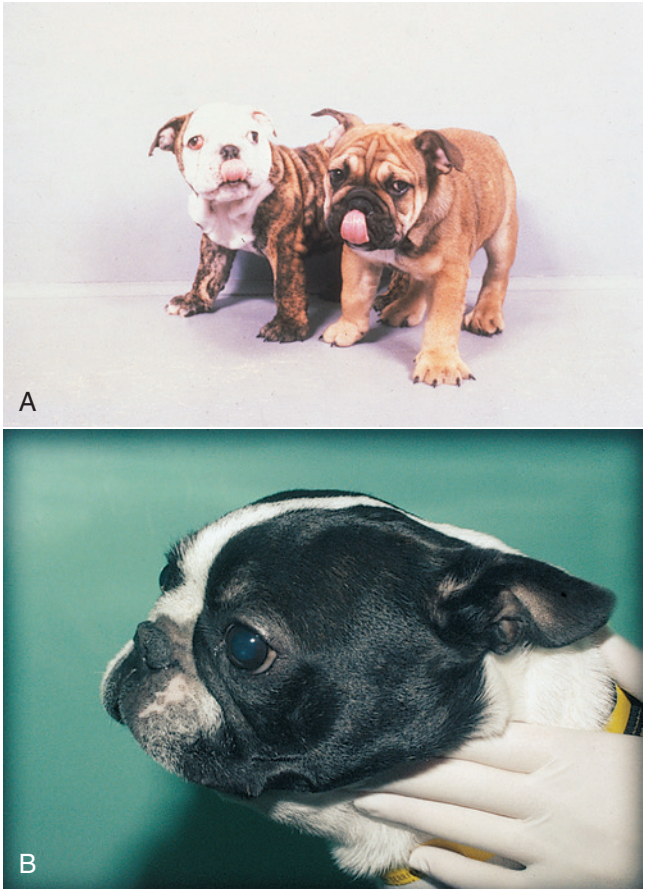

FIG 18.1
Two Bulldog puppies **(A)** and a Boston Terrier **(B)** with brachycephalic airway syndrome. Abnormalities can include stenotic nares, elongated soft palate, everted laryngeal saccules, laryngeal collapse, and hypoplastic trachea. Abnormal nasal turbinate development contributes significantly to obstruction.

As a result, some dogs may be presented with life-threatening upper airway obstruction that requires immediate emergency therapy. Concurrent gastrointestinal signs are commonly reported.

Diagnosis

A tentative diagnosis is made on the basis of breed, clinical signs, and appearance of the external nares (Fig. 18.2). Stenotic nares are generally bilaterally symmetric, and the alar folds may be sucked inward during inspiration, thereby worsening the obstruction to airflow. Laryngoscopy (see Chapter 17) and radiographic evaluation of the trachea (see Chapter 20) are necessary to fully assess the extent and severity of abnormalities. Computed tomography and rhinoscopy would be required to fully assess the turbinates; however, availability of treatment by laser turbinectomy is currently limited. Most other causes of upper airway obstruction (see Chapter 25 and Boxes 16.1 and 16.2) can also be ruled in or out on the basis of the results of these diagnostic tests.

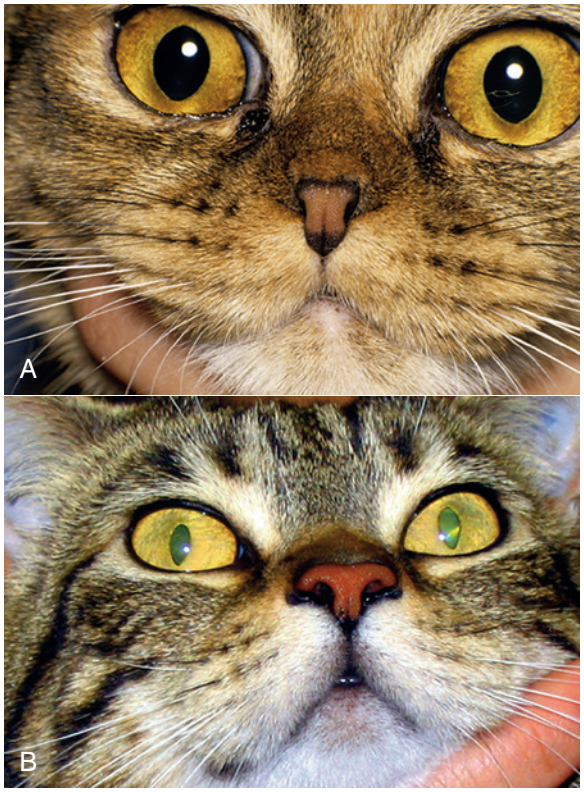

FIG 18.2
Cat with severely stenotic nares **(A)** as compared with the nares of a normal cat **(B).** Early correction of stenotic nares and other amenable upper airway obstructions, such as an elongated soft palate, is highly recommended.

Treatment

Therapy should be designed to enhance the passage of air through the upper airways and to minimize the factors that exacerbate clinical signs (e.g., excessive exercise and excitement, overheating). Surgical correction of anatomic defects is the treatment of choice. The specific surgical procedure selected depends on the nature of the existing problems and can include widening of the external nares and removal of excessive soft palate and everted laryngeal saccules. Laser turbinectomy has proven successful in improving quality of life but is technically difficult and not readily available (Schuenemann and Oechtering, 2014).

Correction of stenotic nares is a simple procedure and can lead to a surprising alleviation of signs in affected patients. Stenotic nares can be safely corrected at 3 to 4 months of age, *ideally before clinical signs develop*. The soft palate should be evaluated at the same time and corrected if elongated. Such early relief of obstruction should decrease the amount of negative pressure placed on pharyngeal and laryngeal structures during inspiration and may decrease progression of disease.

Medical management consisting of the administration of short-acting glucocorticoids (e.g., prednisone, 0.5 mg/kg given orally q12h initially) and cage rest may reduce the secondary inflammation and edema of the pharynx and larynx and enhance airflow, but it will not eliminate the problem. Emergency therapy may be required to alleviate the upper airway obstruction in animals presenting in respiratory distress (see Chapter 25).

Weight management and concurrent treatment for gastrointestinal disease should not be neglected in patients with brachycephalic airway syndrome.

Prognosis

The prognosis depends on the severity of the abnormalities at the time of diagnosis and the ability to surgically correct them. Clinical signs will progressively worsen if the underlying problems go uncorrected. The prognosis after early surgical correction of the abnormalities is good for many animals. Laryngeal collapse is generally considered a poor prognostic indicator, although even dogs with severe laryngeal collapse can respond well to surgical intervention (Torrez et al., 2006). Permanent tracheostomy can be considered as a salvage procedure in animals with severe collapse that are not responsive. A hypoplastic trachea is not surgically correctable, but there is no clear relationship between the degree of hypoplasia and morbidity or mortality. Using the objective measurement of tracheal diameter:thoracic inlet distance, six English Bulldog puppies (2-6 months of age) had improvement in relative tracheal diameter when reevaluated radiographically after 6 months or longer (Clarke et al., 2011). These findings suggest partial resolution is possible in some puppies as they develop.

OBSTRUCTIVE LARYNGITIS

Nonneoplastic infiltration of the larynx with inflammatory cells can occur in dogs and cats, causing irregular proliferation, hyperemia, and swelling of the larynx. Clinical signs of an upper airway obstruction may result. The larynx may appear grossly neoplastic during laryngoscopy but is differentiated from neoplasia on the basis of the histopathologic evaluation of biopsy specimens. Inflammatory infiltrates can be granulomatous, pyogranulomatous, or lymphocytic-plasmacytic. Etiologic agents have not been identified.

This syndrome is poorly characterized and probably includes several different diseases. Some animals respond to glucocorticoid therapy. Prednisone or prednisolone (1 mg/kg given orally q12h) is used initially. Once the clinical signs have resolved, the dose of prednisone can be tapered to the lowest amount that effectively maintains remission of clinical signs. Conservative excision of the tissue obstructing the airway may be necessary in animals with severe signs of upper airway obstruction or large granulomatous masses.

The prognosis varies, depending on the size of the lesion, the severity of laryngeal damage, and the responsiveness of the lesion to glucocorticoid therapy.

LARYNGEAL NEOPLASIA

Neoplasms originating from the larynx are uncommon in dogs and cats. More commonly, tumors originating in tissues adjacent to the larynx, such as thyroid carcinoma and lymphoma, compress or invade the larynx and distort normal laryngeal structures. Clinical signs of extrathoracic (upper) airway obstruction result. Laryngeal tumors include carcinoma (squamous cell, undifferentiated, and adenocarcinoma), lymphoma, melanoma, mast cell tumors and other sarcomas, and benign neoplasia. Lymphoma is the most common tumor in cats.

Clinical Features

The clinical signs of laryngeal neoplasia are similar to those of other laryngeal diseases and include noisy respiration, stridor, increased inspiratory efforts, cyanosis, syncope, and a change in bark or meow. Mass lesions can also cause concurrent dysphagia, aspiration pneumonia, or visible or palpable masses in the ventral neck.

Diagnosis

Extralaryngeal mass lesions are often identified by palpation of the neck. Primary laryngeal tumors are rarely palpable and are best identified by laryngoscopy. Laryngeal radiographs, ultrasonography, or computed tomography can be useful in assessing the extent of disease. Differential diagnoses include obstructive laryngitis, nasopharyngeal polyp, foreign body, traumatic granuloma, and abscess. Cytologic examination of fine-needle mass aspirates may provide a diagnosis. Yield and safety are increased with ultrasound guidance. A definitive diagnosis of neoplasia requires histologic examination of a biopsy specimen of the mass. A diagnosis of malignant neoplasia should not be made on the basis of gross appearance alone.

Treatment

The therapy used depends on the type of tumor identified histologically. Benign tumors should be excised surgically, if possible. Complete surgical excision of malignant tumors is rarely possible, although ventilation may be improved and time may be gained to allow other treatments such as radiation or chemotherapy to become effective. Complete laryngectomy and permanent tracheostomy may be considered in select animals.

Prognosis

The prognosis in animals with benign tumors is excellent if the tumors can be totally resected. Malignant neoplasms are associated with a poor prognosis.

CHAPTER 19

Clinical Manifestations of Lower Respiratory Tract Disorders

CLINICAL SIGNS

In this discussion, the term *lower respiratory tract disorders* refers to diseases of the trachea, bronchi, bronchioles, alveoli, interstitium, and vasculature of the lung (Box 19.1). Dogs and cats with diseases of the lower respiratory tract are commonly seen for evaluation of cough. Lower respiratory tract diseases that interfere with the oxygenation of blood can result in respiratory distress, exercise intolerance, weakness, cyanosis, or syncope. Nonlocalizing signs such as fever, anorexia, weight loss, and depression also occur and are the only presenting sign in some animals. Auscultation and thoracic radiography help localize the disease to the lower respiratory tract in these animals. The two major presenting signs in animals with lower respiratory tract disease—cough and respiratory distress—can be further characterized by a careful history and physical examination.

COUGH

A cough is an explosive release of air from the lungs through the mouth. It is generally a protective reflex to expel material from the airways, although inflammation or compression of the airways can also stimulate cough. Cough is sometimes caused by disease outside of the lower respiratory tract. Chylothorax and laryngeal disease can cause cough. Although not well documented in dogs or cats, gastroesophageal reflux and postnasal drip are common causes of cough in people.

Classically in human medicine, differential diagnoses for cough are divided into those that cause productive cough and those that cause nonproductive cough. A productive cough results in the delivery of mucus, exudate, edema fluid, or blood from the airways into the oral cavity, whereas a nonproductive cough is a dry cough. This distinction is readily made in people because they can report their experience. However, in veterinary medicine, many patients with productive diseases do not appear to have a productive cough, despite careful observation and auscultation. Therefore, if a cough can be identified as productive the list of differential diagnoses can be narrowed (Box 19.2). *However, not hearing or seeing evidence of productivity does not rule out the possibility of its presence, and these differentials should remain under consideration.*

Productive coughs are most commonly caused by inflammatory or infectious diseases involving the airways or alveoli and by heart failure. A moist sound can often be heard during the cough. Animals rarely expectorate the fluid, but swallowing can often be seen after a coughing episode. If expectoration occurs, clients may confuse the cough with vomiting. Cough in cats can be confused with attempts to vomit a hairball. Cats that never produce a hairball are likely coughing (Video 19.1).

Hemoptysis is the coughing up of blood. Blood-tinged saliva may be observed within the oral cavity or dripping from the commissures of the mouth after a cough. Hemoptysis is an unusual clinical sign that most commonly occurs in animals with heartworm disease or pulmonary neoplasia. Less common causes of hemoptysis are mycotic infection, foreign bodies, severe congestive heart failure, thromboembolic disease, lung lobe torsion, and some systemic bleeding disorders, such as disseminated intravascular coagulation (see Box 19.2).

Intensity of cough is useful in prioritizing the differential diagnoses, although exceptions are common. Cough associated with airway inflammation (i.e., bronchitis) or large airway collapse is often loud, harsh, and paroxysmal. The cough associated with tracheal collapse is often described as a "goose-honk." Cough resulting from tracheal disease can usually be induced by palpation of the trachea, although there is often concurrent involvement of the deeper airways. Cough associated with pneumonias and pulmonary edema is often soft.

The association of coughing with temporal events can be helpful. Cough resulting from tracheal disease is exacerbated by pressure on the neck, such as pulling on the animal's collar. Cough caused by heart failure tends to occur more frequently at night, whereas cough caused by airway inflammation (bronchitis) tends to occur more frequently upon rising from sleep or during and after exercise or exposure to cold air. The client's perception of frequency may be biased

BOX 19.1

Differential Diagnoses for Lower Respiratory Tract Disease in Dogs and Cats

Disorders of the Trachea and Bronchi

Canine infectious respiratory disease complex
Canine chronic bronchitis
Tracheobronchomalacia (collapsing trachea and/or bronchi)
Feline bronchitis (idiopathic)
Allergic bronchitis
Bacterial, including *Mycoplasma,* infections
Oslerus osleri infection
Neoplasia
Foreign body
Tracheal tear
Bronchial compression
- Left atrial enlargement
- Hilar lymphadenopathy
- Neoplasia

Disorders of the Pulmonary Parenchyma and Vasculature

Infectious diseases
- Viral pneumonias
  - Canine influenza
  - Canine distemper
  - Calicivirus
  - Feline infectious peritonitis
- Bacterial pneumonia
- Protozoal pneumonia
  - Toxoplasmosis
- Fungal pneumonia
  - Blastomycosis
  - Histoplasmosis
  - Coccidioidomycosis
- Parasitic disease
  - Heartworm disease
  - Pulmonary parasites
    - *Paragonimus* infection
    - *Aelurostrongylus* infection
    - *Capillaria* infection
    - *Crenosoma* infection

Aspiration pneumonia
Eosinophilic lung disease
Idiopathic interstitial pneumonias
- Idiopathic pulmonary fibrosis

Pulmonary neoplasia
Pulmonary contusions
Pulmonary hypertension
Pulmonary thromboembolism
Pulmonary edema

by the times of day during which they have the most contact with their pets, often in the evenings and during exercise.

It is surprising to note that cats with many of the disorders listed in Box 19.2 do not cough. In cats that cough, the index of suspicion for bronchitis, lung parasites, and heartworm disease is high.

BOX 19.2

Differential Diagnoses for Productive Cough* in Dogs and Cats

Edema

Heart failure
Noncardiogenic pulmonary edema

Mucus or Exudate

Canine infectious respiratory disease complex
Canine chronic bronchitis
Feline bronchitis (idiopathic)†
Allergic bronchitis†
Bacterial infection (bronchitis or pneumonia)
Parasitic disease†
Aspiration pneumonia
Fungal pneumonia (severe)

Blood (Hemoptysis)

Heartworm disease†
Neoplasia
Fungal pneumonia
Thromboembolism
Severe heart failure
Foreign body
Lung lobe torsion
Systemic bleeding disorder

*Because it can be difficult to determine the productive nature of a cough in veterinary medicine, these differential diagnoses should also be considered in patients with nonproductive cough.
†Diseases of the lower respiratory tract most often associated with cough in cats. Cough in cats is rarely identified as productive.

EXERCISE INTOLERANCE AND RESPIRATORY DISTRESS

Diseases of the lower respiratory tract can compromise the lung's function of oxygenating the blood through a variety of mechanisms (see the section on blood gas analysis in Chapter 20). Clinical signs of such compromise begin as mildly increased respirations and subtly decreased activity and progress through exercise intolerance (manifested as reluctance to exercise or respiratory distress with exertion) to overt respiratory distress at rest. Because of compensatory mechanisms, the ability of most pets to self-regulate their activity, and the inability of pets to communicate, many veterinary patients with compromised lung function arrive in overt respiratory distress. Dogs in overt distress will often stand with their neck extended and elbows abducted. Movements of the abdominal muscles may be exaggerated. Healthy cats have minimally visible respiratory efforts. Cats that show noticeable chest excursions or open-mouth breathing are severely compromised. Patients in overt distress require rapid physical assessment and immediate stabilization before further diagnostic testing, as discussed in Chapter 25.

Resting Respiratory Rate

Resting respiratory rate can be used as an objective indicator of pulmonary function in patients that are not yet in respiratory distress. The measurement is ideally made at home by the owner, eliminating the effect of the stress of the veterinary hospital on the respiratory rate. The normal respiratory rate of a dog or cat without stress, at rest, is less than 20 respirations per minute. A rate of up to 30 respirations per minute is generally considered normal during a routine physical examination. Panting is a distinct activity with respiratory rates often exceeding 200 breaths/minute. Panting is primarily associated with the function of heat dissipation but can also be seen as a response to pain or anxiety and in association with hyperadrenocorticism or steroid administration.

Mucous Membrane Color

Cyanosis, in which normally pink mucous membranes are bluish, is a sign of severe hypoxemia and indicates that the increased respiratory effort is not sufficiently compensating for the degree of respiratory dysfunction. Pallor of mucous membranes is a more common sign of acute hypoxemia resulting from respiratory disease.

Breathing Pattern

Patients in respiratory distress resulting from diseases of the lower respiratory tract, excluding the large airways, typically have rapid and often shallow respirations; have increased expiratory or inspiratory efforts, or both; and may have abnormal lung sounds on auscultation. Patients with intrathoracic large airway obstruction (intrathoracic trachea and/or large bronchi) generally have normal to slightly increased respiratory rate; prolonged, labored expiration; and audible or auscultable expiratory sounds (see Chapter 25).

DIAGNOSTIC APPROACH TO DOGS AND CATS WITH LOWER RESPIRATORY TRACT DISEASE

INITIAL DIAGNOSTIC EVALUATION

The initial diagnostic evaluation of dogs or cats with signs of lower respiratory tract disease includes a complete history, physical examination, thoracic radiographs, and complete blood count (CBC). Further diagnostic tests are selected on the basis of information obtained from these procedures; these include tests for specific diseases, the evaluation of specimens collected from the lower respiratory tract, specialized imaging techniques, and pulmonary function tests (Fig. 19.1). Historical information was discussed in previous paragraphs.

Physical Examination

Measurement of respiratory rate, assessment of mucous membrane color, and observation of the breathing pattern

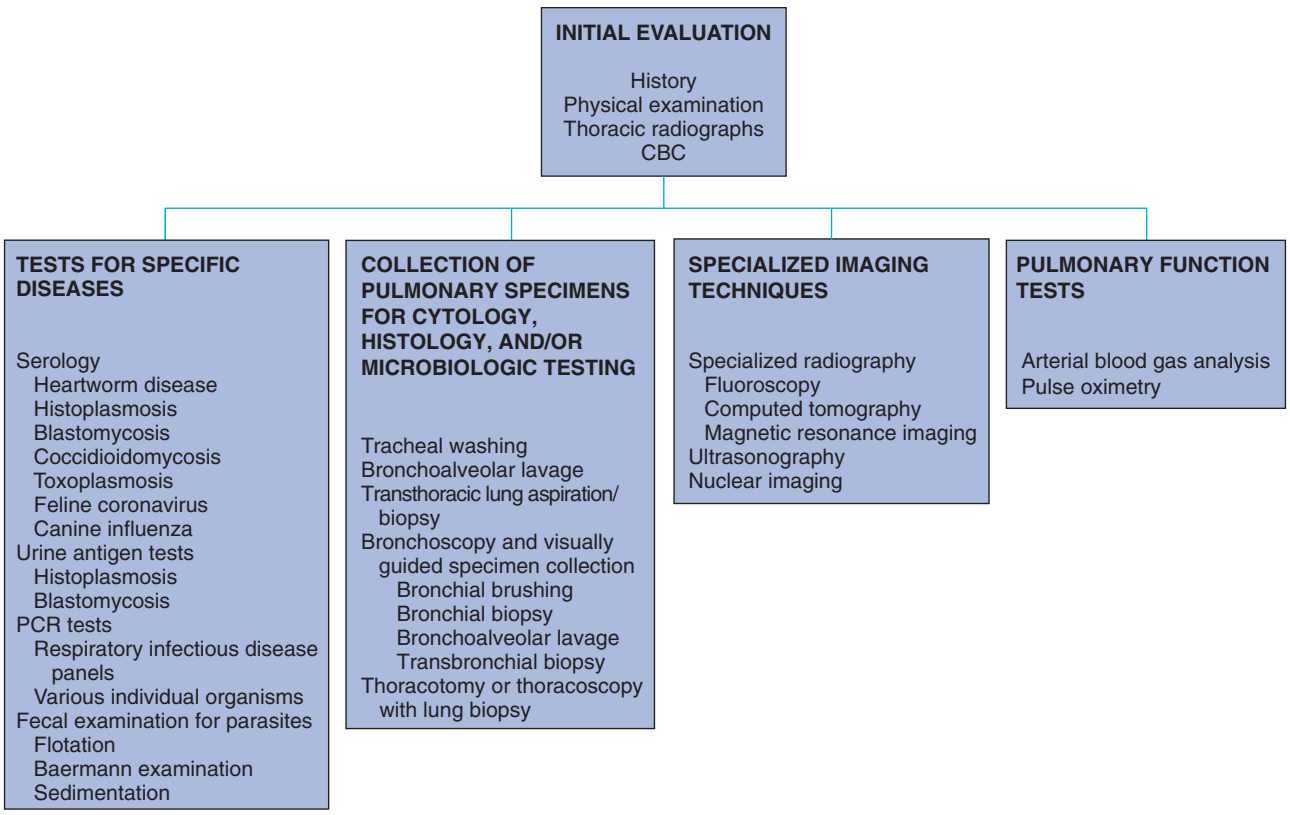

FIG 19.1
Diagnostic approach for dogs and cats with lower respiratory tract disease.

were described in the previous sections. A complete physical examination, including a fundic examination, is warranted to identify signs of disease that may be concurrently or secondarily affecting the lungs (e.g., systemic mycoses, metastatic neoplasia, megaesophagus).

The cardiovascular system should be carefully evaluated. Mitral insufficiency murmurs are frequently auscultated in older small-breed dogs brought to the clinician with the primary complaint of cough. Mitral insufficiency is often an incidental finding, but the clinician must consider both cardiac and respiratory tract diseases as differential diagnoses in these animals. Mitral insufficiency can lead to congestive heart failure with pulmonary edema, and left atrial enlargement itself may contribute to cough. Cough associated with mitral insufficiency has been presumed to be a result of airway compression by an enlarged left atrium, but collapse of the left bronchus appears to be independent of atrial size (Singh et al., 2012). Other factors, such as vibration from a mitral jet or concurrent bronchial inflammation, may be involved. Congestive heart failure most often results in tachypnea or dyspnea, rather than cough (Ferasin et al., 2013), and tachycardia. Other signs of heart disease include prolonged capillary refill time, weak or irregular pulses, abnormal jugular pulses, ascites or subcutaneous edema, gallop rhythms, and pulse deficits. Thoracic radiographs and occasionally echocardiography may be needed before cardiac problems can be comfortably ruled out as a cause of lower respiratory tract signs.

Thoracic auscultation

Careful auscultation of the upper airways and lungs is a critical component of the physical examination in dogs and cats with respiratory tract signs. Auscultation should be performed in a quiet location with the animal calm. Panting and purring do not result in deep inspiration, precluding evaluation of lung sounds. The heart and upper airways should be auscultated first. The clinician can then mentally subtract the contribution of these sounds from the sounds auscultated over the lung fields.

Initially, the stethoscope is placed over the trachea near the larynx (Fig. 19.2). Discontinuous snoring or snorting sounds can be referred from the nasal cavity and pharynx as a result of obstructions stemming from structural abnormalities, such as an elongated soft palate or mass lesions, and excessive mucus or exudate. Collapse of the extrathoracic trachea can also cause coarse sounds. Wheezes, which are continuous high-pitched sounds, occur in animals with obstructive laryngeal conditions, such as laryngeal paralysis, neoplasia, inflammation, and foreign bodies. Discontinuous snoring sounds and wheezes are known as *stertor* and *stridor,* respectively, when they can be heard without a stethoscope. The entire cervical trachea is then auscultated for areas of high-pitched sounds caused by localized airway narrowing. Several breaths are auscultated with the stethoscope in each position, and the phase of respiration in which abnormal sounds occur is noted. Abnormal sounds resulting from extrathoracic disease are generally loudest during inspiration.

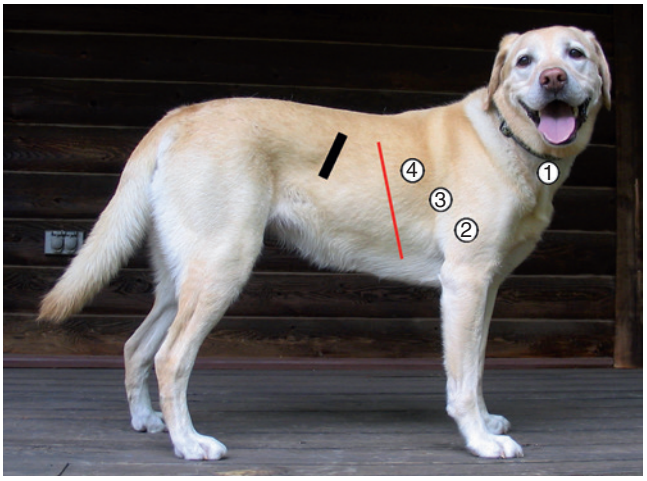

FIG 19.2
Auscultation of the respiratory tract begins with the stethoscope positioned over the trachea (stethoscope position 1). After upper airway sounds are assessed, the stethoscope is positioned to evaluate the cranioventral, central, and dorsal lung fields on both sides of the chest (stethoscope positions 2, 3, and 4). Note that the lung fields extend from the thoracic inlet to approximately the seventh rib along the sternum and to approximately the eleventh intercostal space along the spine *(thin red line)*. Common mistakes are to neglect the cranioventral lung fields, reached by placing the stethoscope between the forelimb and the chest, and to position the stethoscope too far caudally, beyond the lung fields and over the liver. (*Thick black line* indicates position of the thirteenth rib.)

The lungs are auscultated next. Normally, the lungs extend cranially to the thoracic inlet and caudally to about the seventh rib ventrally along the sternum and to approximately the eleventh intercostal space dorsally along the spine (see Fig. 19.2). The cranioventral, central, and dorsal lung fields on both the left and right sides are auscultated systematically. Any asymmetry in the sounds between the left and right sides is abnormal.

Normal lung sounds have been described historically as a mixture of "bronchial or tracheal" and "vesicular" sounds, although all sounds originate from the large airways rather than the alveoli (vesicles). The terms "breath sounds" or "lung sounds" are now preferred. Tracheal and bronchial sounds are louder, harsher, tubular sounds heard over the trachea and, less prominently, in the central regions of the lungs. Over the majority of the lung field, sounds are normally soft and have been likened to a breeze blowing through leaves.

Decreased lung sounds over one or both sides of the thorax occur in dogs and cats with pleural effusion, pneumothorax, diaphragmatic hernia, or mass lesions. It is surprising to note that consolidated lung lobes and mass lesions can result in enhanced lung sounds because of improved transmission of airway sounds from adjacent lobes.

Abnormal lungs sounds are described as increased breath sounds (alternatively, harsh lung sounds), crackles, or wheezes. Increased breath sounds are a nonspecific finding

but are common in patients with pulmonary edema or pneumonia. Crackles are nonmusical, discontinuous noises that sound like paper being crumpled or bubbles popping. Diseases resulting in the formation of edema or an exudate within the airways (e.g., pulmonary edema, infectious or aspiration pneumonia, bronchitis) and some interstitial pneumonias, particularly interstitial fibrosis, can result in crackles. Wheezes are musical, continuous sounds that indicate the presence of airway narrowing. Narrowing can occur as a result of bronchoconstriction, bronchial wall thickening, exudate or fluid within the bronchial lumen, intraluminal masses, or external airway compression. Wheezes are most commonly heard in cats with bronchitis. Wheezes caused by an intrathoracic airway obstruction are loudest during early expiration. Sudden snapping at the end of expiration can be heard in some dogs with intrathoracic tracheal collapse.

Radiography

Thoracic radiographs are indicated in dogs and cats with lower respiratory tract signs. Neck radiographs should also be obtained in animals with suspected tracheal disease. Radiography is perhaps the single most helpful diagnostic tool in the evaluation of dogs and cats with intrathoracic disease. It helps in localizing the problem to an organ system (i.e., cardiac, pulmonary, mediastinal, pleural), identifying the area of involvement within the lower respiratory tract (i.e., vascular, bronchial, alveolar, interstitial), and narrowing the list of potential differential diagnoses. It also helps in the formulation of a diagnostic plan (see Chapter 20). Additional diagnostic tests are necessary in most animals to establish a definitive diagnosis.

Complete Blood Count

The CBC of patients with lower respiratory tract disease may show anemia of inflammatory disease, polycythemia secondary to chronic hypoxia, or a white blood cell response characteristic of an inflammatory process of the lungs. The hematologic changes are insensitive, however, and an absence of abnormalities cannot be used as the basis for ruling out inflammatory lung disease. For instance, only half of dogs with bacterial pneumonia have a neutrophilic leukocytosis and a left shift.

PULMONARY SPECIMENS AND SPECIFIC DISEASE TESTING

On the basis of results of the history, physical examination, thoracic radiographs, and CBC, a prioritized list of differential diagnoses is developed. Additional diagnostic tests (Fig. 19.1) are nearly always required to achieve a definitive diagnosis, which is necessary for optimal therapy and outcome. Selection of appropriate tests is based on the most likely differential diagnoses, the localization of disease within the lower respiratory tract (e.g., diffuse bronchial disease, single mass lesion), the degree of respiratory compromise of the patient, and the client's motivation for optimal care.

Invasive and noninvasive tests are available. Noninvasive tests have the obvious advantage of being nearly risk free but are usually aimed at confirming a specific diagnosis. Patients with persistent lower respiratory tract disease often require collection of a pulmonary specimen for microscopic and microbiologic analysis to further narrow the list of differential diagnoses or to make a definitive diagnosis. Although the procedures for specimen collection from the lung are considered invasive, they carry varying degrees of risk, depending on the procedure used and the degree of respiratory compromise of the patient. The risk is minimal in many instances.

Noninvasive tests include serology, urine antigen tests, and polymerase chain reaction (PCR) tests for pulmonary pathogens, fecal examinations for parasites, and specialized imaging techniques such as fluoroscopy, angiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and nuclear imaging. Techniques for collection of pulmonary specimens that can be performed without specialized equipment include tracheal wash, nonbronchoscopic bronchoalveolar lavage, and transthoracic lung aspiration. Visually guided specimens can be collected during bronchoscopy. Bronchoscopy offers the additional benefit of allowing visual assessment of the airways. If analysis of lung specimens and results of reasonable noninvasive tests do not provide a diagnosis in a patient with progressive disease, thoracoscopy or thoracotomy with lung biopsy is indicated.

Valuable information about patients with lower respiratory tract disease can also be obtained by assessing lung function through arterial blood gas analysis. Results are rarely helpful in making a final diagnosis, but they are useful in determining degree of compromise and in monitoring response to therapy. Pulse oximetry, a noninvasive technique used to measure oxygen saturation of the blood, is particularly valuable in monitoring patients with respiratory compromise during anesthetic procedures or respiratory crises.

CHAPTER 20

Diagnostic Tests for the Lower Respiratory Tract

THORACIC RADIOGRAPHY

GENERAL PRINCIPLES

Thoracic radiographs play an integral role in the diagnostic evaluation of dogs and cats with clinical signs related to the lower respiratory tract. They are also indicated for the evaluation of animals with vague, nonspecific signs of disease to detect occult pulmonary disease. Thoracic radiographs can be helpful in localizing disease processes, narrowing and prioritizing the differential diagnoses, determining the extent of disease involvement, and monitoring the progression of disease and response to treatment.

A minimum of two views of the thorax should be taken in all dogs and cats, but three views will improve the detection of lesions. Right lateral and ventrodorsal (VD) views are standard. The addition of the left lateral view improves the sensitivity of radiographs in the detection of disease of the right middle lung lobe, single nodules or metastatic disease, and other subtle changes. The side of the lung away from the table is more aerated, thereby providing more contrast for soft tissue opacities, and is slightly magnified compared with the side against the table. Dorsoventral (DV) views are taken to evaluate the dorsal pulmonary arteries in animals with suspected heartworm disease, pulmonary thromboembolism, or pulmonary hypertension to enhance contrast of the dorsally oriented vessels. Patients in respiratory distress are evaluated with DV, rather than VD, views to minimize stress. Horizontal beam lateral radiographs with the animal standing can be used to evaluate animals with suspected cavitary lesions or pleural effusion.

Careful technique is essential to ensure that thoracic radiographs are obtained that yield useful information. Poor technique can lead to underinterpretation or overinterpretation of abnormalities. Appropriate exposure settings should be used and the settings recorded so that the same technique can be used when future images of the patient are obtained; this allows for more critical comparison of progression of disease. Radiographs should be interpreted using a large, high-resolution monitor and dim ambient lighting.

The dog or cat should be restrained adequately to prevent movement, and a short exposure time used. Radiographs should be taken during maximum inspiration. Fully expanded lungs provide the greatest air contrast for soft tissue opacities, and motion is minimized during this phase of the respiratory cycle. Radiographic indications of maximum inspiration include widening of the angle between the diaphragm and the vertebral column (representing maximal expansion of caudal lung lobes); a lucent region in front of the heart shadow (representing maximal expansion of the cranial lung lobes); flattening of the diaphragm; minimal contact between the heart and the diaphragm; and a well-delineated, nearly horizontal vena cava. Radiographs of the lungs obtained during phases of respiration other than peak inspiration are difficult to interpret. Incomplete expansion of the lungs can cause increased pulmonary opacities to be seen that appear pathologic, resulting in misdiagnosis.

Animals that are panting should be allowed to calm down before thoracic radiographs are obtained. It may be necessary to sedate some animals.

All structures of the thorax should be evaluated systematically in every animal to enhance diagnostic accuracy. Extrapulmonary abnormalities may develop secondary to pulmonary disease and may be the only radiographic finding (e.g., subcutaneous emphysema after tracheal laceration). Conversely, pulmonary disease may occur secondary to other evident thoracic diseases, such as mitral valve insufficiency, megaesophagus, and neoplasia of the body wall.

TRACHEA

The trachea and, in young animals, the thymus are recognizable in the cranial mediastinum. Radiographs of the cervical trachea are obtained from dogs and cats with suspected upper airway obstruction or primary tracheal disease, including tracheal collapse (tracheal malacia) in dogs. During evaluation of the trachea, it is important to obtain radiographs of the cervical portion during inspiration and of the thorax during both inspiration and expiration to identify dynamic changes in luminal diameter. As previously discussed, avoid over-reading lung lesions in the expiratory exposures.

Only the inner wall of the trachea should be visible. Visibility of the outer wall of the trachea is suggestive of pneumomediastinum. The trachea normally has a uniform diameter and is straight, deviating ventrally from the vertebral bodies on lateral views as it progresses toward the carina. It may appear elevated near the carina if the heart is enlarged or if pleural effusion is present. Flexion or extension of the neck may cause bowing of the trachea. On VD views, the trachea may deviate to the right of midline in some dogs. The tracheal cartilage becomes calcified in some older dogs and chondrodystrophic breeds.

The overall size and continuity of the tracheal lumen should also be evaluated. The normal tracheal lumen is nearly as wide as the laryngeal lumen. Hypoplastic tracheas are most often found in English Bulldogs and have a lumen less than half the normal size (Fig. 20.1). The ratio of tracheal diameter to thoracic inlet diameter (TD:TI) can be used to more objectively define tracheal size in these patients. If identified in dogs less than 1 year of age, the hypoplasia may partially resolve with maturity (Clarke et al., 2011). Strictures and fractured cartilage rings can cause an abrupt, localized narrowing of the air stripe.

Mass lesions in the tissues adjacent to the trachea can compress the trachea, causing a more gradual, localized narrowing of the air stripe. The air contrast of the trachea sometimes allows foreign bodies or masses to be visualized within the trachea. Most foreign bodies lodge at the level of the carina or within the bronchi. The inability to radiographically identify a foreign body does not rule out the diagnosis, however.

The radiographic diagnosis of tracheobronchomalacia (tracheal collapse) can be challenging, and radiographic signs should be interpreted with some caution. In theory, the diagnosis should be straightforward. In animals with extrathoracic tracheal collapse, the tracheal air stripe would be narrowed in the cervical region during inspiration. In animals with intrathoracic tracheal collapse, the air stripe would be narrowed within the thorax during expiration. In reality, a diagnosis of tracheal collapse may be missed simply because the intra- to extra-airway pressure differential is insufficient for a dog lying on the radiology table to create visible narrowing of the trachea. Further, in the cervical trachea, a soft tissue opacity extending along the dorsal margin of the trachea may represent either abnormal sagging of the dorsal tracheal membrane or overlying esophagus (or other soft tissue). Fluoroscopy, available primarily through referral centers, provides a more sensitive assessment of tracheal collapse.

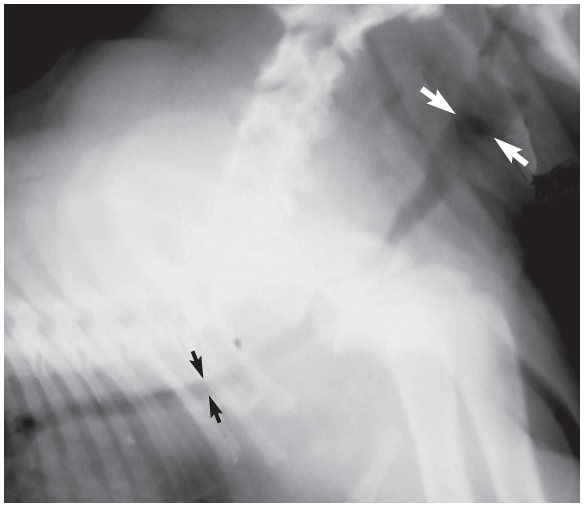

FIG 20.1
Lateral radiograph of a Bulldog with a hypoplastic trachea. The tracheal lumen *(narrow arrows)* is less than half the size of the larynx *(broad arrows)*.

LUNGS

The clinician must be careful not to overinterpret lung abnormalities on thoracic radiographs. A definitive diagnosis is not possible in most animals, and microscopic examination of pulmonary specimens, further evaluation of the heart, or testing for specific diseases is necessary. The lungs are examined for the possible presence of four major abnormal patterns: vascular, bronchial, alveolar, and interstitial. Mass lesions are considered with the interstitial patterns. Lung lobe consolidation, atelectasis, pulmonary cysts, and lung lobe torsions are other potential abnormalities. The distribution of lesions within the lungs is also noted. Diseases of airway origin, such as bronchopneumonia and aspiration pneumonia, typically have more severe radiographic disease affecting the gravity-dependent lung lobes (right middle and cranial, and/or left cranial lobes). Diseases originating from the vasculature or lymphatics, such as metastatic neoplasia and systemic mycoses, may affect the caudal lung lobes more severely. Animals in severe respiratory distress localized to the lungs by history and physical examination and normal thoracic radiograph usually have thromboembolic disease or have suffered a very recent insult to the lungs, such as trauma or aspiration (Box 20.1).

Vascular Pattern

The pulmonary vasculature is assessed by evaluating the vessels to the cranial lung lobes on the lateral view and the vessels to the caudal lung lobes on the VD or DV view. Normally, the blood vessels should taper gradually from the left atrium (pulmonary vein) or the right ventricle (pulmonary arteries) toward the periphery of the lungs. Companion arteries and veins should be similar in size. Arteries and veins have a consistent relationship with each other and with the associated bronchus. On lateral radiographs, the pulmonary artery is dorsal and the pulmonary vein is ventral to the bronchus. On VD or DV radiographs, the pulmonary artery is lateral and the pulmonary vein is medial to the bronchus. Vessels that are pointed directly toward or away from the X-ray beam are "end-on" and appear as circular nodules. They are distinguished from lesions by their association with a linear vessel and adjacent bronchus.

Abnormal vascular patterns generally involve an increase or decrease in the size of arteries or veins (Box 20.2). The

BOX 20.1

Common Lower Respiratory Tract Differential Diagnoses for Dogs and Cats With Respiratory Signs and Normal Thoracic Radiographs

Respiratory Distress

Pulmonary thromboembolism

Canine chronic bronchitis
Collapsing trachea
Feline bronchitis (idiopathic)
Acute foreign body inhalation
Gastroesophageal reflux*

*Gastroesophageal reflux is a common cause of cough in people. Documentation in dogs and cats is limited, but the possibility should be considered.

finding of arteries larger than their companion veins indicates the presence of pulmonary hypertension or thromboembolism, most commonly caused by heartworm disease—a finding seen in both dogs and cats (Fig. 20.2). The pulmonary arteries often appear tortuous and truncated in such animals. Concurrent enlargement of the main pulmonary artery and the right side of the heart may be seen in affected dogs. Interstitial, bronchial, or alveolar infiltrates may also be present in cats and dogs with heartworm disease as a result of concurrent inflammation, edema, or hemorrhage. Infection with *Aelurostrongylus abstrusus* can also cause pulmonary artery enlargement.

Veins larger than their companion arteries indicate the presence of congestion resulting from left-sided heart failure. Pulmonary edema may also be present.

Dilation of both arteries and veins is an unusual finding, except in young animals. The finding of pulmonary overcirculation is suggestive of left-to-right cardiac or vascular shunts, such as patent ductus arteriosus and ventricular septal defects.

The finding of smaller-than-normal arteries and veins may indicate the presence of pulmonary undercirculation or hyperinflation. Undercirculation most often occurs in combination with microcardia resulting from hypoadrenocorticism or other causes of severe hypovolemia. Pulmonic

  - Hypoadrenocorticism
- Pulmonic valve stenosis

Hyperinflation of the lungs
- Feline bronchitis (idiopathic)
- Allergic bronchitis

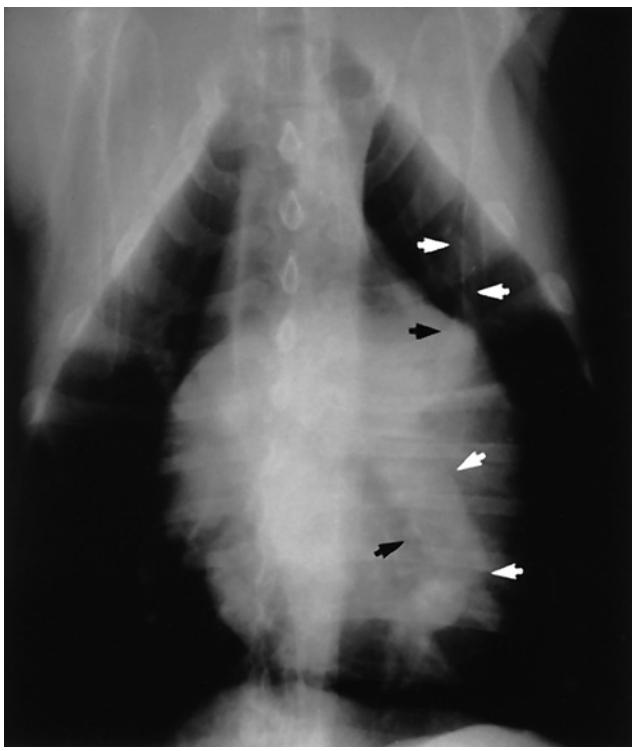

FIG 20.2
Dilation of pulmonary arteries is apparent on this ventrodorsal view of the thorax in a dog with heartworm disease. The artery to the left caudal lung lobe is extremely enlarged. *Arrowheads* delineate the borders of the arteries to the left cranial and caudal lobes.

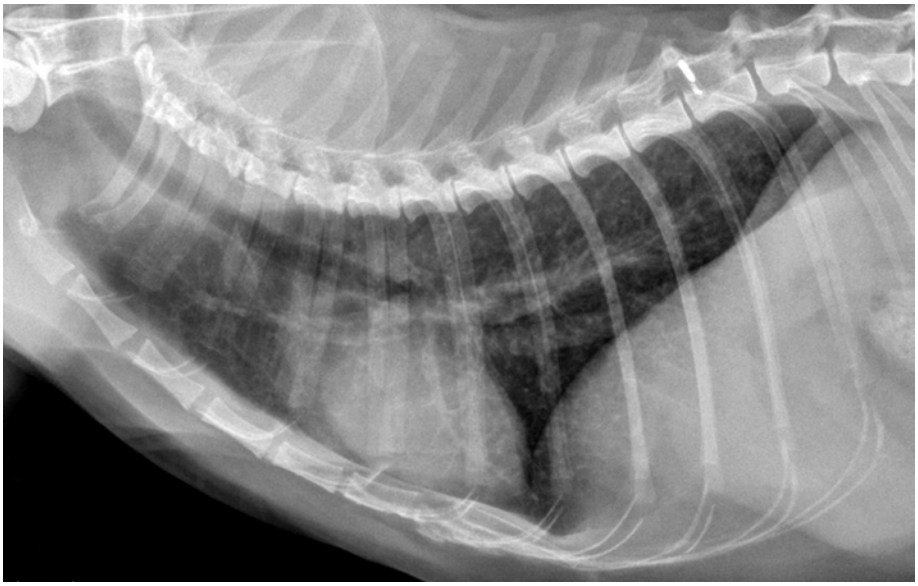

FIG 20.3
A bronchointerstitial pattern is present in this lateral radiograph from a cat with idiopathic bronchitis. The bronchial component results from thickening of the bronchial walls and is characterized by "doughnuts" and "tram lines." In this radiograph, the bronchial changes are most apparent in the caudal lung lobes.

stenosis may also cause radiographically visible undercirculation in some dogs. Hyperinflation is associated with obstructive airway disease, such as allergic or idiopathic feline bronchitis.

Bronchial Pattern

Bronchial walls are most easily discernible at the hilus on radiographs of normal dogs and cats. They should taper and grow thinner as they extend toward the periphery of each lung lobe. Bronchial structures are not normally visible radiographically in the peripheral regions of the lungs. The cartilage may be calcified in older dogs and in chondrodystrophic breeds, making the walls more prominent but still sharply defined.

Thickening of the bronchial walls or bronchial dilation results in a bronchial pattern. Thickened bronchial walls are visible as "tram lines" and "doughnuts" in the peripheral regions of the lung (Fig. 20.3). Tram lines are produced by airways that run transverse to the X-ray beam, causing the appearance of parallel thick lines with an air stripe in between. Doughnuts are produced by airways that are pointing directly toward or away from the beam, causing a thick circle to be seen radiographically, with the airway lumen creating the "hole." The walls of the bronchi tend to be indistinct. The finding of thickened walls indicates the presence of bronchitis and results from an accumulation of mucus or exudate along the walls within the lumens, an infiltration of inflammatory cells within the walls, muscular hypertrophy, epithelial hyperplasia, or a combination of these changes. Potential causes of bronchial disease are listed in Box 20.3.

Chronic bronchial inflammation can result in irreversible dilation of the airways, which is termed *bronchiectasis*. It is identified radiographically by the presence of widened, nontapering airways (Fig. 20.4). Bronchiectasis can be cylindrical (tubular) or saccular (cystic). Cylindrical bronchiectasis is characterized by fairly uniform dilation of the airway. Saccular bronchiectasis additionally has localized dilations peripherally that can lead to a honeycomb appearance. All major bronchi are usually affected, though localized disease can occur.

BOX 20.3

Differential Diagnoses for Dogs and Cats With Bronchial Patterns on Thoracic Radiographs*

Canine chronic bronchitis
Feline bronchitis (idiopathic)
Allergic bronchitis
Canine infectious respiratory disease complex
Bacterial infection
Mycoplasmal infection
Pulmonary parasites

*Bronchial disease can occur in conjunction with parenchymal lung disease. See Boxes 20.4 to 20.6 for additional differential diagnoses if mixed patterns are present.

Alveolar Pattern

Alveoli are not normally visible radiographically. Alveolar patterns occur when the alveoli are filled with fluid-dense material. The fluid opacity may be caused by edema, inflammation, hemorrhage, or neoplastic infiltrates, which generally originate from the interstitial tissues (Box 20.4). The

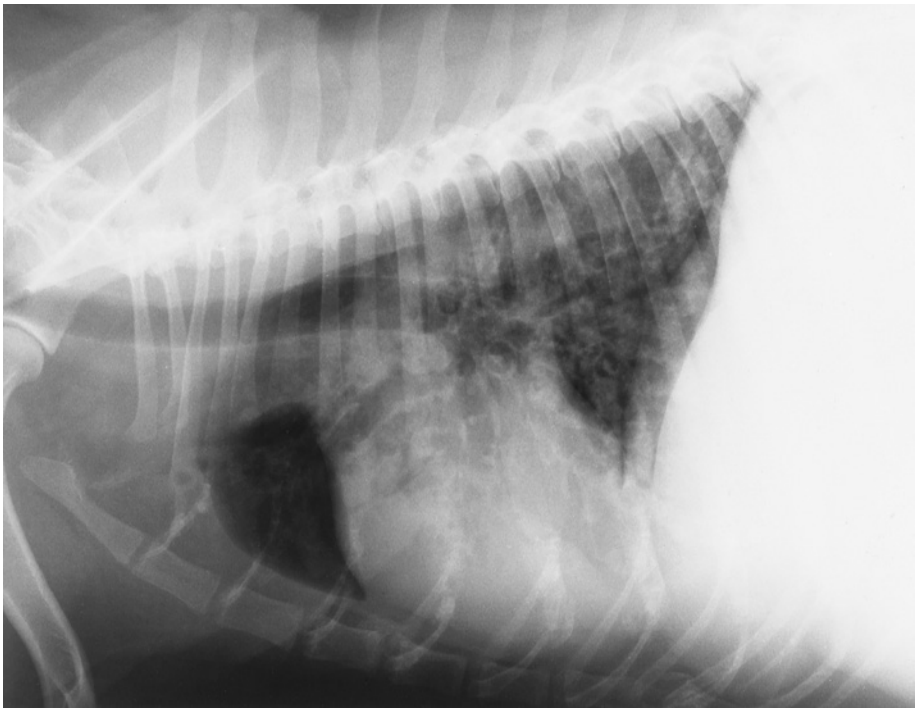

FIG 20.4
Lateral radiograph of a dog with chronic bronchitis and bronchiectasis. The airway lumens are greatly enlarged, and normal tapering of the airway walls is not seen.

BOX 20.4

Differential Diagnoses for Dogs and Cats With Alveolar Patterns on Thoracic Radiographs*

Pulmonary Edema
Severe Inflammatory Disease
- Bacterial pneumonia
- Aspiration pneumonia

Hemorrhage
- Pulmonary contusion
- Pulmonary thromboembolism
- Neoplasia
- Fungal pneumonia
- Systemic coagulopathy

*Any of the differential diagnoses for interstitial patterns (see Boxes 20.5 and 20.6) can cause an alveolar pattern if associated with severe inflammation, edema, or hemorrhage.

fluid-filled alveoli are silhouetted against the walls of the airways they surround. The result is a visible stripe of air from the airway lumen in the absence of definable airway walls. This stripe is an air bronchogram (Fig. 20.5). If fluid continues to accumulate, the airway lumen eventually will also become filled with fluid, resulting in the formation of solid areas of fluid opacity, or consolidation. When fluid-dense regions are located at the edge of the lung lobe, a *lobar sign* occurs. The curvilinear edge of the affected lung lobe is visible in contrast with the adjacent, aerated lobe.

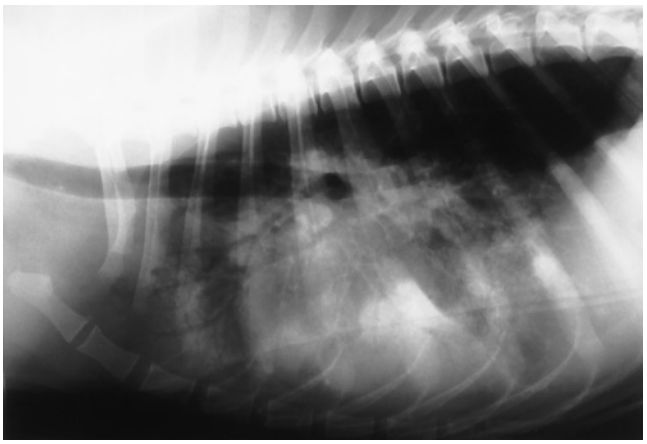

FIG 20.5
Lateral view of the thorax of a dog with aspiration pneumonia. An alveolar pattern is evident by the increased soft tissue opacity with air bronchograms. Air bronchograms are bronchial air stripes without visible bronchial walls. In this radiograph the pattern is most severe in the ventral (dependent) regions of the lung, consistent with bacterial or aspiration pneumonia.

Edema most often results from left-sided heart failure (see Chapter 22). In dogs the fluid initially accumulates in the perihilar region, and eventually the entire lung is affected. In cats patchy areas of edema can be present initially throughout the lung fields. The finding of enlarged pulmonary veins supports the cardiac origin of the infiltrates. Noncardiogenic edema is typically most severe in the caudal lung lobes.

Inflammatory infiltrates can be caused by infectious agents, noninfectious inflammatory disease, or neoplasia. The location of the infiltrative process can often help establish a tentative diagnosis. For example, diseases of airway origin, such as most bacterial and aspiration pneumonias, primarily affect the dependent lung lobes (i.e., the right middle and cranial lobes and the left cranial lobe). In contrast, diseases of vascular origin, such as dirofilariasis, thromboemboli, systemic fungal infection, and bacterial infection of hematogenous origin primarily affect the caudal lung lobes. Localized processes involving only one lung lobe suggest the presence of a foreign body, neoplasia, abscess, granuloma, or lung lobe torsion.

Hemorrhage usually results from trauma. Thromboembolism, neoplasia, coagulopathies, and fungal infections can also cause hemorrhage into the alveoli.

Interstitial Pattern

The pulmonary interstitial tissues confer a fine, lacy pattern to the pulmonary parenchyma of many dogs and cats as they age, in the absence of clinically apparent respiratory disease. They are not normally visible on inspiratory radiographs in young adult animals.

Abnormal interstitial patterns are reticular (unstructured), nodular, or reticulonodular in appearance. A nodular interstitial pattern is characterized by the finding of roughly circular, fluid-dense lesions in one or more lung lobes. However, the nodules must be nearly 1 cm in diameter to be routinely detected. Interstitial nodules may represent active or inactive inflammatory lesions or neoplasia (Box 20.5).

Active inflammatory nodules often have poorly defined borders. Mycotic infections typically result in the formation of multiple, diffuse nodules. The nodules may be small (miliary; Fig. 20.6) or large and coalescing. Parasitic granulomas are often multiple, although paragonimiasis can result in the formation of a single pulmonary nodule. Abscesses can form as a result of foreign bodies or as a sequela to bacterial pneumonia. Nodular patterns may also be seen on the radiographs obtained in animals with some eosinophilic lung diseases and idiopathic interstitial pneumonias.

Inflammatory nodules can persist as inactive lesions after the disease resolves. In contrast to active inflammatory nodules, however, the borders of inactive nodules are often well demarcated. Nodules may become mineralized in some conditions, such as histoplasmosis. Well-defined, small, inactive nodules are sometimes seen in healthy older dogs without a history of disease. Radiographs taken several months later in these animals typically show no change in the size of these inactive lesions.

Neoplastic nodules may be singular or multiple (Fig. 20.7). They are often well defined, although secondary inflammation, edema, or hemorrhage can obscure the margins. No radiographic pattern is diagnostic for neoplasia.

BOX 20.5

Differential Diagnoses for Dogs and Cats With Nodular Interstitial Patterns

- Neoplasia
- Mycotic Infection
  - Blastomycosis
  - Histoplasmosis
  - Coccidioidomycosis
- Pulmonary Parasites
  - *Aelurostrongylus* infection
  - *Paragonimus* infection
- Abscess
  - Bacterial pneumonia
  - Foreign body
- Eosinophilic Lung Disease
- Idiopathic Interstitial Pneumonia
- Inactive Lesions

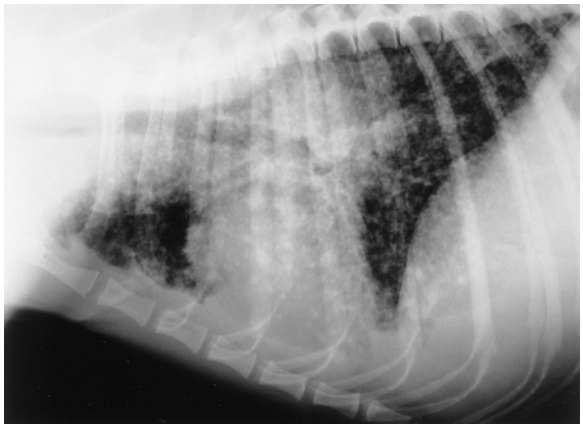

FIG 20.6
Lateral view of the thorax in a dog with blastomycosis. A miliary, nodular interstitial pattern is present. Increased soft tissue opacity above the base of the heart may be the result of hilar lymphadenopathy.

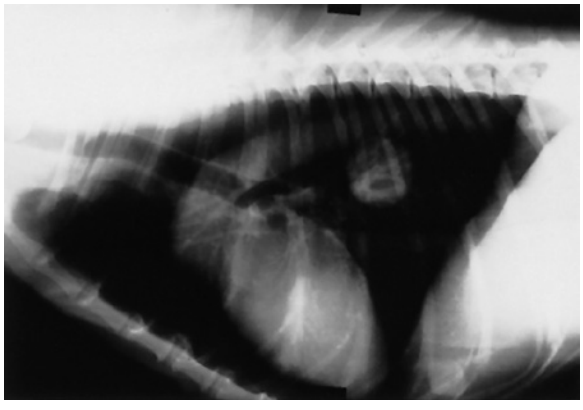

FIG 20.7
Lateral view of the thorax of a dog with malignant neoplasia. A well-circumscribed, solid, circular mass is present in the caudal lung field. Papillary adenocarcinoma was diagnosed after surgical excision.

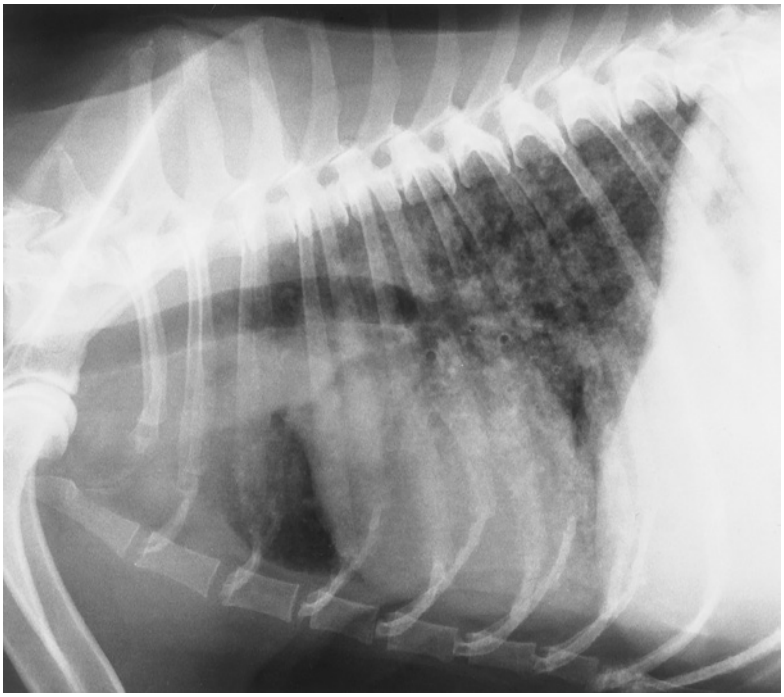

FIG 20.8
Lateral radiograph of a dog with pulmonary carcinoma. An unstructured pattern is present, as is an increased bronchial pattern.

Lesions caused by parasites, fungal infections, and some eosinophilic lung diseases or idiopathic interstitial pneumonias may be indistinguishable from neoplastic lesions. In the absence of strong clinical evidence, malignant neoplasia must be confirmed cytologically or histologically. If this is not possible, radiographs can be obtained again 4 weeks later to evaluate for progression of disease.

Neoplastic involvement of the pulmonary parenchyma cannot be totally excluded on the basis of thoracic radiograph findings because malignant cells are present for a while before lesions reach a radiographically detectable size. The sensitivity of radiography in identifying neoplastic nodules can be improved by obtaining left and right lateral views of the thorax.

The reticular interstitial pattern is characterized by a diffuse, unstructured, lacy increase in the opacity of the pulmonary interstitium, which partially obscures normal vascular and airway markings. Reticular interstitial patterns frequently occur in conjunction with nodular interstitial patterns (also called *reticulonodular patterns*) and alveolar and bronchial patterns (Fig. 20.8).

Increased reticular interstitial opacity can result from edema, hemorrhage, inflammatory cells, neoplastic cells, or fibrosis within the interstitium (Box 20.6). The interstitial space surrounds the airways and vessels, and is normally extremely small in dogs and cats. With continued accumulation of fluid or cells, however, the alveoli can become flooded, which produces an alveolar pattern. Visible focal interstitial accumulations of cells, or nodules, can also develop with time. Any of the diseases associated with alveolar and interstitial nodular patterns can cause a reticular interstitial pattern early in the course of disease (see Boxes 20.4 and 20.5). This pattern is also often seen in older dogs with no clinically apparent disease, presumably as a result of pulmonary fibrosis; this further decreases the specificity of the finding.

BOX 20.6

Differential Diagnoses for Dogs and Cats With Reticular (Unstructured) Interstitial Patterns

Pulmonary Edema (Mild)
Infection
- Viral pneumonia
- Bacterial pneumonia
- Toxoplasmosis
- Mycotic pneumonia
- Parasitic infection (more often bronchial or nodular interstitial pattern)

Neoplasia
Eosinophilic Lung Disease
Idiopathic Interstitial Pneumonia
- Idiopathic pulmonary fibrosis

Hemorrhage (Mild)

Lung Lobe Consolidation

Lung lobe consolidation is characterized by a lung lobe that is entirely of soft tissue opacity (Fig. 20.9, *A*). Consolidation

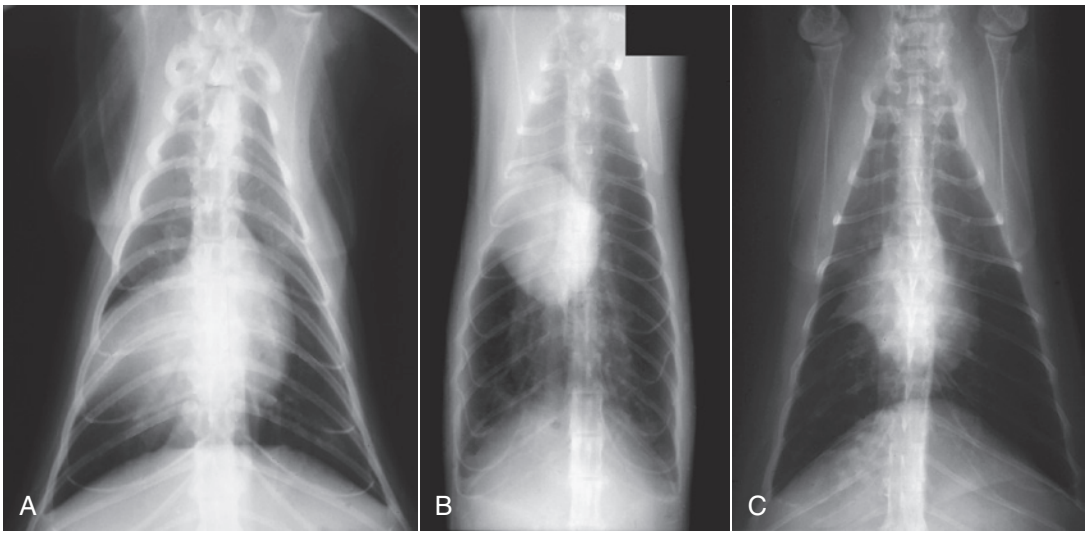

FIG 20.9
Thoracic radiographs from three different patients, ventrodorsal projections. Radiograph A shows consolidation of the right middle lung lobe caused by neoplasia. Note that the soft tissue density of the lung silhouettes with the shadow of the heart. Radiograph B shows atelectasis of the middle region of the right lung and marked hyperinflation of the remaining lungs in a cat with idiopathic bronchitis. Note the shift of the heart shadow toward the collapsed region. Radiograph C shows atelectasis of the right middle lung lobe in another cat with idiopathic bronchitis. In this patient the adjacent lung lobes have expanded into the area previously occupied by the right middle lobe, preventing displacement of the heart.

occurs when an alveolar or interstitial disease process progresses to the point at which the entire lobe is filled with fluid or cells. Common differential diagnoses for lung lobe consolidation are severe bacterial or aspiration pneumonia, neoplasia, lung lobe torsion, and hemorrhage. Inhalation of plant material can also result in consolidation of the involved lung lobe as a result of the inflammatory reaction to foreign material and secondary infection. This differential diagnosis should be considered especially in regions of the country where foxtails are prevalent.

Atelectasis

Atelectasis is also characterized by a lobe that is entirely of soft tissue opacity. In this instance, the lobe is collapsed as a result of airway obstruction. All the air within the lobe has been absorbed and not replaced. It is distinguished from consolidation by the small size of the lobe (see Fig. 20.9, *B*). Often the heart is displaced toward the atelectatic lobe. Atelectasis is most commonly seen involving the right middle lobe of cats with bronchitis (see Fig. 20.9, *C*). Displacement of the heart may not occur in these cats.

Cavitary Lesions

Cavity lesions describe any abnormal air accumulation in the lung. They can be congenital, acquired, or idiopathic. Specific types of cavitary lesions include bullae, which result from ruptured alveoli due to congenital weakness of tissues and/or small airway obstruction, as seen in some cats with idiopathic bronchitis; blebs, which are bullae located within the pleura; and cysts, which are cavitary lesions lined by airway epithelium. Parasitic "cysts" (not lined by epithelium) can form around *Paragonimus* flukes. Thoracic trauma is a common cause of cavitary lesions. Other differential diagnoses include neoplasia, lung infarction (from thromboembolism), abscess, and granuloma. Cavitary lesions may be apparent as localized accumulations of air or fluid, often with a partially visible wall (Fig. 20.10). An air-fluid interface may be visible when standing horizontal beam projections are used. Bullae and blebs are rarely apparent radiographically.

Cavitary lesions may be discovered incidentally or on thoracic radiographs of dogs and cats with spontaneous pneumothorax. If pneumothorax is present, surgical excision of the lesion is usually indicated (see Chapter 24). If inflammatory or neoplastic disease is suspected, further diagnostic testing is indicated. If the lesion is found incidentally, animals can be periodically reevaluated radiographically to determine whether the lesion is progressing or resolving. If the lesion does not resolve during the course of 1 to 3 months, surgical removal is considered for diagnostic purposes and to prevent potentially life-threatening spontaneous pneumothorax.

Lung Lobe Torsion

Lung lobe torsion can develop spontaneously, particularly in deep-chested dogs, or as a complication of pleural effusion

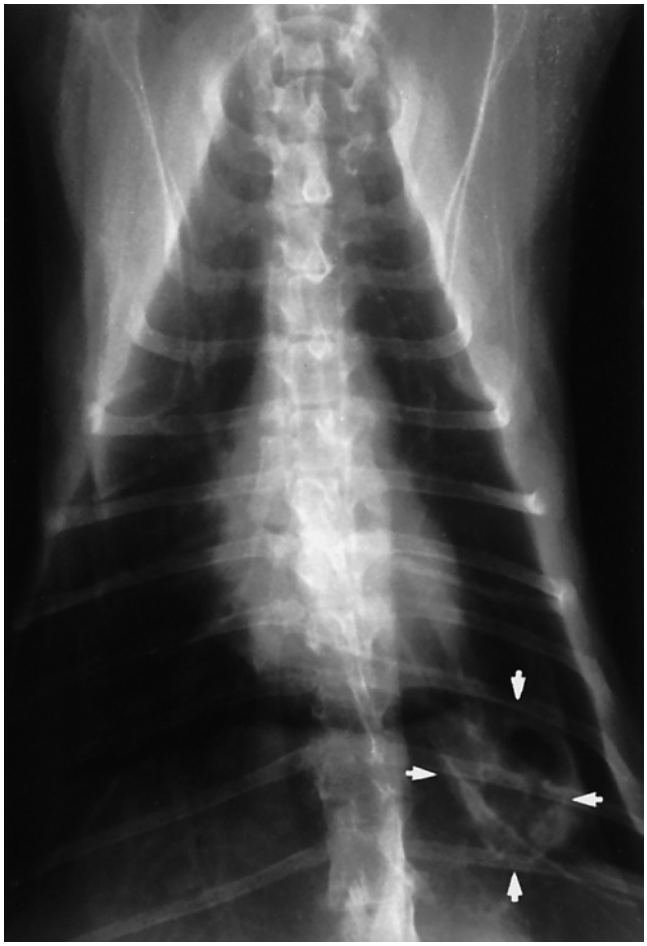

FIG 20.10
Ventrodorsal view of the thorax in a cat showing a cystic lesion *(arrowheads)* in the left caudal lung lobe. Differential diagnoses included neoplasia and *Paragonimus* infection.

or pneumonectomy in dogs and cats. The right middle and left cranial lobes are most commonly involved. The lobe usually twists at the hilus, obstructing the flow of blood into and out of the lung lobe. Venous drainage is obstructed before arterial flow, causing the lung lobe to become congested with blood. Inflammation and necrosis ensue. Over time, air is absorbed from the alveoli and atelectasis can occur.

Lung lobe torsion is difficult to identify radiographically. Severe bacterial or aspiration pneumonia resulting in consolidation of these same lobes is far more common and produces similar radiographic changes. The finding of pulmonary vessels or bronchi traveling in an abnormal direction is strongly suggestive of torsion. Unfortunately, pleural fluid, if not present initially, often develops and obscures the radiographic image of the affected lobe. Ultrasonography is often useful in detecting a torsed lung lobe. Bronchoscopy, bronchography, computed tomography (CT), or thoracotomy is necessary to confirm the diagnosis in some animals.

ULTRASONOGRAPHY

In the emergency setting, thoracic ultrasonography is used for the rapid identification of pleural effusion. Its application in the rapid diagnosis of pulmonary edema and other parenchymal disease is growing. In this setting the acronyms TFAST (Thoracic Focused Assessment with Sonography for Trauma) and VetBLUE (Veterinary Bedside Lung Ultrasound Examination) are used (Lisciandro, 2011; Lisciandro et al., 2014).

In the nonemergent setting, ultrasonography is used to evaluate pulmonary mass lesions adjacent to the body wall, diaphragm, or heart and also consolidated lung lobes (Fig. 20.11). Because air interferes with sound waves, aerated lungs and structures surrounded by aerated lungs cannot be examined. However, some patients with a reticular interstitial pattern on thoracic radiographs have sufficient infiltrates to be visualized where they abut the body wall. The consistency of lesions often can be determined to be solid, cystic, or vascularized. Some solid masses are hypolucent and appear to be cystic on ultrasonograms. Vascular structures may be visible, particularly with Doppler ultrasound, and this can be helpful in identifying lung lobe torsion. Ultrasonography can also be used to guide needles or biopsy instruments into solid masses for specimen collection. It is used in evaluating the heart of animals with clinical signs that cannot be readily localized to the cardiac or the respiratory system. Ultrasonographic evaluation of patients with pleural disorders is discussed in Chapter 23.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

CT and magnetic resonance imaging (MRI) are used routinely in human medicine for the diagnostic evaluation of lung disease. The accessibility of CT in particular has led to its increased use in dogs and cats and it is now used routinely in the diagnostic evaluation of challenging respiratory cases. The resultant three-dimensional images are more sensitive and specific for the identification of certain airway, vascular, and parenchymal diseases as compared with thoracic radiography. In one study of dogs with metastatic neoplasia, only 9% of nodules detected by CT were identified by thoracic radiography (Nemanic et al., 2006). Images are routinely obtained before and after the intravenous injection of a contrast agent, which further enhances the characterization of lesions and allows for the identification of macrothrombi and emboli. Thoracic CT has also become routine for the planning of thoracic surgery. Compared with standard radiography, the extent of mass lesions and their relationship to major vessels and other critical structures is better defined, and multifocal disease is more likely to be identified (e.g., metastatic lesions or multiple cavitary lesions). The risks associated with CT scanning are minimal except that light, general anesthesia is required to eliminate patient motion and to allow for breath-holding

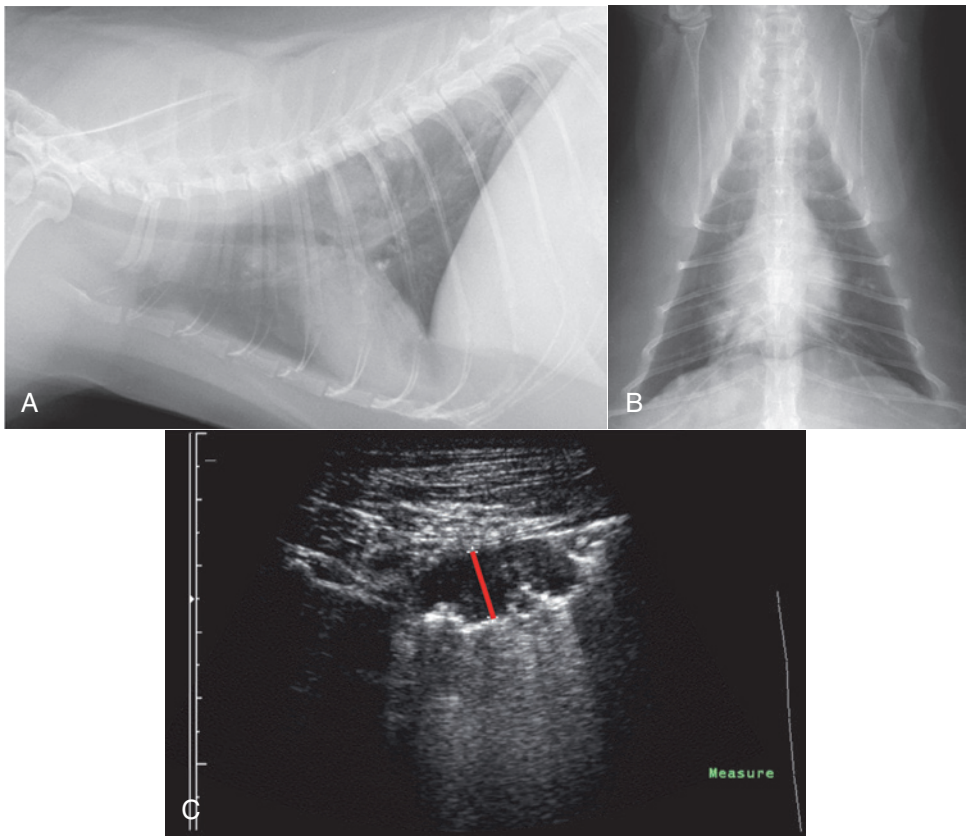

FIG 20.11
Multiple pulmonary nodules are easily visible on the lateral radiograph **(A)** from a cat with a 1-year history of cough and recent episodes of respiratory distress with wheezing. Nodules do not obviously extend to the chest wall as seen on the ventrodorsal radiograph. **(B)** However, a 1-cm mass was found on ultrasonographic examination of the right thorax; **(C)** a *red line* has been positioned between ultrasound markers to indicate site of measurement. An ultrasound-guided aspirate was performed. The presence of eosinophils in the aspirate prompted the performance of fecal examinations for pulmonary parasites, and a diagnosis of paragonimiasis was made through identification of characteristic ova.

during image exposure. For unstable patients for which results of a noncontrast enhanced CT are considered to be critical, heavy sedation and physical restraints can be used.

NUCLEAR IMAGING

Mucociliary clearance can be measured by placing a drop of technetium-labeled albumin at the carina and observing its movement with a gamma camera to assist in the diagnosis of ciliary dyskinesia. Nuclear imaging can be used for the relatively noninvasive measurement of pulmonary perfusion and ventilation, valuable for the diagnosis of pulmonary thromboembolism. Restrictions for handling radioisotopes and the need for specialized recording equipment limit the availability of these tools to specialty centers.

PARASITOLOGY

Parasites involving the lower respiratory tract are identified by direct observation, blood tests, cytologic analysis of respiratory tract specimens, or fecal examination. *Oslerus osleri* reside in nodules near the carina, which can be identified bronchoscopically. Rarely, other parasites may be seen. Blood tests are often used to diagnose heartworm disease (see Chapter 10).

Larvae that may be present in fluid from tracheal or bronchial washings include *O. osleri, Aelurostrongylus abstrusus* (Fig. 20.12, *A*), and *Crenosoma vulpis* (Fig. 20.12, *B*). Eggs that may be present include those of *Capillaria (Eucoleus) aerophila* and *Paragonimus kellicotti* (Fig. 20.12, *C* and *D*). Larvated eggs or larvae from *Filaroides hirthi* or *Aelurostrongylus milksi* can be present but are rarely associated with clinical signs. The more common organisms are described in Table 20.1.

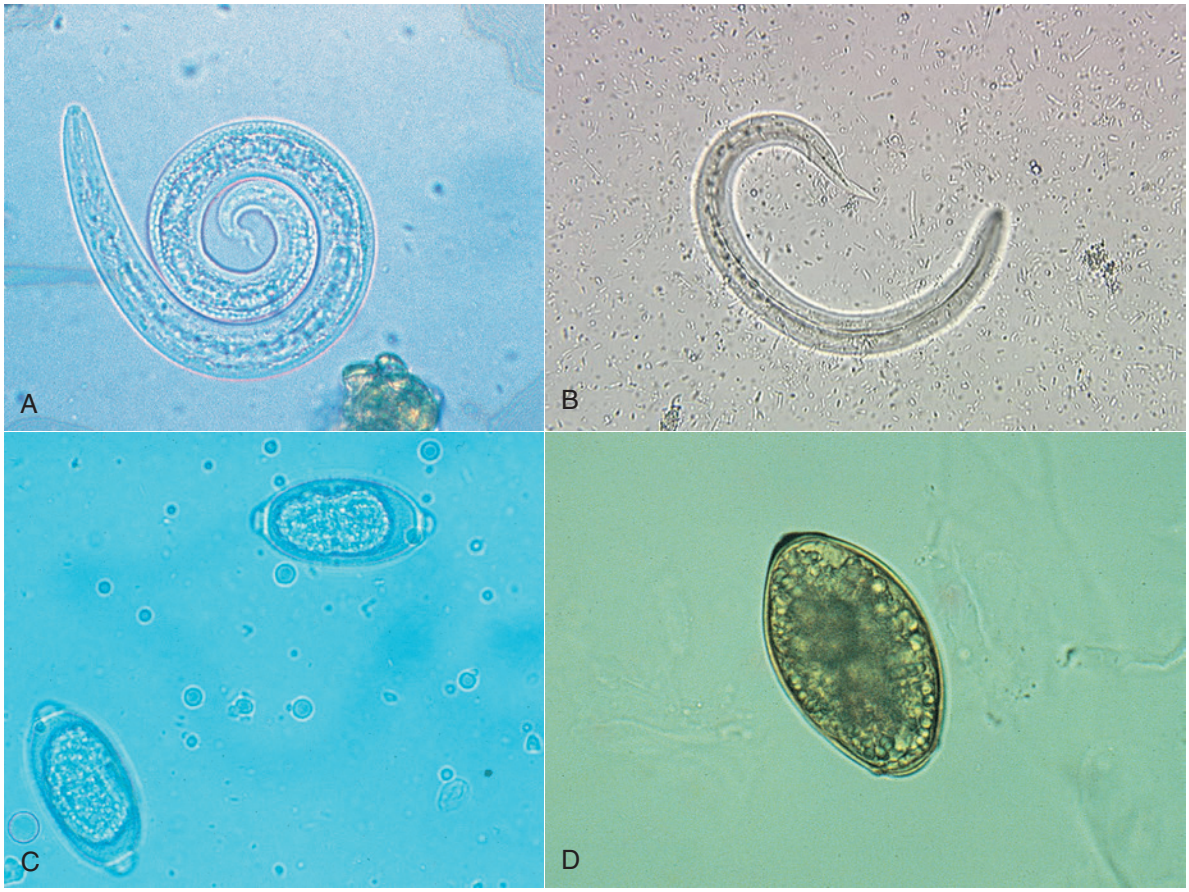

FIG 20.12
(A) Larva of *Aelurostrongylus abstrusus*. **(B)** Larva of *Crenosoma vulpis*. **(C)** Double operculated ova of *Capillaria* sp. **(D)** Single operculated ova of *Paragonimus kellicotti*.

TABLE 20.1

Characteristics of Eggs or Larvae From Respiratory Parasites

PARASITE	HOST	STAGE	SOURCE	DESCRIPTION
Capillaria aerophila	Dog and cat	Eggs	Routine flotation of feces, airway specimens	Barrel-shaped, yellow, with prominent, transparent, asymmetric bipolar plugs; slightly smaller than Trichuris eggs; 60-80 µm × 30-40 µm
Paragonimus kellicotti	Dog and cat	Eggs	High-density flotation or sedimentation of feces, airway specimens	Oval, golden-brown, single, operculated; operculum flat with prominent shoulders; 75-118 µm × 42-67 µm
Aelurostrongylus abstrusus	Cat	Larvae	Baermann technique of feces, airway specimens	Larvae with S-shaped tail; dorsal spine present; 350-400 µm × 17 µm; eggs or larvated eggs may be seen in airway specimens
Oslerus osleri	Dog	Larvae, eggs	Tracheal wash, bronchial brushing of nodules, zinc-sulfate flotation of feces	Larvae have S-shaped tail without dorsal spine; rarely found eggs are thin-walled, colorless, and larvated; 80 µm × 50 µm
Crenosoma vulpis	Dog	Larvae	Baermann technique of feces, airway specimens	Larvae have tapered tail without severe kinks or spines; 250-300 µm; larvated eggs may be seen in airway specimens

The hosts of lung parasites generally cough up and swallow the eggs or larvae, which then are passed in the feces to infect the next host or an intermediate host. Fecal examination for eggs or larvae is a simple, noninvasive tool for the diagnosis of such infestations. However, because shedding is intermittent, parasitic disease cannot be included solely on the basis of negative fecal examination findings. Multiple (at least three) examinations should be performed in animals that are highly suspected of having parasitic disease. If possible, several days should be allowed to elapse between collections of feces.

Routine fecal flotation can be used to concentrate eggs from *C. aerophila*. High-density fecal flotation (specific gravity [s.g.], 1.30 to 1.35) can be used to concentrate *P. kellicotti* eggs. Sedimentation techniques are preferred for concentrating and identifying *P. kellicotti* eggs, particularly if few eggs are present. Larvae are identified through the use of the Baermann technique. However, *O. osleri* larvae are insufficiently motile for reliable identification with this technique, and zinc sulfate (s.g., 1.18) flotation is recommended. Even so, false-negative results are common in cases with *O. osleri*.

All of these techniques can be readily performed in-house at minimal expense, but the infrequent identification of respiratory parasites in small-animal patients makes submission of feces to an external laboratory with greater experience in organism identification appealing. However, timing should be carefully arranged to ensure that fresh feces are available for prompt evaluation by laboratory personnel.

Toxoplasma gondii occasionally causes pneumonia in dogs and cats. Dogs do not shed *Toxoplasma* organisms in the feces, but cats may. However, the shedding of eggs is part of the direct life cycle of the organisms and does not correlate with the presence of systemic disease resulting from the indirect cycle. Infection is therefore diagnosed by the finding of tachyzoites in pulmonary specimens or indirectly on the basis of serologic findings.

Migrating intestinal parasites can cause transient pulmonary signs in young animals. Migration most often occurs before the mature adults develop in the intestine, thus eggs may not be found in feces. Migration of *Toxocara cati* has been implicated as a cause of idiopathic feline bronchitis in adult cats, but no practical means of diagnosis exists (Dillon et al., 2013).

SEROLOGY

Serologic tests can detect a variety of pulmonary pathogens. Antibody tests provide only indirect evidence of infection, however. In general, they should be used only to confirm a suspected diagnosis, not to screen for disease. Whenever possible, identification of infectious organisms is the preferred method of diagnosis. Tests available for common pulmonary pathogens include those for *Histoplasma, Blastomyces, Coccidiodomyces, Toxoplasma,* and feline coronavirus. These tests are discussed fully in Chapter 97. Antibody tests for canine influenza are discussed further in Chapter 22. Serum antigen tests for *Cryptococcus* (see Chapter 97) and adult heartworms are also available (see Chapter 10). Antibody tests for dirofilariasis are available and are used primarily to support the diagnosis of feline heartworm disease (see Chapter 10).

URINE ANTIGEN TESTS

Urine antigen tests for the detection of *Histoplasma* and *Blastomyces* antigens are available. The test for *Blastomyces* is more sensitive than serum antibody testing by agar gel immunodiffusion for the diagnosis of blastomycosis (Spector et al., 2008). See Chapter 97 for further discussion.

POLYMERASE CHAIN REACTION TESTS

Molecular diagnostic tests are available for identification of a wide range of individual respiratory pathogens. Panels of tests are commercially available for multiple agents commonly involved in acute respiratory tract infection in dogs or cats. Specimens that can be tested include swabs from the oropharynx, nasal cavity, or conjunctiva; tracheal wash or bronchoalveolar lavage specimens; airway brushings; and tissue. Best results are obtained when the timing and the site of collection are chosen on the basis of the pathophysiology of the target organism. For collection of material by swab, polyester swabs should be used. Consultation with the diagnostic laboratory is recommended for specimen collection and handling to maximize results.

TRACHEAL WASH

Indications and Complications

Tracheal wash can yield valuable diagnostic information in animals with cough or respiratory distress resulting from disease of the airways or pulmonary parenchyma and in animals with vague presenting signs and pulmonary abnormalities detected on thoracic radiographs (i.e., most animals with lower respiratory tract disease). Tracheal wash is generally performed after results of the history, physical examination, thoracic radiography, and other routine components of the database are known.

Tracheal wash provides fluid and cells that can be used to identify diseases involving the major airways while bypassing the normal flora and debris of the oral cavity and pharynx. Representative specimens are often obtained from patients with disease of the small airways (e.g., bronchitis) or alveoli (e.g., bacterial pneumonia or aspiration pneumonia) because diagnostic material is carried to the major airways by mucociliary clearance, cough, or the extension of disease (Table 20.2). The fluid obtained is evaluated cytologically and microbiologically and therefore should be collected before antibiotic treatment is initiated, whenever possible.

TABLE 20.2

Comparisons of Techniques for Collecting Specimens From the Lower Respiratory Tract

TECHNIQUE	SITE OF COLLECTION	SPECIMEN SIZE	ADVANTAGES	DISADVANTAGES	INDICATIONS
Tracheal wash	Large airways Small airway and alveoli (through mucociliary clearance, cough, and extension)	Moderate	Simple technique Minimal expense No special equipment Complications rare Volume adequate for cytology and culture	Airways must be involved for specimen to represent disease May induce bronchospasm in patients with hyperreactive airways, particularly cats	Bronchial and alveolar disease (particularly bacterial bronchopneumonia and aspiration pneumonia) Because of safety and ease, consider for any lung disease Less likely to be representative of interstitial or small focal processes
Bronchoalveolar lavage	Small airways, alveoli, sometimes interstitium	Large	Nonbronchoscopic technique requires no special equipment and minimal expense Bronchoscopic technique allows airway evaluation and directed sampling Resultant hypoxemia is transient and responsive to oxygen supplementation Safe for animals in stable condition Large volume of lung sampled High cytologic quality Large volume for analysis	General anesthesia required Special equipment and expertise required for bronchoscopic collection Generally not recommended for animals with tachypnea, increased respiratory efforts, or respiratory distress Capability to provide oxygen supplementation for an hour or more is required May induce bronchospasm in patients with hyperreactive airways, particularly cats	Primarily diffuse interstitial disease; also small airway and alveolar disease. Routine during bronchoscopy
Lung aspirate	Interstitium, alveoli when flooded	Small	Simple technique Minimal expense No special equipment Solid masses adjacent to body wall: excellent representation with minimal risk	Potential for complications: pneumothorax, hemothorax, pulmonary hemorrhage Relatively small area of lung sampled Specimen adequate only for cytology Specimen blood contaminated	Solid masses adjacent to chest wall (for solitary/localized disease, see also Thoracotomy or Thoracoscopy with Lung Biopsy) Diffuse interstitial disease
Thoracotomy or thoracoscopy with lung biopsy	Small airways, alveoli, interstitium	Large	Ideal specimen Allows histologic examination in addition to culture	Relatively expensive Requires expertise Requires general anesthesia Major surgical procedure	Localized process where excision may be therapeutic as well as diagnostic Any progressive disease not diagnosed by less invasive methods

Tracheal wash is less likely to provide representative material from interstitial and focal disease processes. However, the procedure is inexpensive and minimally invasive, and this makes it reasonable to perform in most animals with lower respiratory tract disease if the risks of other methods of specimen collection are deemed too great.

Potential complications are rare and include tracheal laceration, subcutaneous emphysema, and pneumomediastinum. Bronchospasm may be induced by the procedure in patients with hyperreactive airways, particularly cats with bronchitis.

TECHNIQUES

Tracheal wash is performed with the use of transtracheal or endotracheal techniques. Transtracheal wash is performed by passing a catheter into the trachea to the level of the carina through the cricothyroid ligament or between the tracheal rings in an awake or sedated animal. Endotracheal wash is performed by passing a catheter through an endotracheal tube in an anesthetized animal. The endotracheal technique is preferred in cats and very small dogs, although either technique can be used in any animal. Patients with airways that may be hyperreactive, particularly cats, are treated with bronchodilators (see the section on endotracheal technique).

Transtracheal Technique

Transtracheal wash fluid is collected by inserting a short, large bore over-the-needle catheter through the cricothyroid ligament or between tracheal rings; removing the needle; passing a long, smaller bore, flushing catheter through the catheter into the trachea to reach just cranial to the carina; then performing the saline wash. Options for catheters include a prepackaged kit containing a 14-gauge introduction catheter and a 10- to 28-inch flushing catheter (Mila International, Inc., Florence, Kentucky) or a 14-gauge over-the-needle catheter and a 3.5F polypropylene male dog urinary catheter. For the latter, the ability to pass a specific brand of urinary catheter through a specific over-the-needle catheter should be tested before use, as the fit may be too tight in some instances. Alternatively, a 12-inch-long, 18- to 22-gauge through-the-needle intravenous catheter can be used, but in our area, these catheters are no longer commercially available. The flushing catheter should be long enough to reach the carina, which is located at approximately the level of the fourth intercostal space.

The dog can sit or lie down, depending on what position is more comfortable for the animal and the clinician. The dog is restrained with its nose pointing toward the ceiling at about 45 degrees from horizontal (Fig. 20.13, *A*). Overextension of the neck causes the animal to be more resistant. Dogs that cannot be restrained should be tranquilized. If tranquilization is needed, premedication with atropine or glycopyrrolate is considered to minimize contamination of the trachea with oral secretions. Narcotics are avoided to preserve the cough reflex, which can facilitate the retrieval of fluid.

The cricothyroid ligament is identified by palpating the trachea in the ventral cervical region and following it dorsally toward the larynx to the raised, smooth, narrow band of the cricoid cartilage. Immediately above the cricoid cartilage is a depression, where the cricothyroid ligament is located (see Fig. 20.13, *B*). If the trachea is entered above the cricothyroid ligament, the catheter is passed dorsally into the pharynx and a nondiagnostic specimen is obtained. Such dorsal passage of the catheter often results in excessive gagging and retching but may go unrecognized in sedate patients.

Lidocaine is always injected subcutaneously at the site of entry. The skin over the cricothyroid ligament is prepared surgically, and sterile gloves are worn to pass the catheter. The over-the-needle catheter is held with the bevel of the needle facing ventrally. The skin over the ligament is then tented, and the needle is passed through the skin. The larynx is stabilized with the nondominant hand. To properly stabilize it, the clinician should grasp at least 180 degrees of the circumference of the airway between the fingers and the thumb. Failure to hold the airway firmly is the most common technical mistake. Next, the tip of the needle is rested against the cricothyroid ligament and inserted through the ligament with a quick, short motion. The syringe end of the catheter is raised without withdrawing the needle, and the catheter is threaded down the trachea. The hand stabilizing the trachea is then used to pinch the hub at the skin, with the hand kept firmly in contact with the neck, while the needle is removed. By keeping the hand holding the hub of the catheter against the neck of the animal so that the hand, needle, and neck can move as one, the clinician prevents laceration of the larynx or trachea and inadvertent removal of the catheter from the trachea.

The flushing catheter is then threaded through the over-the-needle catheter. Threading the catheter provokes coughing. Little or no resistance to passage of the catheter should be noted. Elevating the hub of the over-the-needle catheter slightly so that the tip points more ventrally facilitates passage of the flushing catheter if it is abutting the opposite tracheal wall. Once the catheter has been completely threaded into the airway, the head can be restrained in a natural position

Note that if the flushing catheter will not pass despite adjustments in position of the over-the-needle catheter, the over-the-needle catheter *must be completely removed* and the procedure repeated from the beginning. Attempting to reinsert the needle into the over-the-needle catheter while it is within the patient is dangerous as it can result in a piece of the catheter being sheared off and lost deep within the airways.

It is convenient to have six to eight 12-mL syringes ready, each filled with 3 to 5 mL of 0.9% sterile preservative-free sodium chloride solution. The entire bolus of saline in one syringe is injected into the flushing catheter. Immediately after this, many aspiration attempts are made. After each aspiration, the syringe must be disconnected from the catheter and the air evacuated without loss of any of the retrieved fluid. Attachment of a three-way stopcock between the

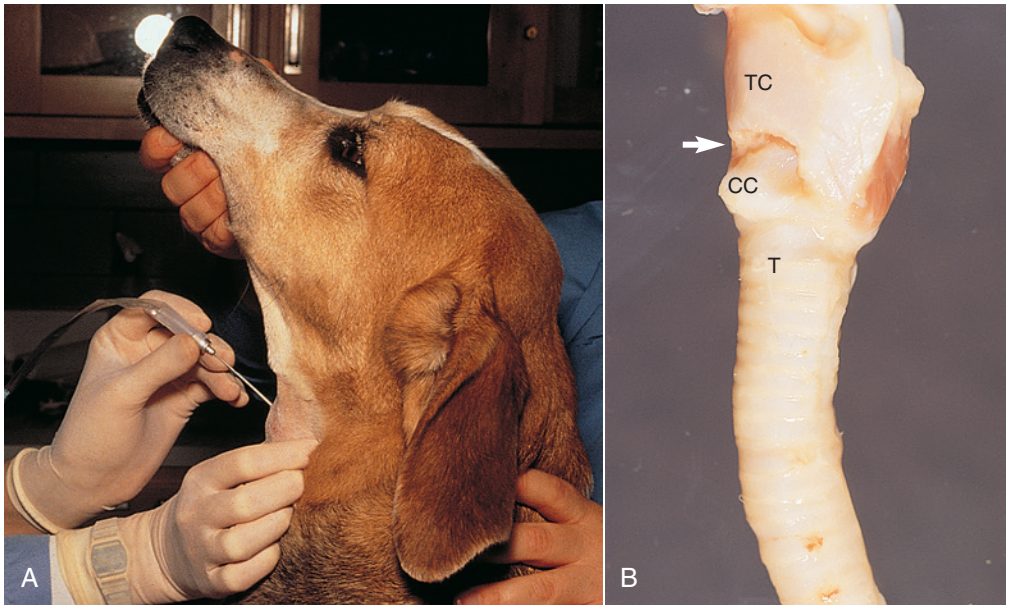

FIG 20.13
(A) When a transtracheal wash is performed, the animal is restrained in a comfortable position with the nose pointed toward the ceiling. The ventral neck is clipped and scrubbed, and the clinician wears sterile gloves. The cricothyroid ligament is identified as described in **(B).** After an injection of lidocaine, the needle of the catheter (whether a through-the-needle catheter as is shown here, or an over-the-needle catheter as described in the text) is placed through the skin. The larynx is grasped firmly with the fingers and the thumb at least 180 degrees around the airway. The needle can then be inserted through the cricothyroid ligament into the airway lumen. **(B)** The lateral view of this anatomic specimen demonstrates the trachea and larynx in a position similar to that of the dog in **(A).** The cricothyroid ligament *(arrow)* is identified by palpating the trachea *(T)* from ventral to dorsal until the raised cricoid cartilage *(CC)* is palpated. The cricothyroid ligament is the first depression above the cricoid cartilage. The cricothyroid ligament attaches cranially to the thyroid cartilage *(TC)*. The palpable depression above the thyroid cartilage *(not shown)* should not be entered.

catheter and the syringe can make it easier to connect and disconnect the syringe. Aspirations should be forceful and should be repeated at least five or six times, so that small volumes of airway secretions that have been aspirated into the catheter are pulled the entire length of the catheter into the syringe.

The procedure is repeated using additional boluses of saline until a sufficient amount of fluid is retrieved for analysis. A total of 2 to 3 mL of turbid fluid is adequate in most instances. The clinician does not need to be concerned about "drowning" the animal with infusion of the modest volumes of fluid described because the fluid is rapidly absorbed into the circulation. Failure to retrieve adequate volumes of visibly turbid fluid can be the result of several technical difficulties, as outlined in Fig. 20.14.

The catheter is removed after sufficient fluid is collected. A sterile gauze sponge with antiseptic ointment is then immediately placed over the catheter site, and a light bandage is wrapped around the neck. This bandage is left in place for several hours while the animal rests quietly in a cage. These precautions minimize the likelihood that subcutaneous emphysema or pneumomediastinum will develop.

Endotracheal Technique

The endotracheal technique is performed by passing a 5F red rubber or male dog urinary catheter through a sterilized endotracheal tube. The length of the catheter must be sufficient to extend beyond the end of the endotracheal tube by several centimeters and to nearly reach the carina.

The animal is anesthetized with a short-acting intravenous agent to a sufficient depth to allow intubation. Propofol or, in cats, a combination of ketamine and acepromazine or diazepam is effective. Premedication with atropine, particularly in cats, is considered to minimize contamination of the trachea with saliva. Cats with lower respiratory tract disease may have airway hyperreactivity and generally should be administered a bronchodilator before the tracheal wash. Terbutaline (0.01 mg/kg) can be given subcutaneously to cats not already receiving oral bronchodilators. It is also prudent to keep a metered dose inhaler of albuterol at hand to be administered through the endotracheal tube or by mask if breathing becomes labored or wheezes are auscultated.

A sterilized endotracheal tube should be passed without dragging the tip through the oral cavity. The animal's mouth is opened wide with the tongue pulled out, a laryngoscope

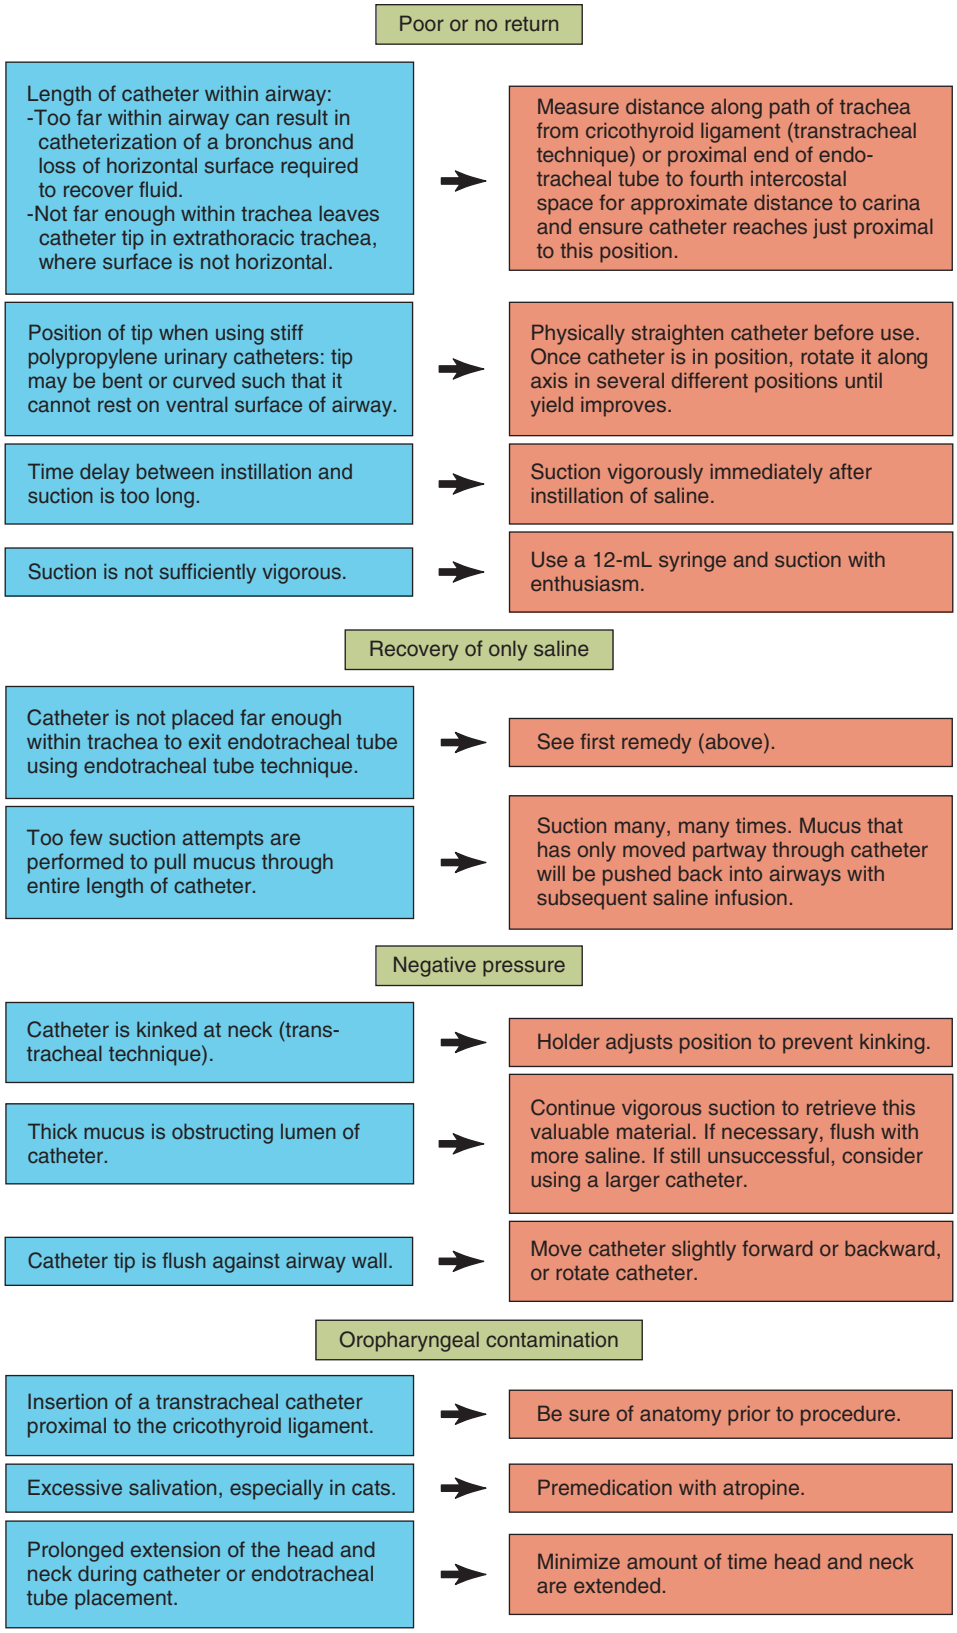

FIG 20.14

is used, and, in cats, sterile topical lidocaine is applied to the laryngeal cartilages to ease passage of the tube with minimal contamination. The tip of the endotracheal tube should be positioned beyond the larynx but sufficiently in front of the carina to allow the flushing catheter to rest against the floor of the trachea.

The catheter is passed through the endotracheal tube to just proximal to the level of the carina (approximately the fourth intercostal space), while sterile technique is maintained. The wash procedure is performed as described for the transtracheal technique. Slightly larger boluses of saline may be required, however, because of the larger volume of the catheter. Use of a catheter larger than 5F seems to reduce the yield of the wash, except when secretions are extremely viscous.

SPECIMEN HANDLING

The cells collected in the wash fluid are fragile. The fluid is ideally processed within 30 minutes of collection, with minimal manipulation. Bacterial culture is performed on at least 0.5 to 1 mL of fluid. Fungal cultures can be performed if mycotic disease is a differential diagnosis, and *Mycoplasma* culture or polymerase chain reaction (PCR) testing is considered for cats and dogs with signs of bronchitis. Cytologic preparations are made both from the fluid and from any mucus within the fluid. Both fluid and mucus are examined because infectious agents and inflammatory cells can be concentrated in the mucus, but the proteinaceous material causes cells to clump and interferes with evaluation of the cell morphology. Mucus is retrieved with a needle, and squash preparations are made. Direct smears of the fluid itself can be made, but such specimens are usually hypocellular. Sediment or cytocentrifuge preparations are generally necessary to make adequate interpretation possible. Straining the fluid through gauze to remove the mucus is discouraged because infectious agents may be lost in the process. Routine cytologic stains are used.

Microscopic examination of slides includes identification of cell types, qualitative evaluation of cells, and examination for infectious agents. Cells are evaluated qualitatively for evidence of macrophage activation, neutrophil degeneration, lymphocyte reactivity, and characteristics of malignancy. Epithelial hyperplasia secondary to inflammation should not be overinterpreted as neoplasia, however. Infectious agents such as bacteria, protozoa *(Toxoplasma gondii),* fungi (*Histoplasma, Blastomyces,* and *Cryptococcus* organisms), and parasitic larvae or eggs may be present (see Fig. 20.12, and Figs. 20.15 through 20.17). Because only one or two organisms may be present on an entire slide, a thorough evaluation of each slide is indicated.

INTERPRETATION OF RESULTS

Normal tracheal wash fluid contains primarily respiratory epithelial cells. Few other inflammatory cells are present (Fig. 20.18). Occasionally, macrophages are retrieved from the small airways and alveoli because the catheter was extended into the lungs beyond the carina, or because relatively large volumes of saline were used. Most macrophages are not activated. In these instances the presence of macrophages does not indicate disease but rather reflects the acquisition of material from the deep lung (see the section on nonbronchoscopic bronchoalveolar lavage).

Slides are examined for evidence of overt oral contamination, which can occur during transtracheal washing if the catheter needle was inadvertently inserted proximal to the cricothyroid ligament. Rarely, dogs can cough up the catheter into the oropharynx. Oral contamination can also result from drainage of saliva into the trachea, which usually occurs in cats that hypersalivate or dogs that are heavily sedated,

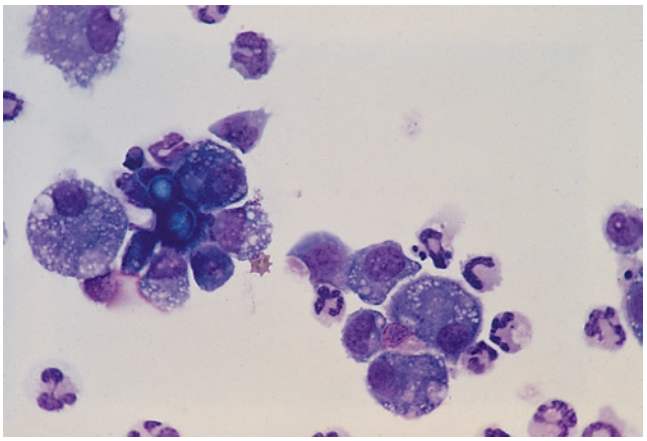

FIG 20.15
Photomicrograph of a *Blastomyces* organism from the lungs of a dog with blastomycosis. The organisms stain deeply basophilic, are 5 to 15 µm in diameter, and have a thick refractile cell wall. Often, as in this figure, broad-based budding forms are seen. The cells present are alveolar macrophages and neutrophils. (Bronchoalveolar lavage fluid, Wright stain.)

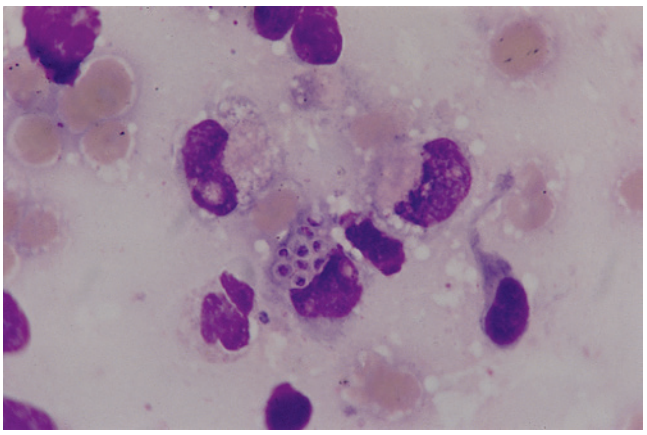

FIG 20.16
Photomicrograph of *Histoplasma* organisms from the lungs of a dog with histoplasmosis. The organisms are small (2-4 µm) and round, with a deeply staining center and a lighter-staining halo. They are often found within phagocytic cells—in this figure, an alveolar macrophage. (Bronchoalveolar lavage fluid, Wright stain.)

particularly if the head and neck are extended more than briefly for passage of the endotracheal tube or transtracheal catheter. Oral contamination is indicated by the finding of numerous squamous epithelial cells, often coated with bacteria, and *Simonsiella* organisms (Fig. 20.19). *Simonsiella* organisms are large basophilic rods that are frequently found stacked uniformly on top of one another along their broad side. Specimens with overt oral contamination may not provide accurate information about the airways, particularly with regard to bacterial infection.

Cytologic results of tracheal wash fluid are most useful when pathogenic organisms or malignant cells are identified. The presence of pathogens such as *Toxoplasma gondii,* systemic fungal organisms, and parasites provides a definitive

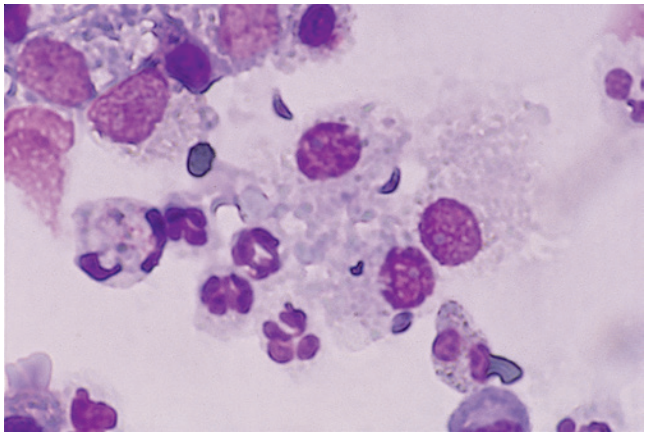

FIG 20.17
Photomicrograph of *Toxoplasma gondii* tachyzoites from the lungs of a cat with acute toxoplasmosis. The extracellular tachyzoites are crescent shaped with a centrally placed nucleus. They are approximately 6 µm in length. (Bronchoalveolar lavage fluid, Wright stain.)

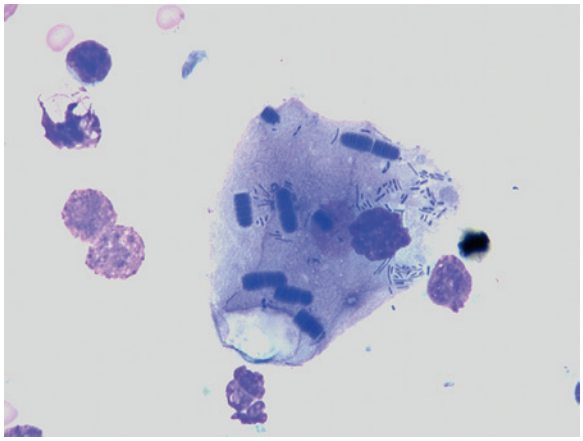

FIG 20.19
Tracheal wash fluid showing evidence of oropharyngeal contamination. The numerous, uniformly stacked basophilic rods are *Simonsiella* organisms—normal inhabitants of the oral cavity. These organisms, as well as many other bacteria, are adhering to a squamous epithelial cell. Squamous epithelium is another indication of contamination from the oral cavity.

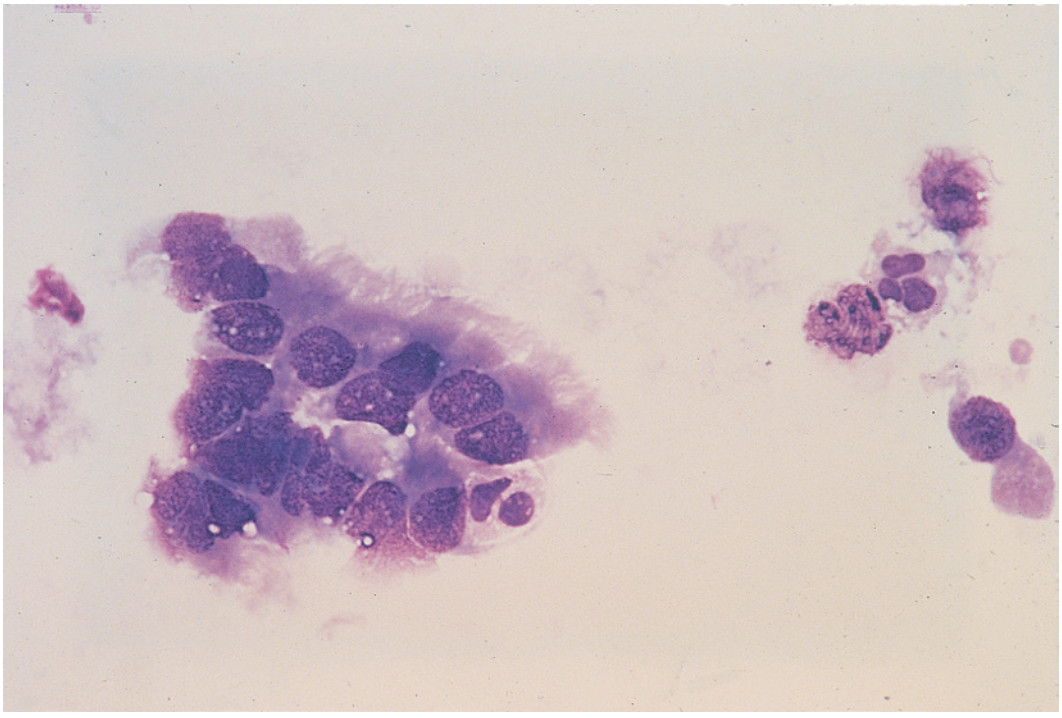

FIG 20.18

diagnosis. The finding of intracellular bacterial organisms in cytologic preparations without evidence of oral contamination indicates the presence of infection. The growth of any of the systemic mycotic agents in culture is also clinically significant, whereas the growth of bacteria in culture may or may not be significant because low numbers of bacteria can be present in the large airways of healthy animals. In general, the cytologic identification of bacteria and their growth in culture without multiplication in enrichment broth are significant findings.

Bacteria that are not seen cytologically and that grow only after incubation in enrichment media can result from several situations. For example, the bacteria may be causing infection without being present in high numbers because of the prior administration of antibiotics, or because of the collection of a nonrepresentative specimen. The bacteria may also be clinically insignificant and represent normal tracheal inhabitants, or they may result from contamination during collection. Other clinical data must therefore be considered when such findings are interpreted.

The role of *Mycoplasma* spp. in respiratory disease of the dog and cat is not well understood. These organisms cannot be seen on cytologic preparations and are difficult to grow in culture. Specific transport media are necessary. Growth of *Mycoplasma* organisms from tracheal wash fluid may indicate primary or secondary infection or may be an insignificant finding. Testing for *Mycoplasma* by PCR is also available. Treatment is generally recommended if inflammation was documented cytologically.

Criteria of malignancy for making a diagnosis of neoplasia must be interpreted with extreme caution. Overt characteristics of malignancy must be present in many cells in the absence of concurrent inflammation for a definitive diagnosis to be made.

The type of inflammatory cells present in tracheal wash fluid can assist in narrowing the differential diagnoses, although a mixed inflammatory response is common. Neutrophilic (suppurative) inflammation is common in bacterial infections. Before antibiotic therapy is initiated, the neutrophils may be (but are not always) degenerative, and organisms can often be seen. Neutrophilic inflammation may be a response to a variety of other diseases. For instance, it can be caused by other infectious agents or seen in patients with canine chronic bronchitis, idiopathic pulmonary fibrosis, or other idiopathic interstitial pneumonias, or even neoplasia. Some cats with idiopathic bronchitis have neutrophilic inflammation rather than the more classic eosinophilic response (see Chapter 21). The neutrophils in these instances are generally nondegenerative.

Eosinophilic inflammation reflects a hypersensitivity response, and diseases commonly resulting in eosinophilic inflammation include allergic bronchitis, parasitic disease, and eosinophilic lung disease. Parasites that affect the lung include primary lungworms or flukes, migrating intestinal parasites, and heartworms. Over time, mixed inflammation can occur in patients with hypersensitivity. It is occasionally possible for nonparasitic infection or neoplasia to cause eosinophilia, usually as part of a mixed inflammatory response.

Macrophagic (granulomatous) inflammation is characterized by the finding of increased numbers of activated macrophages, generally present as a component of mixed inflammation, along with increased numbers of other inflammatory cells. Activated macrophages are vacuolated and have increased amounts of cytoplasm. This response is nonspecific unless an etiologic agent can be identified.

Lymphocytic inflammation alone is uncommon. Viral or rickettsial infection, idiopathic interstitial pneumonia, and lymphoma are considerations.

True hemorrhage can be differentiated from a traumatic specimen collection by the presence of erythrophagocytosis and hemosiderin-laden macrophages. An inflammatory response is also usually present. Hemorrhage can be caused by neoplasia, mycotic infection, heartworm disease, thromboembolism, foreign body, lung lobe torsion, or coagulopathies. Evidence of hemorrhage is seen occasionally in animals with congestive heart failure or severe bacterial pneumonia. Of note is that hemosiderosis is found in tracheal wash fluid collected from cats with a wide range of diseases, including idiopathic bronchitis.

NONBRONCHOSCOPIC BRONCHOALVEOLAR LAVAGE

Indications and Complications

Nonbronchoscopic bronchoalveolar lavage (NB-BAL) is considered for the diagnostic evaluation of patients with lung disease involving the interstitium, small airways, or alveoli that are not tachypneic or otherwise showing signs of respiratory distress (see Table 20.2). This author prefers tracheal wash for patients with diffuse airway disease, bacterial bronchopneumonia, or aspiration pneumonia because tracheal wash carries less risk and can be expected to result in a representative specimen in these situations. Further, NB-BAL using a catheter for dogs as described in the following text will usually sample a caudal lung lobe and could bypass the exudate from pneumonia of airway origin. Therefore NB-BAL is considered primarily for patients with diffuse interstitial lung disease. Bronchoscopically guided BAL is performed as a routine part of bronchoscopy and is indicated when focal disease is present.

A large volume of lung is sampled by BAL (Figs. 20.20 and 20.21). The collected specimens are of large volume, providing more than adequate material for routine cytology, cytology involving special stains (e.g., Gram stains, acid-fast stains), multiple types of cultures (e.g., bacterial, fungal, mycoplasmal), or other specific tests that might be helpful in particular patients (e.g., flow cytometry, PCR). Cytologic preparations from BAL fluid are of excellent quality and consistently provide large numbers of well-stained cells for examination.

Although general anesthesia is required, the procedure is associated with few complications in *stable* patients. The

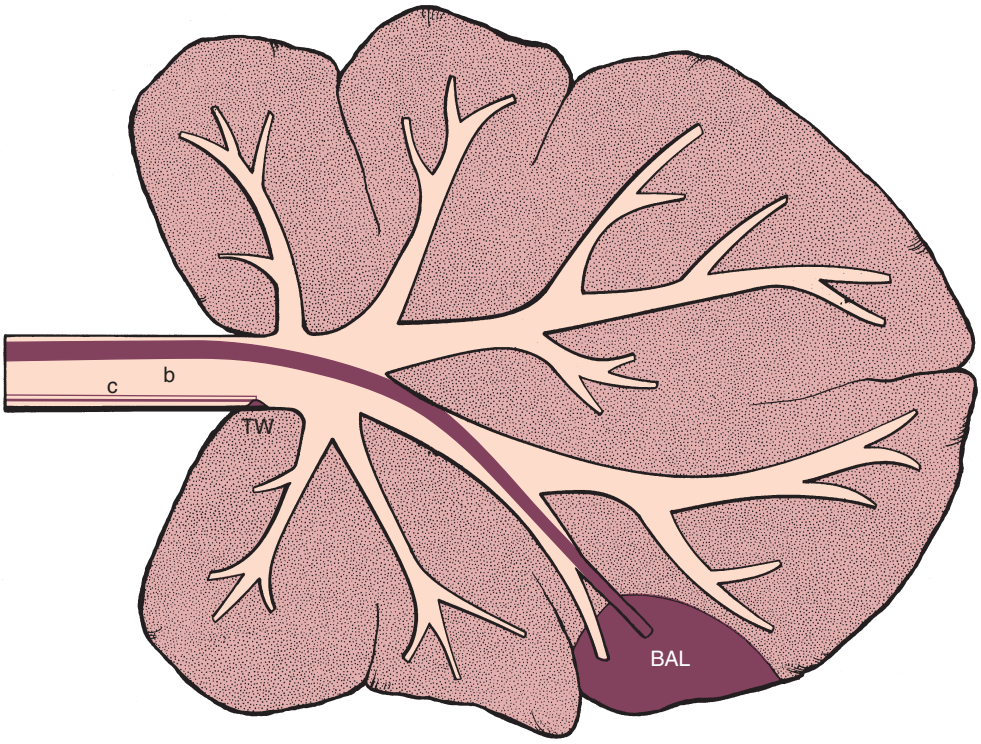

FIG 20.20
The region of the lower respiratory tract that is sampled by bronchoalveolar lavage *(BAL)* in comparison with the region sampled by tracheal wash *(TW)*. The solid line *(b)* within the airways represents a bronchoscope or a modified feeding tube. The open lines *(c)* represent the tracheal wash catheter. Bronchoalveolar lavage yields fluid representative of the deep lung, whereas tracheal wash yields fluid representative of processes involving major airways, including diffuse bronchitis, bacterial bronchopneumonia, and aspiration pneumonia.

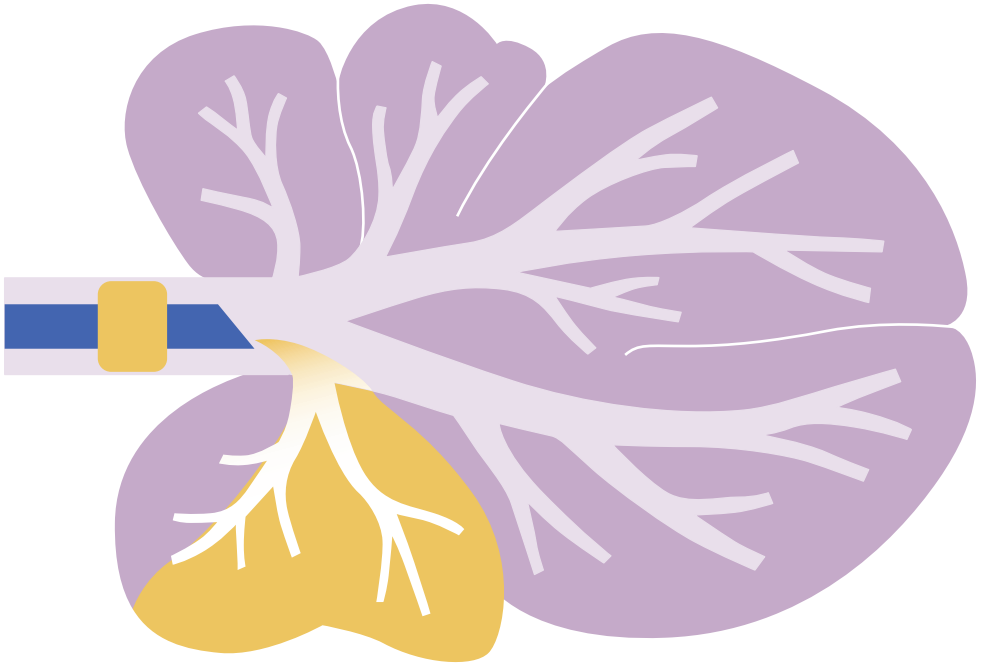

FIG 20.21
The region of the lower respiratory tract presumed to be sampled by nonbronchoscopic bronchoalveolar lavage in cats using an endotracheal tube.

primary complication of BAL is hypoxemia. Hypoxemia generally can be corrected with oxygen supplementation, but animals exhibiting increased respiratory efforts or respiratory distress in room air are not good candidates for this procedure. Patients may have poor lung function without overt signs, so the ability to provide oxygen supplementation for an hour or longer is necessary to minimize the risk of patient decompensation. Patients with hyperreactive airways, particularly cats, are treated with bronchodilators, as described previously for endotracheal washing.

In addition to the methods described, other techniques for NB-BAL have been reported in which a long, thin, sterile catheter is passed through a sterile endotracheal tube until the catheter is lodged in a distal airway, and relatively small volumes of saline are infused and recovered. Foster and Martin (2011) used a 6F to 8F dog urinary catheter and two 5- to 10-mL aliquots of sterile saline. Such methods likely result in less hypoxemia than those described here but would be expected to sample a smaller portion of lung. Critical evaluation of different techniques for BAL in disease states has not been performed.

TECHNIQUE FOR NB-BAL IN CATS

A sterile endotracheal tube and a syringe adapter are used in cats to collect lavage fluid (Fig. 20.22; see also Fig. 20.21). Cats, particularly those with signs of bronchitis, should be treated with bronchodilators before the procedure, as described previously for tracheal wash (endotracheal technique), to decrease the risk of bronchospasm. The cat may be premedicated with atropine (0.05 mg/kg subcutaneously) to minimize oral secretions, and is anesthetized with ketamine and acepromazine or diazepam, given intravenously. The endotracheal tube is passed as cleanly as possible through the larynx to minimize oral contamination. To achieve sufficient cleanliness, the tip of the tongue is pulled out, a laryngoscope is used, and sterile lidocaine is applied topically to the laryngeal mucosa. The cuff is then inflated sufficiently to create a seal, but overinflation is avoided to prevent tracheal rupture (i.e., use a 3-mL syringe and inflate the cuff in 0.5-mL increments only until no leak is audible when gentle pressure is placed on the oxygen reservoir bag).

The cat is placed in lateral recumbency with the most diseased side, as determined by physical and radiographic findings, against the table. Oxygen (100%) is administered for several minutes through the endotracheal tube. The anesthetic adapter then is removed from the endotracheal tube and replaced with a sterile syringe adapter, with caution to avoid contamination of the end of the tube or adapter. Immediately, a bolus of warmed, sterile 0.9% saline solution (5 mL/kg body weight) is infused through the tube over approximately 3 seconds. Immediately after infusion, suction is applied by syringe. Air is eliminated from the syringe, and several aspiration attempts are made until fluid is no longer recovered. The procedure is repeated using a total of two or three boluses of saline solution. The cat is allowed to expand its lungs between infusions of saline solution. After the last infusion, the syringe adapter is removed (because it greatly interferes with ventilation) and excess fluid is drained from the large airways and endotracheal tube by elevating the caudal half of the cat a few inches off of the table. At this point, the cat is cared for as described in the section on recovery of patients after BAL.

TECHNIQUE FOR NB-BAL IN DOGS

An inexpensive 122-cm 16F Levin-type polyvinyl chloride stomach tube can be used in dogs to collect lavage fluid. The tube must be modified for best results. Sterile technique is maintained throughout. The distal end of the tube is cut off for removal of the side openings. The proximal end is cut off for removal of the flange and shortening of

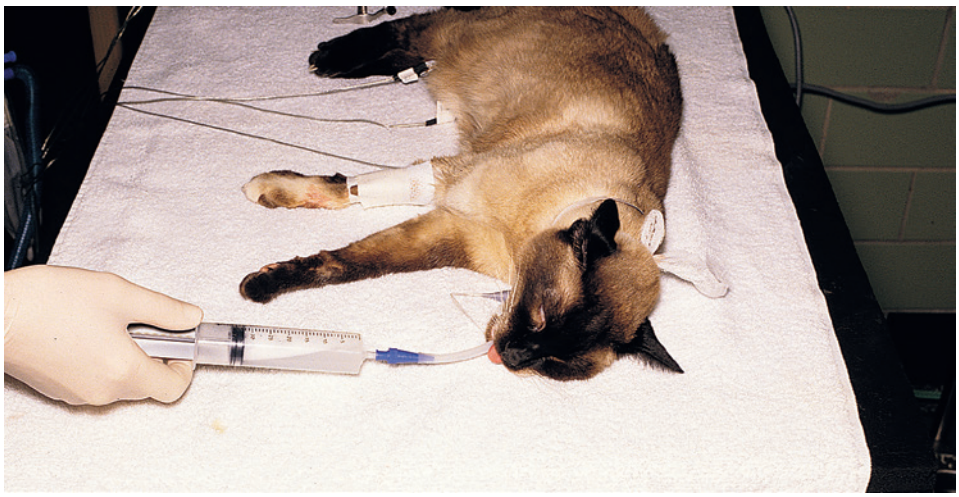

FIG 20.22
Bronchoalveolar lavage using an endotracheal tube in a cat. The fluid retrieved is grossly foamy because of the surfactant present. The procedure is performed quickly because the airway is completely occluded during infusion and aspiration of fluid.

the tube to a length slightly greater than the distance from the open end of the dog's endotracheal tube to the last rib. A syringe adapter is placed within the proximal end of the tube (Fig. 20.23).

Recovery of BAL fluid can be improved by tapering the distal end of the tube. Tapering is readily achieved using a metal, single-blade, handheld pencil sharpener that has been autoclaved and is used only for this purpose (see Fig. 20.23, *A* and *B*).

The dog may be premedicated with atropine (0.05 mg/kg subcutaneously) or glycopyrrolate (0.005 mg/kg subcutaneously) to minimize oral secretions and is anesthetized using a short-acting protocol that will allow intubation, such as with propofol, a short-acting barbiturate, or the combination of medetomidine and butorphanol. If the dog is of sufficient size to accept a size 6 or larger endotracheal tube, the dog is intubated with a sterile endotracheal tube placed as cleanly as possible to minimize oral contamination of the specimen. The modified stomach tube will not fit through a smaller endotracheal tube, so the technique must be performed without an endotracheal tube, or a smaller stomach tube must be used. If no endotracheal tube is used, extreme care must be taken to minimize oral contamination in passing the modified stomach tube, and an appropriately sized endotracheal tube should be available to gain control of the airway in case of complications and for recovery.

Oxygen (100%) is provided through the endotracheal tube or by face mask for several minutes. The modified stomach tube is passed through the endotracheal tube using sterile technique until resistance is felt. The goal is to wedge the tube snugly into an airway rather than have it abut an airway division. Therefore the tube is withdrawn slightly, then is passed again, until resistance is consistently felt at the same depth. Rotating the tube slightly during passage may help achieve a snug fit. Remember that if the endotracheal tube is not much larger than the stomach tube, ventilation is restricted at this point and the procedure should be completed expediently.

For medium-size dogs and larger, two 35-mL syringes are prepared in advance, each with 25 mL of saline and 5 mL of air. While the modified stomach tube is held in place, a 25-mL bolus of saline is infused through the tube, followed by the 5 mL of air, by holding the syringe upright during infusion (Fig. 20.24). Gentle suction is applied immediately after infusion, using the same syringe. It may be necessary to withdraw the tube slightly if negative pressure is felt. The tube should not be withdrawn more than a few millimeters. If it is withdrawn too far, air will be recovered instead of fluid. The second bolus of saline is infused and recovered in the same manner, with the tube in the same position. The dog is cared for as described in the next section.

In very small dogs, it is prudent to reduce the volume of saline used in each bolus, particularly if a smaller-diameter stomach tube is used. Overinflation of the lungs with excessive fluid volumes should be avoided.

RECOVERY OF PATIENTS AFTER BAL

Regardless of the method used, BAL causes a transient decrease in the arterial oxygen concentration. In most patients this hypoxemia responds to oxygen supplementation. Patients are monitored with pulse oximetry (discussed later in this chapter) before and throughout the procedure and during recovery. Immediately after the procedure, 100% oxygen is provided through an endotracheal tube for as long as the dog or cat will allow intubation. Several gentle "sighs" are performed with the anesthesia bag to help expand any collapsed portions of lung. Bronchospasms are a reported

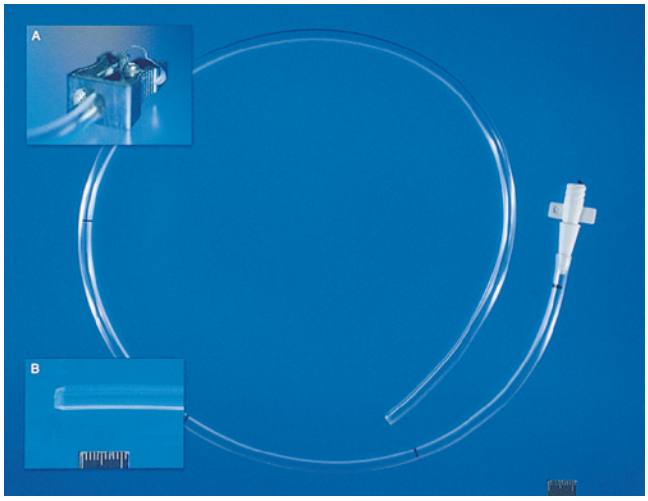

FIG 20.23
The catheter used for nonbronchoscopic bronchoalveolar lavage in dogs is a modified 16F Levin-type stomach tube. The tube is shortened by cutting off both ends. A simple pencil sharpener *(inset A)* is used to taper the distal end of the tube *(inset B)*. A syringe adapter is added to the proximal end. Sterility is maintained throughout.

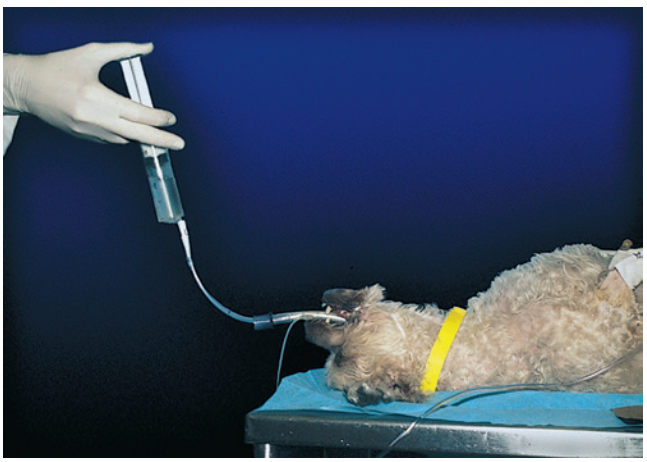

FIG 20.24
Bronchoalveolar lavage using a modified stomach tube in a dog. The tube is passed through a sterile endotracheal tube and is lodged in a bronchus. A syringe preloaded with saline and air is held upright during infusion so that saline is infused first, followed by air.

complication of BAL in people, and increased airway resistance has been documented in cats after bronchoscopy and BAL (Kirschvink et al., 2005). Albuterol in a metered dose inhaler should be on hand to administer through the endotracheal tube or by spacer and mask if needed.

After extubation the mucous membrane color, pulses, and the character of respirations are monitored closely. Crackles can be heard for several hours after BAL and are not cause for concern. Treatment with oxygen supplementation is continued by mask, oxygen cage, or nasal catheter if there are any indications of hypoxemia. Oxygen supplementation is rarely necessary for longer than 10 to 15 minutes after BAL in patients that were stable in room air before the procedure; however, the ability to provide supplementation for an hour or longer is a prerequisite for performance of this procedure, in case decompensation occurs. Considerations for patients who continue to require oxygen supplementation or whose condition deteriorates include pneumothorax, resulting from rupture of a bulla or other cavitary lesion; aspiration, as a complication of anesthesia; or cardiogenic edema from fluid overload.

SPECIMEN HANDLING

Successful BAL yields fluid that is grossly foamy, as a result of surfactant from the alveoli. Approximately 50% to 80% of the total volume of saline instilled is expected to be recovered. Less will be obtained from dogs with tracheobronchomalacia (collapsing airways). The fluid is placed on ice immediately after collection and is processed as soon as possible, with minimum manipulation to decrease cell lysis. For convenience, retrieved boluses can be combined for analysis; however, fluid from the first bolus usually contains more cells from the larger airways, and fluid from later boluses is more representative of the alveoli and interstitium.

BAL fluid is analyzed cytologically and microbiologically. Nucleated cell counts are performed on undiluted fluid using a hemocytometer. Cells are concentrated onto slides for differential cell counts and qualitative analysis using cytocentrifugation or sedimentation techniques. Slides then are stained using routine cytologic procedures. Differential cell counts are performed by counting at least 200 nucleated cells. Slides are scrutinized for evidence of macrophage activation, lymphocyte reactivity, neutrophil degeneration, and criteria of malignancy. All slides are examined thoroughly for possible etiologic agents, such as fungi, protozoa, parasites, and bacteria (see Figs. 20.12 and 20.15 to 20.17). As described for tracheal wash, visible strands of mucus can be examined for etiologic agents by squash preparation.

Approximately 5 mL of fluid is used for bacterial culture. Additional fluid is submitted for fungal culture if mycotic disease is among the differential diagnoses. *Mycoplasma* cultures or PCR are considered in cats and dogs with signs of bronchitis.

INTERPRETATION OF RESULTS

Normal cytologic values for BAL fluid are inexact because of inconsistency in the techniques used and variability among individual animals of the same species. In general, total nucleated cell counts in normal animals are less than 400 to 500/µL. Differential cell counts from healthy dogs and cats are listed in Table 20.3. Note that the provided values are means from groups of healthy animals. *Values from individual patients should not be considered abnormal unless the values are at least one or two standard deviations above these*

mean values. **In our canine studies we have used values of ≥12% neutrophils, 14% eosinophils, or 16% lymphocytes as indicative of inflammation.**

Interpretation of BAL fluid cytology and cultures is essentially the same as that described for tracheal wash fluid, although the specimens are more representative of the deep lung than the airways. In addition, the normal cell population of macrophages must not be misinterpreted as being indicative of macrophagic or chronic inflammation (Fig. 20.25). As for all cytologic specimens, definitive diagnoses are made through identification of organisms or abnormal cell populations. Fungal, protozoal, or parasitic organisms may be present in extremely low numbers in BAL specimens; therefore the entire concentrated slide preparation must be carefully scanned. Profound epithelial hyperplasia can occur in the presence of an inflammatory response and should not be confused with neoplasia.

If quantitative bacterial culture is available, growth of organisms at greater than 1.7×10^3 colony-forming units (CFUs)/mL has been reported to indicate infection (Peeters et al., 2000). In the absence of quantitative numbers, growth of organisms on a plate directly inoculated with BAL fluid is considered significant, whereas growth from fluid that occurs only after multiplication in enrichment broth may be a result of normal inhabitants or contamination. Patients that are already receiving antibiotics at the time of specimen collection may have significant infection with few or no bacteria by culture.

DIAGNOSTIC YIELD

A retrospective study of BAL fluid cytologic analysis in dogs at referral institutions showed that BAL findings served as the basis for a definitive diagnosis in 25% of cases and were supportive of the diagnosis in an additional 50%. Only dogs in which a definitive diagnosis was obtained by any means were included. Definitive diagnoses were possible on the basis of BAL only in those animals in which infectious organisms were identified, or in those cases in which overtly malignant cells were present in specimens in the absence of marked inflammation. BAL has been shown to be more sensitive than radiographs in identifying pulmonary involvement with lymphosarcoma. Carcinoma was definitively identified in 57% of cases, and other sarcomas were not found in BAL fluid. Fungal pneumonia was confirmed in only 25% of cases, although organisms were found in 67% of cases in a previous study of dogs with overt fungal pneumonia.

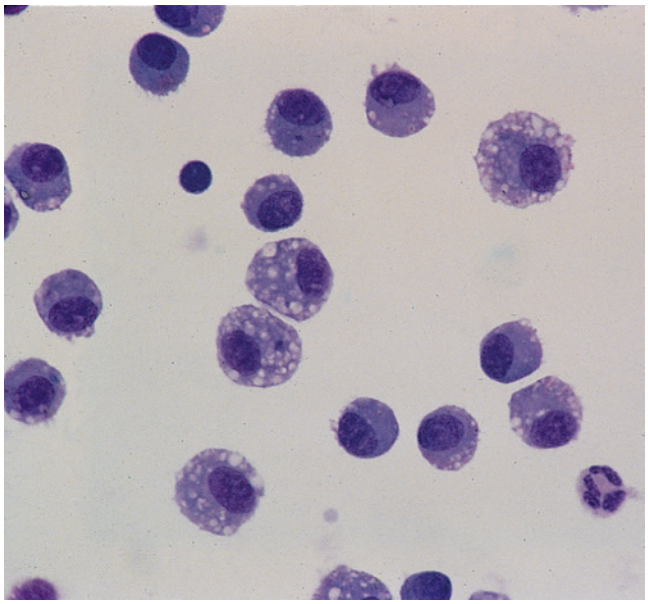

FIG 20.25
Bronchoalveolar lavage fluid from a normal dog. Note that alveolar macrophages predominate.

TRANSTHORACIC LUNG ASPIRATION AND BIOPSY

Indications and Complications

Pulmonary parenchymal specimens can be obtained by transthoracic needle aspiration or biopsy. Although only a small region of lung is sampled by these methods, collection can be guided by radiographic findings or ultrasonography to improve the likelihood of obtaining representative specimens. As with tracheal wash and BAL, a definitive diagnosis will be possible in patients with infectious or neoplastic disease. Patients with noninfectious inflammatory diseases require thoracoscopy or thoracotomy with lung biopsy for a definitive diagnosis.

Potential complications of transthoracic needle aspiration or biopsy include pneumothorax, hemothorax, and pulmonary hemorrhage. These procedures are not recommended in animals with suspected cysts, abscesses, pulmonary hypertension, or coagulopathies. Severe complications are uncommon, but these procedures should not be performed unless the clinician is prepared to place a chest tube and otherwise support the animal if necessary.

Lung aspirates and biopsy specimens are indicated for the nonsurgical diagnosis of intrathoracic mass lesions that are in contact with the thoracic wall. The risk of complications in these animals is relatively low because the specimens can be collected without disrupting aerated lung. Obtaining aspirates or biopsy specimens from masses that are far from the body wall and near the mediastinum carries the additional risk of lacerating important mediastinal organs, vessels, or nerves. If a solitary localized mass lesion is present, thoracotomy and biopsy should be considered rather than transthoracic sampling because this permits both the diagnosis of the problem and the potentially therapeutic benefits of complete excision.

Transthoracic lung aspirates can be obtained in animals with a diffuse interstitial radiographic pattern. In some of these patients, solid areas of infiltrate in lung tissue immediately adjacent to the body wall can be identified ultrasonographically even though they are not apparent on thoracic radiographs (see Fig. 20.11). Ultrasound guidance of the

aspiration needle into the areas of infiltrate should improve diagnostic yield and safety. If areas of infiltrate cannot be identified ultrasonographically, BAL should be considered before lung aspiration in animals that can tolerate the procedure because it yields a larger specimen for analysis and, in this author's opinion, carries less risk than unguided transthoracic aspiration in patients that are not experiencing increased respiratory efforts or distress. Tracheal wash and appropriate ancillary tests are also considered before lung aspiration in these patients because they carry little risk.

TECHNIQUES

The site of collection in animals with localized disease adjacent to the body wall is best identified with ultrasonography. If ultrasonography is not available, or if the lesion is surrounded by aerated lung, the site is determined on the basis of two radiographic views. The location of the lesion during inspiration in all three dimensions is identified by its relationship to external landmarks: the nearest intercostal space or rib, the distance from the costochondral junctions, and the depth into the lungs from the body wall. If available, fluoroscopy or CT also can be used to guide the needle or biopsy instrument.

The site of collection in animals with diffuse disease is a caudal lung lobe. The needle is inserted between the seventh and ninth intercostal spaces, approximately two thirds of the distance from the costochondral junctions to the spine.

The animal must be restrained for the procedure, and sedation or anesthesia is necessary in some. Anesthesia is avoided, if possible, because the hemorrhage created by the procedure is not cleared as readily from the lungs in an anesthetized dog or cat. The skin at the site of collection is shaved and surgically prepared. Lidocaine is injected into subcutaneous tissues and intercostal muscles to provide local anesthesia.

Lung aspiration can be performed with an injection needle, a spinal needle, or a variety of thin-walled needles designed specifically for lung aspiration in people. Spinal needles are readily available in most practices, are sufficiently long to penetrate through the thoracic wall, and have a stylet. A 22-gauge, 1.5- to 3.5-inch (3.75- to 8.75-cm) spinal needle is usually adequate.

The clinician wears sterile gloves. The needle with stylet is advanced through the skin several rib spaces from the desired biopsy site. The needle and skin are then moved to the biopsy site. This is done because air is less likely to enter the thorax through the needle tract after the procedure if the openings in the skin and chest wall are not aligned. The needle is then advanced through the body wall to the pleura. The stylet is removed, and the needle hub is immediately covered by a finger to prevent pneumothorax until a 12-mL syringe can be placed on the hub. During inspiration the needle is thrust into the chest to a depth predetermined from the radiographs, usually about 1 inch (2.5 cm), while suction is applied to the syringe (Fig. 20.26). To keep from inserting the needle too deeply, the clinician may pinch the needle shaft with the thumb and forefinger of the nondominant hand at the desired maximum depth of insertion. During insertion, the needle can be twisted along its long axis in an attempt to obtain a core of tissue. The needle is then immediately withdrawn to the level of the pleura. Several quick stabs into the lung can be made along different lines to increase the yield.

FIG 20.26
Transthoracic lung aspiration performed with a spinal needle. Note that sterile technique is used. The needle shaft can be pinched with finger and thumb at the maximum depth to which the needle should be passed. The finger and thumb thus act as a guard to prevent overinsertion of the needle. Although this patient is under general anesthesia, this is not usually indicated.

Each stab should take only a second. Prolonging the time that the needle is within the lung tissue increases the likelihood of complications. The lung tissue will be moving with respirations, resulting in laceration of tissue, even if the needle is held steady.

The needle is withdrawn from the body wall with a minimal amount of negative pressure maintained by the syringe. It is unusual for the specimen to be large enough to have entered the syringe. The needle is removed from the syringe, the syringe is filled with air and reattached to the needle, and the contents of the needle are then forced onto one or more slides. Grossly, the material is bloody in most cases. Squash preparations are made. Slides are stained using routine procedures and then are evaluated cytologically. Increased numbers of inflammatory cells, infectious agents, or neoplastic cell populations are potential abnormalities. Alveolar macrophages are normal findings in parenchymal specimens and should not be interpreted as representing chronic inflammation. They should be carefully examined for evidence of phagocytosis of bacteria, fungi, or red blood cells and for signs of activation. Epithelial hyperplasia can

occur in the presence of inflammation and should not be confused with neoplasia. Sometimes the liver is aspirated inadvertently, particularly in deep-chested dogs, yielding a population of cells that may resemble those from adenocarcinoma. However, hepatocytes typically contain bile pigment. Bacterial culture is indicated in some animals, although the volume of material obtained is quite small.

Transthoracic lung core biopsies can be performed in animals with mass lesions immediately adjacent to the chest wall. Specimens are collected after an aspirate has proved to be nondiagnostic. Needle biopsy instruments can be used (e.g., EZ Core biopsy needles, Products Group International, Lyons, Colorado). Smaller-bore, thin-walled lung biopsy instruments can be obtained from medical suppliers for human patients. These instruments collect smaller pieces of tissue but are less disruptive to normal lung. Ideally, sufficient material is collected for histologic evaluation. If not, squash preparations are made for cytologic studies.

BRONCHOSCOPY

Indications

Bronchoscopy is indicated for the evaluation of the major airways in animals with suspected structural abnormalities, for visual assessment of airway inflammation or pulmonary hemorrhage, and as a means of collecting specimens in animals with undiagnosed lower respiratory tract disease. Bronchoscopy can be used to identify structural abnormalities of the major airways, such as tracheal collapse, mass lesions, tears, strictures, lung lobe torsions, bronchiectasis, bronchial collapse, and external airway compression. Foreign bodies or parasites may be identified. Hemorrhage or inflammation involving or extending to the large airways may also be seen and localized.

Specimen collection techniques performed in conjunction with bronchoscopy are valuable diagnostic tools because they can be used to obtain specimens from deeper regions of the lung than is possible with the tracheal wash technique, and visually directed sampling of specific lesions or lung lobes is also possible. Animals undergoing bronchoscopy must receive general anesthesia, and the presence of the scope within the airways compromises ventilation. Therefore bronchoscopy is contraindicated in animals with severe respiratory tract compromise unless the procedure is likely to be therapeutic (e.g., foreign body removal).

TECHNIQUE

Bronchoscopy is technically more demanding than most other endoscopic techniques. The patient is often experiencing some degree of respiratory compromise, which poses increased anesthetic and procedural risks. Airway hyperreactivity may be exacerbated by the procedure, particularly in cats. A small-diameter, flexible endoscope is needed and should be sterilized before use. The bronchoscopist should be thoroughly familiar with normal airway anatomy to ensure that every lobe is examined. BAL is routinely performed as part of diagnostic bronchoscopy after thorough visual examination of the airways. The reader is referred elsewhere for details about performing bronchoscopy and bronchoscopic BAL (Dear and Johnson, 2013; Hawkins, 2004; McKiernan, 2005; Padrid, 2011). Bronchoscopic images of normal airways are shown in Fig. 20.27. Reported cell counts from bronchoscopically collected BAL fluid are provided in Table 20.3.

Abnormalities that may be observed during bronchoscopy, and their common clinical correlations are listed in Table 20.4. A definitive diagnosis is rarely possible on the basis of the findings yielded by gross examination alone. Specimens are collected through the biopsy channel for cytologic, histopathologic, and microbiologic analysis. Bronchial specimens are obtained by bronchial washing, bronchial brushing, or pinch biopsy. Material for bacterial culture can be collected with guarded culture swabs. The deeper lung is sampled by BAL or transbronchial biopsy. Foreign bodies are removed with retrieval forceps.

THORACOTOMY OR THORACOSCOPY WITH LUNG BIOPSY

Thoracotomy and surgical biopsy are performed in animals with progressive clinical signs of lower respiratory tract disease that has not been diagnosed using less invasive means. Although thoracotomy carries a greater risk than the previously mentioned diagnostic techniques, the modern anesthetic agents, surgical techniques, and monitoring capabilities now available have made this procedure routine in many veterinary practices. Analgesic drugs are used to manage postoperative pain, and complication-free animals are discharged as soon as 2 to 3 days after surgery. Surgical biopsy provides excellent-quality specimens for histopathologic analysis, culture, PCR, and other specific tests for infectious diseases or neoplasia. Abnormal lung tissue and accessible lymph nodes are biopsied.

Excisional biopsy of abnormal tissue can be therapeutic in animals with localized disease. Removal of localized neoplasms, abscesses, cysts, and foreign bodies can be curative. The removal of large localized lesions can improve the matching of ventilation and perfusion, even in animals with evidence of diffuse lung involvement, thereby improving the oxygenation of blood and reducing clinical signs.

In practices where thoracoscopy is available, this less invasive technique can be used for initial assessment of intrathoracic disease. Similarly, a "mini" thoracotomy can be performed through a relatively small incision. If disease is obviously disseminated throughout the lungs such that surgical intervention will not be therapeutic, biopsy specimens of abnormal tissue can be obtained with these methods via small incisions. If access by thoracoscopy or "mini" thoracotomy is insufficient based on initial findings, these procedures can be transitioned to a full thoracotomy during the same anesthesia.

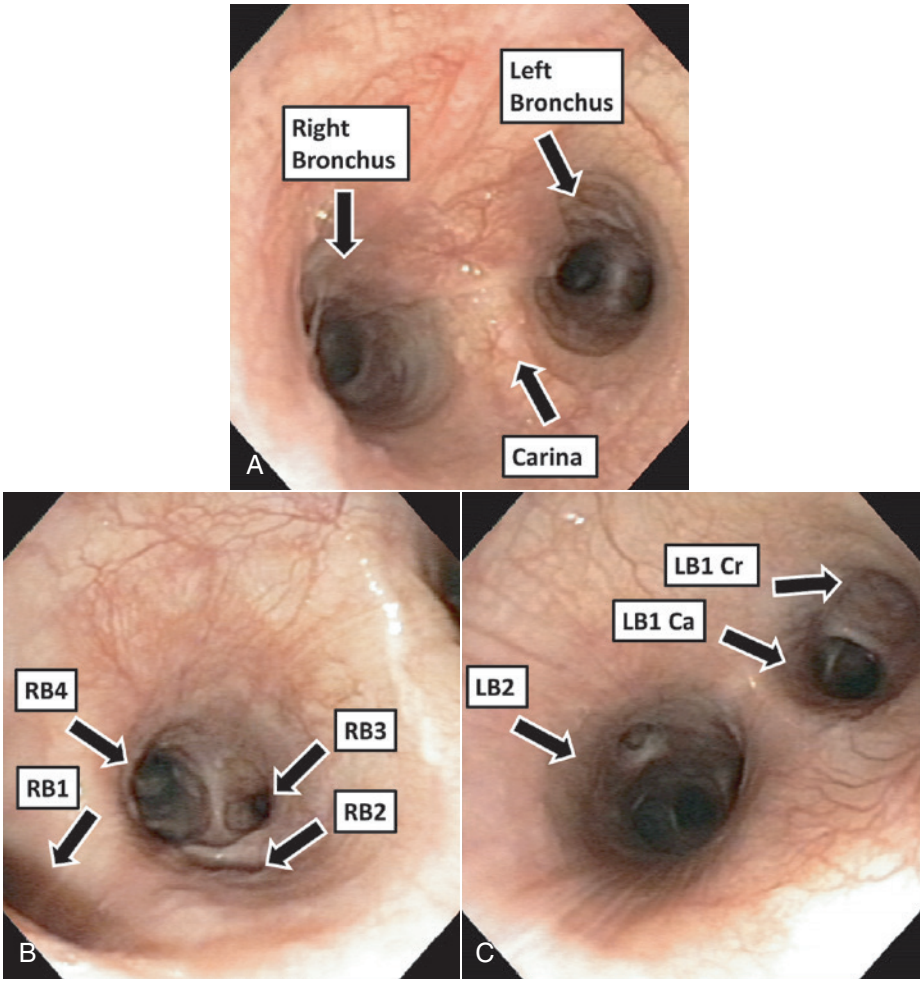

FIG 20.27
Bronchoscopic images of normal airways. The labels for the lobar bronchi are derived from a useful nomenclature system for the major airways and their branches presented by Amis et al. (1986). **(A)** Carina, the division between the right and left mainstem bronchi. **(B)** Right mainstem bronchus. The carina is off the right side of the image. Openings to the right cranial *(RB1),* right middle *(RB2),* accessory *(RB3),* and right caudal *(RB4)* bronchi are visible. **(C)** Left mainstem bronchus. The carina is off the left side of the image. The openings to the left cranial *(LB1)* and left caudal *(LB2)* bronchi are visible. The left cranial lobe *(LB1)* divides immediately into cranial *(Cr)* and caudal *(Ca)* branches. (From Amis TC et al.: Systematic identification of endobronchial anatomy during bronchoscopy in the dog, *Am J Vet Res* 47:2649, 1986.)

BLOOD GAS ANALYSIS

Indications

Measurement of partial pressures of oxygen (Pa_{O_2}) and carbon dioxide (Pa_{CO_2}) in arterial blood specimens provides information about pulmonary function. Venous blood analysis is less useful because venous blood oxygen pressures are greatly affected by cardiac function and peripheral circulation. Arterial blood gas measurements are indicated to document pulmonary failure, to differentiate hypoventilation from other causes of hypoxemia, to help determine the need for supportive therapy, and to monitor the response to therapy. Respiratory compromise must be severe for abnormalities to be measurable because the body has tremendous compensatory mechanisms.

TECHNIQUES

Arterial blood is collected in a heparinized syringe. Dilution of specimens with liquid heparin can alter blood gas results. Therefore commercially available syringes preloaded with lyophilized heparin are recommended. Alternatively, 0.5 mL of liquid sodium heparin is drawn into a 3-mL syringe with a 25-gauge needle. The plunger is drawn back to the 3 mL mark. All air is then expelled from the syringe. This procedure for expelling air and excess heparin is repeated three times.

TABLE 20.4

Bronchoscopic Abnormalities and Their Clinical Correlations

ABNORMALITY	CLINICAL CORRELATION
Trachea	
Hyperemia, loss of normal vascular pattern, excess mucus, exudate	Inflammation
Redundant tracheal membrane	Usually associated with flattened rings
Flattened cartilage rings	Tracheomalacia
Uniform narrowing	Hypoplastic trachea
Strictures	Prior trauma
Mass lesions	Fractured rings, foreign body granuloma, neoplasia
Tears	Usually caused by excessive endotracheal tube cuff pressure
Carina	
Widened	Hilar lymphadenopathy, extraluminal mass
Multiple raised nodules	*Oslerus osleri*
Foreign body	Foreign body
Bronchi	
Hyperemia, excess mucus, exudate	Inflammation
Collapse of airway during expiration	Chronic inflammation, bronchomalacia
Collapse of airway, inspiration and expiration, ability to pass scope through narrowed airway	Chronic inflammation, bronchomalacia
Collapse of airway, inspiration and expiration, inability to pass scope through narrowed airway	Extraluminal mass lesions (neoplasia, granuloma, abscess)
Collapse of airway with "puckering" of mucosa	Lung lobe torsion
Hemorrhage	Neoplasia, fungal infection, heartworm, thromboembolic disease, coagulopathy, trauma (including foreign body related)
Single mass lesion	Neoplasia
Multiple polypoid masses	Usually chronic bronchitis; at carina, *Oslerus*
Foreign body	Foreign body

The femoral artery is commonly used (Fig. 20.28). The animal is placed in lateral recumbency. The upper rear limb is abducted, and the rear limb resting on the table is restrained in a partially extended position. The femoral artery is palpated in the inguinal region, close to the abdominal wall, using two fingers. The needle is advanced into the artery between these fingers. The artery is thick-walled and loosely attached to adjacent tissues; thus the needle must be sharp and positioned exactly on top of the artery. A short, jabbing motion facilitates entry.

The dorsal pedal artery is useful for arterial collection in medium-size and large dogs. The position of the artery is illustrated in Fig. 20.29.

Once the needle has penetrated the skin, suction is applied. On entry of the needle into the artery, blood should enter the syringe quickly, sometimes in pulses. Unless the animal is severely compromised, the blood will be bright red compared with the dark red of venous blood. Dark red blood or blood that is difficult to draw into the syringe may be obtained from a vein. Mixed samples from both the artery and the vein can be collected accidentally, particularly from the femoral site.

After removal of the needle, pressure is applied to the puncture site for 5 minutes to prevent hematoma formation. Pressure is applied even after unsuccessful attempts if there is any possibility that the artery was entered.

All air bubbles are eliminated from the syringe. The needle is covered by a cork or rubber stopper, and the entire syringe is placed in crushed ice unless the blood specimen is to be analyzed immediately. Specimens should be analyzed as soon as possible after collection. Minimal alterations occur in specimens stored on ice during the few hours required to transport the specimen to a human hospital if a blood gas analyzer is not available on site. Because of the availability of reasonably priced blood gas analyzers, point-of-care testing is now possible.

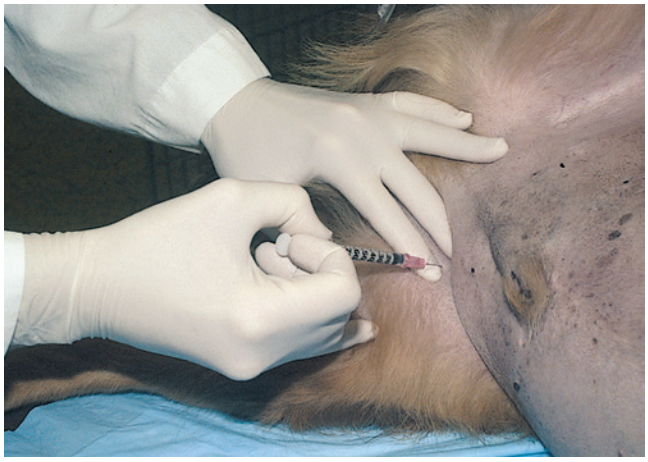

FIG 20.28
Position for obtaining an arterial blood specimen from the femoral artery. The dog is in left lateral recumbency. The right rear limb is being held perpendicular to the table to expose the left inguinal area. The pulse is palpated in the femoral triangle between two fingers to accurately locate the artery. The needle is laid directly on top of the artery, then is stabbed into it with a short, jabbing motion.

TABLE 20.5

Approximate Ranges of Arterial Blood Gas Values for Normal Dogs and Cats Breathing Room Air

MEASUREMENT	ARTERIAL BLOOD
Pa_{O_2} (mm Hg)	85-100
Pa_{CO_2} (mm Hg)	35-45
H_{CO_3} (mmol/L)	21-27
pH	7.35-7.45

FIG 20.29
Position for obtaining an arterial blood specimen from the dorsal pedal artery. The dog is in left lateral recumbency, with the medial surface of the left leg exposed. A pulse is palpated just below the tarsus on the dorsal surface of the metatarsus between the midline and the medial aspect of the distal limb.

INTERPRETATION OF RESULTS

Approximate arterial blood gas values for normal dogs and cats are provided in Table 20.5. More exact values should be obtained for normal dogs and cats using the actual analyzer.

Pa_{O_2} and Pa_{CO_2}

Abnormal Pa_{O_2} and Pa_{CO_2} values can result from technical error. The animal's condition and the collection technique are considered in the interpretation of blood gas values. For example, an animal in stable condition with normal mucous membrane characteristics evaluated for exercise intolerance is unlikely to have a resting Pa_{O_2} of 45 mm Hg. The collection of venous blood is a more likely explanation for this abnormal value.

Hypoxemia is present if the Pa_{O_2} is below the normal range. The oxyhemoglobin dissociation curve describing the relationship between the saturated hemoglobin level and Pa_{O_2} is sigmoid in shape, with a plateau at higher Pa_{O_2} values (Fig. 20.30). Normal hemoglobin is almost totally saturated with oxygen when the Pa_{O_2} is greater than 80 to 90 mm Hg, and clinical signs are unlikely in animals with such values. The curve begins to decrease more quickly at lower Pa_{O_2} values. A value of less than 60 mm Hg corresponds to a hemoglobin saturation that is considered dangerous, and treatment for hypoxemia is indicated. (See the section on oxygen content, delivery, and utilization later in this chapter.)

In general, animals become cyanotic when the Pa_{O_2} reaches 50 mm Hg or less, which results in a concentration of nonoxygenated (unsaturated) hemoglobin of 5 g/dL or more. Cyanosis occurs as a result of the increased concentration of nonoxygenated hemoglobin in the blood and is not a direct reflection of the Pa_{O_2}. The development of cyanosis depends on the total concentration of hemoglobin, as well as on the oxygen pressure; cyanosis develops more quickly in animals with polycythemia than in animals with anemia. Acute hypoxemia resulting from lung disease more often

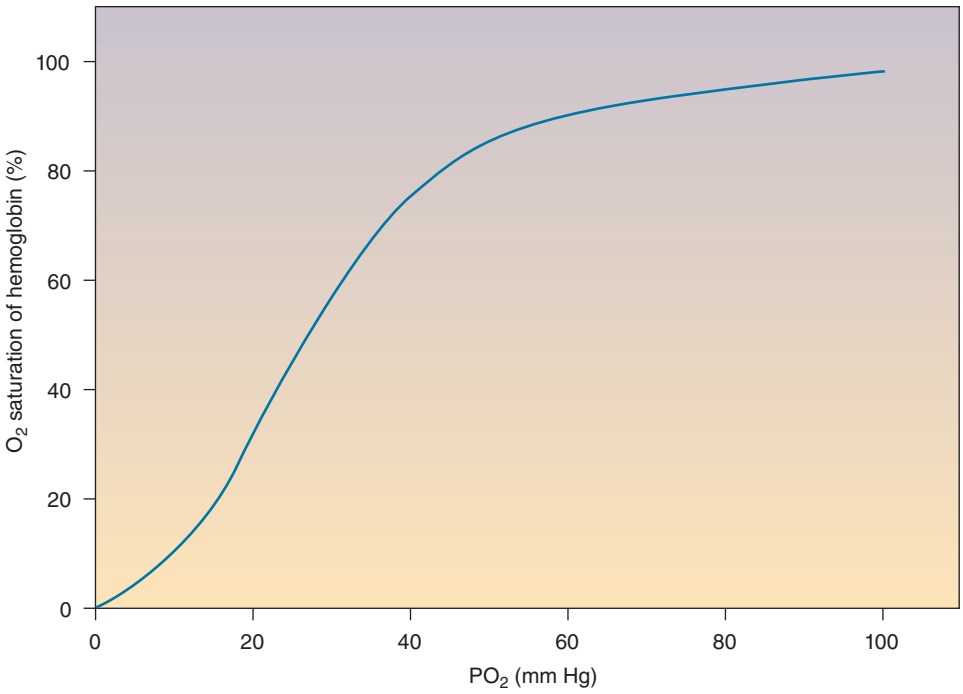

FIG 20.30
Oxyhemoglobin dissociation curve (approximation).

produces pallor in an animal than cyanosis. Treatment for hypoxemia is indicated for all animals with cyanosis.

Determining the mechanism of hypoxemia is useful in selecting appropriate supportive therapy. These mechanisms include hypoventilation, inequality of ventilation and perfusion within the lung, and diffusion abnormality. Hypoventilation is the inadequate exchange of gases between the outside of the body and the alveoli. Both Pa_{O_2} and Pa_{CO_2} are affected by lack of gas exchange, and hypercapnia occurs in conjunction with hypoxemia. Causes of hypoventilation are listed in Box 20.7.

The ventilation and perfusion of different regions of the lung must be matched for the blood leaving the lung to be fully oxygenated. The relationship between ventilation ($\dot{V}$) and perfusion ($\dot{Q}$) can be described as a ratio ($\dot{V}/\dot{Q}$). Hypoxemia can develop if regions of lung have a low or a high $\dot{V}/\dot{Q}$.

Poorly ventilated portions of lung with normal blood flow have a low $\dot{V}/\dot{Q}$. Regionally decreased ventilation occurs in most pulmonary diseases for reasons such as alveolar flooding, alveolar collapse, or small airway obstruction. The flow of blood past totally nonaerated tissue is known as a venous admixture or shunt ($\dot{V}/\dot{Q}$ of zero). The alveoli may be unventilated as a result of complete filling or collapse, resulting in physiologic shunts, or the alveoli may be bypassed by true anatomic shunts. Unoxygenated blood from these regions then mixes with oxygenated blood from ventilated portions of the lung. The immediate result consists of decreased Pa_{O_2} and increased Pa_{CO_2}. The body responds to hypercapnia by increasing ventilation, effectively returning the Pa_{CO_2} to normal or even lower than normal. However,

BOX 20.7

Clinical Correlations of Blood Gas Abnormalities

Decreased Pa_{O_2} and Increased Pa_{CO_2} (Normal A-a Gradient)

Venous specimen
Hypoventilation
- Airway obstruction
- Decreased ventilatory muscle function
  - Anesthesia
  - Central nervous system disease
  - Polyneuropathy
  - Polymyopathy
  - Neuromuscular junction disorders (myasthenia gravis)
  - Extreme fatigue (prolonged distress)
- Restriction of lung expansion
  - Thoracic wall abnormality
  - Excessive thoracic bandage
  - Pneumothorax
  - Pleural effusion
- Increased dead space (low alveolar ventilation)
  - Severe chronic obstructive pulmonary disease/emphysema

End-stage severe pulmonary parenchymal disease
Severe pulmonary thromboembolism

Decreased Pa_{O_2} and Normal or Decreased Pa_{CO_2} (Wide A-a Gradient)

Ventilation/perfusion ($\dot{V}/\dot{Q}$) abnormality
- Most lower respiratory tract diseases (see Box 19.1)

increased ventilation cannot correct the hypoxemia because blood flowing by ventilated alveoli is already maximally saturated.

Except where shunts are present, the Pao_2 can be improved in dogs and cats with lung regions with low $\dot{V}/\dot{Q}$ by providing supplemental oxygen therapy administered by face mask, oxygen cage, or nasal catheter. Positive-pressure ventilation may be necessary to combat atelectasis (see Chapter 25).

Ventilation of areas of lung with decreased circulation (high $\dot{V}/\dot{Q}$) occurs in dogs and cats with thromboembolism. Initially there may be little effect on arterial blood gas values because blood flow is shifted to unaffected regions of the lung. However, blood flow in normal regions of the lungs increases with increasing severity of disease, and $\dot{V}/\dot{Q}$ is decreased enough in those regions that a decreased Pao_2 and a normal or decreased $Paco_2$ may occur, as described previously. Both hypoxemia and hypercapnia are seen in the setting of extremely severe embolization.

Diffusion abnormalities alone do not result in clinically significant hypoxemia but can occur in conjunction with $\dot{V}/\dot{Q}$ mismatching in diseases such as idiopathic pulmonary fibrosis and noncardiogenic pulmonary edema. Gas is normally exchanged between the alveoli and the blood by diffusion across the respiratory membrane. This membrane consists of fluid lining the alveolus, alveolar epithelium, alveolar basement membrane, interstitium, capillary basement membrane, and capillary endothelium. Gases must also diffuse through plasma and red blood cell membranes. Functional and structural adaptations that facilitate diffusion between alveoli and red blood cells provide an efficient system for this process, which is rarely affected significantly by disease.

A-a Gradient

Hypoventilation is differentiated from $\dot{V}/\dot{Q}$ abnormalities by evaluation of the $Paco_2$ in conjunction with the Pao_2. Qualitative differences are described in the preceding paragraphs. Hypoventilation is associated with hypoxemia and hypercapnia, and $\dot{V}/\dot{Q}$ abnormalities are generally associated with hypoxemia and normocapnia or hypocapnia. It is possible to quantify this relationship by calculating the alveolar-arterial oxygen gradient (*A-a* gradient), which factors out the effects of ventilation and the inspired oxygen concentration on Pao_2 (Table 20.6).

TABLE 20.6

Relationships of Arterial Blood Gas Measurements

FORMULA	DISCUSSION
$Pao_2 \propto Sao_2$	Relationship is defined by sigmoid oxyhemoglobin dissociation curve. Curve plateaus at greater than 90% Sao_2 with Pao_2 values greater than 80 mm Hg. Curve is steep at Pao_2 values of between 20 and 60 mm Hg (assuming normal hemoglobin, pH, temperature, and 2,3-diphosphoglycerate concentrations).
$Cao_2 = (Sao_2 \times Hgb \times 1.34) + (0.003 \times Pao_2)$	Total oxygen content of blood is greatly influenced by Sao_2 and hemoglobin concentration. In health, more than 60 times more oxygen is delivered by hemoglobin than is dissolved in plasma (Pao_2).
$Paco_2 = PAco_2$	These values are increased with hypoventilation at alveolar level and are decreased with hypoventilation.
$PAo_2 = Flo_2 (P_B - PH_2O) - Paco_2/R$ On room air at sea level: $PAo_2 = 150$ mm Hg $- Paco_2/0.8$	Partial pressure of oxygen in alveolar air available for exchange with blood changes directly with inspired oxygen concentration and inversely with $Paco_2$. R is assumed to be 0.8 for fasting animals. With normally functioning lungs (minimal $\dot{V}/\dot{Q}$ mismatch), alveolar hyperventilation results in increased PAo_2 and subsequently increased Pao_2, whereas hypoventilation results in decreased PAo_2 and decreased Pao_2.
A-a = $PAo_2 - Pao_2$	*A-a* gradient quantitatively assesses $\dot{V}/\dot{Q}$ mismatch by eliminating contribution of alveolar ventilation and inspired oxygen concentration to measured Pao_2. Low Pao_2, with a normal *A-a* gradient (10 mm Hg in room air) indicates hypoventilation alone. Low Pao_2 with a wide *A-a* gradient (>15 mm Hg in room air) indicates a component of $\dot{V}/\dot{Q}$ mismatch.
$Paco_2 \propto 1/pH$	Increased $Paco_2$ causes respiratory acidosis; decreased $Paco_2$ causes respiratory alkalosis. Actual pH depends on metabolic (Hco_3) status as well.

A-a, Alveolar-arterial oxygen gradient (mm Hg); *Cao_2,* oxygen content of arterial blood (mL of O_2/dL); *Flo_2,* fraction of oxygen in inspired air (%); *Hgb,* hemoglobin concentration (g/dL); *$Paco_2$,* partial pressure of CO_2 in arterial blood (mm Hg); *$PAco_2$,* partial pressure of O_2 in alveolar air (mm Hg); *Pao_2,* partial pressure of O_2 in arterial blood (mm Hg); *PAo_2,* partial pressure of O_2 in alveolar air (mm Hg); *P_B,* barometric (atmospheric) pressure (mm Hg); *PH_2O,* partial pressure of water in alveolar air (100% humidified) (mm Hg); *pH,* negative logarithm of H^+ concentration (decreases with increased H^+); *R,* respiratory exchange quotient (ratio of O_2 uptake per CO_2 produced); *Sao_2,* amount of hemoglobin saturated with oxygen (%); *$\dot{V}/\dot{Q}$,* ratio of ventilation to perfusion of alveoli.

The premise of the *A-a* gradient is that Pa_{O_2} *(a)* is nearly equal (within 10 mm Hg in room air) to the partial pressure of oxygen in the alveoli, PA_{O_2} *(A),* in the absence of a diffusion abnormality or $\dot{V}/\dot{Q}$ mismatch. In the presence of a diffusion abnormality or a $\dot{V}/\dot{Q}$ mismatch, the difference widens (greater than 15 mm Hg in room air). Examination of the equation reveals that hyperventilation, resulting in a lower Pa_{CO_2}, leads to a higher PA_{O_2}. Conversely, hypoventilation, resulting in a higher Pa_{CO_2}, leads to a lower PA_{O_2}. Physiologically the Pa_{O_2} can never exceed the PA_{O_2}, however, and the finding of a negative value indicates an error. The error may be found in one of the measured values or in the assumed R value (see Table 20.6).

Clinical examples of the calculation and interpretation of the *A-a* gradient are provided in Box 20.8.

Oxygen Content, Delivery, and Utilization

The commonly reported blood gas value Pa_{O_2} reflects the pressure of oxygen dissolved in arterial blood. This value is critical for assessing lung function. However, the clinician must remember that other variables are involved in oxygen delivery to the tissues besides Pa_{O_2}, and that tissue hypoxia can occur in spite of a normal Pa_{O_2}. The formula for calculating the total oxygen content of arterial blood (Ca_{O_2}) is provided in Table 20.6. The greatest contribution to Ca_{O_2} in health is oxygenated hemoglobin. In a normal dog (Pa_{O_2}, 100 mm Hg; hemoglobin, 15 g/dL), oxygenated hemoglobin accounts for 20 mL of O_2/dL, whereas dissolved oxygen accounts for only about 0.3 mL of O_2/dL.

The quantity of hemoglobin is routinely appraised by the complete blood count. It can also be estimated on the basis of the packed cell volume (by dividing the packed cell volume by 3). The oxygen saturation of hemoglobin (Sa_{O_2}) is dependent on the Pa_{O_2}, as depicted by the sigmoid shape of the oxyhemoglobin dissociation curve (see Fig. 20.30). However, the Sa_{O_2} is also influenced by other variables that can shift the oxyhemoglobin dissociation curve to the left or right (e.g., pH, temperature, 2,3-diphosphoglycerate concentrations) or interfere with oxygen binding with hemoglobin (e.g., carbon monoxide toxicity, methemoglobinemia). Some laboratories measure Sa_{O_2}.

Oxygen must be successfully delivered to the tissues, and this depends on cardiac output and local circulation. Ultimately, the tissues must be able to effectively use the oxygen—a process interfered with in the presence of toxicities such as carbon monoxide or cyanide poisoning. Each of these processes must be considered when the blood gas values in an individual animal are interpreted.

Acid-Base Status

The acid-base status of an animal can be assessed using the same blood sample that is used to measure blood gases. Acid-base status is influenced by the respiratory system (see Table 20.6). Respiratory acidosis results if carbon dioxide is retained as a result of hypoventilation. If the problem persists for several days, compensatory retention of bicarbonate by the kidneys occurs. Excess removal of carbon dioxide by the lungs caused by hyperventilation results in respiratory alkalosis. Hyperventilation is usually an acute phenomenon, potentially caused by shock, sepsis, severe anemia, anxiety, or pain; therefore compensatory changes in the bicarbonate concentration are rarely seen.

The respiratory system partially compensates for primary metabolic acid-base disorders, and this can occur quickly. Hyperventilation and a decreased Pa_{CO_2} occur in response to metabolic acidosis. Hypoventilation and an increased Pa_{CO_2} occur in response to metabolic alkalosis.

In most cases, acid-base disturbances can be identified as primarily respiratory or primarily metabolic in nature on the basis of the pH. The compensatory response will never be excessive and alter the pH beyond normal limits. An animal with acidosis (pH of less than 7.35) has a primary respiratory acidosis if the Pa_{CO_2} is increased and a compensatory respiratory response if the Pa_{CO_2} is decreased. An animal with alkalosis (pH of greater than 7.45) has a primary respiratory alkalosis if the Pa_{CO_2} is decreased and a compensatory respiratory response if the Pa_{CO_2} is increased.

If both the Pa_{CO_2} and the bicarbonate concentration are abnormal, such that both contribute to the same alteration in pH, a mixed disturbance is present. For instance, an animal with acidosis, an increased Pa_{CO_2}, and a decreased HCO_3 has a mixed metabolic and respiratory acidosis.

BOX 20.8

Calculation and Interpretation of *A-a* Gradient: Clinical Examples

Example 1: A healthy dog breathing room air has a Pa_{O_2} of 95 mm Hg and a Pa_{CO_2} of 40 mm Hg. His calculated PA_{O_2} is 100 mm Hg. ($PA_{O_2} = FI_{O_2}[P_B - PH_2O] - Pa_{CO_2}/R = 0.21\ [765\ mm\ Hg - 50\ mm\ Hg] - [40\ mm\ Hg/0.8]$.) The *A-a* gradient is 100 mm Hg – 95 mm Hg = 5 mm Hg. This value is normal.

Example 2: A dog with respiratory depression due to an anesthetic overdose has a Pa_{O_2} of 72 mm Hg and a Pa_{CO_2} of 56 mm Hg in room air. His calculated PA_{O_2} is 80 mm Hg. The *A-a* gradient is 8 mm Hg. His hypoxemia can be explained by hypoventilation.

Later the same day, the dog develops crackles bilaterally. Repeat blood gas analysis shows a PaO_2 of 60 mm Hg and a $PaCO_2$ of 48 mm Hg. His calculated PAO_2 is 90 mm Hg. The *A-a* gradient is 30 mm Hg. Hypoventilation continues to contribute to the hypoxemia, but hypoventilation has improved. The widened *A-a* gradient indicates $\dot{V}/\dot{Q}$ mismatch. This dog has aspirated gastric contents into his lungs.

PULSE OXIMETRY

Indications

Pulse oximetry is a method of monitoring the oxygen saturation of blood. The saturation of hemoglobin with oxygen is

related to the Pa_{O_2} by the sigmoid oxyhemoglobin dissociation curve (see Fig. 20.30). Pulse oximetry is noninvasive, can be used to continuously monitor a dog or cat, provides immediate results, and is affordable for most practices. It is a particularly useful device for monitoring animals with respiratory disease that must undergo procedures requiring anesthesia. It can also be used in some cases to monitor the progression of disease or the response to therapy. More and more clinicians are using these devices for routine monitoring of animals under general anesthesia.

METHOD

Most pulse oximeters have a probe attached to a fold of tissue, such as the tongue, lip, ear flap, inguinal skin fold, toe, or tail (Fig. 20.31). This probe measures light absorption through the tissues. Other models measure reflected light and can be placed on mucous membranes or within the esophagus or rectum. Artifacts resulting from external light sources are minimized in the latter sites. Arterial blood is identified by the oximeter as that component which changes in pulses. Nonpulsatile absorption is considered background.

INTERPRETATION

Values provided by the pulse oximeter must be interpreted with care. The instrument must record a pulse that matches the palpable pulse of the animal. Any discrepancy between actual pulse and the pulse received by the oximeter indicates an inaccurate reading. Common problems that can interfere with the accurate detection of pulses include the position of the probe, animal motion (e.g., respirations, shivering), and weak or irregular pulse pressures (e.g., tachycardia, hypovolemia, hypothermia, arrhythmias).

The value measured indicates the saturation of hemoglobin in the local circulation. However, this value can be affected by factors other than pulmonary function, such as vasoconstriction, low cardiac output, and local stasis of blood. Other intrinsic factors that can affect oximetry readings include anemia, hyperbilirubinemia, carboxyhemoglobinemia, and methemoglobinemia. External lights and the location of the probe can also influence results. Pulse oximetry readings of oxygen saturation are less accurate when values are below 80%.

These sources for error should not discourage the clinician from using this technology, however, because changes in saturation in an individual animal provide valuable information. Rather, results must be interpreted critically.

Examination of the oxyhemoglobin dissociation curve (see Fig. 20.30) in normal dogs and cats shows that animals with Pa_{O_2} values exceeding 85 mm Hg will have a hemoglobin saturation greater than 95%. If Pa_{O_2} values decrease to 60 mm Hg, the hemoglobin saturation will be approximately 90%. Any further decrease in Pa_{O_2} results in a precipitous decrease in hemoglobin saturation, as illustrated by the steep portion of the oxyhemoglobin dissociation curve. Ideally, then, hemoglobin saturation should be maintained at greater than 90% by means of oxygen supplementation or ventilatory support (see Chapter 25) or specific treatment of the underlying disease. However, because of the many variables associated with pulse oximetry, such strict guidelines are not always valid. In practice, a baseline hemoglobin saturation value is measured, and subsequent changes in that value are then used to assess improvement or deterioration in oxygenation. Ideally, the baseline value is compared with the Pa_{O_2} obtained from an arterial blood sample collected concurrently to ensure the accuracy of the readings.

FIG 20.31
Monitoring oxygen saturation in a cat under general anesthesia using a pulse oximeter with a probe *(P)* clamped onto the tongue *(T)*.

CHAPTER 21

Disorders of the Trachea and Bronchi

GENERAL CONSIDERATIONS

Common diseases of the trachea and bronchi include canine infectious respiratory disease complex (CIRDC), canine chronic bronchitis, feline bronchitis, collapsing trachea, and allergic bronchitis. *Oslerus osleri* infection is an important consideration in young dogs.

Other diseases may involve the airways, either primarily or concurrently with pulmonary parenchymal disease. These diseases, such as viral and bacterial pneumonia, other parasitic infections, and neoplasia are discussed in Chapter 22. Feline bordetellosis can cause signs of bronchitis (e.g., cough) but is more often associated with signs of upper respiratory disease (see the section on feline upper respiratory infection in Chapter 15) or bacterial pneumonia (Chapter 22).

CANINE INFECTIOUS RESPIRATORY DISEASE COMPLEX, INCLUDING CANINE INFLUENZA

Etiology and Client Communication Challenges

CIRDC, also known as *canine infectious tracheobronchitis* or "kennel cough," is a highly contagious, acute disease involving the airways. In most dogs, CIRDC is self-limiting, with resolution of clinical signs in approximately 2 weeks. Many different viral and bacterial pathogens can cause this syndrome (Box 21.1). The role of *Mycoplasma* spp. in respiratory infection of any kind is likely complex, with frequent isolation of organisms from apparently healthy individuals. However, several studies strongly support a role for *Mycoplasma cynos*, in particular, in CIRDC. Co-infection with two or more of the organisms listed in Box 21.1 is common and may result in more severe clinical signs.

Some dogs infected with organisms of CIRDC will develop pneumonia. The pneumonia can be a direct effect of the CIRDC organism, particularly with infections with *B. bronchiseptica* and canine influenza. Secondary bacterial infection can also occur, enabled by damage to host defenses. For instance, *Bordetella* organisms infect ciliated respiratory epithelium (Fig. 21.1) and decrease mucociliary clearance. Pneumonias are discussed further in Chapter 22.

Many clients have the misunderstanding that kennel cough equals infection with *Bordetella bronchiseptica*. They believe that the "kennel cough" vaccine (meaning, a *Bordetella* vaccine) prevents the disease and that antibiotics should cure the disease. They are confused by conflicting information about canine influenza virus infections. Some have read about devastating pneumonia, some have been told by boarding facilities that they must vaccinate their dog before they can use the facility, and some have been told by their veterinarian that vaccination is not indicated.

An effective means of educating clients is to emphasize the similarities between CIRDC and colds and flu in people (Box 21.2). The human medical profession has made strong efforts to educate the public on influenza in the context of vaccination, and colds in the context of the overuse of antibiotics. Further, most people have direct personal experience with colds and flu.

In both CIRDC and "colds and flu," many different agents are involved. Being infected with one agent does not preclude being infected with another. A person is more likely to develop infection if he, she, or family members regularly find themselves in group settings (e.g., daycare, working environments with large staff, interaction with the public), just as dogs are more likely to be infected with frequent exposure to other dogs (e.g., boarding or grooming facilities, dog parks, dog shows and trials, pet stores, shelters). Most people and dogs recover without antibiotics or supportive care, and, in fact, viruses will not respond to antibacterial drugs, but some people and dogs develop pneumonia and require aggressive treatment. Rarely, people and dogs die from their infection or its consequences. Vaccines for specific agents involved in CIRDC do not prevent infection, and none is completely effective in preventing signs, just as the influenza vaccine does not prevent all infections or signs in people. People and dogs are more likely to become seriously ill if they are compromised in some way before infection, but sometimes a particularly virulent strain of organism will arise with severe consequences for even healthy people or dogs.

BOX 21.1

Agents Associated With Canine Infectious Respiratory Disease Complex (Infectious Tracheobronchitis, "Kennel Cough")

Viruses

Canine adenovirus 2
Canine influenza viruses (H3N8, H3N2)
Canine parainfluenza virus
Canine herpesvirus—type1
Canine respiratory coronavirus
Canine pneumovirus

Bacteria

Bordetella bronchiseptica
Streptococcus equi, subsp. *zooepidemicus*
Mycoplasma cynos
Other *Mycoplasma* spp.

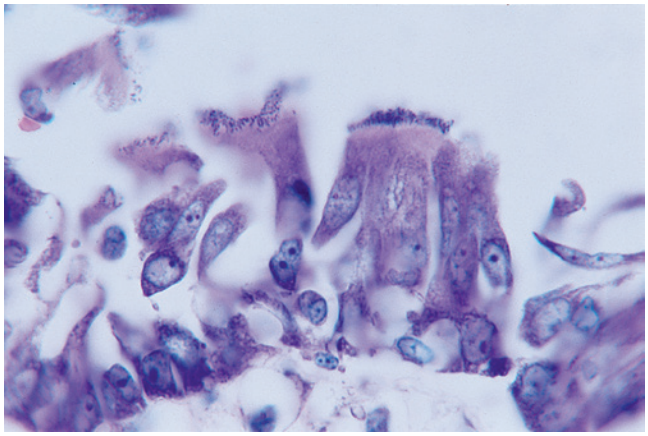

FIG 21.1
Photomicrograph of a tracheal biopsy specimen from a dog infected with *Bordetella bronchiseptica*. The organisms are small basophilic rods that are visible along the ciliated border of the epithelial cells. (Giemsa stain courtesy D. Malarkey.)

Be aware that, although rare, *B. bronchiseptica* has been documented to cause infection in people. A discussion regarding the potential exposure of a dog with CIRDC to immunocompromised individuals is warranted.

Clinical Features

Affected dogs are first seen because of the sudden onset of a severe productive or nonproductive cough, which is often exacerbated by exercise, excitement, or pressure of the collar on the neck. Palpating the trachea easily induces the cough. Gagging, retching, or nasal discharge can also occur. A recent history (i.e., within 2 weeks) of boarding, hospitalization, or exposure to a puppy or dog that has similar signs is common. Puppies recently obtained from pet stores, kennels, or shelters have often been exposed to the pathogens.

BOX 21.2

Client Education for Canine Infectious Respiratory Disease Complex (CIRDC)

CIRDC is like colds and flu in people. The following information is often well understood by the general public regarding colds and flu and correlates well with CIRDC.

- More than one type of organism is responsible
  - Being infected with, or vaccinated for, one organism does not prevent being infected with another
- Some people never get sick
- Some people get sick frequently
- More people get sick if they are frequently exposed to children or the general public
- Most people recover without any specific treatment
- Some people develop pneumonia and some people die, usually as a result of:
  - Particularly virulent organisms
  - Underlying respiratory disease (such as bronchitis or asthma)
  - Immune compromise or debilitation
  - Being very old or very young
- Vaccines are not completely effective
- Antibiotics are not usually necessary and are ineffective against viruses

Most dogs with CIRDC are considered to have "uncomplicated," self-limiting disease and do not show signs of systemic illness. Therefore dogs showing respiratory distress, weight loss, persistent anorexia, or signs of involvement of other organ systems, such as diarrhea, chorioretinitis, or seizures, may have some other, more serious disease, such as canine distemper or a mycotic infection. Secondary bacterial pneumonia can develop particularly in puppies, immunocompromised dogs, and dogs that have preexisting lung abnormalities such as chronic bronchitis. Dogs with chronic airway disease or tracheal collapse can experience an acute, severe exacerbation of their chronic problems, and extended management may be necessary to resolve the signs associated with infection in these animals. *B. bronchiseptica* infection has been associated with canine chronic bronchitis.

Diagnosis

Uncomplicated cases of CIRDC are diagnosed on the basis of presenting signs. However, differential diagnoses should also include the early presentation of a more serious disease. Diagnostic testing is indicated for dogs with systemic, progressive, or unresolving signs. Tests to be considered include thoracic radiographs, a complete blood count (CBC), tracheal wash fluid analysis, polymerase chain reaction (PCR) testing, paired serology, or other tests for the respiratory pathogens listed in Box 21.1. Tracheal wash fluid cytology shows acute inflammation, and bacterial culture of the fluid can be useful for identifying any bacteria involved in the

disease and for obtaining antibiotic sensitivity information to guide antibiotic selection.

Testing for specific pathogens by serology or PCR rarely provides information that will redirect treatment of an individual dog but may be helpful in managing outbreaks. Consultation with the diagnostic laboratory is recommended for optimizing results. The timing and recommended site of specimen collection varies with the infection of greatest concern. Serology for canine influenza viruses is the most sensitive method to detect infection but will be falsely negative before seroconversion. Influenza viruses are most readily identified by PCR from nasal swabs. The H3N8 strain is only shed early in the course of disease, whereas the H3N2 strain has been identified for as long as 26 days (Newbury et al., 2016). Testing by PCR for other CIRDC organisms is generally performed on pharyngeal swabs, although testing of bronchial brushings or airway washings would minimize false positive results from the carrier state. Positive PCR results can be obtained for up to 28 days in dogs that have been vaccinated with intranasal *B. bronchiseptica*, canine parainfluenza virus (PIV), and canine adenovirus 2 (CAV2) (Ruch-Galle et al., 2016). A negative PCR result for any of the CIRDC organisms does not rule out the possibility of their involvement.

Treatment

Uncomplicated CIRDC is a self-limiting disease. Rest for at least 7 days, specifically avoiding exercise and excitement, is indicated to minimize the continual irritation of the airways caused by excessive coughing. Cough suppressants are valuable for the same reason but should not be given if the cough is overtly productive or if exudate is suspected to be accumulating in the lungs on the basis of auscultation or thoracic radiograph findings. Because CIRDC is a tracheobronchitis, dogs with CIRDC will have exudate and excess mucus in their airways whether apparent externally or not. Therefore cough suppressants should be used judiciously to treat frequent or severe cough, to allow for restful sleep, and to prevent exhaustion.

A variety of cough suppressants can be used in dogs (Table 21.1). Dextromethorphan is available in over-the-counter preparations; however, it has questionable efficacy in dogs. Cold remedies with additional ingredients such as antihistamines and decongestants should be avoided. Pediatric liquid preparations are palatable for most dogs, and the alcohol contained in them may have a mild tranquilizing effect. Narcotic cough suppressants are more likely to be effective. Butorphanol is available as a veterinary labeled product (Torbutrol, Zoetis, Parsippany, NJ). Hydrocodone bitartrate is a potent alternative for dogs with refractory cough.

In theory, antibiotics are not indicated for most dogs with CIRDC for two reasons: (1) The disease is usually self-limiting and tends to resolve spontaneously, regardless of any specific treatment that is implemented, and (2) no antibiotic protocol has been proven to eliminate *Bordetella* or *Mycoplasma* organisms from the airways. The Antimicrobial Guidelines Working Group of the International Society for Companion Animal Infectious Disease (ISCAID) recommends that antimicrobial treatment be considered within the first 10 days of signs ONLY if fever, lethargy, or inappetence is present together with mucopurulent discharges (Lappin et al., 2017). In practice, however, antibiotics are often prescribed, and their use is justified because of the potential presence of these organisms. Doxycycline (5 mg/kg q12h or 10 mg/kg q24h, followed by a bolus of water) is effective against *Mycoplasma* spp. and many *Bordetella* isolates. Although the ability of doxycycline to reach therapeutic concentration within the airways has been questioned because it is highly protein bound in the dog, the presence of inflammatory cells may increase locally available concentrations of the drug and account for its anecdotal success. Amoxicillin with clavulanate (11 mg/kg orally q8h) is effective, in vitro, against many *Bordetella* isolates. Fluoroquinolones provide the advantage of reaching high concentrations in the airway secretions, but their use is ideally reserved for more serious infections. Bacterial susceptibility data from tracheal wash fluid can be used to guide the selection of an appropriate antibiotic. Antibiotics are administered for 5 days beyond the time the clinical signs resolve, or for at least 10 days.

Glucocorticoids should not be used. No field studies have demonstrated any benefit of steroid therapy, either alone or in combination with antibiotics.

If clinical signs have not resolved within 2 weeks, further diagnostic evaluation is considered. As with colds and flu in people, signs may be prolonged in some instances but careful monitoring is in order. See Chapter 22 for the management of bacterial pneumonia.

TABLE 21.1

Common Cough Suppressants for Use in Dogs*

AGENT	DOSAGE
Dextromethorphan†	1-2 mg/kg PO q6-8h
Butorphanol	0.5 mg/kg PO q6-12h
Hydrocodone bitartrate	0.25-0.5 mg/kg PO q6-12h

PO, By mouth.
*Centrally acting cough suppressants are rarely, if ever, indicated for use in cats and can result in adverse reactions. The preceding dosages are for dogs only.
†Efficacy is questionable in dogs.

Prognosis

The prognosis for recovery from uncomplicated CIRDC is excellent.

Prevention

CIRDC can be prevented by minimizing an animal's exposure to organisms and by providing vaccination programs. Excellent nutrition, routine deworming, and avoidance of stress improve the dog's ability to respond appropriately to infection without showing serious signs. Studies in shelters

and rehoming facilities have shown that the major variable associated with development of cough in newly arrived dogs is time in the facility.

Organisms can be shed by infected dogs before the onset of clinical signs. After the onset of signs, canine influenza virus (H3N2) was isolated from an infected dog after 26 days, although most dogs were negative by PCR of nasal swabs after 20 days (Newbury et al., 2016). Therefore a minimum isolation period of at least 21 days for dogs with signs of CIRDC is prudent. *Bordetella* may persist in the airways of dogs for up to 3 months after infection, but it has been assumed that shedding is minimal once clinical signs have completely resolved.

To minimize exposure to CIRDC organisms, dogs are kept isolated from puppies or dogs that have been recently boarded. Careful sanitation should be practiced in kenneling facilities. Caretakers should be instructed in the disinfection of cages, bowls, and runs, and everyone working with the dogs must wash their hands after handling each animal. Dogs should not be allowed to have face-to-face contact. Adequate air exchange and humidity control are necessary in rooms housing several dogs. Recommended goals are at least 10 to 15 air exchanges per hour and less than 50% humidity. An isolation area is essential for the housing of dogs with clinical signs of infectious tracheobronchitis. Facilities experiencing chronic problems should be referred to a shelter medicine specialist (www.sheltervet.org).

In the veterinary setting, reception staff should be trained to recognize historic signs that could be associated with CIRDC. Dogs with such signs should not be allowed into the waiting room but rather taken directly (ideally through a different entrance away from any other dogs) into an examination room. Protective clothing should be worn as some organisms can survive on clothing. Careful disinfection practices should be followed.

Injectable and intranasal vaccines are available for three of the major pathogens involved in CIRDC (i.e., *B. bronchiseptica*, PIV, and CAV2). An oral vaccine is available for *B. bronchiseptica*. Injectable modified-live virus vaccines are available against CAV2 and PIV. Killed, injectable vaccines are available for both identified strains of canine influenza virus (H3N8 and H3N2), including in combination as a bivalent vaccine.

Modified-live CAV2 and PIV are conveniently included in most combination distemper vaccines and are considered core vaccines. Because maternal antibodies interfere with the response to vaccines, puppies must be vaccinated with the combination distemper vaccines every 2 to 4 weeks, beginning at 6 to 8 weeks of age and through 14 to 16 weeks of age. At least two vaccines must be given initially. For most healthy dogs, a booster is recommended after 1 year, followed by subsequent vaccinations every 3 years (see Chapter 93).

Dogs at high risk for disease, such as those in kennels where the disease is endemic, those that participate in group dog sports or activities, or those that are frequently boarded, may benefit from annual vaccination against *B. bronchiseptica* and canine influenza. These vaccines do not prevent infection but aim to decrease clinical signs should infection occur. They may also reduce the duration of shedding of organisms after infection. A study by Ellis et al. (2001) indicated that both intranasal and parenteral *Bordetella* vaccines afford similar protection based on antibody titers, clinical signs, upper airway cultures, and histopathologic examination of tissues after exposure to organisms. The greatest benefit was achieved by administering both forms of vaccine sequentially at 2-week intervals (two doses of parenteral vaccine and then a dose of intranasal vaccine), but such an aggressive schedule is not routinely recommended. Also in experimental settings, protection against challenge after intranasal vaccination against *B. bronchiseptica* and PIV began by 72 hours (but not earlier) after vaccination and persisted for at least 13 months (Gore, 2005; Jacobs et al., 2005). Again in an experimental setting, intranasal vaccination against *B. bronchiseptica* provided superior protection compared with oral vaccination (Ellis et al., 2016). Intranasal *Bordetella* vaccines occasionally cause clinical signs, predominantly cough. The signs are generally self-limiting but are disturbing to most owners.

Canine influenza vaccines are killed products, and a booster vaccination is required 2 to 4 weeks after initial vaccination to achieve protection. Annual vaccination is recommended thereafter for dogs at risk.

CANINE CHRONIC BRONCHITIS

Etiology

Canine chronic bronchitis is a disease syndrome defined clinically as cough that occurs on most days of 2 or more consecutive months in the past year in the absence of other active disease. Histologic changes in the airways are those of long-term inflammation and include fibrosis, epithelial hyperplasia, glandular hypertrophy, and inflammatory infiltrates. Some of these changes are irreversible. Excessive mucus is present within the airways, and small airway obstruction occurs. In people, chronic bronchitis is strongly associated with smoking. It is presumed that canine chronic bronchitis is a consequence of a long-standing inflammatory process initiated by infection, allergy, or inhaled irritants or toxins. A continuing cycle of inflammation likely occurs as mucosal damage, mucus hypersecretion, and airway obstruction impair normal mucociliary clearance, and inflammatory mediators amplify the response to irritants and organisms.

Clinical Features

Chronic bronchitis occurs most often in middle-aged or older, small-breed dogs. Breeds commonly affected include Terriers, Poodles, and Cocker Spaniels. Small-breed dogs are also predisposed to the development of tracheobronchomalacia and mitral insufficiency with left atrial enlargement. These causes for cough must be differentiated, and their contribution to the development of the current clinical features determined, for appropriate management to be implemented.

Dogs with chronic bronchitis are evaluated because of loud, harsh cough. Mucus hypersecretion is a component of the disease, but the cough may sound productive or nonproductive. The disease has usually progressed slowly over months to years, although clients typically report the initial onset as acute. There should be no systemic signs of illness such as anorexia or weight loss. As the disease progresses, exercise intolerance becomes evident; then incessant coughing or overt respiratory distress is seen.

Potential complications of chronic bronchitis include bacterial or mycoplasmal infection, tracheobronchomalacia (discussed later in this chapter), pulmonary hypertension (see Chapter 22), and bronchiectasis. *Bronchiectasis* is the term for permanent dilation of the airways (Fig. 21.2; see also Fig. 20.4). Bronchiectasis can be present secondary to other causes of chronic airway inflammation or airway obstruction, and in association with certain congenital disorders such as ciliary dyskinesia (i.e., immotile cilia syndrome). Bronchiectasis caused by traction on the airways, rather than bronchial disease, can be seen with idiopathic pulmonary fibrosis. Generally, all the major airways are dilated in dogs with bronchiectasis, but occasionally the condition is localized. Recurrent bacterial infection and overt bacterial pneumonia are common complications in dogs with bronchiectasis.

Dogs with chronic bronchitis are often brought to a veterinarian because of a sudden exacerbation of signs. The change in signs may result from transient worsening of the chronic bronchitis, perhaps after a period of unusual excitement, stress, or exposure to irritants or allergens; from a secondary complication, such as bacterial infection; or from the development of a concurrent disease, such as left atrial enlargement or heart failure (Box 21.3). In addition to providing a routine complete history, the client should be carefully questioned about the character of the cough and the progression of signs. Detailed information should be obtained regarding the following: environmental conditions, particularly exposure to smoke, other potential irritants and toxins, or allergens; exposure to infectious agents, such as boarding or exposure to puppies; and all previous and current medications and responses to treatment.

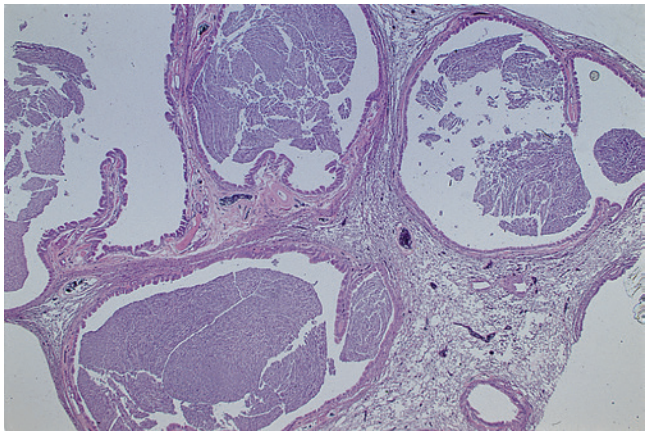

FIG 21.2
Photomicrograph of a lung biopsy specimen from a dog with severe bronchiectasis. The airways are filled with exudate and are greatly dilated (hematoxylin and eosin [H&E] stain).

On physical examination, increased breath sounds, crackles, or occasionally wheezes are auscultated in animals with chronic bronchitis. End-expiratory clicks caused by mainstem bronchial or intrathoracic tracheal collapse may be heard in animals with advanced disease. A prominent or split second heart sound occurs in animals with secondary pulmonary hypertension. Dogs with respiratory distress (end-stage disease) characteristically show marked expiratory efforts because of narrowing and collapse of the intrathoracic large airways. The presence of a fever or other systemic signs is suggestive of other disease, such as bacterial pneumonia.

Diagnosis

Canine chronic bronchitis is defined as a cough that occurs on most days of 2 or more consecutive months in the past year *in the absence of other active disease*. Therefore chronic bronchitis is diagnosed on the basis of not only clinical signs but also the elimination of other diseases from the list of differential diagnoses (see Box 21.3). The possibility of secondary or concurrent disease complicates this simple definition.

BOX 21.3

Diagnostic Considerations for Dogs With Signs Consistent With Canine Chronic Bronchitis

Other Active Disease (Rather Than Canine Chronic Bronchitis)

Bacterial infection
Mycoplasmal infection
Left atrial enlargement
Pulmonary parasites
Heartworm disease
Allergic bronchitis
Neoplasia
Foreign body
Chronic aspiration
Gastroesophageal reflux*

Potential Complications of Canine Chronic Bronchitis

Tracheobronchomalacia
Pulmonary hypertension
Bacterial infection
Mycoplasmal infection
Bronchiectasis

Most Common Concurrent Cardiopulmonary Diseases

Tracheobronchomalacia
Left atrial enlargement
Heart failure

*Gastroesophageal reflux is a common cause of chronic cough in people. Documentation in dogs and cats is limited.

A bronchial pattern with increased interstitial markings is typically seen on thoracic radiographs, but changes are often mild and difficult to distinguish from clinically insignificant changes associated with aging, and radiographs may be completely unremarkable. Thoracic radiographs are most useful for identifying *other* causes of cough or secondary diseases.

Tracheal wash or bronchoalveolar lavage (BAL) fluid should be collected at the time of the initial presentation and after a persistent exacerbation of signs. Tracheal wash will usually provide a sufficient specimen in diffuse airway disease. Neutrophilic or mixed inflammation and increased amounts of mucus are usually present. The finding of degenerative neutrophils indicates the possibility of a bacterial infection. Airway eosinophilia is suggestive of a hypersensitivity reaction, as can occur with allergy, parasitism, or heartworm disease. Slides should be carefully examined for organisms. Bacterial cultures are performed and the results interpreted as discussed in Chapter 20. Although the role of *Mycoplasma* infection in these cases is not well understood, *Mycoplasma* cultures or PCR are also considered.

Bronchoscopy, with specimen collection, is performed in selected cases, primarily to help rule out other diseases. The maximal benefit of bronchoscopy is obtained early in the course of disease, before severe permanent damage has occurred and while the risk of the procedure is minimal. Gross abnormalities visualized by bronchoscopy include an increased amount of mucus, roughened mucosa, and hyperemia (Video 21.1). Major airways may collapse during expiration as a result of weakened walls (Fig. 21.3), and polypoid mucosal proliferation may be present. Bronchial dilation may be visualized in animals with bronchiectasis.

Further diagnostic procedures are indicated to rule out other potential causes of chronic cough, and selection of these depends on the presenting signs and results of the previously discussed diagnostic tests. Diagnostic tests to be considered include heartworm tests, fecal examinations for pulmonary parasites (flotation, Baermann, and sediment examinations), echocardiography, and systemic evaluation (i.e., CBC, serum biochemical panel, urinalysis). Echocardiography may reveal evidence of secondary pulmonary hypertension, including right heart enlargement (i.e., cor pulmonale).

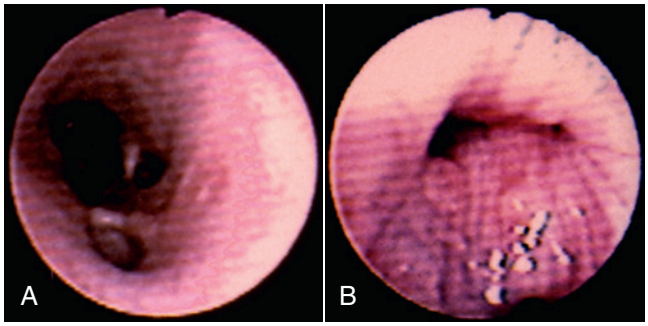

FIG 21.3
Bronchoscopic view of the right caudal bronchus of a dog with chronic bronchitis and severe bronchomalacia. The airways appear normal during inspiration **(A)** but completely collapse during expiration, obliterating the lumen of the airway **(B).**

Ciliary dyskinesia, in which ciliary motion is abnormal, is uncommon but should be considered in young dogs with bronchiectasis or recurrent bacterial infection. Abnormalities exist in all ciliated tissues, and situs inversus (i.e., lateral transposition of the abdominal and thoracic organs, such that left-sided structures are found on the right and vice versa) is seen in 50% of such dogs. Dextrocardia that occurs in association with chronic bronchitis is extremely suggestive of this disease. Sperm motility can be evaluated in intact male dogs. The finding of normal sperm motility rules out a diagnosis of ciliary dyskinesia. The disease is diagnosed on the basis of the rate at which radioisotopes deposited at the carina are cleared and the findings from electron microscopic examination of bronchial biopsy, nasal biopsy, or sperm specimens.

Treatment

Chronic bronchitis is managed symptomatically, with specific treatment possible only for concurrent or complicating diseases that are identified. Each dog with chronic bronchitis is presented at a different stage of the disease, with or without concurrent or secondary cardiopulmonary disease (see Box 21.3). Hence each dog must be managed individually. Ideally, medications are initiated one at a time to allow assessment of the most effective combination. It will likely be necessary to modify treatment over time.

GENERAL MANAGEMENT

Exacerbating factors, either possible or proven, are avoided. Potential allergens are considered in dogs with eosinophilic inflammation and trial elimination pursued (see the section on allergic bronchitis). Exposure to irritants such as smoke (from tobacco or fireplace) and perfumed products should be avoided in all dogs. Motivated clients can take steps to improve the air quality in their home through carpet, furniture, and drapery cleaning; cleaning of the furnace and frequent replacement of air filters; and the use of an air cleaner. The American Lung Association has a useful Web site with nonproprietary recommendations for improving indoor air quality (www.lung.org). Excitement or stress can cause an acute worsening of signs in some animals, and short-term tranquilization with acepromazine or sedation with phenobarbital can be helpful in relieving the signs for short periods. Anxiolytic drugs, such as trazadone, may be beneficial if long-term control is needed.

It is normal for flora from the oropharynx to be aspirated into the airways. Routine dental prophylaxis and teeth brushing will help maintain a healthy oral flora and may decrease any contributions of normal aspiration to ongoing airway inflammation in patients with reduced mucociliary clearance.

Airway hydration should be maintained to facilitate mucociliary clearance. Adequate airway hydration is best

achieved by maintaining systemic hydration. Therefore diuretic therapy is not recommended in these patients. For severely affected dogs, placing the animal in a steamy bathroom or in a room with a vaporizer daily may provide symptomatic relief, although the moisture does not penetrate very deeply into the airways. Nebulization of saline will allow moisture to go more deeply into the lungs. This technique is discussed further in the section on bacterial pneumonia in Chapter 22.

Patients that are overweight and/or unfit may benefit from weight loss (see Chapter 51) and exercise. Exercise should be tailored to the dog's current fitness level and degree of pulmonary dysfunction to keep from causing excessive respiratory efforts or even death. Observing the dog during specific exercise, such as a short walk, while in the client's presence may be necessary to make initial recommendations. Instructing clients in measurement of respiratory rate, observation of mucous membrane color, and signs of increased respiratory effort will improve their ability to assess the dog's status during exercise.

DRUG THERAPIES

Medications to control clinical signs include bronchodilators, glucocorticoids, and cough suppressants.

Theophylline, a methylxanthine bronchodilator, has been used for years for the treatment of chronic bronchitis in people and dogs (Box 21.4). This drug became unpopular with physicians when newer bronchodilators with fewer side effects became available. However, research in people suggests that theophylline is effective in treating the underlying inflammation of chronic bronchitis, even at concentrations below those resulting in bronchodilation (hence, reducing side effects), and that the antiinflammatory effects may be synergistic with those of glucocorticoids. Theophylline may also improve mucociliary clearance, decrease fatigue of respiratory muscles, and inhibit the release of mast cell mediators of inflammation. The potential beneficial effects of theophylline beyond bronchodilation may be of particular importance in dogs because their airways are not as reactive (i.e., likely to bronchospasm) as those of cats and people. However, theophylline alone is rarely sufficient to control the clinical signs of chronic bronchitis except in mild cases

Another advantage associated with theophylline is that plasma concentrations of drug can be easily measured by commercial diagnostic laboratories. A disadvantage of theophylline is that other drugs, such as fluoroquinolones, can delay its clearance, causing signs of theophylline toxicity if the dosage is not reduced by one third to one half, or the dosage interval doubled. Potential adverse effects include gastrointestinal signs, cardiac arrhythmias, nervousness, and seizures. Serious adverse effects are extremely rare at therapeutic concentrations.

Variability in sustained plasma concentrations has been noted for different theophylline products. At the time of this writing, only immediate-acting products are commercially available. If beneficial effects are not seen at the initial dosage selected, if the patient is predisposed to adverse effects, or if adverse effects occur, plasma theophylline concentrations should be measured. Therapeutic peak concentration for bronchodilation, based on data from people, ranges from 10 to 20 µg/mL, whereas antiinflammatory effects may occur at 5 to 10 µg/mL (Barnes, 2003). To confirm that plasma concentrations are being maintained in this range, blood is collected immediately before the next scheduled dose.

Sympathomimetic drugs are preferred by some clinicians as bronchodilators (see Box 21.4). Terbutaline and albuterol are selective for β2-adrenergic receptors, lessening their cardiac effects. Potential adverse effects include nervousness, tremors, hypotension, and tachycardia. Clinical use of bronchodilators delivered by MDI, such as albuterol and ipratropium (a parasympatholytic), has not been investigated for dogs with chronic bronchitis.

Glucocorticoids are generally the most effective treatment for controlling the signs of chronic bronchitis and may slow the development of permanent airway damage by decreasing inflammation. They may be particularly helpful in dogs with eosinophilic airway inflammation. Potential negative effects include increased susceptibility to infection in dogs already impaired by decreased airway clearance; a tendency toward obesity, hepatomegaly, and muscle weakness that may adversely affect ventilation; and pulmonary thromboembolism. Therefore short-acting products are used, the dose is tapered to the lowest effective one, and the drug is discontinued if no beneficial effect is seen.

Prednisone is initially given at a dose of 0.5 to 1 mg/kg orally q12h, with a positive response expected within 1 week. The initial dosage is continued until the cough has resolved or its intensity and frequency have reached a plateau. The subsequent taper should be slow, until the least effective dose is reached (ideally 0.5 mg/kg orally q48h or less of prednisone). Dogs with highly motivated owners, and dogs that

require relatively high dosages of prednisone, have unacceptable adverse effects, or have conditions for which glucocorticoids are relatively contraindicated (e.g., diabetes mellitus) may benefit from local treatment with metered dose inhalers (MDIs). This route of administration is discussed in greater detail later in this chapter, in the section on feline bronchitis.

Cough suppressants are used cautiously because cough is an important mechanism for clearing airway secretions. In some dogs, however, the cough is incessant and exhausting, or ineffective, because of marked tracheobronchomalacia. Cough suppressants can provide significant relief for such animals and may even facilitate ventilation and decrease anxiety. Although the doses given in Table 21.1 are the ones that provide prolonged effectiveness, less frequent administration (i.e., only during times of the day when coughing is most severe) may preserve some beneficial effect of cough. For dogs with severe cough, hydrocodone may provide the greatest relief.

Maropitant may be considered as a cough suppressant in dogs that cannot tolerate even low dosages of narcotic antitussives. Although there was no benefit in reducing airway inflammation, Grobman and Reinero (2016) reported a decrease in cough as described by owners of dogs with bronchitis. Maximal effect may not be seen before 1 to 2 weeks of treatment.

MANAGEMENT OF COMPLICATIONS

Antibiotics are often prescribed for dogs with chronic bronchitis. If possible, confirmation of infection and antibiotic sensitivity information should be obtained by culture of an airway specimen (e.g., tracheal wash fluid). Because cough in dogs with chronic bronchitis often waxes and wanes in severity, it is difficult to make a diagnosis of infection on the basis of the patient's response to therapy. Furthermore, organisms involved in bronchial infections generally originate from the oropharynx. They are frequently gram-negative with unpredictable antibiotic sensitivity patterns. The role of *Mycoplasma* organisms in canine chronic bronchitis is not well understood. They may be an incidental finding, or they may be pathogenic. Ideally, antibiotic selection is based on results of culture. Antibiotics that are generally effective against *Mycoplasma* include doxycycline, azithromycin, chloramphenicol, and fluoroquinolones.

In addition to the susceptibility of identified organisms, the ability of candidate antibiotics to penetrate the airway secretions to the site of infection should be considered when selecting an antibiotic. Antibiotics that are likely to reach concentrations effective against susceptible organisms include fluoroquinolones, azithromycin, chloramphenicol, and possibly amoxicillin with clavulanate. β-Lactam antibiotics do not generally reach therapeutic concentrations in airway secretions of healthy (not inflamed) subjects. If used for bronchial infection, the high end of the dosage range should be used.

Doxycycline is often recommended because *Mycoplasma* and many *Bordetella* isolates are susceptible to this drug. It may confer an additional benefit of mild antiinflammatory properties. The ability of doxycycline to reach therapeutic concentration within the airways is questionable because in the dog it is highly protein bound, but the presence of inflammatory cells may increase locally available concentrations of the drug. It is preferable to reserve fluoroquinolones for cases of serious infection.

If an antibiotic is effective, a positive response is generally seen within 1 week. Treatment is then continued for at least 1 week beyond the time when the clinical signs stabilize because complete resolution is unlikely in these animals. Antibiotic treatment usually is necessary for 3 to 4 weeks. Even longer treatment may be necessary in some cases, particularly if bronchiectasis or overt pneumonia is present. The use of antibiotics for the treatment of respiratory tract infection is also discussed in the section on CIRDC in this chapter and in the section on bacterial pneumonia in Chapter 22.

Tracheobronchomalacia is discussed later in this chapter, and pulmonary hypertension is discussed in Chapter 22.

Prognosis

Canine chronic bronchitis cannot be completely cured. The prognosis for the control of signs and for a satisfactory quality of life in animals is good if owners are conscientious about performing the medical management aspects of care and are willing to adjust treatment over time and treat secondary problems as they occur.

FELINE BRONCHITIS (IDIOPATHIC)

Etiology

Cats with respiratory disease of many origins present with signs of bronchitis or asthma. Cat airways are much more reactive and prone to bronchoconstriction than those of dogs. The common presenting signs of bronchitis (i.e., cough, wheezing, and/or respiratory distress) can occur in cats with diseases as varied as lung parasites, heartworm disease, allergic bronchitis, bacterial or viral bronchitis, toxoplasmosis, idiopathic pulmonary fibrosis, carcinoma, and aspiration pneumonia (Table 21.2). Veterinarians often assume that cats with presenting signs of bronchitis or asthma have idiopathic disease because in most cats an underlying cause cannot be found. However, as with canine chronic bronchitis, a diagnosis of idiopathic feline bronchitis can be made only by ruling out other active disease. **Care should be taken when using the terms *feline bronchitis* or *feline asthma* to distinguish between a presentation consistent with bronchitis in a broad sense and a clinical diagnosis of idiopathic disease.** Cats with idiopathic bronchitis often have some degree of airway eosinophilia, typical of an allergic reaction. This author prefers to reserve the diagnosis of allergic bronchitis for patients who respond dramatically to the elimination of a suspected allergen (see the section on allergic bronchitis later in this chapter).

A wide variety of pathologic processes can affect individual cats with idiopathic bronchitis. Clinically, the range in

TABLE 21.2

Differential Diagnoses (Etiologic) for Cats With Presenting Signs of Bronchitis

DIAGNOSIS	DISTINGUISHING FEATURES COMPARED WITH IDIOPATHIC FELINE BRONCHITIS
Allergic bronchitis	Dramatic clinical response to elimination of suspected allergen(s) from environment or diet.
Pulmonary parasites *(Aelurostrongylus abstrusus, Capillaria aerophila, Paragonimus kellicotti)*	Thoracic radiographs may have a nodular pattern; larvae *(Aelurostrongylus)* or eggs identified in tracheal wash or BAL fluid or in the feces. See Chapter 20 for appropriate procedures for fecal testing.
Heartworm disease	Pulmonary artery enlargement may be present on thoracic radiographs; positive heartworm antigen test or identification of adult worm(s) on echocardiography (see Chapter 10).
Bacterial bronchitis	Intracellular bacteria in tracheal wash or BAL fluid and significant growth on culture (see Chapter 20).
Mycoplasmal bronchitis	Positive PCR test or growth of *Mycoplasma* on specific culture of tracheal wash or BAL fluid (presence may indicate primary infection or secondary infection, or may be incidental).
Idiopathic pulmonary fibrosis	Radiographs may show more severe infiltrates than expected in cats with idiopathic bronchitis. CT findings may be supportive. Diagnosis requires lung biopsy (see Chapter 22).
Carcinoma	Radiographs may show more severe infiltrates than expected in cats with idiopathic bronchitis. Cytologic or histologic identification of malignant cells in tracheal wash or BAL fluid, lung aspirates, or lung biopsy. CT findings may be supportive. Histologic confirmation is ideal.
Toxoplasmosis	Systemic signs usually present (fever, anorexia, depression). Radiographs may show more severe infiltrates than expected in cats with idiopathic bronchitis, possibly with a nodular pattern. Diagnosis is confirmed by identification of organisms (tachyzoites) in tracheal wash or BAL fluid. Rising serum antibody titers or elevated IgM concentrations are supportive of the diagnosis (see Chapter 98).
Aspiration pneumonia	Unusual in cats. History supportive of a predisposing event or condition. Radiographs typically show an alveolar pattern, worse in the dependent (cranial and middle) lung lobes. Neutrophilic inflammation, usually with bacteria, in tracheal wash fluid.
Idiopathic feline bronchitis	Elimination of other diseases from the differential diagnoses.

BAL, Bronchoalveolar lavage; *CT,* computed tomography; *PCR,* polymerase chain reaction.

severity of signs and responses to therapy shows this diversity. Different combinations of factors that result in small airway obstruction—a consistent feature of feline bronchial disease—are present in each animal (Box 21.5). Some of these factors (e.g., bronchospasm, inflammation) are reversible, and others (e.g., fibrosis, emphysema) are permanent. The classification proposed by Moise et al. (1989), which was formulated on the basis of similar pathologic processes that occur in people, is recommended as a way to better define bronchial disease in individual cats for the purpose of treatment recommendations and prognostication (Box 21.6). A cat can have more than one type of bronchitis. Although it is not always possible to absolutely determine the type or types of bronchial disease present without performing sophisticated pulmonary function testing, routine clinical data (i.e., history and physical examination findings, thoracic radiographs, analysis of airway specimens,

BOX 21.5

Factors That Can Contribute to Small Airway Obstruction in Cats With Bronchial Disease

Bronchoconstriction
Bronchial smooth muscle hypertrophy
Increased mucus production
Decreased mucus clearance
Inflammatory exudate in airway lumens
Inflammatory infiltrate in airway walls
Epithelial hyperplasia
Glandular hypertrophy
Fibrosis
Emphysema

BOX 21.6

Classification of Feline Bronchial Disease

Bronchial Asthma

Predominant feature: reversible airway obstruction primarily resulting from bronchoconstriction
Other common features: hypertrophy of smooth muscle, increased mucus production, eosinophilic inflammation

Acute Bronchitis

Predominant feature: reversible airway inflammation of short duration (<1-3 months)
Other common features: increased mucus production, neutrophilic or macrophagic inflammation

Chronic Bronchitis

Predominant feature: chronic airway inflammation (>2-3 months) resulting in irreversible damage (e.g., fibrosis)
Other common features: increased mucus production; neutrophilic, eosinophilic, or mixed inflammation; isolation of bacteria or *Mycoplasma* organisms causing infection or as nonpathogenic inhabitants; concurrent bronchial asthma

Emphysema

Predominant feature: destruction of bronchiolar and alveolar walls resulting in enlarged peripheral air spaces
Other common features: cavitary lesions (bullae); result of or concurrent with chronic bronchitis

Adapted from Moise NS et al.: Bronchopulmonary disease. In Sherding RG, ed.: *The cat: diseases and clinical management,* New York, 1989, Churchill Livingstone.

progression of signs) can be used to classify the disease in most cats.

Clinical Features

Idiopathic bronchitis can develop in cats of any age, although it most commonly develops in young adult and middle-aged animals. The major clinical feature is cough or episodic respiratory distress or both. Some clients will confuse cough in cats with attempts to vomit a hairball. Cats that never produce a hairball are likely coughing. Owners may report audible wheezing during an episode. The signs are often slowly progressive. Weight loss, anorexia, depression, and other systemic signs are not present. If systemic signs are identified, another diagnosis should be aggressively pursued.

Owners should be carefully questioned regarding an association with exposure to potential allergens or irritants. Irritants in the environment can cause worsening of signs of bronchitis regardless of the underlying cause. Environmental considerations include exposure to new litter (usually perfumed), cigarette or fireplace smoke, carpet cleaners, and household items containing perfumes such as deodorant or hair spray. Clients should also be questioned about whether there has been any recent remodeling or any other change in the cat's environment. Seasonal exacerbations are suggestive of potential allergen exposure.

Physical examination abnormalities result from small airway obstruction. Cats that are in distress show tachypnea. Typically the increased respiratory efforts are more pronounced during expiration, and auscultation reveals expiratory wheezes. Crackles are occasionally present. In some patients in distress, hyperinflation of the lungs due to air trapping may result in increased inspiratory efforts and decreased lung sounds. Physical examination findings may be unremarkable between episodes.

Diagnosis

The diagnosis of idiopathic feline bronchitis is made on the basis of typical historical, physical examination, and thoracic radiographic findings and the elimination of other possible differential diagnoses (see Table 21.2). A thorough search for other diagnoses is highly recommended, even though a specific diagnosis is not commonly found, because identifying a cause for the clinical signs may enable specific treatment and even cure of an individual cat. Factors to consider when developing a diagnostic plan include the clinical condition of the cat and the client's tolerance for expense and risk. Cats that are in respiratory distress or are otherwise in critical condition should not undergo any stressful testing until their condition has stabilized. Sufficiently stable cats that have any indication of a diagnosis other than idiopathic disease on the basis of presenting signs and thoracic radiographs or any subsequent test results require a thorough evaluation. Certain tests are completely safe, such as fecal testing for pulmonary parasites, and their inclusion in the diagnostic plan is based largely on financial considerations. In most cats with signs of bronchitis, collection of tracheal wash fluid for cytology and culture and tests for pulmonary parasitism and heartworm disease are recommended.

A CBC is often performed as a routine screening test. Cats with idiopathic bronchitis are often thought to have peripheral eosinophilia. However, this finding is neither specific nor sensitive and cannot be used to rule out or definitively diagnose feline bronchitis.

The presence of a bronchial pattern on thoracic radiographs is supportive of a diagnosis of bronchitis (see Fig. 20.3). Increased reticular interstitial markings and patchy alveolar opacities may also be present. The lungs may be seen to be overinflated as a result of trapping of air, and occasionally collapse (i.e., atelectasis) of the right middle lung lobe is seen (see Fig. 20.9). However, radiographs are insensitive for the detection of bronchial disease and may be normal in cats with bronchitis. Radiographs are also scrutinized for signs of specific diseases (see Table 21.2).

Tracheal wash or BAL fluid cytologic findings are generally representative of airway inflammation and consist of increased numbers of inflammatory cells and an increased amount of mucus. Inflammation can be eosinophilic, neutrophilic, or mixed. Although not a specific finding, eosinophilic inflammation is suggestive of a hypersensitivity response to allergens or parasites. Neutrophils should

be examined for signs of degeneration, suggestive of bacterial infection. Slides should be carefully scrutinized for the presence of organisms, particularly bacteria and parasitic larvae or ova. Fluid should be cultured for bacteria, although it is important to note that the growth of organisms may or may not indicate the existence of true infection (see Chapter 20). Cultures or PCR for *Mycoplasma* spp. may also prove helpful.

Testing for heartworm disease is described in Chapter 10. Multiple fecal examinations using special concentrating techniques are performed to identify pulmonary parasites, particularly in young cats and cats with airway eosinophilia (see Chapter 20). Other tests may be indicated for individual cats.

Treatment

EMERGENCY STABILIZATION

The condition of cats in acute respiratory distress should be stabilized before diagnostic tests are performed. Successful treatment includes administration of a bronchodilator, rapid-acting glucocorticoids, and oxygen supplementation. Terbutaline can be administered subcutaneously—a route that avoids additional patient stress (see Box 21.4). Dexamethasone sodium phosphate (0.1 to 0.5 mg/kg) is administered intravenously. If intravenous administration is too stressful, it can be given subcutaneously or intramuscularly. After the drugs are administered, the cat is placed in a cool, stress-free, oxygen-enriched environment. If additional bronchodilation is desired, albuterol can be administered by nebulization or MDI. Administration of drugs by MDI is described later in this section. (See Chapter 25 for further discussion of cats with respiratory distress.)

ENVIRONMENT

The potential influence of the environment on clinical signs should be investigated. Allergic bronchitis is diagnosed through the elimination of potential allergens from the environment (see the section on allergic bronchitis). However, even cats with idiopathic bronchitis can benefit from improvement in indoor air quality through the reduction of irritants or unidentified allergens. Potential sources of allergens or irritants are determined through careful owner questioning as described in the section on clinical features. Smoke can often aggravate signs through its local irritating effects. The effect of litter perfumes can be evaluated by replacing the litter with sandbox sand or plain clay litter. Indoor cats may show improvement in response to measures taken to decrease the level of dusts, molds, and mildew in the home. Such measures include carpet, furniture, and drapery cleaning; cleaning of the furnace and frequent replacement of air filters; and the use of an air cleaner. The American Lung Association has a useful Web site with nonproprietary recommendations for improving indoor air quality (www.lung.org). Any beneficial response to an environmental change is usually seen within 1 to 2 weeks.

GLUCOCORTICOIDS

Therapy with glucocorticoids, with or without bronchodilators, is necessary for most cats with idiopathic bronchitis. Results can be dramatic. However, drug therapy can interfere with environmental testing; therefore the ability of the animal to tolerate a delay in the start of drug therapy must be assessed on an animal-by-animal basis. Glucocorticoids can relieve the clinical signs in most cats and may protect the airways from the detrimental effects of chronic inflammation. Short-acting products such as prednisolone are recommended because the dose can be tapered to the lowest effective amount. A dose of 0.5 to 1 mg/kg is administered orally q12h initially, with the dose doubled if signs are not controlled within 1 week. Once the signs are well controlled, the dose is tapered. A reasonable goal is to administer 0.5 mg/kg or less every other day. Although not ideal, outdoor cats that cannot be treated frequently can be administered depot steroid products, such as methylprednisolone acetate (10 mg/cat intramuscularly may be effective for up to 4 weeks).

Glucocorticoids, such as fluticasone propionate (Flovent, GSK), can also be administered locally to the airways by MDI, as is routine for treating asthma in people. Advantages include minimal systemic side effects and relative ease of administration in some cats compared with pilling. Theoretical concerns about the oronasal deposition of the potent glucocorticoid in cats, compared with people, include the high incidence of periodontal disease and latent herpesvirus infections and the inability to effectively rinse the mouth with water after use. Local dermatitis can be caused by mites, dermatophytes, or bacteria. However, veterinarians have been using glucocorticoid MDIs to treat idiopathic feline bronchitis for many years without frequent, obvious adverse effects.

This author prefers to obtain a clinical remission of signs using an orally administered drug first, except in cats with relative contraindications for systemic glucocorticoid therapy, such as diabetes mellitus. Cats that require a relatively low dose of oral glucocorticoids to control clinical signs, that have no noticeable adverse effects, and that can be pilled without difficulty are often well maintained with oral therapy. Otherwise, once signs are in remission, treatment by MDI is initiated and the dosage of oral prednisolone gradually reduced.

A spacer must be used for effective administration of drugs by MDI to cats or dogs, and the airflow generated by the cat must be sufficient to activate the spacer valve. Spacers with masks specifically designed for use in cats or dogs are available (AeroKat and AeroDawg, Trudell Medical International, London, Ontario, Canada). This design includes a plastic tab that moves with each breath, making it easier for the client to determine whether the cat is inhaling the drug. The cat is allowed to rest comfortably on a table or in the client's lap. The client places his or her arms on either side of the cat or gently steadies the cat's neck and head to provide restraint (Fig. 21.4). The MDI, attached to the spacer, is actuated (i.e., pressed) twice. The mask is placed immediately on

FIG 21.4
Administering drugs by metered dose inhaler (MDI) to a cat. The mask and chamber apparatus is the Aerokat (Trudell Medical International, London, Ontario, Canada).

the cat's face, with the mouth and nose covered completely, and is held in place while the cat takes 7 to 10 breaths, inhaling the drug into its airways. Excellent videotaped examples of clients treating their cats are readily available by web search.

The following treatment schedule has been recommended (Padrid, 2000): cats with mild daily symptoms should receive 220 µg of fluticasone propionate by MDI twice daily and albuterol by MDI as needed. The maximal effect of fluticasone is not expected until after 7 to 10 days of treatment. Cats with moderate daily symptoms should receive treatments with MDI as described for mild symptoms; in addition, prednisolone is administered orally for 10 days (1 mg/kg q12h for 5 days, then q24h for 5 days). For cats with severe symptoms, dexamethasone is administered once (0.5-1 mg/kg, intravenously), albuterol is administered by MDI every 30 minutes for up to 4 hours, and oxygen is administered. Once stabilized, these cats are prescribed 220 µg of fluticasone propionate by MDI every 12 hours and albuterol by MDI every 6 hours as needed. Oral prednisolone is administered as needed.

Studies using cats with experimentally induced allergic bronchitis have demonstrated beneficial effects with a lower dosage of 44 µg/puff (Cohn et al., 2010). This form of bronchitis may be less complicated than that seen in clinical patients, so I prefer to begin treatment with higher concentrations and then taper to the least effective dose. Fluticasone is also available at 110 µg/puff, which is a reasonable compromise for clinically stable cats.

Disturbing findings were reported from a study by Cocayne et al. (2011), indicating that 7 of 10 cats with naturally occurring bronchitis that had resolution of clinical signs during treatment with oral prednisolone had detectable airway inflammation based on BAL cytology. The long-term clinical significance of the persistent inflammation is not yet known, but this matter deserves further study.

BRONCHODILATORS

Cats that require relatively large quantities of glucocorticoids to control clinical signs, that react unfavorably to glucocorticoid therapy, or that suffer from periodic exacerbations of signs can benefit from bronchodilator therapy. Recommended doses of these drugs are listed in Box 21.4.

This author prefers to use theophylline because it is inexpensive and often is effective with once-daily administration; moreover, the plasma concentrations can be easily measured for monitoring of difficult cases. Additional properties of theophylline, potential drug interactions, and adverse effects are described in the previous section on canine chronic bronchitis.

The pharmacokinetics of theophylline products are different in cats than in dogs, resulting in different dosages (see Box 21.4). Variability in sustained plasma concentrations in both species has been found for different manufacturers of theophylline products, and long-acting products are not currently available. If beneficial effects are not seen, if the patient is predisposed to adverse effects, or if adverse effects occur, plasma theophylline concentrations should be measured. Therapeutic peak concentrations, based on data from human subjects, are 10 to 20 µg/mL. Plasma for determination of these concentrations should be collected immediately before the next scheduled dose.

Sympathomimetic drugs can also be effective bronchodilators. Terbutaline is selective for β2-adrenergic receptors, lessening its cardiac effects. Potential adverse effects include nervousness, tremors, hypotension, and tachycardia. It can be administered subcutaneously for the treatment of respiratory emergencies; it can also be administered orally. Note that the recommended oral dose for cats (one eighth to one fourth of a 2.5-mg tablet; see Box 21.4) is lower than the commonly cited dose of 1.25 mg/cat. The subcutaneous dose is lower still: 0.01 mg/kg, repeated once in 5 to 10 minutes if necessary.

Bronchodilators can be administered to cats by MDI for the immediate treatment of acute respiratory distress (asthma attack). Cats with idiopathic bronchitis are routinely prescribed an albuterol MDI, a spacer, and a mask (see the section on glucocorticoids for details) to be kept at home for emergencies.

OTHER POTENTIAL TREATMENTS

A therapeutic trial with an antibiotic effective against *Mycoplasma* is considered because of the difficulty in documenting infection with this organism. Doxycycline (5 mg/kg orally q12h or 10 mg/kg q24h) is administered for 14 days as a therapeutic trial. For cats that are difficult to medicate, azithromycin (5-10 mg/kg orally q12h for 1 day, then every 3 days) can be tried. If a *Mycoplasma* is isolated from airway specimens or if a therapeutic response is seen, prolonged treatment for months may be required to eliminate infection. Further study is needed. Remember that administration of doxycycline should always be followed by a bolus of water to minimize the incidence of esophageal stricture. In addition to antibacterial effects, evidence is

mounting that in people these drugs have antiinflammatory properties.

Much interest has been shown by clients and veterinarians in the use of oral leukotriene inhibitors in cats (e.g., Accolate, Singulair, Zyflo). However, the clinician should be aware that in people, leukotriene inhibitors are *less* effective than glucocorticoids in the management of asthma. Their main advantages for people lie in decreased side effects, compared with glucocorticoids, and ease of administration. To date, toxicity studies have not been performed on these drugs in cats. Furthermore, several preliminary studies suggest that leukotriene inhibition in cats would not be expected to have efficacy comparable with that in people. Therefore routine use of leukotriene inhibitors in cats is not currently advocated.

FAILURE TO RESPOND

The clinician should ask himself or herself the questions listed in Box 21.7 if cats fail to respond to glucocorticoid and bronchodilator therapy, or if exacerbation of signs occurs during long-term treatment.

Prognosis

The prognosis for the control of clinical signs of idiopathic feline bronchitis is good for most cats, particularly if extensive permanent damage has not yet occurred. Complete cure is unlikely, and most cats require continued medication. Cats that have severe, acute asthmatic attacks are at risk for sudden death. Cats with persistent, untreated airway inflammation can develop the permanent changes of chronic bronchitis and emphysema.

BOX 21.7

Considerations for Cats With Bronchitis That Fail to Respond to Glucocorticoid and Bronchodilator Therapy

Is the Cat Receiving Prescribed Medication?

Measure plasma theophylline concentrations.
Initiate trial therapy with repositol glucocorticoids.

Was an Underlying Disease Missed on Initial Evaluation?

Repeat diagnostic evaluation, including complete history for potential allergens, thoracic radiographs, tracheal wash fluid analysis, heartworm tests, and fecal examinations for parasites. In addition, perform complete blood count, serum biochemical analysis, and urinalysis.
Initiate trial therapy with anti-*Mycoplasma* drug.
Initiate trial environmental manipulations to minimize potential allergen and irritant exposure.

Has a Complicating Disease Developed?

Repeat diagnostic evaluation as described in the preceding sections.

TRACHEOBRONCHOMALACIA (COLLAPSING TRACHEA)

Etiology

The normal trachea is seen to be circular on cross section (see Figs. 21.7, *B*, and 20.27, *A*). An open lumen is maintained during all phases of quiet respiration by the cartilaginous tracheal rings, which are connected by fibroelastic annular ligaments to maintain flexibility, thereby allowing movement of the neck without compromising the airway. The cartilaginous rings are incomplete dorsally. The dorsal tracheal membrane, consisting of the longitudinal tracheal muscle and connective tissue, completes the rings. The term *tracheal collapse* refers to narrowing of the tracheal lumen resulting from weakening of the cartilaginous rings, redundancy of the dorsal tracheal membrane, or both.

This common description of tracheal collapse represents an oversimplification of the disease, which has several clinical pictures. Collapse can be the result of a congenital abnormality of small-breed dogs. In many dogs, a congenital predisposition is exacerbated by subsequent inflammatory disease or other exacerbating factors. Collapse can also occur in dogs of breeds *not* known to be congenitally predisposed, as a consequence of chronic airway inflammation. Further, the bronchi can be involved along with the trachea or alone, as the bronchial lumen is normally supported by rafts of cartilage within its walls. In human medicine the term *tracheobronchomalacia* (TBM) is used, and TBM is classified further as primary (congenital) or secondary (acquired). This terminology more accurately describes the range of disease observed in dogs and should be adopted by the veterinary profession.

That TBM can have a congenital basis in dogs is supported by its high prevalence in small-breed dogs. Also, several studies have demonstrated ultrastructural differences in the tracheal cartilage of toy breed dogs with collapsed tracheas, compared with those with normal tracheas. Signs may not develop until later in life in many of these dogs. Presumably, the onset of signs is initiated by an "acute on chronic" event. An exacerbating problem develops in an affected dog, which results in increased respiratory efforts, airway inflammation, and/or cough. Exacerbating problems could include upper airway obstruction, canine infectious respiratory disease complex (CIRDC), heart enlargement or failure, or parasitic disease, perhaps with contributions from obesity, exposure to tobacco smoke, or poor oral health. Changes in intrathoracic pressures and airway pressures during increased respiratory efforts or cough contribute to narrowing of the trachea and stretching of the dorsal ligament. With severe collapse, fluttering or physical trauma to the mucosa may further stimulate cough. Inflammation also contributes to an ongoing cycle of cough and collapse. Collagenases and proteases released by inflammatory cells may weaken the structure of the airways. Damage to the tracheal epithelium and changes in mucus composition and secretion impair airway clearance. Previously tolerable irritants and organisms may perpetuate inflammation and cough.

If the described exacerbating factors are sufficiently severe or chronic, even dogs without congenitally weak cartilages may develop TBM. Of course it is possible that these dogs, too, have congenital cartilage abnormalities, imbalances in their proinflammatory and antiinflammatory mediators, or other predisposing factors that as yet are not understood.

The clinical consequences of TBM include chronic, progressive cough that can ultimately lead to large airway obstruction. In some cases the signs of extrathoracic large airway obstruction predominate in the absence of cough. Most of these dogs develop increased inspiratory efforts with activity or stress, inspiratory stertor, and, eventually, episodes of hypoxemia. Because the chronic progressive cough of TBM is similar to that of chronic airway inflammation (e.g., idiopathic chronic bronchitis, eosinophilic bronchopneumopathy, bacterial bronchitis, parasitic disease), and because TBM can be a consequence of (or coincidental with) these conditions, a thorough and careful diagnostic evaluation is essential.

The prevalence of TBM in dogs is not known. Studies often originate from referral institutions and may overrepresent dogs with poorly responsive signs. In a report of bronchoscopies performed on 58 dogs, half had some form of airway collapse (Johnson et al., 2010). Bronchial collapse was reported in 35 of 40 (87.5%) brachycephalic dogs undergoing bronchoscopy (Delorenzi et al., 2009). We reported findings from 115 dogs with chronic cough, of which 59 (51%) had tracheobronchomalacia (Hawkins et al., 2010). In addition, 31 of 32 (97%) toy-breed dogs had TBM among their diagnoses.

Tracheal collapse is rare in cats and most often occurs secondary to a tracheal obstruction, such as from a tumor, foreign body, or traumatic injury.

Clinical Features

Tracheobronchomalacia can be primary or secondary and can affect the trachea and/or bronchi. More important, from a clinical perspective, is that collapse may occur predominantly in either the extrathoracic (cervical trachea and/or thoracic inlet) or intrathoracic (intrathoracic trachea and/or bronchial) airways. Dogs with predominantly extrathoracic tracheal collapse can present with signs of upper airway obstruction, including respiratory distress most pronounced on inspiration and audible stertorous sounds. If respiratory distress occurs in dogs with intrathoracic airway collapse, it tends to be more pronounced on expiration and is usually associated with an audible, loud wheeze/cough (Video 21.2).

It is possible that a relationship exists whereby extrathoracic airway collapse is more often associated with primary (congenital) TBM, and intrathoracic airway collapse is more often associated with secondary (occurring in a predisposed or nonpredisposed breed) TBM. This conjecture is partially supported by a study of tidal breathing flow-volume loops in toy and small-breed dogs with tracheal collapse and no evidence of other respiratory disease, in which abnormalities were seen predominantly in the inspiratory limb (Pardali et al., 2010). In a study of 18 dogs with bronchomalacia, but no tracheal collapse, inflammation was identified on BAL and bronchial biopsy, and the presenting cough was described as mild and wheezing (Adamama-Moraitou et al., 2012).

Overall, although any signalment is possible, TBM occurs most commonly in middle-aged toy and miniature dogs. Signs may occur acutely but then may slowly progress over months to years. The primary clinical feature in most dogs is a nonproductive cough, described as a "goose honk." The cough is worse during excitement or exercise, or when the collar exerts pressure on the neck. Eventually (usually after years of chronic cough), respiratory distress caused by obstruction to airflow may be brought on by excitement, exercise, or overheating. Systemic signs such as weight loss, anorexia, and depression are not expected.

As discussed, some dogs are presented primarily for signs of upper airway obstruction without cough, also exacerbated during excitement, exercise, or hot weather. Stertorous sounds may be heard during periods of increased respiratory efforts.

Tracheal collapse in cats is rare and usually secondary to another obstructive disease. Careful questioning regarding possible trauma and exposure to foreign bodies is indicated.

On physical examination a cough can usually be elicited by palpation of the trachea, particularly in those dogs presented with cough as the predominant sign. An end-expiratory snap or click may be heard during auscultation as a result of complete intrathoracic collapse. Patients with exercise intolerance or respiratory distress will demonstrate increased inspiratory efforts and stertorous sounds from collapse of the extrathoracic trachea, and an audible expiratory wheeze/cough from collapse of the intrathoracic trachea. It may be helpful to exercise dogs whose signs are moderate or intermittent to identify characteristic breathing patterns or sounds.

History and physical examination should also emphasize a search for exacerbating or complicating disease. The frequent association with canine chronic bronchitis has been mentioned. Other possibilities include cardiac disease causing left atrial enlargement from mitral valve dysplasia or pulmonary edema; airway inflammation caused by bacterial infection, allergic bronchitis, exposure to smoke (e.g., from cigarettes or fireplaces), or recent intubation; upper airway obstruction caused by elongated soft palate, stenotic nares, or laryngeal paralysis or collapse; and systemic disorders such as obesity or hyperadrenocorticism.

Diagnosis

Tracheobronchomalacia is most often diagnosed on the basis of clinical signs in conjunction with findings from cervical and thoracic radiography. Radiographs of the neck to evaluate the size of the lumen of the extrathoracic trachea are taken during inspiration (Fig. 21.5), when narrowing caused by tracheal collapse is more evident because of negative airway pressure. Conversely, the size of the lumen of the intrathoracic trachea is evaluated on thoracic radiographs taken during expiration, when increased intrathoracic pressures make collapse more apparent (Fig. 21.6). Radiographs

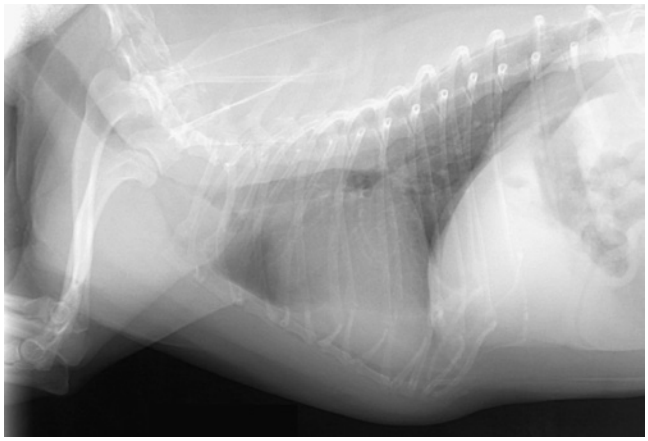

FIG 21.5
Lateral radiograph of the thorax and neck of a dog with collapsing trachea taken during inspiration. The extrathoracic airway stripe is severely narrowed cranial to the thoracic inlet.

of the thorax should also be taken during inspiration to detect concurrent bronchial or parenchymal abnormalities. (See Chapter 20 for further discussion of radiography.) It should be noted that the common radiographic finding of a redundant dorsal tracheal membrane can be a result of overlying soft tissue (most likely esophagus) rather than from TBM (Bylicki et al., 2015).

Fluoroscopic evaluation provides a "motion picture" view of large airway dynamics, making changes in luminal diameter easier to identify than by routine radiography. The sensitivity of fluoroscopy in detecting airway collapse is enhanced if the patient can be induced to cough during the evaluation by pressure applied to the trachea. Some degree of collapse is probably normal during cough, and in people a diagnosis of tracheobronchomalacia is generally made if luminal diameter decreases by more than 70% during forced exhalation. This criterion was recently increased from 50% because studies in people have shown that a strong cough can result in near total collapse in some apparently healthy individuals.

Bronchoscopy is also useful in the diagnosis of airway collapse (Fig. 21.7; see also Fig. 21.3). The bronchi of smaller dogs may be difficult to evaluate by radiography or fluoroscopy but are easily examined bronchoscopically. Bronchoscopy and the collection of airway specimens (such as by BAL and bronchial brushings) are useful for identifying exacerbating or concurrent conditions.

Bronchoscopy is performed with the patient under general anesthesia, which interferes with the ability to induce cough. However, allowing the patient to reach a light plane of anesthesia while the airways are manipulated will often cause more forceful respirations that increase the likelihood of identifying airway collapse.

Additional tests are performed to identify exacerbating or concurrent conditions. Tracheal wash fluid is analyzed by cytology and culture if bronchoscopy with specimen collection is not done. Other considerations include upper airway

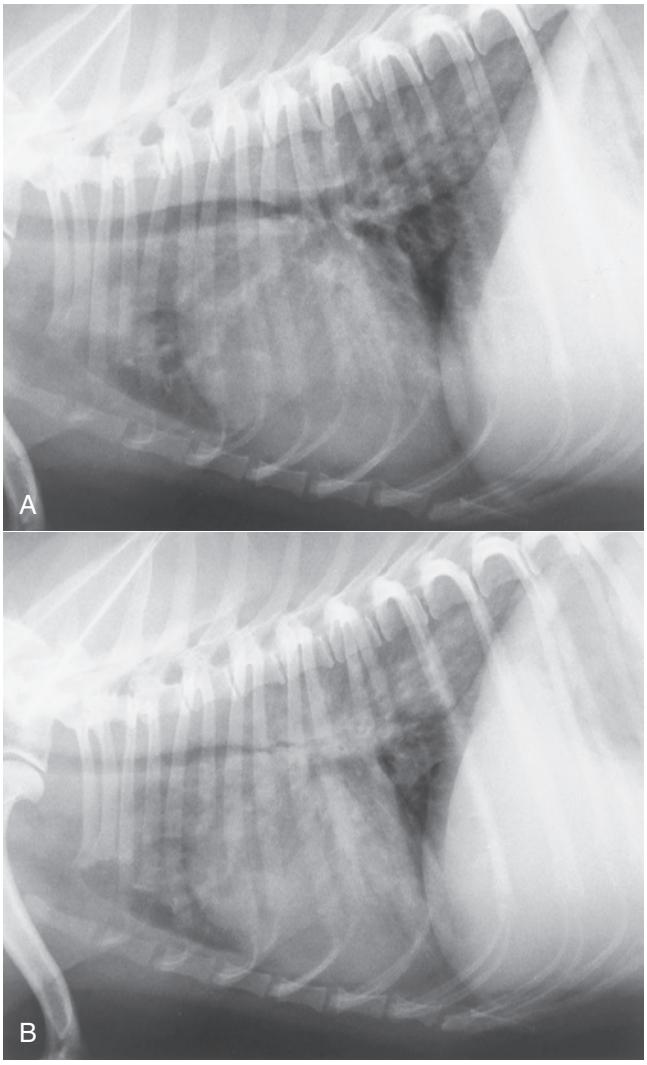

FIG 21.6
Lateral radiographs of a dog with tracheobronchomalacia. During inspiration **(A)** the trachea and mainstem bronchi are nearly normal. During expiration **(B)** the intrathoracic trachea and mainstem bronchi are markedly narrowed. Evaluation of the pulmonary parenchyma should not be attempted using films exposed during expiration.

examination, cardiac evaluation, and screening for systemic disease.

Treatment

Medical therapy is adequate treatment for most animals. In a study of 100 dogs by White et al. (1994), medical therapy resulted in resolution of signs for at least 1 year in 71% of cases. Dogs that are overweight are placed on a weight-reducing diet. Harnesses should be used instead of collars, and owners should be counseled to keep their dogs from becoming overheated (e.g., they should not be left in a car). Excessive excitement should be avoided. Sedatives such as phenobarbital are prescribed for some animals for short-term use, and these can be administered before known stressful events. In some patients, anxiolytic drugs such as trazadone may be beneficial for prolonged management.

Cough suppressants are used to control signs and to disrupt the potential cycle of perpetuating cough (see Table 21.1). The dose and frequency of administration of cough suppressants are adjusted as needed. Initially, high, frequent dosing may be needed to break the cycle of coughing. Subsequently, it is often possible to decrease the frequency of administration and the dose. For refractory cases, the addition of maropitant or gabapentin is an option. The cough suppressant effect of maropitant may not be apparent for 1-2 weeks (Grobman and Reinero, 2016). Gabapentin has been used to aid in the control refractory chronic cough in people through mechanisms similar to interfering with neuropathic pain (Ryan, 2015).

Antiinflammatory doses of *glucocorticoids* can be given for a short period during exacerbation of signs (prednisone, 0.5-1 mg/kg orally q12h until signs have subsided, then tapered and discontinued over 3-4 weeks). Long-term use is ideally avoided to prevent potential detrimental side effects such as obesity but is often necessary to control signs, particularly in patients with chronic bronchitis. Inhaled corticosteroids can be tried if a positive therapeutic response is seen to minimize systemic side effects.

Bronchodilators may be beneficial in dogs with concurrent chronic bronchitis. Beneficial effects are likely attributable to antiinflammatory effects, enhancement of steroid activity, or improved mucociliary clearance rather than from bronchodilation. The use of glucocorticoids and bronchodilators for treatment of inflammatory airway disease is discussed in more detail in the sections on canine chronic bronchitis and feline bronchitis.

Dogs with signs referable to mitral insufficiency are managed for this disease (see Chapter 6). Dogs with abnormalities causing upper airway obstruction are treated with corrective surgical procedures.

Antibiotics are not indicated for the routine management of TBM. Dogs in which tracheal wash or BAL fluid analysis has revealed evidence of infection should be treated with appropriate antibiotics (selected on the basis of the results of sensitivity testing). Because most antibiotics do not reach high concentrations in the airways, relatively high doses of antibiotics should be administered for several weeks, as described for canine chronic bronchitis. Any other potentially related problems identified during the diagnostic evaluation are addressed.

A novel approach to treating TBM as reported by Adamama-Moraitou et al. (2012) uses *stanozolol* to improve tracheal wall strength, but this treatment has not been widely adopted. Possible mechanisms include enhanced protein or collagen synthesis, increased chondroitin sulfate content, increased lean body mass, and decreased inflammation. Dogs with tracheal collapse, but not bronchitis, were treated with 0.3 mg/kg stanozolol divided twice daily for 2 months orally, then tapered for 15 days. Dogs in the stanozolol group had improved clinical signs by some measures after 30 days, and improvement in grade of collapse was seen on tracheoscopy at 75 days.

Management of dogs in acute distress with signs of either extrathoracic airway obstruction or intrathoracic large airway obstruction is discussed in Chapter 25.

Tracheal stenting should be considered for dogs with TBM that cannot effectively ventilate due to airway obstruction despite aggressive medical management. Stenting can also be attempted in dogs with refractory cough, but the outcome for this use is often unsatisfactory. The introduction of intraluminal tracheal stents has greatly reduced the morbidity and improved the success of surgical intervention. The most commonly used stents are self-expanding and made of nickel-titanium alloys (Fig. 21.8). In experienced hands, these stents are simple to place during a short period of anesthesia under fluoroscopic or bronchoscopic guidance. Minimal morbidity is associated with stent placement, and response is immediate and often dramatic. However, clinical signs may not completely resolve, collapse of airways beyond the trachea and concurrent conditions are not directly addressed (nearly always resulting in the continued need for medical management), and complications such as infection, ingrowth of tissue, and stent fracture can occur. In particular, cough is usually significantly worse in the weeks

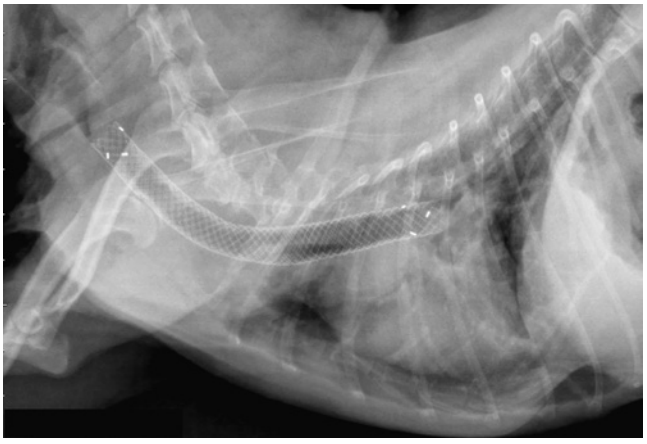

FIG 21.8
Lateral radiograph of the dog with tracheal collapse (shown in Fig. 21.6) after placement of an intraluminal stent. The stent has a mesh-like structure and extends nearly the entire length of the trachea.

immediately after stent placement and must be controlled to minimize trauma to the stent. Initially, cough results from direct damage to the tracheal endothelium by the stent. In addition, ongoing cough from airway inflammation may be exacerbated by areas of mucus accumulation where the stent does not lie perfectly against the epithelium and chronic infections. Results after intraluminal stent placement are sufficiently encouraging that motivated clients with a dog that is failing medical management of tracheal collapse, particularly related to ventilation, should be referred to someone experienced in stent placement for consideration of this option.

Extraluminal stenting can also be performed with the use of plastic rings. This procedure provides the benefit of great durability over many years. The procedure is technically more difficult than intraluminal stenting, perioperative morbidity is high as a result of damage to laryngeal nerves or other cervical structures, and only the cervical trachea is readily accessible. However, good success has been reported, even in dogs with intrathoracic collapse (Becker et al., 2012). This procedure may be worth considering, particularly in very young dogs that otherwise might be expected to outlive an intraluminal stent.

Prognosis

In most dogs clinical signs can be controlled with conscientiously performed medical management, with diagnostic evaluations performed during episodes of persistent exacerbation of signs. Animals in which severe signs develop despite appropriate medical care have a guarded prognosis, and motivated clients should be referred for possible stent placement. The following survival data was provided in a study of 27 dogs after intraluminal stent placement: median survival was 502 days; 78% of dogs survived 6 months; 60% of dogs survived 1 year; and 26% of dogs survive at least 2 years (Rosenheck et.al., 2017). Ongoing medical management is required, and the rate of serious complications from stents has been reported to be approximately 40% (Rosenheck et al., 2017; Tinga et al., 2015).

ALLERGIC BRONCHITIS

Allergic bronchitis is a hypersensitivity response of the airways to an allergen or allergens. The offending allergens are presumably inhaled, although food allergens could also be involved. A definitive diagnosis requires identification of allergen(s) and resolution of signs after elimination of the allergen(s) or successful hyposensitization. It is well documented that purposeful exposure of cats to inhaled allergens can produced feline bronchitis, but large controlled clinical studies describing allergic bronchitis in dogs or cats are lacking and are complicated by the challenges of ruling out other potential etiologies of bronchitis and differentiating allergic bronchitis from idiopathic chronic bronchitis (Trzil and Reinero, 2014).

A study by Prost (2004) presented as an abstract found that 15 of 20 cats had positive intradermal skin tests to aeroallergens. For cats that reacted to storage mites or cockroach antigen, discontinuation of any dry food was recommended (i.e., only canned food was provided). Remission of signs occurred in three cats given only this treatment. Immunotherapy (desensitization) appeared to reduce or eliminate signs in some of the other cats. As a preliminary study, other treatments were also given to the study cats, and a control population was not described.

It is likely that some patients with allergic bronchitis are misdiagnosed because of difficulty in identifying specific allergens. In dogs, long-standing allergic bronchitis may result in the permanent changes recognized as canine chronic bronchitis. In cats, failure to identify specific allergen(s) results in a diagnosis of idiopathic feline bronchitis.

Allergic bronchitis in dogs may result in acute or chronic cough. Rarely, respiratory distress and wheezing occur. Physical examination and radiographic findings reflect the presence of bronchial disease, as described in the section on canine chronic bronchitis. Eosinophilic inflammation is expected in tracheal wash or BAL fluid. Heartworm tests and fecal examinations for pulmonary parasites are performed to eliminate parasitism as the cause of eosinophilic inflammation. In dogs younger than 2 years of age, bronchoscopic evaluation for *O. osleri* also should be considered (see the following section).

Allergic bronchitis in cats has the same presentation and results of diagnostic testing as described for idiopathic feline bronchitis, with eosinophilia expected in airway specimens.

Management of allergic bronchitis is initially focused on identifying and eliminating potential allergens from the environment (see the section on feline bronchitis). Diet trials with novel protein and carbohydrate sources also can be considered. According to the preliminary study previously described, a change in diet to canned food may be beneficial in some cases. Such experimentation with environment and diet is possible only in patients with clinical signs that are sufficiently mild to delay the administration of glucocorticoids and bronchodilators, as described in the sections on canine chronic bronchitis and feline bronchitis (idiopathic). Elimination trials can still be pursued once clinical signs are controlled with medications, but confirmation of a beneficial effect will require discontinuation of the medication and, for a definitive diagnosis to be made, reintroduction of the allergen. The latter may not be necessary or practical in all cases.

Specific immunotherapy for cats with artificially induced allergic bronchitis has been reported. Hyposensitization regimens for cats and dogs with naturally occurring allergic bronchitis hold promise, but criteria for patient selection and expected success rate have not been established.

OSLERUS OSLERI

Etiology

Oslerus osleri is an uncommon parasite of young dogs, usually those younger than 2 years of age. Adult worms live at the carina and mainstem bronchi and cause a local,

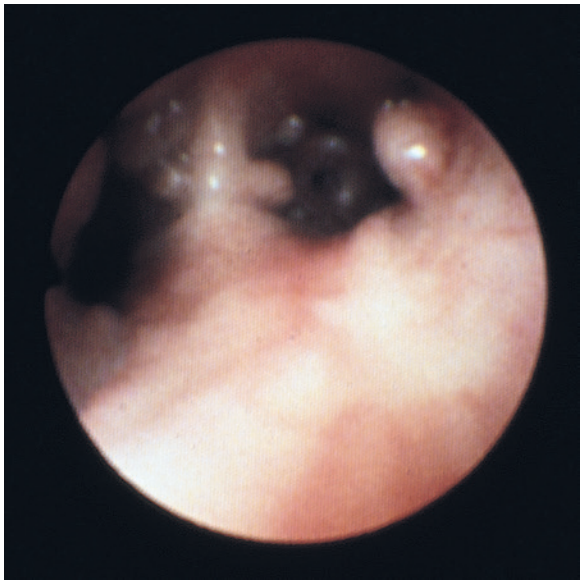

FIG 21.9
Bronchoscopic view of multiple nodules at the carina of a dog infected with *Oslerus osleri*.

nodular inflammatory reaction with fibrosis. First-stage larvae are coughed up and swallowed. The main cause of infection in dogs appears to be intimate contact with their dam as puppies.

Clinical Features

Young affected dogs have an acute, loud, nonproductive cough and occasionally exhibit wheezing. The dogs appear otherwise healthy, making the initial presentation indistinguishable from that of canine infectious respiratory disease complex (CIRDC). However, the cough persists, and eventually airway obstruction occurs as a result of the formation of reactive nodules.

Diagnosis

Nodules at the carina occasionally can be recognized radiographically. Cytologic examination of tracheal wash fluid in some dogs reveals the characteristic ova or larvae, providing the basis for a definitive diagnosis (see Table 20.1). Rarely, larvae are found in fecal specimens with the use of zinc sulfate (specific gravity [s.g.], 1.18) flotation (preferred) or the Baermann technique.

The most sensitive diagnostic method, bronchoscopy, enables the nodules to be readily seen (Fig. 21.9). Brushings of the nodules are obtained and are immediately evaluated cytologically for detection of the larvae. Material can be examined directly in saline solution or stained with new methylene blue. If a definitive diagnosis is not obtained by analysis of the brushings, biopsy specimens are obtained.

Treatment

Treatment with ivermectin (400 µg/kg orally or subcutaneously) is recommended for appropriate breeds of dogs. The same dose is administered again every 3 weeks for four treatments. It cannot be administered to Collies or related breeds. An alternative treatment is fenbendazole (50 mg/kg q24h for 7-14 days).

Prognosis

The prognosis for dogs treated with ivermectin is good; the drug appears to be successful in eliminating infection in the limited number of dogs that have been treated. Follow-up of individual patients is indicated to ensure successful elimination.

CHAPTER 22

Disorders of the Pulmonary Parenchyma and Vasculature

VIRAL PNEUMONIAS

Most respiratory viruses cause self-limiting signs of tracheobronchitis in dogs (see Canine Infectious Respiratory Disease Complex, CIRDC, in Chapter 21) or upper respiratory infection in cats (see Feline Upper Respiratory Infection in Chapter 15). In dogs, *Bordetella bronchiseptica*, canine influenza viruses, and canine distemper virus can directly result in pneumonia. *B. bronchiseptica* and canine influenza are discussed primarily with CIRDC in Chapter 21; canine distemper is discussed in Chapter 94. Secondary bacterial infections can complicate infections with these, or other, CIRDC organisms. Treatment is supportive for viral infection. The diagnostic approach and management of bacterial pneumonia is discussed in the next section.

In cats, calicivirus can cause pneumonia, but this manifestation of infection is rare. The dry form of feline infectious peritonitis can affect the lungs, but cats are generally seen because of signs of involvement of other organs. Feline infectious peritonitis is discussed in Chapter 94.

BACTERIAL PNEUMONIA

Etiology

A wide variety of bacteria can infect the lungs. Common bacterial isolates from dogs and cats with pulmonary infection include *B. bronchiseptica, Streptococcus* spp., *Staphylococcus* spp., *Escherichia coli, Pasteurella* spp., *Klebsiella* spp., *Proteus* spp., and *Pseudomonas* spp. Anaerobic organisms can be part of mixed infections, particularly in animals with aspiration pneumonia or with lung lobe consolidation. *Mycoplasma* spp. has been isolated from dogs and cats with pneumonia, but its exact role is not known. *Mycoplasma cynos,* in particular, may be pathogenic in dogs.

Bacteria can colonize the airways, alveoli, or interstitium. The term *pneumonia* means inflammation of the lung, but the term is not specific for bacterial disease. Infection that clinically appears to be limited to the airways and peribronchial tissues is called *bacterial bronchitis.* If all three regions are involved, the disease is called either *bacterial bronchopneumonia* or *bacterial pneumonia.* Many cases of bacterial pneumonia result from entry of bacteria of the oral cavity and pharynx into the lungs via the airways, which causes a bronchopneumonia involving primarily the gravity-dependent cranial and ventral lung lobes (see Fig. 20.5). Bacteria that enter the lung through the hematogenous route usually cause pneumonia that assumes a caudal or diffuse pattern and marked interstitial involvement. Bacterial pneumonia of hematogenous origin was documented in more than half of cats with bacterial pneumonia on the basis of postmortem examination findings (MacDonald et al., 2003).

Bacterial pneumonia is a common lung disease, particularly in dogs. Community-acquired infectious pneumonia has been described in puppies (Radhakrishnan et al., 2007), most often caused by *B. bronchiseptica* (49% of cases). Coinfection with complicated infectious respiratory disease complex (CIRDC) viruses was identified in 8 of 20 household dogs with bacterial pneumonia (7 with canine parainfluenza virus and 1 with canine respiratory corona virus) (Viitanen et al., 2015). However, consideration should also be given to predisposing abnormalities. *A predisposing abnormality often exists in adult dogs whose bacterial pneumonia is not associated with CIRDC.* Abnormalities to consider in all patients include aspiration of ingested material or gastric contents caused by cleft palate, megaesophagus, or other conditions associated with aspiration pneumonia (discussed separately in a later section); decreased clearance from the lungs of normally inhaled debris, particularly in animals with chronic bronchitis, ciliary dyskinesia, or bronchiectasis; immunosuppression resulting from drugs, malnutrition, stress, or endocrinopathies; inhalation or migration of foreign bodies; and, rarely, neoplasia or fungal or parasitic infection. Immunosuppression from infection with feline leukemia virus or immunodeficiency virus is also a consideration for cats.

Clinical Features

Dogs and cats with bacterial pneumonia are evaluated because of respiratory signs, systemic signs, or both. Respiratory signs can include cough (which is often, but not always, productive), bilateral mucopurulent nasal discharge, exercise

intolerance, and respiratory distress. Cough is less common in cats with pneumonia. Systemic signs may include lethargy, anorexia, fever, and weight loss. The animal may have a history of chronic airway disease or regurgitation. Cats, particularly kittens, from stressful housing situations (e.g., overcrowding) appear predisposed to develop pneumonia as a result of *Bordetella* infection. Dogs with CIRDC may have a recent history of harsh cough and a history consistent with exposure, as described in Chapter 21. Other potential predisposing factors, as listed in the preceding section, are pursued through careful history taking.

Fever may be noted on physical examination but is identified in only about half of patients. Crackles and occasionally expiratory wheezes may be auscultated, with abnormal lung sounds often prominent over the cranioventral lung fields in patients with infection of airway origin.

Diagnosis

Bacterial pneumonia is diagnosed on the basis of the complete blood count (CBC), thoracic radiographic findings, and results from tracheal wash fluid cytologic analysis and bacterial culture. A CBC showing neutrophilic leukocytosis with a left shift, neutropenia with a degenerative left shift, or moderate to marked neutrophil toxicity is supportive of bacterial pneumonia. However, a normal or stress leukogram is as likely to be found.

Abnormal patterns on thoracic radiographs vary with the underlying disease. The typical abnormality is an alveolar pattern, possibly with consolidation, which is most severe in the dependent lung lobes (see Fig. 20.5). Increased bronchial and interstitial markings are often present. Infection secondary to foreign bodies can be localized to any region of the lung. An interstitial pattern alone may be present in animals with early or mild disease or in those with infection of hematogenous origin. A bronchial pattern alone may be present in animals with a primarily bronchial infection. Radiographs are also evaluated for the presence of megaesophagus and other extrapulmonary disease.

Ideally, pulmonary specimens are evaluated cytologically and microbiologically (bacterial and, ideally, *Mycoplasma* cultures or polymerase chain reaction (PCR)) to establish a definitive diagnosis and provide guidance in antibiotic selection. To maximize the diagnostic yield, specimens should be collected before antibiotic therapy is initiated. A tracheal wash specimen is generally sufficient. Septic neutrophilic inflammation is typically found in animals with bacterial pneumonia, and growth of organisms on bacterial culture is expected. Examination of a gram-stained preparation will provide early guidance in antibiotic selection pending results of culture and will assist in the identification of anaerobes or other organisms that may not be easily grown in culture (e.g., *Mycobacteria,* filamentous organisms).

A conscientious effort is made to identify any underlying problems. In some animals, such as those with megaesophagus, the initiating cause is obvious. Further diagnostic tests are indicated in other animals, depending on the results of the clinicopathologic evaluation. These may include bronchoscopy to search for airway abnormalities or foreign bodies, conjunctival scrapings to look for distemper virus, serologic or PCR tests to detect specific viral or fungal organisms, and hormonal assays to determine whether the animal has hyperadrenocorticism. Ciliary dyskinesia is discussed briefly in Chapter 21. Diagnostic evaluation for aspiration pneumonia is discussed in the section dedicated to aspiration pneumonia.

Treatment

Antibiotics

Treatment for bacterial pneumonia consists of antibiotics and supportive care, with follow-up evaluation (Box 22.1). The antibiotic sensitivity of involved organisms is difficult to predict. Gram-negative infection and infection with multiple organisms are common. Antibiotics are initially selected on the basis of severity of clinical signs and cytologic characteristics (i.e., morphology and gram-staining) of organisms found in pulmonary specimens. Antibiotic selection is subsequently modified, as needed, according to clinical response and sensitivity data from bacterial cultures of pulmonary specimens.

The extent to which an antibiotic can penetrate into the airway secretions does not need to be a major consideration in patients with bacterial pneumonia. Antibiotics generally achieve concentrations within the pulmonary parenchyma

BOX 22.1

Therapeutic Considerations for Bacterial Pneumonia

Antibiotics

Ideally, selected on basis of results from Gram staining and culture and sensitivity testing of pulmonary specimens. See text for specific guidelines.

Airway Hydration

Maintenance of systemic hydration
Saline nebulization

Physiotherapy

Turning of recumbent animals every 1 to 2 hours
Mild exercise of animals in stable condition
Coupage

Bronchodilators

As needed, particularly in cats

Oxygen Supplementation

As needed

AVOID

Diuretics
Cough suppressants
Corticosteroids

equal to those in plasma. Nebulization of antibiotics is rarely indicated.

Based on recommendations of the Antimicrobial Guidelines Working Group of the International Society for Companion Animal Infectious Diseases (ISCAID), dogs and cats with mild pneumonia suspected based on history to be from infection with *B. bronchiseptica* or *Mycoplasma spp* can be treated with doxycycline (5 mg/kg q12h PO or 10 mg/kg q24h; followed by a bolus of water). However, broader coverage is indicated in these patients if systemic signs of disease such as fever, dehydration, lethargy, or respiratory compromise is present (Lappin et al., 2017).

For other animals with mild or moderate clinical signs, oral antibiotics that can be initiated include amoxicillin-clavulanate (dogs, 11 mg/kg q8h; cats, 12.5 mg/kg q8h), cephalexin (22-25 mg/kg q12h), and trimethoprim-sulfonamide (15 mg/kg q12h). Fluoroquinolones are reserved for animals with resistant gram-negative infections.

Animals with severe clinical signs or possible sepsis should be treated initially with broad-spectrum intravenous antibiotics that provide coverage for gram-negative and gram-positive aerobes and anaerobes. A fluoroquinolone in combination with ampicillin with sulbactam (20 mg/kg of ampicillin q6-8h) is commonly used. This combination has the advantages of availability of oral formulations for continuation of therapy after hospitalization, and the flexibility of de-escalation if clinical response and culture results support doing so. Alternatively, meropenem (8.5 mg/kg SC q12h or 24 mg/kg IV q12h in dogs; 10 mg/kg IV, IM, SC q12h in cats) or the combination of an aminoglycoside (e.g., amikacin, 15 mg/kg IV q24h in dogs and 10 mg/kg IV q24h in cats) and ampicillin with sulbactam can be used. If *Toxoplasma* infection is among the differential diagnoses, usually in cats, clindamycin (10-15 mg/kg PO, SC q12h in cats) can substituted for the ampicillin with sulbactam in combination with a fluoroquinolone (see Chapter 98).

Antibiotic treatment should be continued for at least 1 week after clinical signs have resolved. Guidelines for patient monitoring are provided later in this section.

Airway Hydration

Drying of secretions results in increased viscosity and decreased ciliary function, which interfere with the normal clearance mechanisms of the lung. Thus the water content of airway secretions must be maintained and airways must be hydrated in animals with pneumonia. Animals with any evidence of dehydration should receive fluid therapy. Diuretics can cause dehydration, and their use is relatively contraindicated in such animals.

Additional moisture for the airways can be provided through humidification or nebulization. Such therapy is particularly recommended for animals with areas of consolidation or with suspected decreased airway clearance, such as those with bronchiectasis. *Humidification* refers to the saturation of air with water vapor. Depending on the temperature, the volume of water that remains as vapor is limited. Moisture reaches only the nasal cavity and the proximal trachea. Vaporization is not effective in hydrating deeper regions of the lungs. However, the more proximal effect can still provide some relief, particularly in animals with nasal discharge. Humidification is convenient and can be achieved simply by placing the animal in a steamy bathroom or in a small room with an inexpensive vaporizer, which is readily available at pharmacies.

Nebulization is necessary to provide moisture deeper into the airways. Nebulizers generate small, variably sized droplets, with a diameter ranging from 0.5 to 5 µm, as is required to reach the deeper airways. Several types of nebulizers are available. Disposable jet nebulizers are readily available and inexpensive, and they can be attached to bottled oxygen or to an air compressor (Fig. 22.1). Effective, inexpensive portable compressors are commercially available if needed for home use. The nebulizing solution is delivered to the animal through a face mask. The particles can be seen as a mist. Excellent information on the use and cleaning of nebulizing equipment in the home can be found on the Web sites of many large human hospitals where patient information is provided for the management of cystic fibrosis or bronchial asthma.

Sterile saline solution is used as a nebulizing solution because it has mucolytic properties and is relatively nonirritating. Premedication with bronchodilators has been suggested as a way to reduce bronchospasms, although the use of saline alone in dogs does not usually cause problems. It is recommended that nebulization be performed two to six times daily for 10 to 30 minutes each time. Nebulization should be followed immediately by physiotherapy to promote the expectoration of exudate that may have increased in volume with rehydration. Nebulizers and tubing should be replaced after no more than 24 hours of use in

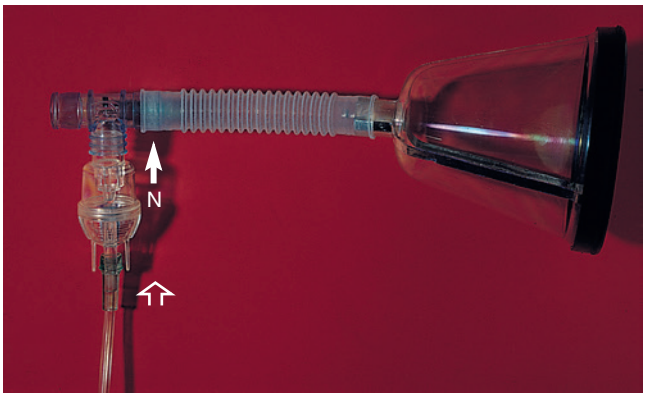

FIG 22.1
Disposable jet nebulizers are readily available and inexpensive. Sterile saline solution is placed in the nebulizer *(N)*. Oxygen enters the bottom of the nebulizer *(open arrow)*, and nebulized air exits the top *(closed arrow)*. Nebulized air is delivered to the animal with a face mask, as shown here, or it can be delivered into an enclosed cage.

actively infected patients, and face masks should be cleaned and disinfected.

Physiotherapy

Animals that are in a sufficiently stable condition and can tolerate the oxygen demands should be mildly exercised. Activity causes animals to take deeper breaths and to cough, which promotes airway clearance. Animals that are recumbent are turned every 2 hours. Lying in one position impairs airway clearance, and lung consolidation can occur if one side remains dependent for prolonged periods.

Physiotherapy is indicated after nebulization to promote coughing and facilitate the clearance of exudate from the lungs. Mild exercise is used when possible. Otherwise, coupage is performed. To perform coupage, the clinician strikes the animal's chest over the lung fields with cupped hands. The action should be forceful but not painful and should be continued for 5 to 10 minutes if tolerated by the patient. Coupage may also be beneficial for animals with lung consolidation that are not receiving nebulization.

Bronchodilators

In cats, bronchospasm can occur secondary to inflammation. Bronchodilators are used in cats that show increased respiratory efforts, particularly if expiratory wheezes are auscultated. Bronchospasm is uncommon in dogs, but bronchodilators (particularly theophylline) may have other potentially advantageous effects. If bronchodilators are administered, patient status should be monitored closely because bronchodilators may worsen ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching, thereby exacerbating hypoxemia. They are discontinued if clinical signs worsen or do not improve. Bronchodilators are discussed in the sections on Canine Chronic Bronchitis and Feline Bronchitis (Idiopathic) in Chapter 21.

Other Treatment

Expectorants are of questionable value in dogs and cats. *Acetylcysteine* is a mucolytic agent that some clinicians believe is beneficial for the treatment of dogs with severe bronchopneumonia when administered intravenously. It is quite possible that the antioxidant effects of this drug, rather than its mucolytic property, account for any benefit that may be seen. Acetylcysteine should not be administered by nebulization because of its irritant effects on the respiratory mucosa. *Glucocorticoids* are relatively contraindicated in animals with bacterial pneumonia. *Oxygen therapy* (see Chapter 25) is provided if clinical signs, arterial blood gas measurements, or pulse oximetry measurements indicate the need for it.

Monitoring

Dogs and cats with bacterial pneumonia should be closely monitored for signs of deteriorating pulmonary function. Respiratory rate and effort and mucous membrane color are monitored at least twice daily. Thoracic radiographs and the CBC are evaluated every 24 to 72 hours. If the animal's condition does not improve within 72 hours, it may be necessary to alter treatment or perform additional tests. Animals that show improvement are sent home and are reevaluated every 10 to 14 days. Once clinical and radiographic signs have resolved, antibiotic treatment is continued for an additional week.

A more objective way to determine adequate duration of therapy may be possible through the monitoring of C-reactive protein (CRP). Eighteen dogs with bacterial pneumonia that were treated for 5 to 7 days beyond the normalization of CRP had a shorter total duration of antibiotic therapy (median 21 days) compared with dogs treated for 3 to 6 weeks in total or 1 to 2 weeks beyond the resolution of alveolar densities on radiographs (median 35 days) without an increase in relapses (Viitanen et al., 2017).

Evidence of infection on initial radiographs can obscure that of focal disease processes such as neoplasia or foreign bodies, and focal opacities may not be apparent while an animal is receiving antibiotics. Therefore radiographs should be reevaluated approximately 1 week after antibiotic therapy has been discontinued in animals with recurrent infection or suspected localized disease. Persistence of localized disease after long-term antibiotic therapy is an indication for computed tomography and bronchoscopy, thoracoscopy, or thoracotomy.

Prognosis

Bacterial pneumonia responds readily to appropriate therapy. The prognosis is more guarded in animals with underlying problems that predispose them to infection, and the likelihood of eliminating these problems must be taken into consideration.

Pulmonary abscess formation is an uncommon complication of bacterial pneumonia. Abscesses are seen as focal lesions on radiographs, and entire lobes may be involved. Horizontal-beam radiographs can be useful in determining whether lesions are filled with fluid. Ultrasonography can also be helpful in characterizing areas of consolidation. Abscesses resolve in response to prolonged medical therapy in some animals, but if improvement is not observed or radiographic evidence of disease reappears after discontinuation of therapy, surgical excision (i.e., lobectomy) is indicated.

TOXOPLASMOSIS

The lungs are a common site of involvement in cats with toxoplasmosis. Thoracic radiographs typically show fluffy alveolar and interstitial opacities throughout the lungs in such animals. Less often, a nodular interstitial, diffuse interstitial, or bronchial pattern, lung lobe consolidation, or pleural effusion is seen. Organisms are rarely recovered from the lungs by tracheal wash. Bronchoalveolar lavage is more likely to retrieve organisms (see Fig. 20.17). Toxoplasmosis is a multisystemic disease and is discussed in detail in Chapter 98.

FUNGAL PNEUMONIA

Common mycotic diseases that can involve the lungs are blastomycosis, histoplasmosis, and coccidioidomycosis. In most cases, organisms enter the body through the respiratory tract. The infection may be successfully eliminated without the animal showing clinical signs, or the animal may show only transient respiratory signs. The infection may also progress to cause disease involving the lungs alone or may spread systemically to various target organs. Cryptococcal organisms also enter the body through the respiratory tract and can infect the lungs, particularly in cats. However, the presenting signs in cats are generally those of nasal infection. Pulmonary signs are most often the primary presenting complaint in dogs with blastomycosis and in cats with histoplasmosis.

Pulmonary mycoses are considered in the differential diagnoses of dogs or cats with progressive signs of lower respiratory tract disease, especially if they occur in conjunction with weight loss, fever, lymphadenopathy, chorioretinitis, or other evidence of multisystemic involvement. Thoracic radiographs typically show a diffuse, nodular, interstitial pattern of the lungs (see Fig. 20.6). The nodules are often miliary. The presence of this pattern in dogs with suspicious clinical signs supports a diagnosis of mycotic infection, although similar radiographic patterns can be seen with neoplasia; parasitic lung disease; infection with atypical bacteria such as *Mycobacterium, Actinomyces* or *Nocardia*; and eosinophilic lung disease. Other potential radiographic abnormalities include alveolar and bronchointerstitial patterns and consolidated regions of lung. Hilar lymphadenopathy can occur, most commonly in animals with histoplasmosis. The lesions caused by histoplasmosis can also be calcified.

Organisms can be retrieved by tracheal wash in some cases. However, because of the interstitial nature of these diseases, bronchoalveolar lavage or lung aspiration may be necessary (see Figs. 20.15 and 20.16). Fungal culture is probably more sensitive than cytologic analysis alone. An inability to find organisms in pulmonary specimens does not rule out the diagnosis of mycotic disease, however. A complete discussion of systemic mycoses is provided in Chapter 97.

PULMONARY PARASITES

Several parasites can cause lung disease. Certain intestinal parasites, especially *Toxocara canis,* can cause transient pneumonia in young animals, usually those younger than a few months of age, as the larvae migrate through the lungs. Infection with *Dirofilaria immitis* can result in severe pulmonary disease through inflammation and thrombosis (see Chapter 10). *Oslerus osleri* resides at the carina and mainstem bronchi of dogs and is discussed in Chapter 21. The other primary lung parasites that are most commonly diagnosed are *Capillaria (Eucoleus) aerophila* and *Paragonimus kellicotti* in dogs and cats, *Aelurostrongylus abstrusus* in cats, and *Crenosoma vulpis* in dogs.

Infection occurs as a result of ingestion of infective forms, often within intermediate or paratenic hosts, that subsequently migrate to the lungs. An eosinophilic inflammatory response often occurs within the lungs, causing clinical signs in some, but not all, infected animals. The definitive diagnosis is made by identification of the characteristic eggs or larvae in respiratory or fecal specimens (see Chapter 20).

CAPILLARIA (EUCOLEUS) AEROPHILA

Capillaria aerophila, also known as *Eucoleus aerophila,* is a small nematode. Adult worms are located primarily beneath the epithelial surfaces of the large airways. Clinical signs develop in very few animals with *Capillaria* infection, and the disease is most often identified through the fortuitous identification of characteristic eggs during routine fecal examination.

The rare animal that displays signs shows signs of allergic bronchitis. Thoracic radiographic findings are generally normal, although a bronchial or bronchointerstitial pattern may be seen. Tracheal wash fluid can show eosinophilic inflammation. *Capillaria* is diagnosed by the finding of characteristic eggs in tracheal wash fluid or fecal flotation material (see Fig. 20.12, *C*).

The treatment of choice for dogs and cats is fenbendazole (50 mg/kg PO q24h for 14 days). Levamisole (8 mg/kg PO for 10-20 days) has also been used successfully in dogs. Ivermectin has been suggested for treatment, but a consistently effective dosage has not been established. The prognosis in animals with the disease is excellent.

PARAGONIMUS KELLICOTTI

Paragonimus kellicotti is a small fluke. Both snails and crayfish are necessary intermediate hosts, thus limiting the disease to animals that have been in the region of the Great Lakes, in the Midwest, or in the southern United States. Pairs of adults are walled off by fibrous tissue, usually in the caudal lung lobes, with connection to an airway to allow for the passage of eggs. A local granulomatous reaction may occur around the adults, or a generalized inflammatory response to the eggs may be noted.

Infection is more common in cats than in dogs. Some dogs and cats have no clinical signs. When clinical signs are present, they may be the same as those seen in animals with allergic bronchitis. Alternatively, signs of spontaneous pneumothorax can result from the rupture of cysts.

The classic radiographic abnormality is single or multiple solid or cavitary mass lesions, most commonly present in the right caudal lobe (see Fig. 20.10). Other abnormal patterns seen on thoracic radiographs can be bronchial, interstitial (reticular or nodular), or alveolar in nature, depending on the severity of the inflammatory response (see Fig. 20.11).

Infection is diagnosed definitively through identification of the ova in fecal specimens (using the sedimentation technique described in Chapter 20), tracheal wash fluid, or bronchoalveolar lavage fluid (see Fig. 20.12, *D*). Multiple fecal

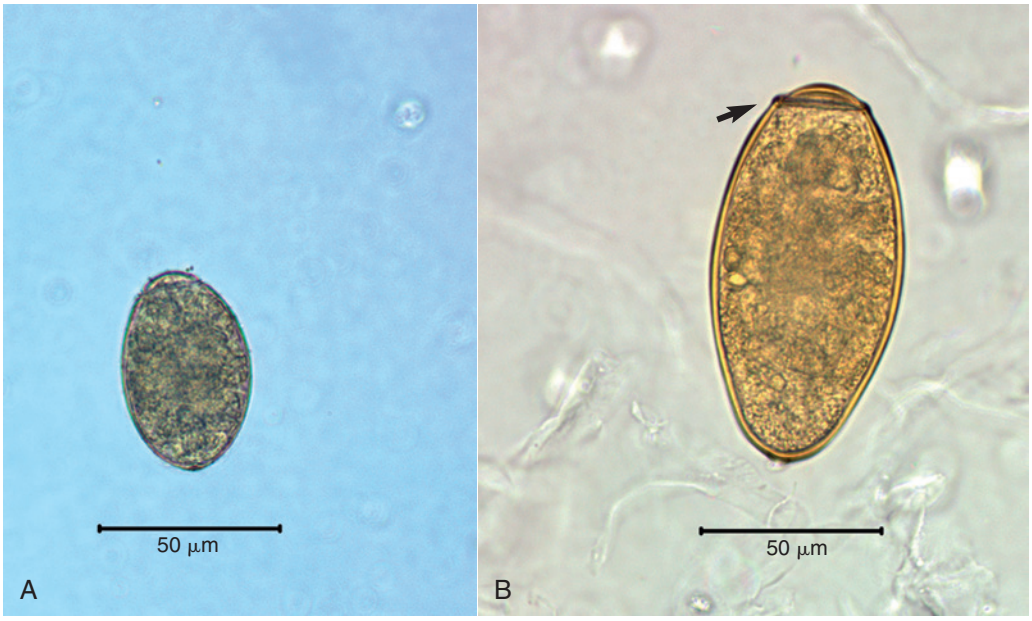

FIG 22.2
The operculated ova from *Spirometra* tapeworms **(A)** can be misdiagnosed as *Paragonimus* ova **(B).** The *Spirometra* ova are smaller and paler than the yellow-brown *Paragonimus* ova. Most notably, *Paragonimus* ova have a distinctly visible shoulder *(arrow)* at the operculated end. (Courtesy James R. Flowers.)

specimens should be examined in suspected cases because the eggs are not always present. A presumptive diagnosis is necessary in some cases. Note that ova from the tapeworm *Spirometra* spp. can be mistakenly identified as ova from *Paragonimus* (Fig. 22.2).

Fenbendazole is used to treat paragonimiasis at the same dosage as that recommended for the treatment of capillariasis. Alternatively, praziquantel can be used at a dosage of 23 mg/kg orally every 8 hours for 3 days.

Thoracocentesis should be used to stabilize the condition of animals with pneumothorax. If air continues to accumulate within the pleural space, however, it may be necessary to place a chest tube and perform suction until the leak has been sealed (see Chapter 24). Surgical intervention is rarely required.

Thoracic radiographs and periodic fecal examinations should be used to monitor the response to treatment. Treatment may have to be repeated in some cases. The prognosis is excellent.

AELUROSTRONGYLUS ABSTRUSUS

Aelurostrongylus abstrusus is a small worm that infects the small airways and pulmonary parenchyma of cats. Snails or slugs serve as intermediate hosts. Most cats with infection have no clinical signs. Those cats that do are usually young. Clinical signs are those of bronchitis. Abnormalities seen on radiographs may also reflect bronchitis, although a diffuse miliary or nodular interstitial pattern is present in some cats. Pulmonary arterial enlargement can occur, making this disease a differential diagnosis in cats with possible heartworm disease. Eosinophilic inflammation may be apparent in peripheral blood and airway specimens.

A definitive diagnosis is made through identification of larvae, which may be present in fecal specimens prepared using the Baermann technique (see Fig. 20.12, *A*) or in airway specimens obtained by tracheal washing or bronchoalveolar lavage. Fecal Baermann examination is most sensitive for the detection of organisms, although multiple fecal specimens should be examined in suspected cases because organisms are shed intermittently. Airway specimens are often negative for organisms, despite infection, and stained squash preparations of mucus are recommended to increase sensitivity (Lacorcia et al., 2009).

Cats should be treated with fenbendazole at the same dosage as that used for the treatment of capillariasis. In one study, the dosage of 50 mg/kg orally every 24 hours for 15 days was effective in eliminating infection in all four cats treated (Grandi et al., 2005). In contrast with a previous report, ivermectin (0.4 mg/kg, administered subcutaneously) was not effective in one cat. Thoracic radiographs and periodic fecal examinations are used to monitor the response to treatment. Treatment may have to be repeated in some cases.

Antiinflammatory therapy with glucocorticoids alone often causes the clinical signs to resolve. However, eliminating the underlying parasitic disease is a preferable treatment goal, and glucocorticoid therapy may interfere with the effectiveness of antiparasitic drugs. Bronchodilators may provide symptomatic relief and presumably do so without interference with antiparasitic drug action. The prognosis in animals with the infection is excellent.

CRENOSOMA VULPIS

Crenosoma vulpis is a lungworm of foxes that can also infect dogs. Dogs living in Atlantic Canada and parts of Europe are most commonly diagnosed with this disease, and the diagnosis remains rare in the United States. However, it is possible that with increased residential development into fox habitats, the frequency of cases in this country will increase. The worm resides in the airways (i.e., trachea, bronchi, bronchioles). Snails or slugs serve as intermediate hosts. The clinical signs are those of allergic or chronic bronchitis. Thoracic radiographs may have a bronchointerstitial or patchy alveolar pattern or occasionally a nodular pattern. Infection is diagnosed definitively through identification of the larvae in fecal specimens (using the Baermann technique), tracheal wash fluid, or bronchoalveolar lavage fluid (see Fig. 20.12, *B*). Multiple fecal specimens should be examined in suspected cases because the larvae are not always present. A single oral dose of milbemycin oxime (0.5 mg/kg) was effective in resolving clinical signs and eliminating larvae from feces collected 4 to 6 weeks after treatment in 32 dogs (Conboy, 2004). This treatment may not be effective against immature larvae. As with other pulmonary parasites, the response to treatment is monitored with thoracic radiographs and periodic fecal examinations.

ASPIRATION PNEUMONIA

Etiology

A small amount of fluid and bacteria is aspirated from the oropharynx into the airways of healthy animals, but normal airway clearance mechanisms prevent infection. Organisms from the oropharynx are thought to be the source of bacteria in many animals with bacterial pneumonia, specifically bacterial bronchopneumonia (see earlier section). In people, such infection is termed *aspiration pneumonia.* In veterinary medicine, the term *aspiration pneumonia* is generally used to refer to the inflammatory lung disease that occurs as a result of the inhalation of overt amounts of solid or liquid material into the lungs. The materials that are usually aspirated are stomach contents or food. Normal laryngeal and pharyngeal function prevents aspiration in healthy animals, although occasionally an excited puppy or a dog running through tall grass aspirates a foreign body. Otherwise, the presence of aspiration pneumonia in an animal of any age indicates an underlying predisposing abnormality (Box 22.2).

Aspiration pneumonia is a common complication of animals with regurgitation. Megaesophagus and esophageal dysmotility are the most common causes of regurgitation (see Chapter 29). Other causes of regurgitation (e.g., reflux esophagitis, esophageal obstruction) are less common. Another cause of aspiration pneumonia is localized or systemic neurologic or muscular disease affecting the normal swallowing reflexes of the larynx or pharynx. These reflexes can also be depressed in dogs or cats with abnormal levels of consciousness or in those that are anesthetized. Laryngeal paralysis has been associated with concurrent esophageal dysfunction (see Chapter 18), and aspiration pneumonia is a complication of therapeutic laryngoplasty. Aspiration pneumonia can also occur in animals with abnormal pharyngeal anatomy resulting from mass lesions, brachycephalic airway syndrome, or cleft palate. Bronchoesophageal fistulae are a rare cause of aspiration pneumonia.

Aggressive force-feeding, especially in mentally depressed animals, and improper placement of stomach tubes into the trachea are iatrogenic causes of aspiration pneumonia. Mineral oil administered to prevent hairballs can be a cause of aspiration pneumonia in cats because the pharynx poorly handles the tasteless and odorless oil.

Damage to the lung resulting from aspiration may stem from chemical damage, obstruction of the airways, infection, and the resulting inflammatory response to each of these factors. Gastric acid causes severe chemical injury to the lower airways. Tissue necrosis, hemorrhage, edema, and bronchoconstriction ensue, and a marked acute inflammatory response is initiated. Hypoxemia resulting from decreased alveolar ventilation and compliance can be fatal.

- Vomiting (in Combination with Other Predisposing Factors), Chapter 28

*Discussions of these abnormalities can be found at the given chapters.

†Overzealous feeding, incorrect tube placement, or loss of lower esophageal sphincter competence because of presence of tube.

Severe respiratory distress can result from physical obstruction of the airways by the aspirated material. In most cases only small airways are obstructed, but rarely a large piece of food will obstruct a major airway. Obstruction is subsequently exacerbated by reflex bronchoconstriction and inflammation. Inhaled solid material initiates an inflammatory reaction that includes an abundance of macrophages. This response can become organized, resulting in the formation of granulomas.

Bacterial infection may result from the aspiration of contaminated material, such as ingesta that remained in the esophagus. Acidic gastric contents are probably sterile, although in people the contents are considered contaminated if antacids have been taken, if an intestinal obstruction is present, or if periodontal disease is present. Note that many veterinary patients have periodontal disease. Regardless of the sterility of the aspirated material, the resultant damage to the lungs by gastric acid predisposes the animal to the development of a secondary infection.

The inhalation of mineral oil elicits a chronic inflammatory response. Clinical signs in this setting are often mild, but in rare instances they may be severe. Radiographic abnormalities persist and can be erroneously interpreted as representing neoplastic lesions.

Clinical Features

Dogs and cats with aspiration pneumonia are frequently presented for acute, severe respiratory signs. Systemic signs such as anorexia and depression are common, and these patients may even present in shock. Vomiting, regurgitation, or eating may have preceded the onset of distress. Other patients are seen because of chronic intermittent or progressive signs of coughing or increased respiratory efforts. Occasionally, patients show only signs of depression or the predisposing disease. A thorough history is obtained, with all organ systems carefully reviewed. Owners are specifically questioned about eating behavior (prehension and swallowing), regurgitation (particularly after eating or drinking), voice change, force-feeding, and medication administration.

Fever may be present, but it is an inconsistent finding. Crackles are often auscultated, particularly over dependent lung lobes. Wheezes are heard in some cases. Once a patient is in stable condition, a thorough neuromuscular examination is performed. The ability of the patient to prehend and swallow food and water should also be observed.

Diagnosis

Aspiration pneumonia is usually diagnosed on the basis of suggestive radiographic findings in conjunction with evidence of a predisposing condition. Thoracic radiographs typically show diffuse, increased interstitial opacities with alveolar flooding (air bronchograms) and consolidation of the dependent lung lobes (see Fig. 20.5). Radiographic abnormalities may not be apparent until 12 to 24 hours after aspiration, however. Occasionally, nodular interstitial patterns are seen in chronic cases. Large nodules can form around solids; miliary nodules often form in animals that have aspirated mineral oil. A marked, diffuse alveolar pattern can be seen in dogs that have severe secondary edema (see the section on pulmonary edema later in this chapter).

The peripheral blood count can reflect the pulmonary inflammatory process, but it is often normal. Neutrophils are examined for the presence of toxic changes suggestive of sepsis.

Tracheal wash is indicated for animals that can tolerate the procedure to identify complicating bacterial infection and obtain antibiotic sensitivity data. A marked inflammatory response characterized by a predominance of neutrophils is seen in cytologic specimens. Blood resulting from hemorrhage may be seen in specimens from animals in the acute period after aspiration. Bacteria may also be seen. Bacterial cultures should always be performed.

Bronchoscopy can be used to grossly examine the airways and detect and remove large solids. However, the likelihood of a large airway obstruction is very small, so bronchoscopy is performed only if clear signs of large airway obstruction are noted (see Chapter 25), or if the animal is not conscious and therefore does not require general anesthesia for the procedure.

Blood gas analysis can be helpful in differentiating hypoventilation from ventilation/perfusion abnormalities (see Chapter 20), although a combination of abnormalities is found in most animals with aspiration pneumonia. Animals with evidence of profound hypoventilation may have a large airway obstruction or muscle weakness secondary to an underlying neuromuscular disorder such as myasthenia gravis. Blood gas analysis also assists in the therapeutic management of these animals and can be used effectively to monitor the response to therapy.

Diagnostic evaluation is indicated to identify potential underlying diseases (see Box 22.2). This may include a thorough oral and pharyngeal examination, contrast-enhanced radiographic studies to evaluate the esophagus, or specific neuromuscular tests.

Treatment

Suctioning of the airways is helpful only for animals that aspirate in the hospital while already anesthetized or unconscious, when it can be performed immediately after aspiration. If a bronchoscope is immediately available, suctioning can be performed through the biopsy channel, which affords visualized guidance. Alternatively, a sterile soft rubber tube attached to a suction pump can be passed blindly into the airways through an endotracheal tube. Excessive suction may result in lung lobe collapse. Therefore low-pressure, intermittent suction is used, followed by expansion of the lungs with several positive-pressure ventilations using an anesthetic or Ambu bag. Therapeutic airway lavage is contraindicated.

Animals in severe respiratory distress should be treated with fluid therapy, oxygen supplementation, bronchodilators, and possibly glucocorticoids. Fluids are administered intravenously at high rates to treat shock (see Chapter 28) and should be continued after initial stabilization of the

animal's condition to maintain systemic hydration, which is necessary to maximize the effectiveness of airway clearance mechanisms. However, overhydration must be avoided because of a tendency for pulmonary edema.

Oxygen supplementation (see Chapter 25) is initiated immediately in compromised animals. Positive-pressure ventilation is required for animals in severe respiratory distress that is unresponsive to oxygen therapy.

Bronchodilators can be administered to decrease bronchospasms and ventilatory muscle fatigue. They are most likely to be effective in cats. Bronchodilators can worsen $\dot{V}/\dot{Q}$ mismatching, exacerbating hypoxemia. They are discontinued if no improvement is seen, or if clinical signs appear to worsen after their administration.

The antiinflammatory effects of glucocorticoids can be beneficial, but glucocorticoids can interfere with normal host defense mechanisms in tissues that have already been severely compromised. This author reserves the use of glucocorticoids for patients that have severe respiratory compromise and a deteriorating clinical picture despite appropriate antibiotic therapy and supportive care. Low (antiinflammatory) doses of short-acting preparations are administered for up to 48 hours.

Animals with a large airway obstruction can benefit from bronchoscopy and foreign body removal. However, routine bronchoscopy is not indicated because of the risk associated with the general anesthesia needed during the procedure and the infrequency of large airway obstructions.

Antibiotics are administered immediately in animals that are presented in severe distress or with overt systemic signs of sepsis. Selected antibiotics should have a broad spectrum of activity and be administered intravenously. Such drugs include the combination of a fluoroquinolone or an aminoglycoside with ampicillin with sulbactam (see the earlier section on bacterial pneumonia).

A tracheal wash is ideally performed in stable patients before antibiotics are initiated, to document the presence of infection and to obtain antibiotic sensitivity data. This information is particularly valuable because prolonged treatment is often needed, and also because research in human medicine has amply demonstrated that resistant secondary infection can develop after aspiration in patients given antibiotics initially or on an empirical basis. As discussed for bacterial pneumonia, the high incidence of gram-negative and mixed infections makes assumptions regarding antibiotic sensitivity prone to error. Pending results of culture, it is reasonable to initiate treatment in stable patients with penicillin with a β-lactamase inhibitor (e.g., amoxicillin-clavulanate or ampicillin with sulbactam). Because infection can occur as a later complication in these patients, frequent monitoring with physical examination, CBC, and thoracic radiographs is necessary to detect any deterioration consistent with secondary infection. Tracheal wash is repeated if infection is suspected.

Further therapeutic and monitoring considerations are discussed in the section on bacterial pneumonia. Underlying diseases are treated to prevent recurrence.

Prognosis

Animals with mild signs of disease and a correctable underlying problem have an excellent prognosis. The prognosis is worse for animals with more severe disease or uncorrectable underlying problems.

EOSINOPHILIC LUNG DISEASE (EOSINOPHILIC BRONCHOPNEUMOPATHY)

Eosinophilic lung disease, or eosinophilic bronchopneumopathy, is a broad term that describes inflammatory lung disease in which the predominant infiltrating cell is the eosinophil. Eosinophilic inflammation can involve primarily the airways or the interstitium. Allergic bronchitis and idiopathic bronchitis are by far the most common eosinophilic lung diseases seen in cats and are discussed in Chapter 21. Interstitial infiltration, with or without concurrent bronchitis, was historically referred to as *pulmonary infiltrates with eosinophils* (PIE) and is typically seen in dogs. ***Eosinophilic pulmonary granulomatosis*** is a severe type of eosinophilic lung disease of dogs and characterized by the development of nodules and often hilar lymphadenopathy. It must be differentiated from mycotic infection and neoplasia. These names are descriptive only and likely encompass a variety of hypersensitivity disorders of the lung.

Because eosinophilic inflammation is a hypersensitivity response, an underlying antigen source is actively pursued in affected animals. Considerations include heartworms, pulmonary parasites, drugs, and inhaled allergens. Food allergy could play a role in these disorders, but this association has not been explored. Potential allergens are discussed further in the section on allergic bronchitis in Chapter 21. Bacteria, fungi, and neoplasia can also induce a hypersensitivity response, but this response often is not the predominant finding. In many cases no underlying disease can be found. Eosinophilic pulmonary granulomatosis is strongly associated with heartworm disease.

Clinical Features

Eosinophilic lung diseases are seen in young and older dogs. Affected dogs are evaluated because of progressive respiratory signs such as cough, increased respiratory efforts, and exercise intolerance. Systemic signs such as anorexia and weight loss are usually mild. Lung sounds are often normal, although crackles or expiratory wheezes are possible.

Diagnosis

The finding of peripheral eosinophilia is not present in all animals with the eosinophilic lung disease, nor is it a specific finding. A diffuse interstitial or bronchointerstitial pattern is seen on thoracic radiographs. Eosinophilic pulmonary granulomatosis results in the formation of nodules, usually with indistinct borders. These nodules can be quite large, and hilar lymphadenopathy may also be present. A patchy

alveolar opacity and consolidation of the lung lobes can occur as well.

Pulmonary specimens must be examined to establish a diagnosis. In some cases, particularly those with bronchial involvement, evidence of eosinophilic inflammation may be found in tracheal wash fluid. More aggressive techniques for collecting pulmonary specimens, such as bronchoalveolar lavage, lung aspiration, or lung biopsy, are required to identify the eosinophilic response in other cases. Other inflammatory cell populations are frequently present in lesser numbers in such specimens.

Potential antigen sources should be considered, and pulmonary specimens should be carefully examined for the presence of infectious agents and features of malignancy. Heartworm tests and fecal examinations for pulmonary parasites (including sedimentation, Baermann and flotation-concentrating techniques) are indicated in all cases.

Treatment

Any primary disease identified during the diagnostic evaluation of these animals is treated directly. Eliminating the source of the antigen that may be triggering the excessive immune response may result in a cure.

Antiinflammatory therapy with glucocorticoids is indicated for dogs in which an antigen source cannot be identified, and for dogs with heartworm disease if the eosinophilic inflammation is causing respiratory compromise (see Chapter 10). Dogs with eosinophilic granulomatosis often require more aggressive immunosuppressive therapy.

Dogs are typically treated with glucocorticoids, such as prednisone, at an initial dosage of 1 to 2 mg/kg orally every 12 hours. Clinical signs and thoracic radiographs are used to monitor the animal's response to therapy, and initially these should be assessed every 1 to 2 weeks. Once the clinical signs have completely resolved, the dosage of glucocorticoids is decreased to the lowest effective one. If signs have remained in remission for 3 months, discontinuation of therapy can be attempted. If signs are exacerbated by glucocorticoid therapy, immediate reevaluation to search for underlying infectious agents is indicated.

Inhaled steroids administered from a metered-dose inhaler using a spacer and mask may be effective in controlling signs, minimizing the systemic effects of oral steroids. This route of administration is most likely to be effective in patients with predominantly bronchial involvement or to maintain remission of signs after initial treatment with oral steroids. The use of inhaled steroids is described in detail with treatment for feline bronchitis (idiopathic) in Chapter 21.

Dogs with large nodular lesions (eosinophilic granulomatosis) should be treated with a combination of glucocorticoids and a cytotoxic agent. Prednisone is administered to these animals at a dosage of 1 mg/kg orally every 12 hours, in combination with cyclophosphamide at a dosage of 50 mg/m^2 orally every 48 hours. Clinical signs and thoracic radiographs are evaluated every 1 to 2 weeks until remission is achieved. CBCs are also done every 1 to 2 weeks to detect excessive bone marrow suppression resulting from the cyclophosphamide. Attempts to discontinue therapy can be made after several months of remission. It may be necessary to discontinue the cyclophosphamide earlier than this because long-term treatment is associated with sterile hemorrhagic cystitis. (See Chapter 77 for further discussion of the adverse effects of cyclophosphamide therapy.) The effectiveness of other immunosuppressive drugs, such as cyclosporine, has not been reported.

Prognosis

A wide spectrum of disease is seen in terms of both the severity of signs and the underlying causes. The prognosis is generally fair to good. However, the prognosis is guarded in dogs with severe eosinophilic pulmonary granulomatosis.

IDIOPATHIC INTERSTITIAL PNEUMONIAS

The term *idiopathic interstitial pneumonia* generally denotes inflammatory infiltration and/or fibrosis of the lungs involving primarily the alveolar septa. Small airways, alveoli, and the pulmonary vasculature may also be affected. The alveolar septa include alveolar epithelium, epithelial basal lamina, capillary endothelial basal lamina, and capillary endothelium. Other cells include fibroblasts and alveolar macrophages. For a diagnosis of idiopathic disease, the known etiologies of interstitial lung disease must be ruled out as completely as possible. Causes of interstitial lung disease are numerous and include many infectious agents and some toxins and neoplasia.

Idiopathic pulmonary fibrosis is the best described idiopathic interstitial pneumonia in dogs and cats. Some of the eosinophilic lung diseases (not including allergic or idiopathic feline bronchitis) may also be part of this group of diseases. Other inflammatory lung diseases of the interstitium in which a cause cannot be identified are occasionally seen in dogs and cats. The lesions may represent a form of vasculitis, a component of systemic lupus erythematosus, immune complex disease, or some other hypersensitivity response. These diseases are rare, however, and are not well documented. A lung biopsy must be performed for a definitive diagnosis to be made. A clinical diagnosis is made only after extensive testing has been done to rule out more common causes of lung disease, particularly infectious agents and neoplasia, and after a prolonged positive response to immunosuppressive therapy.

IDIOPATHIC PULMONARY FIBROSIS

In people idiopathic pulmonary fibrosis is the clinical diagnosis that is defined by the histopathologic diagnosis of *usual interstitial pneumonia*. However, the histopathologic pattern of usual interstitial pneumonia can be seen as a result of other diseases; according to the American Thoracic Society/European Respiratory Society/Japanese Respiratory Society/Latin American Thoracic Association consensus statement (Raghu et al., 2011), the diagnosis of idiopathic pulmonary

fibrosis also requires (1) the exclusion of other known causes of interstitial lung diseases including domestic and occupational environmental exposures, connective tissue disease, and drug toxicity; (2) characteristic pattern on high resolution computed tomography (HRCT) in patients without surgical lung biopsy abnormalities; and (3) specific combinations of HRCT and surgical lung biopsy lesions in patients with biopsy. In veterinary medicine, the latter criterion may be difficult to apply, but attention should be paid to the other criteria.

Characteristic lesions that result in the histopathologic pattern of usual interstitial pneumonia are as follows: fibrosis, areas of fibroblast proliferation, metaplasia of the alveolar epithelium, and mild to moderate inflammation. Honeycomb change may occur as a result of enlarged airspaces lined by abnormal alveolar epithelium. The lungs are heterogeneously affected, with areas of normal lung intermixed with abnormal regions. The abnormal regions are often subpleural. A defect in wound healing has been hypothesized as the cause.

Idiopathic pulmonary fibrosis has been described in cats on the basis of histologic lesions that are quite similar to those in people (Cohn et al., 2004; Williams et al., 2006; Fig. 22.3). Unlike the disease that affects people and cats, the disease in dogs has been associated with the primary lesion of collagen deposition in the alveolar septa with no fibroblastic foci (Norris et al., 2005).

Neoplasia can occur concurrently with idiopathic pulmonary fibrosis in people and was reported in 6 of 23 cats (Cohn et al., 2004). The lesions of pulmonary fibrosis can also be misinterpreted as carcinoma, and 4 of 23 cats considered to have pulmonary fibrosis were initially given a pathologic diagnosis of carcinoma.

Clinical Features

A breed predisposition is seen in dogs with pulmonary fibrosis. West Highland White Terriers are most frequently reported, with fewer cases documented among Staffordshire Bull Terriers, Jack Russell Terriers, Cairn Terriers, and Schipperkes. Both dogs and cats tend to be middle-aged or older at the time of presentation, although characteristic signs have been found in patients as young as 2 years of age.

Signs are most often slowly progressive over months. In cats the duration of signs may be shorter, with 6 of 23 cats having shown signs for only 2 days to 2 weeks (Cohn et al., 2004). Respiratory compromise is the most prominent clinical sign of pulmonary fibrosis, manifested as exercise intolerance and/or rapid, labored breathing. Cough often occurs, but if it is the predominant sign, higher consideration should be given to a diagnosis of bronchitis. Syncope may occur in dogs.

Crackles are the hallmark auscultatory finding in dogs and are noted in some cats. Wheezes are heard in approximately half of dogs and in some cats. The abnormal breathing pattern is typically tachypnea with relatively effortless expiration.

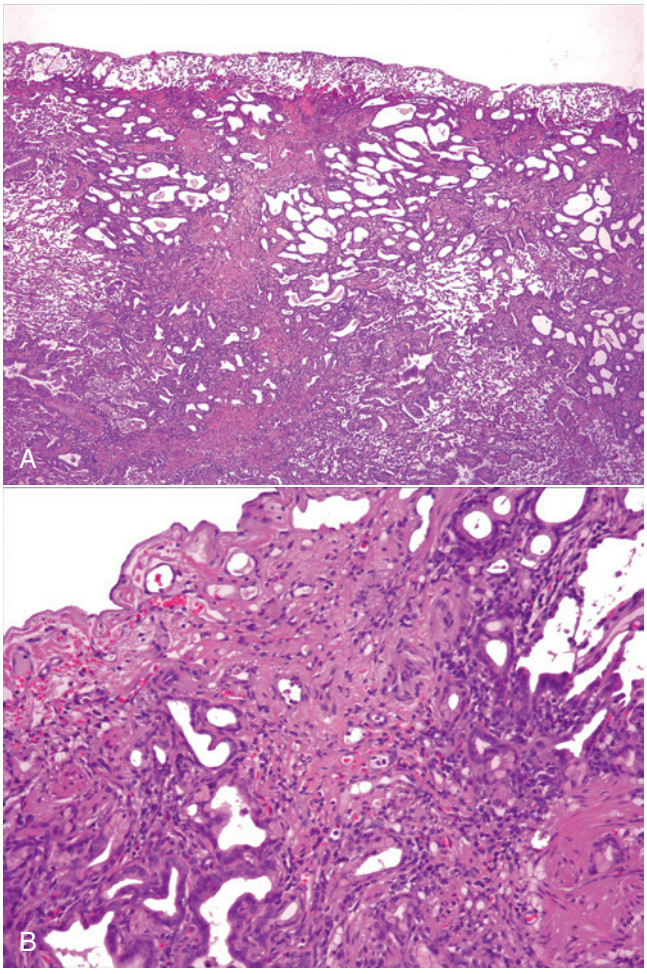

FIG 22.3
Photomicrographs of a lung biopsy from a cat with idiopathic pulmonary fibrosis. At lower power **(A),** distortion and obliteration of the normal pulmonary architecture are evident because of replacement of the parenchyma with disorganized bands of fibrous tissue and scattered mononuclear inflammatory cells. Few recognizable alveoli can be seen in this section. The alveolar septae are thickened, and metaplasia of the alveolar epithelium is present. At higher power **(B),** subpleural alveoli show marked distortion with clear septal fibrosis and type 2 epithelial hyperplasia. Although normal areas of the lung are not shown, the disease is characterized by heterogeneity of lesions within the lung. (Photomicrographs courtesy Stuart Hunter.)

Diagnosis

Thoracic radiographs of dogs with pulmonary fibrosis typically show a diffuse interstitial pattern. The abnormal densities generally must be moderate to severe to be distinguished from age-related change. A bronchial pattern is often noted concurrently, contributing to the overlap in signs between pulmonary fibrosis and chronic bronchitis. Evidence of pulmonary hypertension may be seen (see later in this chapter). Radiographs of cats with this disease may show diffuse or patchy infiltrate (Fig. 22.4). Patterns may be interstitial,

FIG 22.4
Lateral thoracic radiograph from a cat with idiopathic pulmonary fibrosis showing a diffuse interstitial pattern with patchy areas of alveolar disease in the caudal lung lobes. Pericardial and mediastinal fat is also seen. Radiographic abnormalities in cats with fibrosis are quite variable, including the range of interstitial, bronchial, alveolar, or mixed patterns.

bronchial, alveolar, or mixed but are often quite severe. Bronchiectasis, caused by traction on the airways, may be noted in either species with advanced disease.

Results of the CBC, serum biochemistry panel, and urinalysis are generally unremarkable. Polycythemia may be present secondary to chronic hypoxemia. Screening tests to identify other causes of interstitial lung disease include fecal examinations for parasites, heartworm tests, and appropriate infectious disease serology.

Airway specimens should be collected in sufficiently stable patients, primarily to assist in the identification of other causes of lung disease. Be aware that patients may be more compromised than they appear to be based on history and physical examination. Mild to moderate inflammation may be seen in patients with pulmonary fibrosis, but this is a nonspecific finding. Bronchoscopy may be useful in some patients for identifying other causes of lung disease, such as chronic bronchitis.

Typical lesions identified by computed tomography are often used in making a presumptive diagnosis of idiopathic pulmonary fibrosis in people. Similar lesions can be seen in some dogs with the disease (Johnson et al., 2005; Heikkila et al., 2011). Results of computed tomography in cats have not been reported.

Although not yet commercially available, measurement of serum endothlin-1 (ET-1) shows promise as a diagnostic test for idiopathic pulmonary fibrosis in dogs. In a study that included dogs with idiopathic pulmonary fibrosis, chronic bronchitis, or eosinophilic bronchopneumopathy, and healthy Beagle dogs, serum ET-1 concentrations greater than 1.8 pg/mL had a sensitivity of 100% and a specificity of 81% for the diagnosis of idiopathic pulmonary fibrosis (Krafft et al., 2011).

A definitive diagnosis of pulmonary fibrosis requires a lung biopsy obtained by thoracotomy or thoracoscopy. The expense and invasiveness of biopsy preclude its use in some patients. Furthermore, the lack of specific treatment recommendations for pulmonary fibrosis is a deterrent. However, biopsy should be considered in patients that are stable and whose owners have sufficient resources. The less invasive tests cannot completely rule out the existence of a different, directly treatable disease (e.g., atypical bacterial infection, fungal disease, parasitism).

Treatment

Idiopathic pulmonary fibrosis remains a relentless progressive disease even in people (Raghu and Richeldi, 2017). Historically, most individuals were treated with prednisone at low dosages and with azathioprine, as corticosteroids alone were not considered to be effective. Many other drugs, including colchicine, penicillamine, and *N*-acetylcysteine, have not been proven to be effective. A recent placebo-controlled, prospective study carried out by the Idiopathic Pulmonary Fibrosis Clinical Research Network (2012) found that risks of death and hospitalization were actually increased in patients receiving the combination of prednisone, azathioprine, and *N*-acetylcysteine.

Two drugs have been recently approved for the treatment of idiopathic pulmonary fibrosis in people. Nintedanib is an antifibrotic drug, and perfenidone has both antifibrotic and antiinflammatory properties. Their safety and efficacy in treating IPF in dogs or cats is not known. Further, these drugs are prescribed for patients with mild to moderate disease to slow progression of signs and delay the need for lung transplantation.

Most dogs and cats have been treated with corticosteroids and bronchodilators. Theophylline derivatives have the theoretical potential to provide some benefit through potentiation of steroid activity. It is likely that any beneficial effect from this combination is actually due to the presence of a steroid-responsive interstitial lung disease (i.e., not idiopathic pulmonary fibrosis) or control of concurrent bronchitis. Animals with signs of pulmonary hypertension are treated for this complication, as described later in this chapter. Omeprazole may be beneficial, particularly for patients receiving steroids. In people, gastroesophageal reflux is common with idiopathic pulmonary fibrosis, and microaspiration is speculated to play a role in the pathogenesis of the disease. Hypoxemia and corticosteroid administration can make patients more prone to adverse gastrointestinal effects (Heikkila-Laurila and Rajamaki, 2014).

Prognosis

The prognosis for idiopathic pulmonary fibrosis in dogs and cats is poor, with relentless progression of disease expected. Nevertheless, individual patients, particularly dogs, can survive for longer than a year. The mean survival time in dogs in one study was 18 months from the onset of signs, with survival up to 3 years (Corcoran et al., 1999). The prognosis in cats is poorer. Of 23 cats, 14 died or were euthanized

within weeks of onset of signs, and only 7 of 23 survived longer than 1 year (Cohn et al., 2004).

PULMONARY NEOPLASIA

Primary pulmonary tumors, metastatic neoplasia, and multicentric neoplasia can involve the lungs. Most primary pulmonary tumors are malignant. Carcinomas predominate and include adenocarcinoma, bronchoalveolar carcinoma, and squamous cell carcinoma. Sarcomas and benign tumors are much less common. Small cell carcinoma, or oat cell tumor, which occurs frequently in people, is rare in dogs and cats.

The lungs are a common site for the metastasis of malignant neoplasia from other sites in the body and even from primary pulmonary tumors. Neoplastic cells can be carried in the bloodstream and trapped in the lungs, where low blood flow and an extensive capillary network are present. Lymphatic spread or local invasion can also occur.

Multicentric tumors can involve the lungs. Such tumors include lymphoma, malignant histiocytosis, and mastocytoma.

Multiple tumors of different origins can occur in the same animal. In other words, the presence of a neoplasm in one site of the body does not necessarily imply that the same tumor is also present in the lungs.

Clinical Features

Neoplasms are most common in older animals but also occur in young adult animals. Tumors involving the lungs can produce a wide spectrum of clinical signs. These signs are usually chronic and slowly progressive, but peracute manifestations such as pneumothorax or hemorrhage can occur.

Most signs reflect respiratory tract involvement. Infiltration of the lung by the tumor can cause interference with oxygenation, leading to increased respiratory effort and exercise intolerance. Mass lesions can compress airways, provoking cough and obstructing ventilation. Erosion through vessels can result in pulmonary hemorrhage. Blood loss can be sudden, resulting in acute hypovolemia and anemia, in addition to respiratory compromise. Edema, nonseptic inflammation, or bacterial infection can occur secondary to the tumor. Erosion through the airways can result in pneumothorax. Pleural effusion of nearly any character can form. In rare cases, the caudal or cranial venae cavae are obstructed, resulting in the development of ascites or head and neck edema, respectively.

Nonspecific signs in dogs and cats with pulmonary neoplasms include weight loss, anorexia, depression, and fever. Gastrointestinal signs may be the primary complaint. Vomiting and regurgitation may be the presenting signs in cats in particular. Lameness may be the presenting sign in patients with hypertrophic osteopathy secondary to thoracic mass lesions and in cats with metastasis of carcinoma to their digits.

Some animals with lung neoplasia have no clinical signs at all, and the tumor is discovered as an incidental finding on thoracic radiographs or at postmortem examination. Animals with metastatic or multicentric lung neoplasia may have signs of tumor involvement in another organ.

Lung sounds may be normal, decreased, or increased. They are decreased over all lung fields in animals with pneumothorax or pleural effusion. Localized decreased or increased lung sounds can be heard over regions that are consolidated. In a few patients, crackles and wheezes can be auscultated. Evidence of other organ involvement or hypertrophic osteopathy may be noted.

Diagnosis

Neoplasia is definitively diagnosed through the histologic or cytologic identification of criteria of malignancy in populations of cells in pulmonary specimens (Fig. 22.5). Thoracic radiographs are commonly evaluated initially, and findings can support a tentative diagnosis of neoplasia. Radiographs can be used to identify the location of disease; this information helps the clinician select the most appropriate technique for specimen collection.

Good-quality radiographs, including both left and right lateral projections, should be evaluated. Primary pulmonary tumors can cause localized mass lesions (see Figs. 20.7 and 20.10) or the consolidation of an entire lobe (see Fig. 20.9, *A*). Tumor margins are often distinct but can be ill defined as a result of associated inflammation and edema. Cavitation may be evident. Metastatic or multicentric disease results in a diffuse reticular, nodular, or reticulonodular interstitial

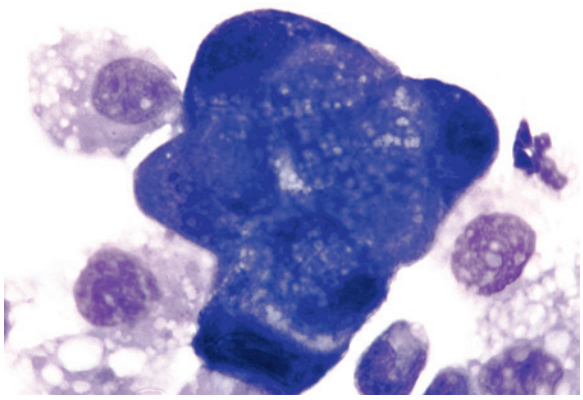

FIG 22.5
Bronchoalveolar lavage fluid from the dog whose lateral thoracic radiograph showing a severe, unstructured interstitial pattern is depicted in Fig. 20.8. Many clumps of deeply staining epithelial cells showing marked criteria of malignancy were seen. One such clump is shown here. A diagnosis of carcinoma was made. Note that a cytologic diagnosis of carcinoma should not be made if concurrent inflammation is noted. The surrounding lighter-staining cells are alveolar macrophages—the normal predominant cell type in bronchoalveolar lavage fluid.

pattern (see Fig. 20.8). In cats primary lung tumors often have a diffuse distribution by the time of presentation, and the radiographic pattern may be suggestive of bronchitis, edema, or pneumonia.

Pulmonary neoplasia is occasionally associated with hemorrhage, edema, inflammation, infection, or airway occlusion that can contribute to the formation of alveolar patterns and consolidation. Lymphadenopathy, pleural effusion, or pneumothorax can also be identified by radiography in some patients with neoplasia.

Non-neoplastic disease, including fungal infection, lung parasites, aspiration of mineral oil, eosinophilic granulomatosis, atypical bacterial infection, and inactive lesions from previous disease, can produce similar radiographic abnormalities. Pulmonary specimens must be evaluated to establish a diagnosis.

Tracheal wash fluid cytology rarely results in a definitive diagnosis. It is generally necessary to evaluate lung aspirates, bronchoalveolar lavage fluid, or lung biopsy specimens. Mass lesions located adjacent to the body wall are readily sampled by transthoracic lung aspiration. Accuracy and safety are improved with ultrasound guidance. Seeding of tumor as a result of aspiration of a pulmonary adenocarcinoma has been reported (Warren-Smith et al., 2011). This complication appears to be rare, but if the identified lesion will likely require surgical excision regardless of cause, the argument can be made to proceed directly to surgery.

It may be appropriate to delay the collection of pulmonary specimens in asymptomatic animals with multifocal disease or in animals with significant unrelated problems. Rather, radiographs are obtained again in 4 to 6 weeks to document the progression of lesions. Such delay is never recommended in dogs or cats with potentially resectable disease.

The confirmation of malignant neoplasia in other organs in conjunction with typical thoracic radiographic abnormalities is often adequate for a presumptive diagnosis of pulmonary metastases. Overinterpretation of subtle radiographic lesions should be avoided. Conversely, the absence of radiographic changes does not eliminate the possibility of metastatic disease.

Evaluation of the thorax by computed tomography should be considered in patients with known or suspected neoplasia. Computed tomography is much more sensitive than thoracic radiography in the detection of metastatic disease (see Chapter 20). In patients with localized disease for whom surgical excision is being planned, computed tomography provides more detailed anatomic information regarding the involvement of adjacent structures and is more accurate in identifying involvement of tracheobronchial lymph nodes, compared with radiography.

Treatment

Solitary pulmonary tumors are treated by surgical resection. To obtain clear margins, usually the entire lung lobe that is involved must be excised. Lymph node biopsy specimens, as well as biopsy specimens from any grossly abnormal lung, are obtained for histologic analysis.

In animals with a large mass lesion, respiratory signs may abate after excision, even if metastatic lesions are present throughout the lungs. If the lesions cannot be removed surgically, chemotherapy can be attempted (see Chapter 76). No protocol is uniformly effective for the treatment of primary lung tumors.

Metastatic neoplasms of the lungs are treated with chemotherapy. In most animals the initial protocol is determined by the expected sensitivity of the primary tumor. Unfortunately, metastatic neoplasms do not always have the same response to specific agents as the primary tumor.

Multicentric tumors are treated with standard chemotherapeutic protocols, regardless of whether the lungs are involved. Multicentric tumors are discussed in Chapter 78.

Prognosis

The prognosis for animals with benign neoplasms is excellent, but these tumors are uncommon. The prognosis for animals with malignant neoplasia is potentially related to several variables, which include tumor histology, the presence of regional lymph node involvement, and the presence of clinical signs. Survival times of several years are possible after surgical excision. Ogilvie et al. (1989) reported that, of 76 dogs with primary pulmonary adenocarcinoma, surgical excision resulted in remission (i.e., elimination of all macroscopic evidence of tumor) in 55 dogs. The median survival time of dogs that went into remission was 330 days, whereas the survival time in dogs that did not achieve remission was 28 days. At the completion of the study, 10 dogs remained alive. McNiel et al. (1997) found that the histologic score of the tumor, the presence of clinical signs, and regional lymph node metastases were significantly associated with the prognosis in 67 dogs with primary lung tumors. Median survival times for dogs with and without clinical signs were 240 and 545 days, respectively. Median survival times for dogs with and without lymph node involvement were 26 and 452 days, respectively. Median survival time for dogs with papillary carcinoma was 495 days, compared with 44 days for dogs with other histologic tumor types. Survival times ranged from 0 to 1437 days. A report of 21 cats with primary lung tumor described a median survival time of 115 days after surgery (Hahn et al., 1998). Cats with moderately differentiated tumors had a median survival time of 698 days (range, 13-1526 days), whereas cats with poorly differentiated tumors had a median survival time of 75 days (range, 13-634 days). The prognosis for animals with multicentric neoplasms is not known to depend on the presence or absence of pulmonary involvement.

PULMONARY HYPERTENSION

Etiology

Pulmonary hypertension is diagnosed when pulmonary systolic pressure exceeds 30 mm Hg. The diagnosis is most accurately made by direct pressure measurements obtained via cardiac catheterization—a procedure rarely performed in

dogs or cats. However, an estimation of pulmonary artery pressure can be made by Doppler echocardiography in patients with pulmonary or tricuspid valvular insufficiency (see Chapter 6). The widespread availability of this technology has increased awareness of the existence of pulmonary hypertension in veterinary medicine. Causes of pulmonary hypertension include obstruction to venous drainage as can occur with left-sided heart disease (see Chapter 6), increased pulmonary blood flow caused by congenital heart lesions (see Chapter 5), and increased pulmonary vascular resistance. When no underlying disease can be identified to explain the hypertension, a clinical diagnosis of primary (idiopathic) pulmonary hypertension is made.

Pulmonary vascular resistance can be increased as a result of pulmonary thromboembolism (PTE; see later) or heartworm disease (see Chapter 10). Vascular resistance can also be increased as a complication of chronic pulmonary parenchymal disease, such as canine chronic bronchitis (see Chapter 21) and idiopathic pulmonary fibrosis (see prior discussion). An overly simplistic explanation for increased vascular resistance as a complication of pulmonary disease is the adaptive response of the lung to improve the matching of ventilation and perfusion ($\dot{V}/\dot{Q}$) through hypoxic vasoconstriction. However, other factors are thought to contribute significantly to the development of hypertension associated with pulmonary disease, including endothelial dysfunction, vascular remodeling, and thrombosis in situ.

Clinical Features and Diagnosis

Pulmonary hypertension is diagnosed more commonly in dogs than in cats. Clinical signs include those of progressive hypoxemia and can be difficult to distinguish from any underlying cardiac or pulmonary disease. Signs include exercise intolerance, weakness, syncope, and respiratory distress. Physical examination may reveal a loud split second heart sound (see Chapter 6). Radiographic evidence of pulmonary hypertension may be present in severely affected patients and includes pulmonary artery enlargement and right-sided cardiomegaly. Radiographs are evaluated closely for underlying cardiopulmonary disease. The diagnosis of pulmonary hypertension is most often made through Doppler echocardiography. Use of this modality to estimate pulmonary artery pressure requires the presence of pulmonary or tricuspid regurgitation and a skilled echocardiographer.

Treatment

Pulmonary hypertension is best treated by identifying and aggressively managing any underlying disease process. In people, pulmonary hypertension associated with chronic bronchitis is usually mild and is not directly treated. Long-term oxygen therapy is often provided, but this treatment is rarely practical for veterinary patients.

Treatment targeted specifically to address the pulmonary hypertension itself is indicated for patients showing clinical signs of pulmonary hypertension when no underlying disease is identified, or when management of underlying disease fails to improve pulmonary arterial pressures or clinical signs. The drug most commonly used in dogs is sildenafil citrate (Viagra, Pfizer), a phosphodiesterase V inhibitor that causes vasodilation through a nitric oxide pathway. A dosage of 1 mg/kg orally every 8 hours was shown in a cross-over study of dogs with pulmonary hypertension to decrease systolic pulmonary arterial pressure and result in increased exercise capacity and quality of life compared with placebo (Brown et al., 2010). However, a retrospective study documented improvement in quality of life but not pressure measurements (Kellum and Stepien, 2007). A range of dosages has been reported from 0.5 to 3.0 mg/kg every 8 to 12 hours. Monitoring for both beneficial and adverse effects is important, with adjustments to dosage as indicated by response.

Pimobendan, a phosphodiesterase III inhibitor, results in decreased pulmonary artery pressure in dogs with pulmonary hypertension associated with chronic valvular heart disease (Atkinson et al., 2009). In a retrospective study, pimobendan was not shown to improve survival times in dogs with severe pulmonary hypertension due to lung disease when combined with sildenafil, compared with treatment with sildenafil alone (Murphy et al., 2017). Pimobendan is discussed further in Chapter 3.

Long-term anticoagulation with warfarin or heparin is often prescribed for people with primary pulmonary hypertension to prevent small thrombi formation. Its potential benefits for veterinary patients are not known.

Prognosis

The prognosis for pulmonary hypertension is presumably influenced by the severity of hypertension, the presence of clinical signs, and any underlying disease.

PULMONARY THROMBOEMBOLISM (PTE)

The extensive low-pressure vascular system of the lungs is a common site for emboli to lodge. It is the first vascular bed through which thrombi from the systemic venous network or the right ventricle pass. Respiratory signs can be profound and even fatal in dogs and cats. Hemorrhage, edema, and bronchoconstriction, in addition to decreased blood flow, can contribute to the respiratory compromise. The attendant increased vascular resistance secondary to physical obstruction by emboli and vasoconstriction results in pulmonary hypertension, which can ultimately lead to the development of right-sided heart failure.

Microthrombi are thought to play a role in pulmonary hypertension, as discussed in the previous section. However, most patients who present primarily with signs of thromboembolism have a predisposing disease in organs other than the lungs, and a search for the underlying cause of clot formation is therefore essential. Abnormalities predisposing to clot formation include venous stasis, turbulent blood flow, endothelial damage, and hypercoagulation. In addition to emboli originating from thrombi, emboli can consist of

bacteria, parasites (particularly heartworms), neoplasia, or fat. Conditions that have been associated with the development of pulmonary emboli, and the chapters where they are discussed, are listed in Box 22.3.

Clinical Features

In many instances, the predominant presenting sign of animals with PTE is peracute respiratory distress. Cardiovascular shock and sudden death can occur. As awareness of PTE has increased, the diagnosis is being made with greater frequency in patients with milder and more chronic signs of tachypnea or increased respiratory efforts. Historical or physical examination findings related to a potential underlying disease increase the index of suspicion for a diagnosis of PTE. A loud or split second heart sound may be heard on auscultation and is indicative of pulmonary hypertension. Crackles or wheezes are heard in occasional cases.

Diagnosis

Routine diagnostic methods do not provide information that can be used to make a definitive diagnosis of PTE. A high index of suspicion must be maintained because this disease is frequently overlooked. The diagnosis is suspected on the basis of clinical signs, thoracic radiography, arterial blood gas analysis, echocardiography, and clinicopathologic data. A definitive diagnosis requires contrast-enhanced computed tomography, pulmonary angiography, selective angiography, or nuclear perfusion scanning, but contrast-enhanced computed tomography is the routine modality for diagnosis.

PTE is suspected in dogs and cats with severe dyspnea of acute onset, particularly if minimal or no radiographic signs of respiratory disease are evident. In many cases of PTE, the lungs appear normal on thoracic radiographs in spite of severe lower respiratory tract signs. When radiographic lesions occur, the caudal lobes are most often involved. Blunted pulmonary arteries, in some cases ending with focal or wedge-shaped areas of interstitial or alveolar opacity resulting from extravasation of blood or edema, may be present. Areas of lung without a blood supply can appear hyperlucent. Diffuse interstitial and alveolar opacities and right-sided heart enlargement can occur. Pleural effusion is present in some cases and is usually mild. Echocardiography may show secondary changes (e.g., right ventricular enlargement, increased pulmonary artery pressures), underlying disease (e.g., heartworm disease, primary cardiac disease), or residual thrombi.

Arterial blood gas analysis can show mild or profound hypoxemia. Tachypnea leads to hypocapnia, except in severe cases, and the abnormal alveolar-arterial oxygen gradient (*A-a* gradient) supports the presence of a ventilation/perfusion disorder (see Chapter 20). A poor response to oxygen supplementation is supportive of a diagnosis of PTE.

Clinicopathologic evidence of a disease known to predispose animals to thromboemboli further heightens suspicion for this disorder. Unfortunately, routine measurements of clotting parameters (e.g., prothrombin time, partial thromboplastin time) are not helpful in making the diagnosis or even in identifying at-risk patients. *Thromboelastography* (TEG) is a diagnostic tool that results in a graph, indicating rate of clot development, clot strength, and subsequent dissolution. Interest has been growing for the use of this technique and related techniques in veterinary critical care settings. The test cannot be used as a diagnostic tool for PTE itself but may prove useful in identifying at-risk patients (those with measured hypercoagulability), directing treatment to affected arms of coagulation, and monitoring the effect of specific treatment on measured coagulability.

In people, measurement of circulating D-dimers (a degradation product of cross-linked fibrin) is used as an indicator of the likelihood of PTE. It is not considered a specific test, so its primary value has been in the elimination of PTE from the differential diagnoses. However, even a negative result can be misleading in certain disease states and in the presence of small subsegmental emboli.

Measurement of D-dimer concentrations is available for dogs through commercial laboratories. A study of 30 healthy dogs, 67 clinically ill dogs without evidence of thromboembolic disease, and 20 dogs with thromboembolic disease provides some guidance for interpretation of results (Nelson et al., 2003). A D-dimer concentration > 500 ng/mL was able to predict the diagnosis of thromboembolic disease with 100% sensitivity but with a specificity of only 70% (i.e., having 30% false-positive results). A D-dimer concentration > 1000 ng/mL decreased the sensitivity of the result to 94% but increased the specificity of the result to 80%. A D-dimer concentration > 2000 ng/mL decreased the sensitivity of the result to 36% but increased the specificity to 98.5%. Thus the degree of elevation in D-dimer concentration must be considered in conjunction with other clinical information.

Computed tomography pulmonary angiography is commonly used in people to confirm a diagnosis of PTE and is being used routinely for the diagnosis in veterinary

medicine. The diagnosis can never be ruled out on the basis of computed tomography because multiple small arteries, rather than one or more large vessels, may be obstructed. Further, changes may be apparent for only a few days after the event. One limitation of thoracic computed tomography in dogs and especially in cats is patient size. In addition, veterinary patients will not hold their breath. Patients must be anesthetized and positive-pressure ventilation applied during scanning for maximal resolution. A high-quality computed tomography scanner and an experienced radiologist are required for accurate interpretation.

Selective angiography is the historic gold standard for the diagnosis of PTE. Sudden pruning of pulmonary arteries or intravascular filling defects and extravasation of dye are characteristic findings. Nuclear scans can provide evidence of PTE with minimal risk to the animal. Unfortunately, this technology has limited availability.

Pulmonary specimens for histopathologic evaluation are rarely collected, except at necropsy. However, evidence of embolism is not always found at necropsy because clots may dissolve rapidly after death. Therefore such tissue should be collected and preserved immediately after death. The extensive vascular network makes it impossible to evaluate all possible sites of embolism, and the characteristic lesions may also be missed.

Treatment

All animals with suspected PTE should be given aggressive supportive care and treatment for any underlying, predisposing conditions. Oxygen therapy (see Chapter 25) is indicated for all patients. Fluids are administered as needed to support circulation, with care to avoid fluid overload. Theophylline may be beneficial in some patients (see Chapter 21). Sildenafil may be helpful for patients with evidence of pulmonary hypertension (see prior discussion of Pulmonary Hypertension in this chapter).

The use of fibrinolytic agents for the treatment of PTE in animals has not been well established. Animals with suspected hypercoagulability are likely to benefit from anticoagulant therapy. The goal of such therapy is to prevent the formation of additional thrombi. Anticoagulant therapy is administered only to animals in which the diagnosis is highly probable. Dogs with heartworm disease suffering from post-adulticide therapy reactions usually are not treated with anticoagulants (see Chapter 10). Potential surgical candidates should be treated with great caution. Clotting times must be monitored frequently to minimize the risk of severe hemorrhage.

Specific recommendations for the treatment and prevention of thromboembolic disease with anti-coagulant drugs are provided in Chapter 12. Because of the serious problems and limitations associated with anticoagulant therapy, eliminating the predisposing problem must be a major priority.

Prevention

No methods of preventing PTE in at-risk patients have been objectively studied in veterinary medicine. Treatments that have potential benefit include the long-term administration of low-molecular-weight heparin, aspirin, or clopidogrel. Aspirin for the prevention of PTE remains controversial because aspirin-induced alterations in local prostaglandin and leukotriene metabolism may be detrimental.

Prognosis

The prognosis depends on the severity of the respiratory signs, the response to supportive care, and the ability to eliminate the underlying process. In general, a guarded prognosis is warranted.

PULMONARY EDEMA

Etiology

The same general mechanisms that cause edema elsewhere in the body cause edema in the pulmonary parenchyma. Major mechanisms include decreased plasma oncotic pressure, vascular overload, lymphatic obstruction, and increased vascular permeability. The disorders that can produce these problems are listed in Box 22.4. Most cases of pulmonary edema resulting primarily from increased vascular permeability fall within the classification system of *acute lung injury* (ALI) and *acute respiratory distress syndrome* (ARDS). ALI is an excessive inflammatory response of the lung to a pulmonary or systemic insult. ARDS describes severe ALI based on degree of hypoxemia. The rapid leakage of high-protein edema fluid from damaged capillaries is a key feature of ALI. In some patients that survive the initial edema, epithelial cell proliferation and collagen deposition add to pulmonary dysfunction and can ultimately result in pulmonary fibrosis within a short time (e.g., weeks).

Regardless of cause, edema fluid initially accumulates in the interstitium. However, because the interstitium is a small compartment, the alveoli are soon involved. When profound fluid accumulation occurs, even the airways become filled. Respiratory function is further affected as a result of the atelectasis and decreased compliance caused by compression of the alveoli and decreased concentrations of surfactant. Airway resistance increases as a result of the luminal narrowing of small bronchioles. Hypoxemia results from ventilation/perfusion abnormalities.

Clinical Features

Animals with pulmonary edema are seen because of cough, tachypnea, respiratory distress, or signs of the inciting disease. Crackles are heard on auscultation, except in animals with mild or early disease. Blood-tinged froth may appear in the trachea, pharynx, or nares immediately preceding death from pulmonary edema. Respiratory signs can be peracute, as in ALI/ARDS, or subacute, as in hypoalbuminemia. However, a prolonged history of respiratory signs (e.g., months) is not consistent with a diagnosis of edema. The list of differential diagnoses in Box 22.4 can often be greatly narrowed by obtaining a thorough history and performing a thorough physical examination.

BOX 22.4

Possible Causes of Pulmonary Edema

Decreased Plasma Oncotic Pressure

Hypoalbuminemia
- Gastrointestinal loss
- Glomerulopathy
- Liver disease
- Iatrogenic overhydration
- Starvation

Vascular Overload

Cardiogenic
- Left-sided heart failure
- Left-to-right shunts

Overhydration

Lymphatic Obstruction (Rare)

Neoplasia

Increased Vascular Permeability

Inhaled agents
- Smoke inhalation
- Gastric acid aspiration
- Oxygen toxicity

Drugs or toxins
- Snake venom
- Cisplatin in cats
- Paraquat

Electrocution

Trauma
- Pulmonary contusions
- Multisystemic

Sepsis or systemic inflammatory response (SIRS)

Pancreatitis

Uremia

Disseminated intravascular coagulation

Inflammation (infectious or noninfectious)

Miscellaneous Causes

Thromboembolism

Upper airway obstruction

Near-drowning

Neurogenic edema
- Seizures
- Head trauma

Diagnosis

Pulmonary edema in most dogs and cats is based on typical radiographic changes in the lungs in conjunction with clinical evidence (from the history, physical examination, radiography, echocardiography, and serum biochemical analysis [particularly albumin concentration]) of a disease associated with pulmonary edema.

Early pulmonary edema assumes an interstitial pattern on radiographs, which progresses to become an alveolar pattern. In dogs edema caused by heart failure is generally more severe in the hilar region. In cats the increased opacities are more often patchy and unpredictable in their distribution. Edema resulting from increased vascular permeability tends to be most severe in the dorsocaudal lung regions.

Radiographs should be carefully examined for signs of heart disease, venous congestion, PTE, pleural effusion, and mass lesions. Echocardiography is helpful in identifying primary cardiac disease if the clinical signs and radiographic findings are ambiguous.

Decreased oncotic pressure can be identified by the serum albumin concentration. Concentrations less than 1 g/dL are usually required before decreased oncotic pressure is considered to be the sole cause of the pulmonary edema. Pulmonary edema resulting purely from hypoalbuminemia is probably rare. In many animals volume overload or vasculitis is a contributing factor. Plasma protein quantitation using a refractometer can indirectly assess albumin concentration in emergency situations.

Vascular permeability edema can result in the full range of compromise, from minimal clinical signs that spontaneously resolve to the frequently fatal, fulminant process of ARDS. A consensus group has determined definitions for ALI/ARDS in veterinary patients (Wilkins et al., 2007). At least four, and ideally five, of the following criteria must be met: acute onset (<72 hours) of tachypnea and labored breathing at rest; known risk factors; evidence of pulmonary capillary leak without increased pulmonary capillary pressure (e.g., bilateral diffuse pulmonary infiltrates on radiography or computed tomography, proteinaceous fluid retrieved from airways); evidence of insufficient gas exchange; and evidence of diffuse pulmonary inflammation based on tracheal wash or BAL fluid analysis. One measure of insufficient gas exchange is a low Pa_{O_2} (partial pressure of oxygen in the blood)/Fi_{O_2} (fraction of inspired oxygen) ratio without the mechanical ventilation technique of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). A ratio of < 300 mm Hg is consistent with ALI. A ratio of < 200 mm Hg is consistent with the more severe form, ARDS. Arterial blood gas analysis and pulse oximetry in dogs and cats with pulmonary edema of any origin are useful in selecting and monitoring therapy. Hypoxemia is present, usually in conjunction with hypocapnia and a widened *A-a* gradient.

Treatment

It is easier for the body to prevent edema fluid from forming than it is to mobilize existing fluid. The initial management of pulmonary edema should be aggressive. Once edema has resolved, the body's own compensatory mechanisms become more effective and the intensity of therapeutic interventions can often be decreased.

All animals with pulmonary edema are treated with cage rest and minimal stress. Dogs and cats with significant hypoxemia should receive oxygen therapy (see Chapter 25). Positive-pressure ventilation is required in severe cases. Methylxanthine bronchodilators (see Chapter 21) may also be beneficial in some patients. They are mild diuretics that also decrease bronchospasms and possibly respiratory

muscle fatigue. However, in some patients bronchodilators exacerbate $\dot{V}/\dot{Q}$ mismatching. The patient's response to bronchodilators should be carefully observed.

Furosemide is indicated for the treatment of most forms of edema but is not used in hypovolemic animals. Animals with hypovolemia actually require conservative fluid supplementation. If this is necessary to maintain vascular volume in animals with cardiac impairment or decreased oncotic pressure, then positive inotropic agents or plasma infusions, respectively, are necessary.

Edema caused by hypoalbuminemia is treated with plasma or colloid infusions. However, it is not necessary for the plasma protein concentrations to reach normal levels for edema to decrease. Furosemide can be administered to more quickly mobilize fluid from the lungs, but clinical dehydration and hypovolemia must be prevented. Diagnostic and therapeutic efforts are directed at the underlying disease.

Treatment of cardiogenic edema is discussed in Chapter 3.

Overhydration is treated by discontinuation of fluid therapy. Furosemide is administered if respiratory compromise is present. If excessive volumes of fluid were not administered inadvertently, causes of fluid intolerance, such as oliguric renal failure, heart failure, and increased vascular permeability, must be sought.

Edema caused by increased vascular permeability is difficult to treat. In some cases, pulmonary compromise is mild and edema transient. Routine supportive care with oxygen supplementation may be sufficient, but mechanical ventilation is often required. Any active underlying problem should be identified and corrected.

Patients with ALI/ARDS respond poorly to management. Ventilator therapy with PEEP is indicated, and even with such aggressive support the mortality rate is high. Furosemide is generally ineffective in treating edema caused by increased vascular permeability, but because of limitations in our diagnostic capabilities it is reasonable to include this drug in the initial management of these patients. Glucocorticoids are of no clear benefit in these patients, but they are frequently given to animals with moderate to severe signs. Many novel therapies for ARDS have been studied in people, although to date none has been shown to be consistently effective in improving outcome. Emphasis is on specific inhibitors of the inflammatory response.

Prognosis

The prognosis for an animal with pulmonary edema depends on the severity of the edema, the response to oxygen therapy, and the ability to eliminate or control the underlying problem. Aggressive management early in the course of edema formation improves the prognosis for an animal with any given disease. Animals with ARDS have a guarded to grave prognosis.

CHAPTER 23

Clinical Manifestations and Diagnostic Tests of Pleural Cavity and Mediastinal Disease

CLINICAL SIGNS

Common abnormalities of the pleural cavity in the dog and cat include the accumulation of fluid (pleural effusion) or air (pneumothorax) in the pleural space. Mediastinal masses and the pneumomediastinum are also discussed in this chapter and the next. Respiratory signs caused by pleural disease result from interference with normal expansion of the lungs. Exercise intolerance is an early sign; overt respiratory distress ultimately occurs. Physical examination findings that assist in localizing the cause of respiratory compromise to the pleural space include increased respiratory rate and decreased lung sounds on auscultation (see Chapter 25). With increasing compromise, increased abdominal excursions during breathing may be seen. Breathing effort may be increased during inspiration relative to expiration, but this finding is not always obvious. Paradoxical breathing refers to a breathing pattern in which the abdominal walls are "sucked in" during inspiration. Paradoxical breathing has been associated with pleural diseases in dogs and cats presented for respiratory distress (LeBoedec et al., 2012). In cats with mediastinal masses, decreased compressibility of the anterior thorax may be palpable.

Pulmonary thromboembolism (PTE) can cause pleural effusion. The effusion is generally mild and may be an exudate or a modified transudate. PTE should be considered as a diagnosis, particularly in patients whose respiratory efforts seem in excess of the volume of effusion (see Chapter 22).

GENERAL DIAGNOSTIC APPROACH

The presence of pleural or mediastinal disease in a dog or cat is usually confirmed by thoracic radiography, thoracic ultrasonography, or thoracocentesis. In animals presented in respiratory distress with suspected pleural effusion or pneumothorax, thoracocentesis is performed immediately to stabilize the animal's condition before radiographs are taken. Although thoracocentesis is more invasive than radiography, the potential therapeutic benefit of the procedure far outweighs the small risk of complications. Animals in stable condition at presentation can be evaluated initially with thoracic radiographs or ultrasound to confirm the presence of air or fluid and the location of fluid before thoracocentesis is performed.

Ultrasonography is a valuable tool for the evaluation of patients with pleural effusion. If equipment is available on site, animals in critical condition can be examined with minimal stress to confirm the presence of fluid and direct needle placement for thoracocentesis. Ultrasonography is also useful in evaluating the thorax for the presence of mass lesions, hernias, and primary cardiac or pericardial disease. Because sound waves cannot pass through aerated lungs, any masses must be adjacent to the chest wall, heart, or diaphragm to be detected by ultrasound. The presence of pleural fluid facilitates ultrasonographic evaluation of the chest. If the patient is stable, it is preferable to evaluate the thorax ultrasonographically before the pleural fluid is removed.

Thoracic radiographs should be taken again after as much fluid or air as possible has been removed from the pleural space and the lungs have had time to reexpand. Full expansion of the lungs is required for accurate evaluation of the pulmonary parenchyma. The presence of fluid also obscures visibility of heart size and shape and mass lesions.

Cytologic analysis of pleural fluid obtained by thoracocentesis is indicated for the diagnostic evaluation of all animals with pleural effusion. Measurement of protein concentration and total nucleated cell count, as well as qualitative assessment of individual cells, is essential for accurate classification of the fluid, formulation of a diagnostic plan, and initiation of appropriate therapy (Table 23.1). The diagnostic approach to patients with pleural effusion based on cytologic findings is described further later. For patients with a mediastinal mass, fine-needle aspirates are obtained with ultrasound guidance for analysis.

TABLE 23.1

Diagnostic Approach in Dogs and Cats With Pleural Effusion Based on Fluid Type

FLUID TYPE	COMMON DISEASE	DIAGNOSTIC TESTS
Pure and modified transudates	Right-sided heart failure	Evaluate pulses, auscultation, ECG, thor rad, echo
	Pericardial disease	See right-sided heart failure
	Hypoalbuminemia (pure transudate)	Serum albumin concentrations
	Neoplasia	Thor rad and US, CT, thoracoscopy, thoracotomy
	Diaphragmatic hernia	Thor rad and US
Nonseptic exudates	Feline infectious peritonitis (FIP)	Pleural fluid cytology is generally sufficient. In questionable cases many tests are available, but none has shown good specificity for diagnosing FIP. Consider systemic evaluation, ophthalmoscopic examination, serum or fluid electrophoresis, coronavirus antibody titer, PCR of tissues or effusion (see Chapter 96)
	Neoplasia	See Neoplasia above
	Diaphragmatic hernia	See Diaphragmatic hernia above
	Lung lobe torsion	Thor rad and US, bronchoscopy, thoracotomy
Septic exudates	Pyothorax	Gram staining, aerobic and anaerobic cultures, serial thor rad
Chylous effusion	Chylothorax	See Box 24.1
Hemorrhagic effusion	Trauma	History
	Bleeding disorder	Systemic examination, coagulation tests (ACT, PT, PTT), platelet count
	Neoplasia	See Neoplasia above
	Lung lobe torsion	See Lung lobe torsion above

ACT, Activated clotting time; *CT,* computed tomography; *ECG,* electrocardiography; *echo,* echocardiography; *PCR,* polymerase chain reaction; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *thor rad,* thoracic radiography; *US,* ultrasonography.

Chest tube (thoracostomy tube) placement is indicated primarily for the treatment of patients with progressive pneumothorax or pyothorax. However, fluid obtained from chest tubes is used for therapeutic monitoring, and a description of chest tube placement and management appears at the end of this chapter.

Thoracic computed tomography (CT) is indicated in patients with pleural or mediastinal disease without a diagnosis after routine imaging and cytologic analysis of fluid or masses. Thoracoscopy and/or thoracotomy may be necessary to obtain a diagnosis in challenging cases.

DIAGNOSTIC APPROACH FOR PLEURAL EFFUSIONS BASED ON FLUID CYTOLOGY

Pleural fluid is classified as a transudate, a modified transudate, or an exudate on the basis of protein concentration and nucleated cell count. Further classification of fluid may be possible on the basis of other cytologic or biochemical features. Additional clinically useful fluid categories include septic exudate, chylous effusion, hemorrhagic effusion, and effusion caused by neoplasia. Although various types of fluid have a typical gross appearance (Fig. 23.1), reliance on gross appearance alone will lead in some cases to the misclassification of fluid and missed diagnoses through failure to identify organisms or abnormal or unexpected cell populations. In addition to the inflammatory cell types included in each cytologic category described in subsequent sections of this chapter, mesothelial cells are generally present and are often reactive.

TRANSUDATES AND MODIFIED TRANSUDATES

Pure transudates are fluids with low protein concentrations of less than 2.5 to 3 g/dL and low nucleated cell counts of less than 500 to 1000/μL. The primary cell types are mononuclear cells, composed of macrophages, lymphocytes, and mesothelial cells. Modified transudates have a slightly higher protein concentration of up to 3.5 g/dL and nucleated cell counts of up to 5000/μL. Primary cell types include neutrophils and mononuclear cells.

Transudates and modified transudates are formed as a result of increased hydrostatic pressure, decreased plasma oncotic pressure, or lymphatic obstruction. Increased hydrostatic pressure occurs in association with right-sided congestive heart failure or pericardial disease. Physical examination findings such as abnormal jugular pulses, gallop rhythms, arrhythmias, or murmurs support a diagnosis of heart disease. Heart sounds may be muffled in animals with pericardial effusion. Thoracic radiography (after fluid removal), electrocardiography, and echocardiography are indicated for cardiac evaluation (see Chapter 2).

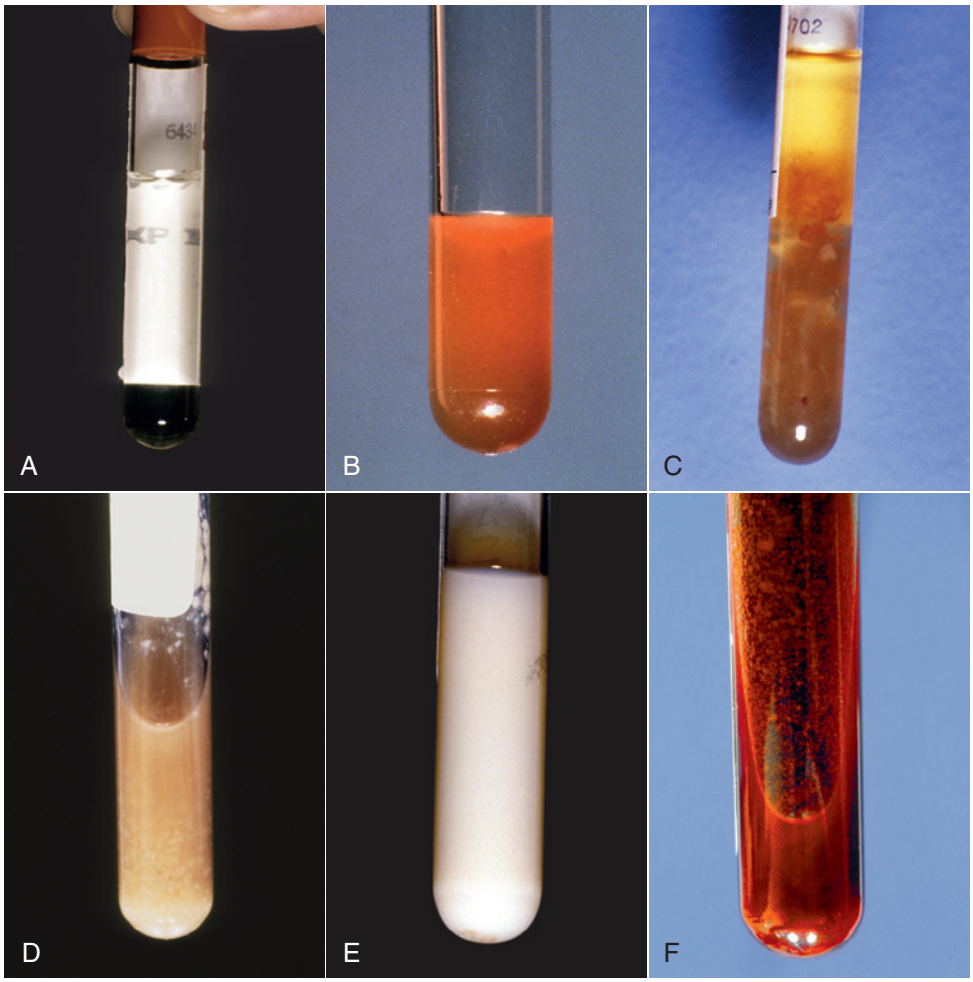

FIG 23.1
Characteristic gross appearance of the various types of pleural effusions. Note that cytologic analysis should always be performed to ensure accurate classification of fluid and to avoid missing diagnostic organisms or neoplastic cells. **(A)** Transudate. Fluid is nearly clear. **(B)** Modified transudate. Fluid is slightly opaque and, in this example, red-tinged. **(C)** Nonseptic exudate. Fluid is more opaque. The fluid shown is from a cat with feline infectious peritonitis (FIP). FIP fluid is characteristically straw-colored with grossly visible fibrin clots. **(D)** Septic exudate. Fluid has a purulent appearance, with cellular debris gravitating toward the bottom of the tube. **(E)** Chylous effusion. Fluid is milky white. **(F)** Hemorrhagic effusion. Hemorrhagic effusions are bright to dark red. In this case, cytologic examination revealed filamentous organisms, demonstrating the importance of cytologic analysis.

Decreased plasma oncotic pressure is a result of hypoalbuminemia. Effusions secondary to hypoalbuminemia alone are pure transudates that have very low protein concentrations. Subcutaneous edema may be detected in dependent areas of the body. Decreased production of albumin causes hypoalbuminemia in patients with liver disease, and increased loss of albumin causes it in patients with glomerulopathy or protein-losing enteropathy. The total plasma protein concentration shown by refractometry during initial evaluation of the dog or cat can serve as a rapid screening test for hypoalbuminemia. Serum biochemical analysis provides an exact measurement of the albumin concentration. In general, albumin concentrations must be lower than 1 g/dL before transudation caused only by hypoalbuminemia occurs. However, a combination of factors may contribute to effusions (e.g., vasculitis, hypoalbuminemia, and fluid overload).

Neoplasia and diaphragmatic hernias can cause lymphatic obstruction. Diaphragmatic hernias should be suspected in any animal with a history of trauma. The trauma may have been recent or may have occurred years ago. Although a modified transudate usually forms as a result of chronic diaphragmatic hernia, an exudative fluid can also be found. Diaphragmatic hernias are identified by radiography or ultrasonography. Occasionally, it is necessary to administer barium orally and perform an upper gastrointestinal series,

to intraperitoneally administer water-soluble iodinated contrast media and perform peritoneography, or perform CT, to confirm the presence of a diaphragmatic hernia.

Neoplasia must be considered as a differential diagnosis for patients with any type of effusion, although it is rare for a pure transudate to develop. (See the section on effusions caused by neoplasia.)

SEPTIC AND NONSEPTIC EXUDATES

Exudates have a high protein concentration (greater than 3 g/dL) compared with that in transudates. Nucleated cell counts are also high (greater than 5000/μL). Cell types in nonseptic exudates include neutrophils, macrophages, eosinophils, and lymphocytes. The macrophages and lymphocytes may be activated, and typically the neutrophils are nondegenerative. There is no evidence of organisms. Differential diagnoses in animals with nonseptic exudates include feline infectious peritonitis (FIP), neoplasia, chronic diaphragmatic hernia, lung lobe torsion, and resolving septic exudates. Prior treatment with antibiotics in animals with a septic effusion can alter the characteristics of the neutrophil population in the fluid, making them appear nondegenerative, and can decrease the number of organisms present in the fluid to an undetectable level. Therefore pleural fluid analysis should be performed before treatment is initiated so that bacterial infection is not overlooked.

Cats with FIP can present with fever or chorioretinitis in addition to respiratory signs (see Chapter 96). The pleural fluid protein concentration is often very high in such animals, approaching serum concentrations. It is common to see fibrin strands or clots in the fluid. Careful cytologic evaluation of the fluid is essential to differentiate FIP fluid from exudates caused by pyothorax or malignant lymphoma. Evaluation of animals for diaphragmatic hernia was described for transudates, and evaluation for neoplasia is discussed later in the section titled Effusion Caused by Neoplasia.

Spontaneous lung lobe torsions are most common in dogs with deep, narrow thoracic cavities. In addition to causing an effusion, torsions can be seen in dogs and cats secondary to pleural effusion. Underlying pulmonary disease resulting in lobe atelectasis can also contribute to the development of torsion. Torsion should be considered in animals with a preexisting effusion or pulmonary disease if their condition suddenly deteriorates. The effusion is often a nonseptic exudate, but it may be chylous or hemorrhagic. Signs of lung lobe torsion may be identified through thoracic radiography or ultrasonography (see Chapter 20). CT, bronchoscopy, or thoracotomy is required to verify the condition in some animals.

Septic exudates often have extremely high nucleated cell counts (e.g., 50,000 to more than 100,000/μL), and degenerate neutrophils are the predominant cells. Bacteria can often be observed within neutrophils and macrophages as well as extracellularly (see Fig. 24.1). The fluid may have a foul odor. Septic exudates are diagnostic for pyothorax, which can occur spontaneously, secondary to wounds that penetrate into the thoracic cavity through the chest wall or esophagus, secondary to migrating grass awns or other foreign bodies, or as an extension of bacterial pneumonia. Sterile technique should be used during thoracocentesis and chest tube placement in all animals with pleural effusion or pneumothorax, to prevent iatrogenic infection.

Gram staining and both aerobic and anaerobic bacterial cultures with antibiotic sensitivity testing should be performed on the fluid. Prolonged incubation should be requested to increase the likelihood of identifying *Actinomyces* and *Nocardia spp*. Culture and sensitivity testing provide valuable information that can be used in selecting appropriate antibiotics and in monitoring therapy. Mixed bacterial infections are common. However, bacteria do not grow from cultures of all septic exudates, and results are not available for several days. Gram staining provides immediate information that can be used to help select antibiotics and is helpful in cases in which bacteria cannot be grown from the fluid.

CHYLOUS EFFUSIONS

Chylous effusion (chylothorax) results from leakage of fluid from the thoracic duct, which carries lipid-rich lymph from the body. Such leakage can be idiopathic or congenital, or it can occur secondary to trauma, neoplasia, cardiac disease, pericardial disease, dirofilariasis, lung lobe torsion, or diaphragmatic hernia. Chyle is usually milky white and turbid (see Fig. 23.1, *E*), largely as a result of chylomicrons that carry fats from the intestines. The fluid is occasionally blood tinged, although this finding may be an artifact from prior thoracocentesis. It is possible to obtain clear and colorless fluids, particularly in anorectic animals, but this is uncommon.

Chyle has the cytologic characteristics of a modified transudate or nonseptic exudate with moderate concentrations of protein, usually greater than 2.5 g/dL. The nucleated cell count is low to moderate, ranging from 400 to 10,000/μL. Early in the disease, the predominant cell type is the small lymphocyte. A few neutrophils may also be present. With time, nondegenerative neutrophils become more predominant, and lymphocytes are fewer. Macrophages also increase in number with time, and plasma cells may be present.

A diagnosis of chylothorax is confirmed by measuring the concentrations of triglycerides in pleural fluid and serum. Each specimen should be well mixed by the laboratory before a portion is analyzed because of the tendency for the lipid portion to rise to the surface. The triglyceride content in chyle is high compared with that in serum. Rarely, the test will need to be repeated after a meal in anorectic animals.

Most cases of chylothorax are idiopathic, but this diagnosis can be made only after other disorders have been ruled out. Treatment is most likely to be successful if an underlying problem is identified and treated directly. (See Chapter 24 for a complete discussion of chylothorax.)

HEMORRHAGIC EFFUSIONS

Hemorrhagic effusions are grossly red as a result of the large red blood cell content. Hemorrhagic effusions consist of more

than 3 g/dL of protein and more than 1000 nucleated cells/μL, with a distribution similar to that of peripheral blood. Over time the numbers of neutrophils and macrophages increase. Hemorrhagic effusions (except those obtained immediately after bleeding into the thorax) are readily distinguished from the recovery of peripheral blood through traumatic thoracocentesis by several features: hemorrhagic effusions show erythrophagocytosis and an inflammatory response on cytologic evaluation; hemorrhagic effusions do not clot; and the packed cell volume of hemorrhagic effusions is lower than that of peripheral blood.

Hypovolemia and anemia may contribute to clinical signs in patients with hemothorax (see Chapter 25). Hemothorax can result from trauma, systemic bleeding disorders, neoplasia, and lung lobe torsion. Rarely, septic exudates are grossly hemorrhagic (see Fig. 23.1, *F*) and are distinguished cytologically. Respiratory distress caused by hemothorax may be the only clinical sign in animals with some bleeding disorders, including rodenticide intoxication. An activated clotting time and platelet count should be performed early in the evaluation of these animals, followed by more specific clotting tests (i.e., prothrombin time and partial thromboplastin time). Hemangiosarcoma of the heart or lungs is a common neoplastic cause of hemorrhagic effusion, but malignant cells are rarely identified cytologically. Neoplastic effusions are discussed further in the next section.

EFFUSION CAUSED BY NEOPLASIA

Neoplasia within the thoracic cavity can result in most types of effusions (modified transudates, exudates, chylous effusion, or hemorrhagic effusion). Neoplasms may involve any of the intrathoracic structures, including lungs, mediastinal tissues, pleura, heart, and lymph nodes. In some cases, neoplastic cells exfoliate from the tumor into the effusion, and an early diagnosis can be made through fluid cytology. This is often possible in patients with mediastinal lymphoma. Unfortunately, other than in cases of lymphoma, it can be difficult or impossible to establish a definitive diagnosis of neoplasia on the basis of cytologic findings in the pleural fluid alone. Inflammation can result in considerable hyperplastic changes in mesothelial cells, which are easily confused with neoplastic cells. *A cytologic diagnosis of neoplasia other than lymphoma should be made with extreme caution.*

In most cases, neoplastic cells are not present in the fluid, or a cytologic diagnosis cannot be made. Thoracic radiography and ultrasonography should be performed to evaluate the thorax for evidence of neoplasia. Ultrasonography can be used to differentiate localized accumulations of fluid from soft tissue masses. If soft tissue masses are detected, aspirates or biopsy specimens are obtained for cytologic or histopathologic evaluation. A definitive diagnosis cannot be made on the basis of radiographic findings or ultrasound images alone.

Diffuse neoplastic infiltration of the pleura and some masses cannot be seen with these imaging techniques. Repeated CT, thoracoscopy, or surgical exploration may be necessary in such cases.

DIAGNOSTIC TESTS FOR THE PLEURAL CAVITY AND MEDIASTINUM

RADIOGRAPHY

Pleural Cavity

The pleura surrounds each lung lobe and lines the thoracic cavity. It is not normally visible radiographically, and individual lung lobes cannot be distinguished. Abnormalities of the pleura and pleural cavity include pleural thickening, pleural effusion, and pneumothorax. The mediastinum in the dog and cat is not an effective barrier between the left and right sides of the thorax, and effusion or pneumothorax therefore is usually bilateral.

Pleural Thickening

Pleural thickening results in a thin, fluid-dense line between lung lobes, where the pleura is perpendicular to the X-ray beam. These lines arc from the periphery toward the hilar region and are known as *pleural fissure lines.* The lines can occur as a result of prior pleural disease and subsequent fibrosis, mild active pleuritis, or low-volume pleural effusion. They can be an incidental finding in older dogs. Infiltration of the pleura with neoplastic cells generally results in effusion rather than thickening.

Pleural Effusion

Pleural effusion is visible radiographically after about 50 to 100 mL has accumulated in the pleural cavity, depending on the size of the animal. A mild effusion assumes the appearance of pleural fissure lines and can be confused with pleural thickening. As fluid accumulates, the lung lobes retract and the lung lobe borders become rounded. Rounding of the caudodorsal angles of the caudal lung lobes is especially noticeable. The fluid silhouettes the heart and the diaphragm, obscuring their borders. The lungs float on top of the fluid, displacing the trachea dorsally and causing the illusion of a mediastinal mass or cardiomegaly (Fig. 23.2, *A*). As more fluid accumulates, the lung parenchyma appears abnormally dense as a result of incomplete expansion. Collapsed lobes should be examined carefully for evidence of torsion (see Chapter 20). Pockets of fluid accumulation or unilateral effusion indicate the possibility of concurrent pleural adhesions (see Fig. 23.2, *B*).

Critical radiographic evaluation of intrathoracic structures, including lungs, heart, diaphragm, and mediastinum, cannot be performed in animals with pleural effusion until the fluid has been removed. Interpretation of radiographs obtained in the presence of fluid is prone to error. An exception to this rule is the finding of gas-filled intestinal loops in the thorax, which is diagnostic of diaphragmatic hernia. Both left and right lateral views should be evaluated, in addition to a ventrodorsal view, to improve the sensitivity of detecting masses.

Pneumothorax

Pneumothorax is the presence of air in the pleural space. Air opacity without vessels or airways can be seen between

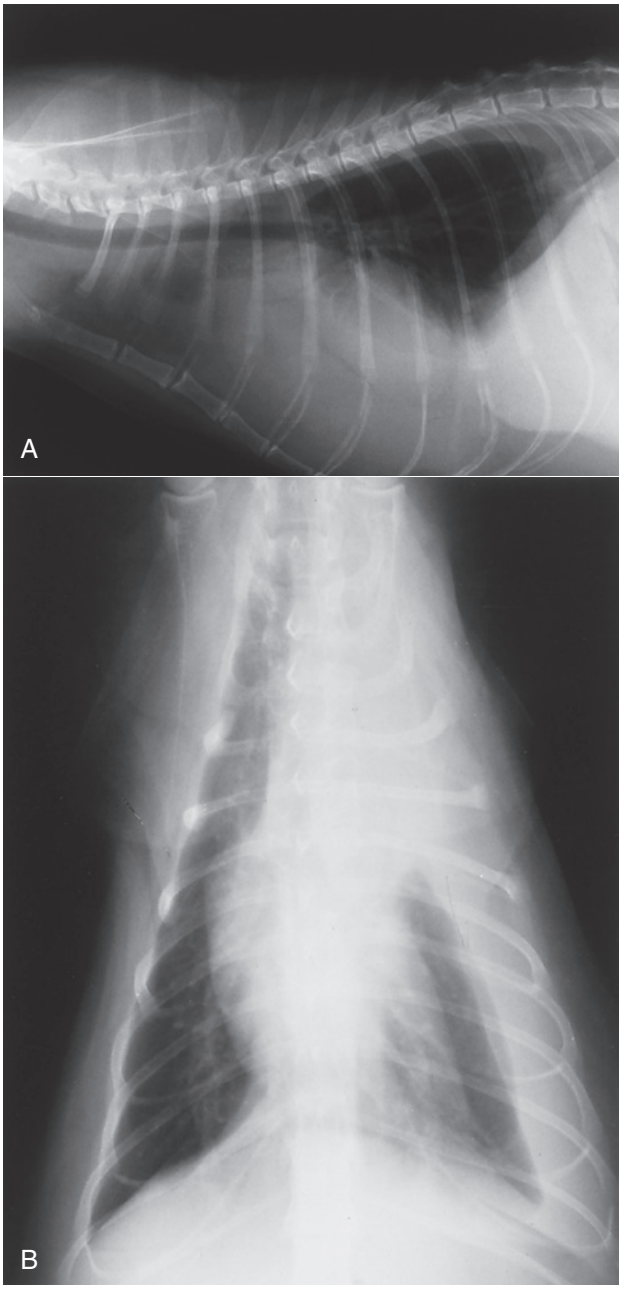

FIG 23.2
(A) Lateral thoracic view of a cat with pleural effusion. See text. **(B)** Ventrodorsal view showing that the effusion is unilateral.

the lung lobes and the chest wall on radiographs. It may be necessary to carefully scrutinize the radiographs with adjustments in contrast to detect mild pneumothorax. As a greater volume of air accumulates in the pleural space, the lung parenchyma becomes more dense because of incomplete expansion, facilitating the radiographic diagnosis. The heart is generally elevated above the sternum, with air opacity apparent between these two structures (Fig. 23.3). Radiographs should be examined carefully for evidence of possible causes of the pneumothorax, such as rib fractures

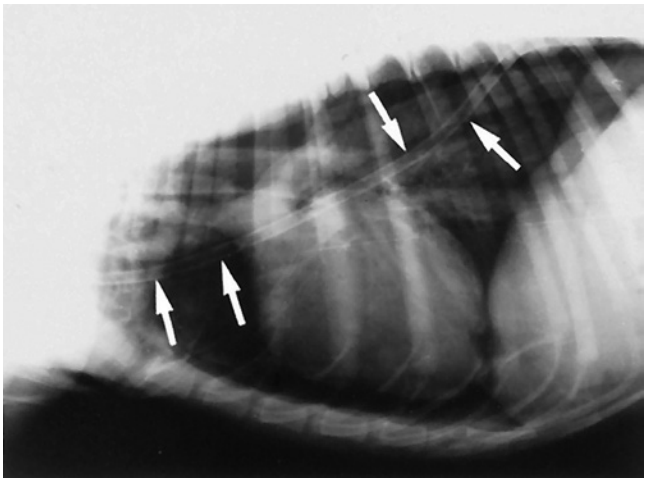

FIG 23.3
Lateral view of a dog with pneumothorax and pneumomediastinum. The pneumothorax is mild and demonstrated by elevation of the heart above the sternum. When the contrast of the original radiographs was decreased, retraction of lung borders could also be seen. It is possible to visualize the outer wall of the trachea and major blood vessels in the anterior mediastinum because of the pneumomediastinum. A chest tube placed to stabilize the dog's condition is also visible *(arrows)*.

(indicating trauma) or cavitary lesions. For accurate evaluation of the pulmonary parenchyma, the air must be removed and the lungs allowed to expand. Cavitary lesions are not always apparent radiographically. Further evaluation for cavitary lesions in patients with spontaneous pneumothorax includes CT.

Mediastinum

The cranial and caudal mediastinum contains the heart and great vessels, esophagus, lymph nodes, and associated support structures. Radiographic abnormalities involving the mediastinum include pneumomediastinum, alterations in size (e.g., mass lesions), displacement, and abnormalities involving structures within the mediastinum (e.g., megaesophagus).

Pneumomediastinum is the accumulation of air within the mediastinum. If pneumomediastinum is present, the outer wall of the trachea and other cranial mediastinal structures, such as the esophagus, major branches of the aortic arch, and the cranial vena cava, are contrasted against the air (see Fig. 23.3). These structures are not normally visible.

Abnormal soft tissue opacities can occur in the cranial mediastinum, although concurrent pleural effusion often obscures mass lesions. Localized lesions can represent neoplasia, abscesses, granulomas, or cysts. Less discrete disease can cause general widening of the mediastinum that is seen to exceed the width of the vertebra on ventrodorsal views. Exudates, edema, hemorrhage, tumor infiltration, and fat can cause a widened mediastinum. Megaesophagus can

often be observed in the cranial mediastinum, especially on lateral views.

The caudal vena cava and the aorta are normally visible in the caudal mediastinum. The most common caudal mediastinal abnormalities are megaesophagus and diaphragmatic hernia. Megaesophagus is an important consideration in animals with respiratory signs because it is a common cause of aspiration pneumonia.

The mediastinum is normally located in the center of the thoracic cavity. An abnormal shift of the mediastinum is identified by a lateral change in the position of the heart on ventrodorsal or dorsoventral views. Atelectasis (i.e., lung lobe collapse), lobectomy, and adhesions of the mediastinum to the chest wall can cause the mediastinum to shift toward the abnormality. Space-occupying lesions can cause the mediastinum to shift in the opposite direction.

The lymph nodes and the heart are mediastinal structures but are considered separately to ensure a careful evaluation. The sternal nodes are located immediately dorsal to the sternum near the thoracic inlet at the level of the first to third sternebrae (Fig. 23.4). Enlargement is seen on lateral views and has the appearance of a discrete mass lesion. The hilar nodes are located at the heartbase around the carina. Enlargement is seen as a generalized increased soft tissue opacity in the perihilar region and is most easily seen on the lateral view. Common differential diagnoses for hilar lymphadenopathy include lymphoma and fungal infection (especially histoplasmosis). Other differential diagnoses include metastatic neoplasia, eosinophilic pulmonary granulomatosis, and mycobacterial infection. Any inflammatory disease can potentially cause lymphadenopathy.

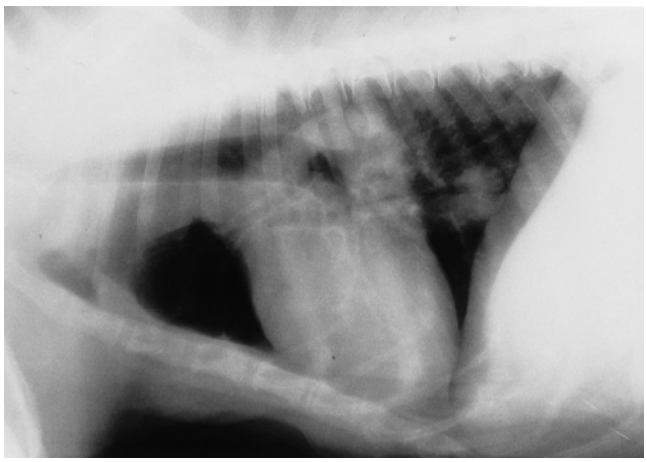

FIG 23.4
Lateral thoracic radiograph obtained in a dog with pulmonary neoplasia and sternal and hilar lymphadenopathy. The sternal node is the soft tissue opacity resting on the caudal half of the second sternebra. The hilar nodes are identified by increased soft tissue opacity around the carina. Several discrete pulmonary nodules are also present.

Other considerations in animals with increased perihilar opacity on radiographs include atrial enlargement and heartbase tumors.

Evaluation of the heart is described in Chapters 1 and 2. Right-sided heart failure and pericardial effusion can cause pleural fluid accumulation.

ULTRASONOGRAPHY

Ultrasonography is indicated in the diagnostic evaluation of dogs and cats with pleural effusion to search for masses, diaphragmatic hernia, lung lobe torsion, and cardiac disease. Mediastinal masses, masses involving the pulmonary parenchyma adjacent to the body wall, and masses extending into the thorax from the body wall may be identified and their echogenicity evaluated. Ultrasonography can also be used to guide aspiration needles or biopsy instruments to the lesion, although biopsies can be done safely only on solid masses. Ultrasonography is also useful for directing needle placement during thoracocentesis in animals with localized accumulations of pleural fluid. Air interferes with the sound waves, so structures surrounded by aerated lung cannot be examined.

In the emergency setting, ultrasonography can be used for rapid, minimally stressful assessment of the pleural space for fluid or air. The acronym for the examination is *TFAST,* which stands for *t*horacic *f*ocused *a*ssessment with *s*onography for *t*rauma. See the reference by Lisciandro (2011) for probe positions and characteristic sonographic signs.

COMPUTED TOMOGRAPHY

As discussed in Chapter 20, CT is more sensitive than radiography in evaluating the thorax. CT is useful for identifying abnormalities (e.g., masses, lung lobe torsion, thromboembolism), determining the extent of mass lesions before thoracotomy, and increasing the likelihood of identifying cavitary lesions in patients with spontaneous pneumothorax.

THORACOCENTESIS

Thoracocentesis is indicated for the collection of diagnostic specimens in dogs and cats with pleural effusion, for removal of pleural fluid or air to stabilize the condition of dogs and cats with impaired ventilation, and before radiographic evaluation of intrathoracic structures in dogs and cats with pleural fluid or air. Possible complications of thoracocentesis are pneumothorax caused by lung laceration, hemothorax, and iatrogenic pyothorax. Complications are rare if careful technique is used.

Thoracocentesis is performed with the animal in lateral or sternal recumbency, depending on which position is less stressful. Fluid or air is usually present bilaterally throughout the pleural space and can be retrieved from the seventh intercostal space (ICS) by placing the needle approximately two thirds of the distance from the costochondral junction toward the spine. If initial attempts are unsuccessful, other sites are tried or the animal's position is changed. Fluid may be more successfully retrieved from

gravity-dependent sites (i.e., closer to costochondral junctions) and air from nondependent sites. Thoracic radiographs are useful in choosing sides for thoracocentesis in the event of unilateral effusion. Ultrasonography is useful for guiding needle placement in patients in which fluid collection proves difficult.

A local anesthetic can be administered at the site of thoracocentesis. Sedation is rarely required but may be useful for decreasing patient stress. The site is shaved and surgically prepared, and the procedure is performed using sterile technique. Most often, a butterfly catheter, a three-way stopcock, and a syringe are used. Removal of fluid or air by syringe is associated with movement of the syringe, and the tubing of the butterfly catheter prevents this movement from affecting the position of the needle within the thoracic cavity. Air and most fluids can be retrieved through a 21-gauge butterfly catheter. A larger needle may be required to collect extremely viscous fluids, such as fluid from FIP or pyothorax. The three-way stopcock is attached to the catheter to keep air from entering the thorax during emptying or changing of the syringe.

With the syringe snugly attached and the stopcock open between the catheter and the syringe (closed to room air), the needle is advanced through the skin only. The needle and the skin are then moved about two rib spaces to the actual collection site. This technique prevents air from entering the chest through the needle tract after the procedure (an unlikely scenario). The needle is then advanced into the thorax immediately in front of the rib to avoid the intercostal vessels and nerves. The needle is held with a hand resting on the chest wall so it will not move relative to respirations or movement of the animal. Slight negative pressure is applied to the catheter by the syringe so that entry into the pleural space is immediately identified by the recovery of fluid or air. Once the needle has entered the pleural space, the tip is aimed away from the lung by lowering the wings of the catheter toward the body wall. Ideally, the bevel of the needle should face toward the lungs.

An alternative to a butterfly catheter is an intravenous over-the-needle catheter. In large dogs a 3¼ or 5¼ (8- or 13-cm) 14- to 16-gauge catheter can be used. These catheters are soft and produce less trauma than is produced by butterfly catheters while in the pleural space; they permit the animal to be repositioned or rolled to improve fluid or air removal. The longer length, compared with a butterfly needle, may be needed to reach the pleural space in large-breed or obese dogs. Extension tubing and a three-way stopcock are attached to the catheter immediately after placement. A small skin incision, just slightly larger than the catheter, will facilitate placement. As with the butterfly catheter, slight negative pressure is maintained by the syringe so that entry into the pleural space is immediately identified. The catheter tip is then directed cranially to allow positioning of the catheter between the lungs and the chest wall, preventing trauma to the lung tissue.

After fluid specimens are saved for cytologic and microbiologic analysis, as much fluid or air as possible is removed, except in patients with acute hemothorax (see Chapter 25).

THORACOSCOPY AND THORACOTOMY

A definitive diagnosis for the cause of pleural effusion is sometimes elusive. In such cases, thoracoscopy or thoracotomy may be necessary to allow visual assessment of the thoracic cavity and the collection of specimens for histologic and microbiologic analysis. Mesotheliomas and pleural carcinomatosis are often diagnosed through these methods.

CHEST TUBES: INDICATIONS AND PLACEMENT

Chest tube placement is indicated for the management of pneumothorax, if air continues to accumulate despite multiple thoracocenteses, and for the treatment of dogs and cats with pyothorax (see Chapter 24). If possible, needle thoracocentesis and therapy for shock are performed to stabilize dogs and cats in critical condition before chest tubes are placed.

The major complication of chest tubes is pneumothorax caused by a leak in the apparatus. Animals with chest tubes must be carefully monitored at all times to make sure that they do not disrupt the tubing connections, pull the tube part of the way out of the chest so that there are fenestrations outside the body wall, or bite through the tubing. Any leaks in the system can result in a life-threatening pneumothorax within minutes. If an animal with a chest tube must be left unattended, the tube should be clamped off close to the body wall and should be well protected by bandage material. Hemothorax or pneumothorax can be caused by lung laceration during tube placement. Iatrogenic pyothorax can result from bacteria introduced during placement or gaining entrance to the chest through the tube itself while it is in place. These complications are generally prevented through careful techniques and aseptic practices.

Pediatric chest tubes can be obtained from hospital supply companies. These tubes have multiple fenestrations, are calibrated along their length, and are radiopaque. For treating pyothorax, the tube should be as large as will fit between the ribs. The size of the tube is less critical for control of pneumothorax. Before placement, the end of the tube is occluded with a syringe adapter, a three-way valve, and a hose clamp (Fig. 23.5, *A*).

Sterile technique is used during placement of the chest tube. In an animal with unilateral disease, the tube is placed in the involved side of the thorax. Either side can be used in an animal with bilateral disease. The lateral side of the animal over the caudal rib cage is shaved and surgically prepared. The animal is anesthetized or heavily sedated. If the animal is sedated, a local anesthetic is placed subcutaneously at the tenth ICS and within the subcutaneous tissues, intercostal

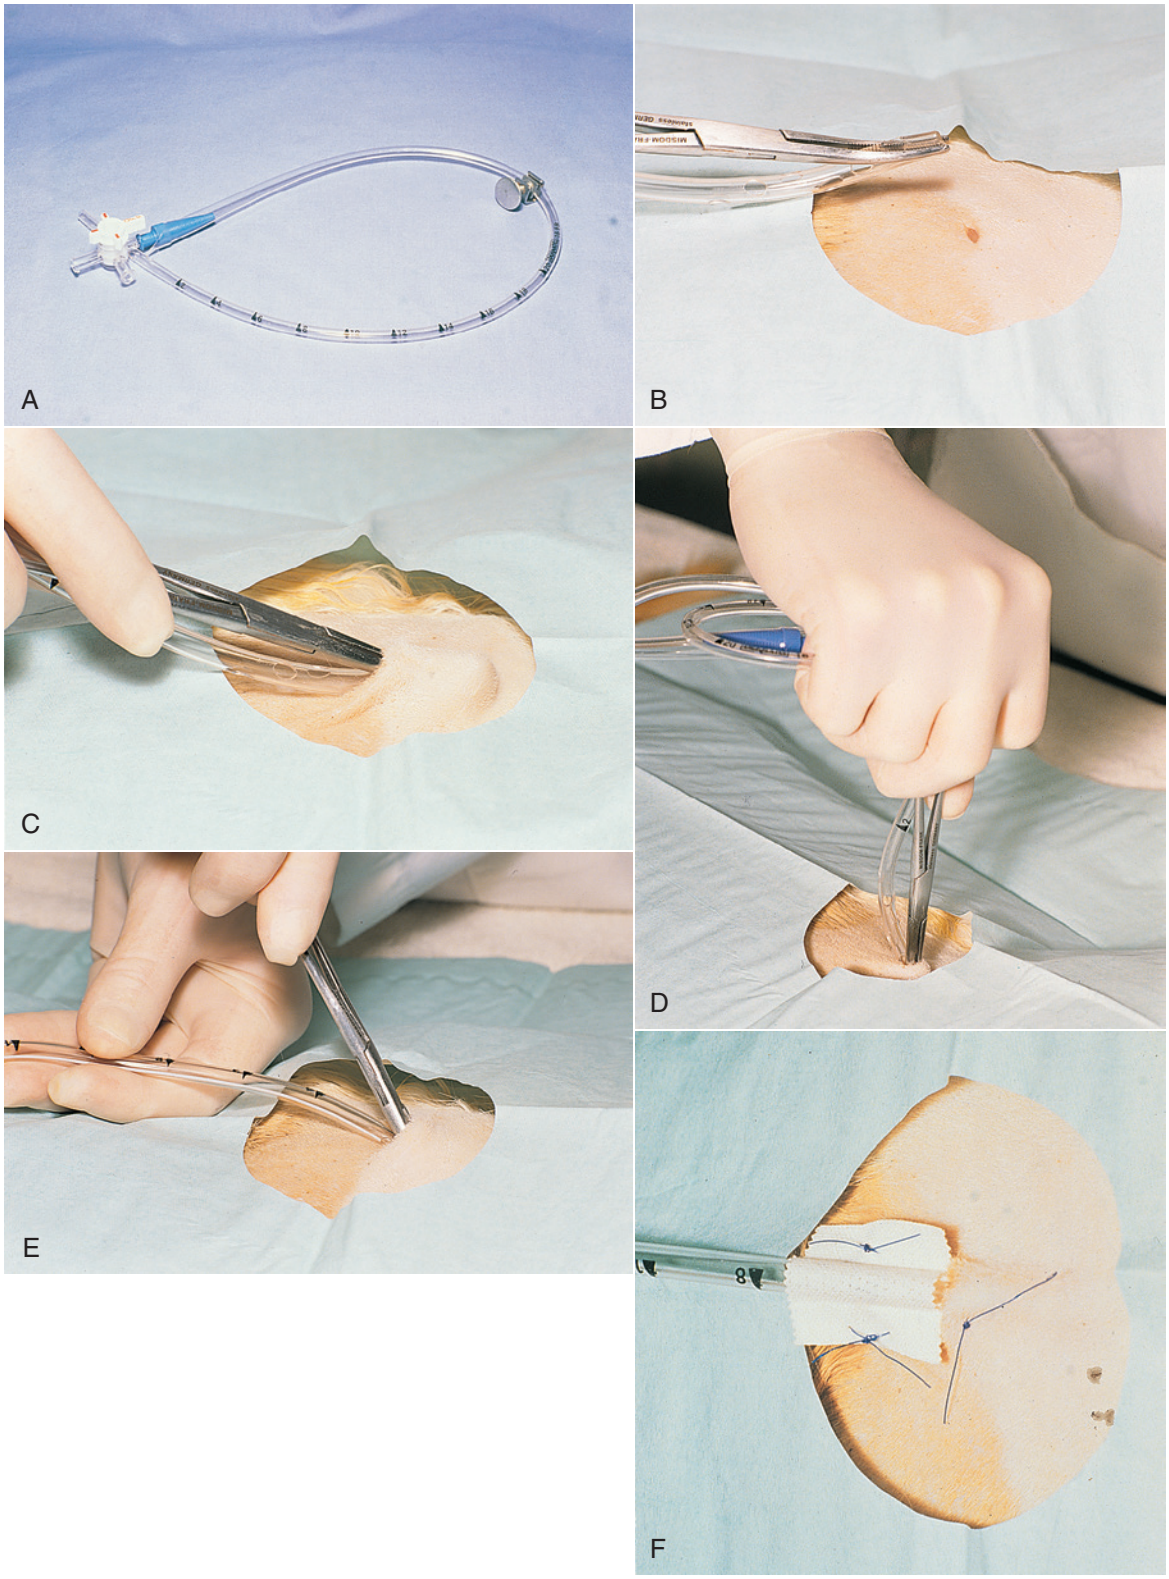

FIG 23.5
Placement of a chest tube. See text.

muscles, and pleura at the seventh ICS. The dorsoventral orientation is one half to two thirds the distance from the costochondral junction to the thoracolumbar musculature. This distance should correspond to the level where the ribs are maximally bowed.

The length of tube to be advanced into the chest must be determined from thoracic radiographs or by external landmarks on the animal. The tube should extend from the tenth ICS to the first rib. The fenestrations in the tube must not extend outside the point of exit from the pleural cavity.

A stab incision is made through the skin at the tenth ICS. A purse-string suture is then placed around the opening but is not tied. Some chest tubes made for humans contain a stylet. Smaller chest tubes are inserted with the aid of curved hemostats. The tip of the tube is grasped with the tip of the hemostats with the tube parallel to the body of the clamps (see Fig. 23.5, *B*).

The tube, with the stylet or hemostats, is then tunneled subcutaneously from the tenth to the seventh ICS. If hemostats are used, the tips are directed away from the animal's body (see Fig. 23.5, *C*). Once the tip reaches the seventh ICS, the stylet or hemostats are raised perpendicular to the chest wall. The palm of the hand is placed over the end of the stylet or the hemostat handles, and the tube is thrust through the body wall with one rapid motion (see Fig. 23.5, *D*). Once the tube has entered the pleural space, it is quickly advanced forward until a predetermined length has entered the chest while the stylet or hemostats are withdrawn (see Fig. 23.5, *E*).

An alternative technique can be used to minimize trauma to the lungs caused when the tube is thrust through the body wall. In this technique, after the skin incision has been made and a purse-string suture placed, an assistant standing at the head of the animal draws the skin of the thorax cranially to pull the skin opening forward from the tenth to the seventh ICS (Fig. 23.6). With the skin held in this position, hemostats are used to bluntly dissect through the thoracic and intercostal musculature to the pleura. At this point, the chest tube with the stylet or hemostats is easily popped through the pleura into the chest with minimal force. The tube is then advanced and the skin released.

Air will be sucked into the pleural cavity during tube placement regardless of the method used. This air is immediately removed through the tube using a 35-mL syringe. The purse-string suture is then tied around the tube. Immediately external to the skin entrance, the tube is attached to the body wall by suturing the tape that is formed as a butterfly around the tube to the skin on either side of it (see Fig. 23.5, *F*) or by using a Chinese finger trap suture around the tube and attached to the skin. This prevents the chest tube from being withdrawn if tension is accidentally applied to the tubing. The opening in the skin is covered with a sterile sponge with antiseptic ointment.

A light wrap is placed around the tube to hold it against the chest wall. *The wrap must not be too tight.* A wrap that is too tight can greatly decrease chest wall compliance and can increase the work of breathing in these compromised animals. The hose clamp is placed on the tube between the animal and the three-way valve to further protect against pneumothorax whenever suction is not being applied to the tube. An Elizabethan collar is always placed on the animal because a single bite through the tube can be fatal.

FIG 23.6
After an assistant pulls the skin forward, an incision can be made through the skin at the seventh intercostal space and blunt dissection is used to reach the pleura. A chest tube can be popped into the pleural space with minimal trauma to the underlying lung. When the skin is released, the tube will course through a subcutaneous tunnel to prevent air leaks around the tube.

Thoracic radiographs are taken to evaluate tube position and the effectiveness of drainage. Two views must be evaluated. Ideally, the tube should extend along the ventral aspect of the pleural space to the thoracic inlet. The most important sign of adequate tube placement is the absence of areas of persistent fluid or air accumulation. If areas of fluid or air persist, it may be necessary to replace the tube or place a second tube in the opposite side.

Once a chest tube is in place and determined to be in a satisfactory position, its effectiveness is monitored every 24 to 48 hours by thoracic radiography and by the gross and cytologic assessment of recovered fluid. The animal must also be monitored for the development of secondary complications. These include infection and leakage of air. The bandage should be removed at least daily. The site where the tube enters the skin should be evaluated for signs of inflammation or subcutaneous emphysema. The tube and skin sutures should be examined for signs of motion. The skin around the tube is kept clean, and a sterile sponge is replaced over the entry site of the tube before re-bandaging. Stopcock ports should be protected with sterile caps when not in use. Gloves should be worn and the stopcock ports wiped with hydrogen peroxide before use.

CHAPTER 24

Disorders of the Pleural Cavity and Mediastinum

PYOTHORAX

Etiology

Septic exudate in the pleural cavity is referred to as *pyothorax*. It is most often idiopathic in origin, particularly in cats. Barrs et al. (2009) propose that the source of organisms in these cases is the oropharynx. Pyothorax can result from foreign bodies, puncture wounds through the chest wall, esophageal tears (usually from ingested foreign bodies), and extension of pulmonary infection. Thoracic foreign bodies are usually migrating grass awns. They are rare in cats and are most common in sporting breeds of dogs in states where there is a large concentration of foxtail grasses (e.g., California).

Clinical Features

Dogs and cats with pyothorax have clinical signs referable to a closed site of infection (abscess) and pleural effusion. Signs may be acute or chronic. Tachypnea, decreased lung sounds, increased abdominal excursions, and paradoxical breathing (abdomen and chest expanding asynchronously) are typical of pleural effusion. In addition, fever, lethargy, anorexia, and weight loss are common. Animals may be presented in septic shock or may demonstrate signs of systemic inflammatory response syndrome.

Diagnosis

The diagnosis of pyothorax is made through thoracic radiography and cytologic evaluation of pleural fluid. Thoracic radiographs are used to confirm the presence of pleural effusion and to determine whether the disease is localized, unilateral, or bilateral. In most animals, fluid is present throughout the pleural space. The finding of a localized accumulation of fluid indicates the possible presence of pleural fibrosis, mass lesions, or lung lobe torsion. Thoracic radiographs are taken again after removal of the fluid to evaluate the pulmonary parenchyma for evidence of underlying disorder (e.g., bacterial pneumonia, foreign body) that may have caused the pyothorax. Ultrasonography is also useful for identifying adhesions or pockets of fluid.

Identification of a septic exudate by pleural fluid analysis establishes the diagnosis of pyothorax. Septic suppurative inflammation is a consistent finding in pleural fluid examined cytologically, except in animals receiving antibiotics (Fig. 24.1; see also Chapter 23). Pleural fluid should be further evaluated by Gram staining, and aerobic and anaerobic bacterial cultures. These tests may identify organisms not apparent by routine cytologic staining and may provide valuable information for antibiotic selection. Anaerobes are usually present in the fluid, and in many dogs and cats more than one type of bacteria is present. All of the types of bacteria involved may not grow in the laboratory in spite of cytologic evidence of their presence, possibly because of competition between organisms or an inhibitory effect of the exudative fluid. Organisms such as *Actinomyces* and *Nocardia* particularly do not grow well if specimens have been cultured using routine procedures, and the laboratory should be notified of the possibility of these organisms. Absence of growth of bacteria does not rule out a diagnosis of pyothorax.

Evaluation of the patient's systemic status may reveal evidence of active inflammation, systemic inflammatory response syndrome, or sepsis. A normal leukogram does not rule out the possibility of pyothorax.

Treatment

Medical therapy for pyothorax includes antibiotics, drainage of the pleural cavity, and appropriate supportive care (e.g., fluid therapy). At first, empirically selected antibiotics are administered intravenously. Results of Gram staining and culture and sensitivity testing are helpful in adjusting antibiotic protocols as they become available. Recently published antimicrobial guidelines for the treatment of respiratory tract disease in dogs and cats (Lappin et al., 2017) recommend initial treatment of an injectable fluoroquinolone (e.g., enrofloxacin or marbofloxacin) with a penicillin (e.g., ampicillin with sulbactam) or clindamycin. The penicillin or clindamycin should be continued regardless of culture results because of the difficulty in growing some anaerobes in the laboratory.

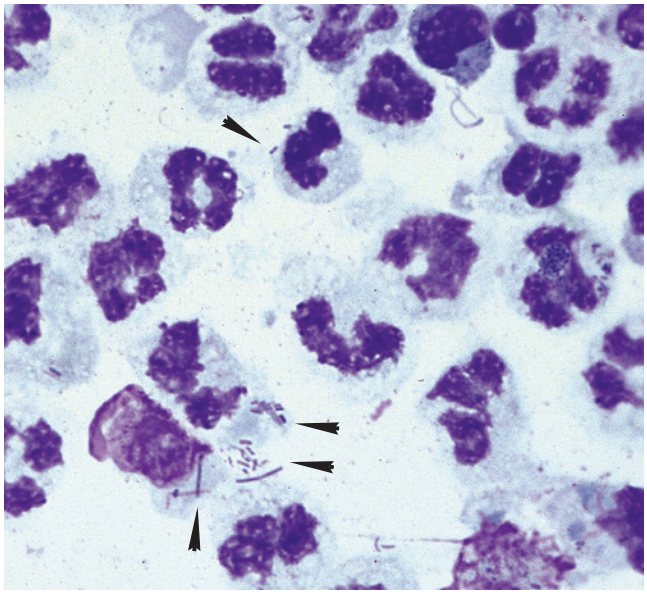

FIG 24.1
Cytologic preparation of a specimen of a pleural effusion from a cat with pyothorax. Degenerative neutrophils predominate, and intracellular and extracellular bacteria are prevalent *(arrowheads)*. Both rods and cocci are seen.

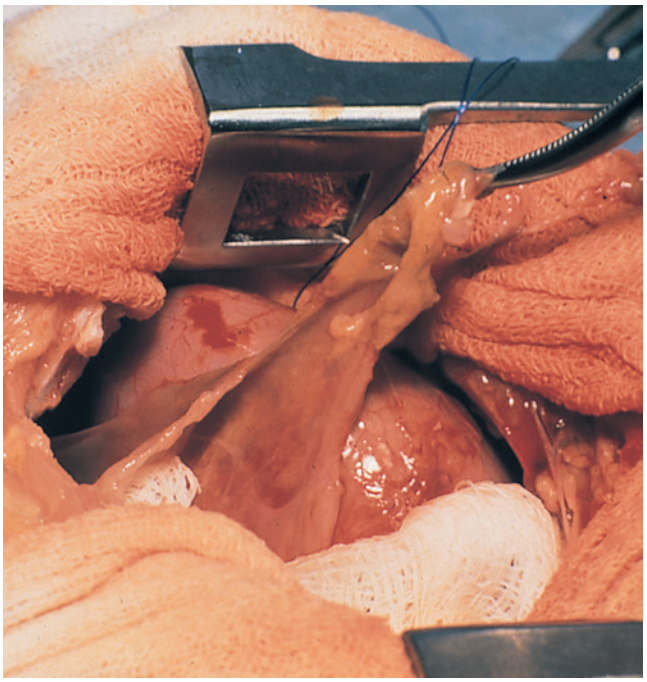

FIG 24.2
Pleural fibrosis manifested by markedly thickened pleura seen during thoracotomy in a cat with chronic pyothorax. Treatment with antibiotics alone was attempted, and several weeks later the cat's condition deteriorated. Fibrosis was too extensive to allow for routine drainage with chest tubes. Surgical debridement, several lobectomies, drainage through surgically placed tubes, and long-term antibiotic therapy resulted in a cure.

Oral antibiotics are used once significant improvement is noted, usually about the time of chest tube removal. Amoxicillin-clavulanate (dogs, 11 mg/kg q8h; cats, 12.5 mg/kg q8h) is used in patients that have responded with ampicillin with sulbactam. Oral antibiotic therapy is continued for an additional 4 to 6 weeks.

Drainage of the septic exudate is an essential part of the treatment of pyothorax. Although treatment with antibiotics alone often causes dramatic improvement in the animal's clinical condition initially, the signs generally recur, and complications of prolonged infection, such as fibrosis and abscessation requiring surgical debridement and drainage, are more likely (Fig. 24.2). Indwelling chest tubes provide the best drainage and can be used to keep the exudate from accumulating during the initial days of antibiotic therapy. Dogs and cats in critical condition at presentation are stabilized through the use of needle thoracocentesis and shock therapy before chest tube placement. Intermittent needle thoracocentesis is a poor substitute for chest tube draining in this setting and is rarely sufficient to achieve resolution of infection. Intermittent thoracocentesis is not recommended unless the owner cannot afford the expense of chest tube management and the remaining option is euthanasia.

Chest tube placement and assessment of positioning are discussed in Chapter 23. Animals probably respond most rapidly to constant suctioning of exudate from the chest, although intermittent suction is certainly adequate and often more feasible. Constant suction is applied with a suction pump and collection unit. Disposable pediatric cage-side collection units (e.g., Argyle Thora-Seal III, Medtronic) are available through hospital supply companies. These units allow monitoring of collected fluid volume and adjustment of suction pressure. An initial suction pressure of 10 to 15 cm H_2O is used, but more or less pressure may be necessary depending on the viscosity of the pleural fluid and the collapsibility of the tubes. The collection systems must be carefully monitored for leaks or malfunctions that could cause a fatal pneumothorax.

Intermittent suction by syringe is ideally performed every 2 hours for the first days of treatment, with arrangements made for drainage to continue during the night. Within a few days the volume of fluid produced will decrease, and the interval can then be lengthened. If such intensive care is not possible, an effort should still be made to empty the chest of fluid at least once late in the evening to minimize the accumulation of exudate overnight.

Lavage of the chest cavity is performed twice daily and consists of the removal of any fluid within the chest, followed by slow infusion of warmed sterile saline solution into the chest. A volume of approximately 10 mL/kg of body weight is infused, but the infusion should be discontinued if any distress is noted. After this the animal is gently rolled from side to side, and the fluid is removed. Sterile technique is used throughout the procedure. The volume recovered should be about 75% of the volume infused. If less fluid is retrieved, this may indicate that the chest tube is no longer providing

adequate drainage and should be assessed by radiography or ultrasonography. No obvious benefit is derived from the addition of antibiotics, antiseptics, or enzymes to the lavage solution. The addition of heparin (1000-1500 U/100 mL) to the lavage fluid may decrease fibrin formation and has been associated with better outcomes (Boothe et al., 2010).

All adapter ports connected to the chest tube should be covered with sterile caps when not in use. When accessing the ports, the clinician should wear gloves and remember to wipe the ports with hydrogen peroxide before use.

Thoracic radiographs are taken every 24 to 48 hours to ensure that the chest is being completely drained of fluid. Failure to monitor the effectiveness of drainage radiographically can lead to costly prolongation of the intensive care required for maintenance of the chest tube.

Serum electrolyte concentrations are also monitored. Many dogs and cats with pyothorax are dehydrated and anorectic at presentation and require intravenous fluid therapy. Supplementation of the intravenous fluid with potassium may be necessary.

The decision to discontinue drainage and remove the chest tube is based on fluid volume and cytologic characteristics. The volume of fluid recovered should have decreased to less than 2 mL/kg/day. Slides of the fluid are prepared daily and evaluated cytologically. Bacteria should no longer be visible intracellularly or extracellularly. Neutrophils will persist but should no longer appear degenerative (Fig. 24.3). When these criteria have been met and no pockets of fluid are seen on thoracic radiographs, the chest tube is removed and the animal is monitored clinically for at least 24 hours for the development of pneumothorax or the recurrence of effusion. Thoracic radiographs can be taken to more sensitively evaluate the animal for these potential problems.

Thoracic radiographs are evaluated 1 week after removal of the chest tube and 1 week and 1 month after discontinuation of antibiotic therapy. These radiographs are obtained so that a localized nidus of disease such as a foreign body or an abscess can be identified, and so that recurrence of a pyothorax can be detected before large volumes of pleural fluid accumulate. Such niduses are often invisible when large volumes of pleural fluid are present or when aggressive therapy is in progress.

Exploratory thoracotomy is indicated for the removal of a suspected nidus of infection and in those animals that do not respond to medical therapy. In the latter instance, surgery may be necessary to remove fibrotic and diseased tissue or a foreign body. Failure to respond is suggested by the continued need for a chest tube for longer than 1 week after the start of appropriate antibiotic treatment and drainage, although reported cases that have undergone complete recovery after medical management have required drainage by chest tubes for longer periods. Furthermore, persistence of large pockets of fluid in spite of appropriate chest tube placement may necessitate the decision to perform a thoracotomy earlier. Computed tomography of the chest may be a more sensitive method than thoracic radiography for

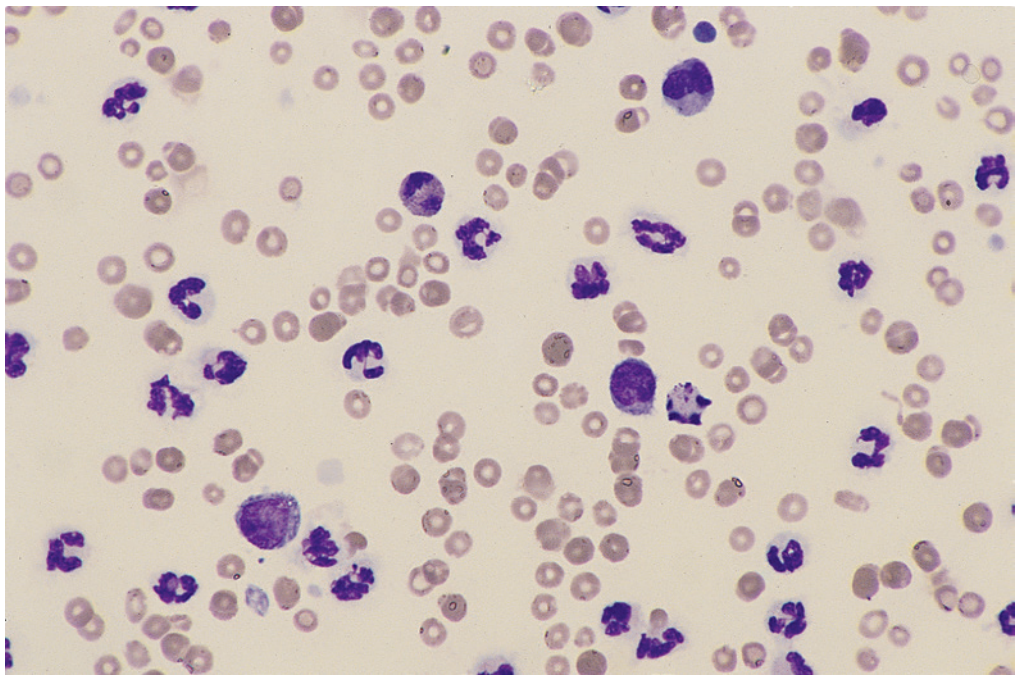

FIG 24.3
Cytologic preparation of a specimen of a pleural effusion from a cat being treated successfully for pyothorax with chest tube drainage and antibiotics. Compared with the fluid shown in Fig. 24.1, the nucleated cell count is low, the neutrophils are nondegenerative, organisms are not present, and mononuclear cells are appearing (cytocentrifuge prep).

detecting persistent pulmonary lesions. Rooney et al. (2002) recommended consideration for thoracotomy particularly in dogs that have radiographic evidence of mediastinal or pulmonary lesions, or if *Actinomyces* spp. are identified in the pleural fluid.

Prognosis

The prognosis for animals with pyothorax is fair to good if it is recognized early and treated aggressively. Waddell et al. (2002) reported a survival rate for cats of 66%, excluding those that were euthanized before treatment. In their report, 5 of 80 cats required thoracotomy. Boothe et al. (2010) reported a 1-year survival rate of 70% for dogs treated with chest tube drainage, with or without surgery, but only 29% for dogs treated with intermittent thoracocentesis. However, in a study by Rooney et al. (2002) of 26 dogs, only 25% of dogs were successfully treated medically, whereas 78% responded favorably to thoracotomy. One possible explanation for the poor success of medical management in the latter study is its geographic location in a region of the country where grass awn migration is common.

Exploratory surgery is necessary to ensure complete resolution of the problem in dogs or cats with foreign bodies in the thoracic cavity. Radiolucent foreign bodies can be difficult to find, however, and the prognosis for pyothorax secondary to them is more guarded. Long-term complications of pyothorax such as pleural fibrosis and restrictive lung disease are uncommon.

CHYLOTHORAX

Etiology

Chylothorax is the accumulation of chyle within the thoracic cavity. The chyle originates from the thoracic duct, which carries triglyceride-rich fluid from the intestinal lymphatics and empties it into the venous system in the anterior thorax. This fluid also contains lymphocytes, protein, and fat-soluble vitamins. Thoracic duct rupture after thoracic trauma can result in transient chylothorax. However, most cases are not the result of a ruptured duct. Possible causes of nontraumatic chylothorax include generalized lymphangiectasia, inflammation, and obstruction of lymphatic flow. Flow can be obstructed for physical reasons, such as neoplasia, or as a result of increased venous pressures.

Chylothorax can be categorized as congenital, traumatic, or nontraumatic. A congenital predisposition may exist in animals in which chylothorax develops later in life. Traumatic events that induce chylothorax can be surgical (e.g., thoracotomy) or nonsurgical (e.g., being hit by a car). Nontraumatic causes of chylothorax include neoplasia, particularly mediastinal lymphoma in cats; cardiomyopathy, dirofilariasis, pericardial disease, and other causes of right-sided heart failure; central venous thromboses; lung lobe torsion; diaphragmatic hernia; and systemic lymphangiectasia. No underlying disease can be identified in most animals, in which case idiopathic chylothorax is diagnosed.

Fibrosing pleuritis and pericarditis can be associated with chylothorax. Cats, in particular, may develop fibrosing pleuritis, which can interfere with normal expansion of the lungs even after thoracocentesis. Inflammation and thickening of the pericardium could contribute to the further formation of chylous effusion.

Clinical Features

Chylothorax can occur in dogs or cats of any age. Afghan Hounds and Shiba Inus appear to be predisposed to the disorder. The primary clinical sign is respiratory distress typical of pleural effusion. Although the distress is often acute in onset, more subtle signs have generally been present for longer than a month. Lethargy, anorexia, weight loss, and exercise intolerance are common. In some cases, cough is the only presenting sign.

Diagnosis

Chylothorax is diagnosed by thoracic radiography and by identification of chyle through cytologic and biochemical evaluation of pleural fluid obtained by thoracocentesis (see Chapter 23). Lymphopenia and panhypoproteinemia may be present in peripheral blood. The complication of fibrosing pleuritis is suspected when lung lobes have rounded borders radiographically and the degree of respiratory compromise subjectively exceeds that expected from the amount of fluid in the pleural space.

Once chylothorax has been diagnosed, further diagnostic tests are performed to identify potential underlying disease (Box 24.1). These tests include thoracic ultrasonography; echocardiography; microfilarial examination and adult antigen testing for heartworm disease; and, in cats, the measurement of thyroid hormone concentrations. Computed tomography will be more sensitive than thoracic radiography in identifying and characterizing localized disease and, when performed with contrast, may identify venous thromboses. Lymphangiography can be used to identify lymphangiectasia, sites of obstruction, and, rarely, sites of leakage from the thoracic duct. Lymphangiography is performed before surgical ligation of lymphatics is attempted.

Treatment

Thoracocentesis and appropriate fluid therapy are used to stabilize dogs and cats with chylothorax, as needed, at presentation. Electrolyte abnormalities may be present. A concerted effort is made to identify any underlying cause of the chylothorax, so that it can be directly treated. Elimination of the underlying problem may result in resolution of the chylothorax, although medical management (as described later for idiopathic chylothorax) is generally required for several weeks or even months. The exception is chylothorax of traumatic origin, which generally resolves within 1 to 2 weeks.

A routinely successful treatment for idiopathic chylothorax has not been established. Medical management is initially attempted because spontaneous remission occurs in some cases. In the absence of resolution with medical therapy,

BOX 24.1

Diagnostic Tests to Identify Underlying Diseases in Dogs and Cats With Chylothorax

Complete Blood Count, Serum Biochemical Panel, Urinalysis

Evaluation of systemic status

Cytologic Examination of Fluid

Infectious agents
Neoplastic cells (especially lymphoma)

Thoracic Radiographs (After Fluid Removal)

Anterior mediastinal masses
Other neoplasia
Cardiac disease
Heartworm disease
Pericardial disease

Ultrasonography (Ideally, in the Presence of Fluid)

Anterior mediastinum
  Mass
Heart (echocardiography)
  Cardiomyopathy
  Heartworm disease
  Pericardial disease
  Congenital heart disease
Other fluid densities adjacent to body wall
  Neoplasia
  Lung lobe torsion

Heartworm Antibody and Antigen Tests

Heartworm disease

Computed Tomography

Often more sensitive than radiography or ultrasonography
With contrast, to identify central venous thromboses

Lymphangiography

Preoperative and postoperative assessment of thoracic duct

surgical treatment that includes thoracic duct ligation and pericardectomy is recommended.

Medical management consists primarily of intermittent thoracocentesis and a low-fat diet. Thoracocentesis is performed as needed on the basis of the owner's observation of increased respiratory rate or effort or decreased activity or appetite. Initially, thoracocentesis may need to be performed every 1 to 2 weeks. The interval between thoracocenteses will gradually lengthen if the chylothorax is responsive to medical management. Ultrasound guidance of the needle during thoracocentesis is especially helpful in removing pockets of chyle from the pleural cavity. By increasing the effectiveness of drainage, it can prolong the interval between thoracocenteses.

Although the benefit of dietary management has been questioned, a low-fat, nutritionally complete diet is fed in patients with good body condition. In humans medium-chain triglyceride oil is absorbed directly into the bloodstream, bypassing the lymphatics, and can be used as a fat supplement. Unfortunately, in dogs these triglycerides have been shown to enter the thoracic duct. Studies have not been performed in cats.

Medical management may be facilitated by the administration of rutin, a benzopyrone drug. Rutin has been used in humans for the treatment of lymphedema. It is thought to decrease the protein content of the effusion by affecting macrophage function. The resorption of effusion may thereby be enhanced and fibrosis of the pleura minimized. The drug is available over the counter at health food stores. A dosage of 50 to 100 mg/kg given orally every 8 hours is recommended.

Surgical management is considered if clinical signs have not improved within 1 to 3 months of medical therapy, or if signs are intolerable. The recommended surgical management of chylothorax includes thoracic duct ligation and pericardectomy, with or without ablation of the cisterna chyli. Thoracic duct ligation is technically difficult and ideally performed by an experienced surgeon. Multiple ligations of the thoracic duct and its collaterals are performed. The ducts are identified by lymphangiography before surgery, and lymphangiography is repeated after ligation to assess the success of ligation. Pericardectomy is recommended at the time of thoracic duct ligation and is associated with an improved outcome (Fossum et al., 2004). Ablation of the cisterna chyli has also been reported to enhance success (McAnulty, 2011).

Placement of pleuroperitoneal or pleurovenous shunts or mesh within the diaphragm to allow fluid to drain away from the pleural space has also been recommended for the management of chylothorax and should be considered if medical and surgical treatment is unsuccessful. These drainage procedures provide a route by which the leaking chyle can reenter the circulation without producing the respiratory compromise associated with pleural effusion. Unfortunately, drains often become nonfunctional within months of placement.

Prognosis

The prognosis for chylothorax is fair, unless the chylothorax was traumatically induced or was the result of a reversible condition. Most studies report a positive response to surgical intervention in the range of 50% to 80% of patients (Singh et al., 2012b). It is not possible to predict the contribution of fibrosing pleuritis to clinical signs in cats with this complication. In cats with continued respiratory difficulties after resolution of effusion, decortication of the lung is considered.

NEOPLASTIC EFFUSION

Neoplastic effusions resulting from mediastinal lymphoma are treated with radiation or chemotherapy (see Chapter 79). Effusions caused by mesothelioma or carcinoma of the

pleural surfaces may respond to palliative therapy with intracavitary infusions of cisplatin or carboplatin (Moore, 1992), with or without concurrent chemotherapy. Placement of pleuroperitoneal shunts or intermittent thoracocentesis to alleviate the degree of respiratory compromise can be considered to prolong the life of patients that have no clinical signs beyond those resulting from the accumulation of pleural effusion.

PNEUMOTHORAX

Pneumothorax is the accumulation of air in the pleural space. The diagnosis is confirmed by means of thoracic radiography. The pleural cavity is normally under negative pressure, which keeps the lungs expanded in health. However, if an opening forms between the pleural cavity and the atmosphere or the airways of the lungs, air is transferred into the pleural space because of this negative pressure. A ***tension pneumothorax*** occurs if a one-way valve is created by tissue at the site of leakage, such that air can enter into the pleural space during inspiration but cannot return to the airways or atmosphere during expiration. Increased intrapleural pressure and resultant respiratory distress occur quickly.

Leaks through the thoracic wall can occur after a traumatic injury or as the result of a faulty pleural drainage system. Air can also enter the thorax during abdominal surgery through a previously undetected diaphragmatic hernia. These causes are readily identified.

Pneumothorax resulting from pulmonary air can occur after blunt trauma to the chest (i.e., traumatic pneumothorax) or as a result of existing pulmonary lesions (i.e., spontaneous pneumothorax). Traumatic pneumothorax occurs frequently, and findings of the history and physical examination allow this to be diagnosed. Pulmonary contusions are often present in these animals.

Less commonly, pneumothorax is a result of tracheal trauma. Tracheal tears within the thorax are usually the result of overinflation of endotracheal tube cuffs, a particular concern in cats. Trauma to the cervical trachea more often results in subcutaneous emphysema, though dissection of air can occur into the mediastinum or thorax.

Spontaneous pneumothorax occurs when preexisting pulmonary lesions rupture. Cavitary lung diseases include blebs, bullae, and cysts, which can be congenital or idiopathic, or can result from prior trauma, chronic airway disease (particularly in cats), or *Paragonimus* infection. Necrotic centers can develop in neoplasms, thromboembolized region (e.g., from dirofilariasis) abscesses, and granulomas involving the airways; these can rupture, allowing air to escape into the pleural space. (See Chapter 20 for further discussion of cavitary lesions.)

TRAUMATIC PNEUMOTHORAX

Dogs and cats with pneumothorax and a recent history of trauma are managed conservatively. Cage rest, removal of accumulating air by periodic thoracocentesis or by chest tube, and radiographic monitoring are indicated. If abnormal radiographic opacities persist without improvement for longer than several days in trauma patients, further diagnostic tests should be performed, as described for spontaneous pneumothorax. Failure of resolution of the pneumothorax over time may necessitate surgical intervention. Treatment with an autologous blood-patch has shown promise in patients for which surgery is not an option (Oppenheimer et al., 2014).

SPONTANEOUS PNEUMOTHORAX

Spontaneous pneumothorax is much less common than traumatic pneumothorax and occurs more often in dogs than in cats. Thoracocentesis is useful for initial stabilization of the animal's condition. If frequent thoracocentesis is needed to control the pneumothorax, a chest tube is placed (see Chapter 23).

Dogs and cats are evaluated for underlying disease with thoracic radiography (repeated after full lung expansion), computed tomography of the thorax, multiple fecal examinations for *Paragonimus* ova (see Chapter 20), heartworm testing, and possibly tracheal wash fluid analysis or bronchoscopy. Computed tomography is much more sensitive for the identification of bullae and should be performed before thoracotomy. In a study by Au et al. (2006), thoracic radiography identified bullae or blebs in only 2 of 12 dogs with spontaneous pneumothorax, whereas computed tomography was successful in identifying lesions in 9 of these dogs.

Pneumothorax in patients with *Paragonimus* infection may respond to treatment with anthelmintics (see Chapter 22) and supportive therapy as described for traumatic pneumothorax. Retrospective studies support surgical intervention for most dogs with spontaneous pneumothorax. In a review of 21 cases, Holtsinger et al. (1993) found that most dogs with spontaneous pneumothorax managed medically with chest tubes and suction ultimately required surgery during initial hospitalization or upon subsequent recurrence of pneumothorax to resolve the problem. Because unobserved recurrence of spontaneous pneumothorax can be fatal, conservative treatment is believed to carry greater risk than is associated with surgery. Furthermore, a report of 64 cases by Puerto et al. (2002) showed that recurrence and mortality rates for dogs with spontaneous pneumothorax were lower in dogs that had surgery compared with dogs that were treated conservatively. Similar data are not available to guide the management recommendations for cats with spontaneous pneumothorax, but supportive therapy is preferred for most cats. In a retrospective study of 35 cats, mortality was high regardless of treatment, with only 19 cats (54%) surviving to discharge (Mooney et al., 2012). Only 1 of 5 cats that had thoracotomy survived.

For patients undergoing thoracotomy, a median sternotomy is generally recommended to allow exposure of all lung lobes because it is often not possible to localize all cavitary lesions preoperatively (Fig. 24.4). Abnormal tissue is evaluated histologically and microbiologically for a definitive diagnosis.

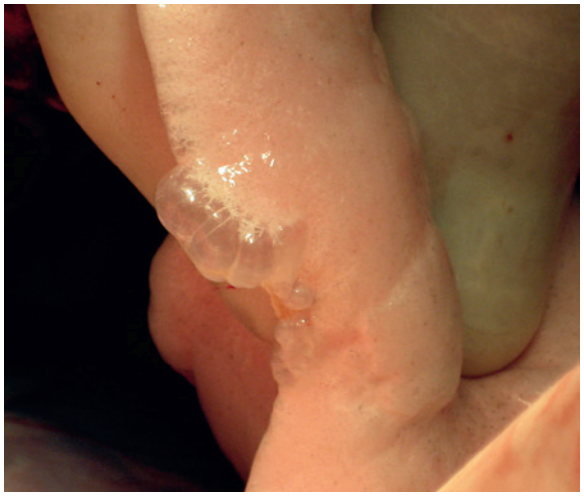

FIG 24.4
Blebs can be seen in this intraoperative image of the lung of a dog that presented with spontaneous pneumothorax. The size of these blebs precluded their identification by thoracic radiography or computed tomography. (Courtesy Dr. Guillaume Pierre Chanoit.)

Pleurodesis is used in the management of people with recurrent pneumothorax. Thus far, a consistently successful technique has not been found for obliterating the pleural space in dogs or cats. The infusion of autologous blood into the pleural cavity has shown some promise in dogs, perhaps functioning as a "patch" over an ongoing leak rather than obliterating the pleural space. Case reports are limited, and dogs with ongoing leakage from traumatic pneumothorax seemed most responsive (Oppenheimer et al., 2014).

Regardless of the treatment used, recurrence is a possibility. Accurate diagnosis of the underlying lung disease and determination of the extent of involvement through a thoracotomy assist in determining the prognosis.

MEDIASTINAL MASSES

Mediastinal masses can cause inspiratory distress as a result of displacement of lung tissue by the mass itself or by the secondary pleural effusion that may develop. Additional clinical signs such as coughing, regurgitation, and facial edema may be present. Neoplasia is the primary differential diagnosis. Lymphoma involving the mediastinum is common, particularly in cats. Other types of neoplasms include thymoma and rarely thyroid carcinoma, parathyroid carcinoma, and chemodectoma. Nonneoplastic mass lesions such as abscesses, granulomas, hematomas, and cysts are other possibilities.

Mediastinal masses in cats can sometimes be palpated during gentle compression of the anterior thorax. Radiographically, mediastinal masses appear as soft tissue opacities in the anterior mediastinum (Fig. 24.5). However, it can be difficult to accurately identify a mediastinal mass if pleural

FIG 24.5
Ventrodorsal view of the thorax of a cat with an anterior mediastinal mass. Soft tissue opacity fills the anterior mediastinum and obscures the border of the heart.

fluid is present. Pleural fluid can both mimic the appearance of a mass and obscure its borders. Ultrasonography done before removal of the pleural fluid is helpful in identifying a mass and determining the extent to which surrounding structures are involved.

Thoracocentesis and fluid analysis should be performed in animals with pleural effusion. Lymphoma can frequently be diagnosed through identification of malignant cells in the effusion. Transthoracic fine-needle aspiration or biopsy can be performed to obtain specimens for microscopic evaluation of the mass itself. Aspiration cytology is generally performed initially, followed by biopsy if a cytologic diagnosis is not obtained. Transthoracic biopsy specimens can often be obtained relatively safely with ultrasound guidance, particularly if the lesion is solid rather than cystic. A study by Lana et al. (2006) demonstrated the usefulness of flow cytometry of mediastinal mass aspirates in differentiating lymphoma from thymoma in dogs.

Surgical exploration or thoracoscopy may be necessary for biopsy of small lesions, cavitary lesions, and lesions adjacent to the heart or main blood vessels. Complete excision

of the mass should be attempted at that time, unless lymphoma is diagnosed. (Specific recommendations for the management of dogs and cats with mediastinal neoplasia are given in Chapter 78.)

PNEUMOMEDIASTINUM

Pneumomediastinum is identified radiographically. Subcutaneous emphysema or pneumothorax can occur concurrently or secondarily. Respiratory compromise most often results from pneumothorax. Mediastinal air commonly originates from rupture or tears in the trachea, bronchi, or alveoli. These leaks can occur as a result of bite wounds of the neck or sudden changes in intrathoracic pressure resulting from coughing, blunt trauma, or excessive respiratory efforts against obstructed airways. Potential iatrogenic causes include tracheal washing, tracheostomy, and endotracheal tube placement (usually by overinflation of the cuff). Air can enter the mediastinum through esophageal tears, generally resulting from foreign bodies.

Strict cage rest is indicated for animals with pneumomediastinum to facilitate natural sealing of the tear. If air continues to accumulate, causing respiratory compromise, bronchoscopy should be performed to identify tracheal or bronchial lacerations that may require surgical repair.

CHAPTER 25

Emergency Management of Respiratory Distress

GENERAL CONSIDERATIONS

Respiratory distress, or *dyspnea,* refers to an abnormally increased effort in breathing. Some authors prefer to use terms such as *hyperpnea* and *increased respiratory effort* in reference to this abnormality because *dyspnea* and *distress* imply feelings that cannot be determined with certainty in animals. Breathing difficulties are extremely stressful for people and are likely so for dogs and cats as well. Dyspnea is also physically exhausting to the animal as a whole and to the respiratory musculature specifically. Animals in respiratory distress at rest should be managed aggressively, and their clinical status should be frequently assessed.

A dog or cat in respiratory distress may show orthopnea, which is difficulty breathing in certain positions. Animals with orthopnea will assume a sitting or standing position with their elbows abducted and neck extended. Movement of the abdominal muscles that assist ventilation may be exaggerated. Cats normally have minimal visible respiratory effort. Cats that show noticeable chest excursions or open-mouth breathing are severely compromised. Cyanosis, in which normally pink mucous membranes are bluish, is a sign of severe hypoxemia and indicates that the increased respiratory effort is not sufficiently compensating for the degree of respiratory dysfunction. Pallor of the mucous membranes is a more common sign of acute hypoxemia resulting from respiratory disease than is cyanosis.

Respiratory distress caused by respiratory tract disease most commonly develops as a result of large airway obstruction, severe pulmonary parenchymal or vascular disease (i.e., pulmonary thromboembolism), pleural effusion, or pneumothorax. Respiratory distress can also occur as a result of primary cardiac disease causing decreased perfusion, pulmonary edema, or pleural effusion (see Chapter 1). In addition, noncardiopulmonary causes of hyperpnea must be considered in animals with apparent distress, including severe anemia, hypovolemia, acidosis, hyperthermia, and neurologic disease. Pain and steroid administration can cause tachypnea and should be considered among the differential diagnoses in patients without other evidence of respiratory disease. Normal breath sounds may be increased in dogs and cats without respiratory disease, but crackles or wheezes are not expected.

A physical examination should be performed rapidly, with particular attention paid to the breathing pattern, auscultatory abnormalities of the thorax and trachea, pulses, and mucous membrane color and perfusion. Attempts at stabilizing the animal's condition should be made before further diagnostic testing is initiated.

Dogs and cats in shock should be treated appropriately (see Chapter 28). Most animals in severe respiratory distress benefit from decreased stress and activity, placement in a cool environment, and oxygen supplementation. Cage rest is extremely important, and the least stressful method of oxygen supplementation should be used initially. An oxygen cage achieves both of these goals, with the disadvantage that the animal is inaccessible. Sedation of the animal may be beneficial (Table 25.1). More specific therapy depends on the location and cause of the respiratory distress (Table 25.2). Ventilatory support is needed for patients that are not adequately oxygenating despite appropriate treatment or who have ventilatory failure. Oxygen supplementation and ventilator support are discussed later in this chapter.

EMERGENCY MANAGEMENT BASED ON LOCALIZATION

LARGE AIRWAY DISEASE

Diseases of the large airways result in respiratory distress by obstructing the flow of air into the lungs. For the purposes of these discussions, extrathoracic large airways (otherwise known as *upper airways*) include the pharynx, larynx, and trachea proximal to the thoracic inlet; intrathoracic large airways include the trachea distal to the thoracic inlet and bronchi. Animals presenting in respiratory distress caused by large airway obstruction typically have a markedly increased respiratory effort with a minimally increased respiratory rate (see Table 25.2). Excursions of the chest may

TABLE 25.1

Drugs Used to Decrease Stress in Animals With Respiratory Distress

Upper Airway Obstruction: Decreases Anxiety and Lessens Respiratory Efforts, Decreasing Negative Pressure Within Upper Airways		
Acepromazine	Dogs and cats	0.01-0.2 mg/kg IV, IM, SC (no more than 3 mg total dose)
Morphine	Dogs only, particularly brachycephalic dogs	0.2-2.0 mg/kg IM, SC; CRI, 0.1-0.3 mg/kg loading dose, then 0.1-0.3 mg/kg/h
Pulmonary Edema: Decreases Anxiety		
Morphine	Dogs only	0.2-2.0 mg/kg IM, SC; CRI, 0.1-0.3 mg/kg loading dose, then 0.1-0.3 mg/kg/h
Acepromazine	Dogs and cats	0.01-0.2 mg/kg IV, IM, SC (no more than 3 mg total dose)
Rib Fractures, After Thoracotomy, Other Trauma: Pain Relief		
Hydromorphone	Dogs and cats	0.1-0.2 mg/kg IV, IM, SC; CRI, 0.025-0.050 mg/kg IV loading dose, then 0.01-0.04 mg/kg/h
Butorphanol	Dogs and cats	0.1-0.8 mg/kg IV, IM, SC; CRI, 0.1-0.2 mg/kg IV loading dose, then 0.1-0.2 mg/kg/h
Buprenorphine	Dogs and cats	0.005-0.020 mg/kg IV, IM

CRI, Continuous-rate infusion; *IM,* intramuscularly; *IV,* intravenously; *SC,* subcutaneously.
Dosage recommendations from Quandt J: Analgesia, anesthesia, and chemical restraint in the emergent small animal patient, *Vet Clin North Am Small Anim Pract* 43:214, 2013.

TABLE 25.2

Localization of Respiratory Tract Disease by Physical Examination Findings in Dogs and Cats With Severe Respiratory Distress

	LARGE AIRWAY DISEASE		PULMONARY PARENCHYMAL DISEASE			
	EXTRATHORACIC (UPPER)	**INTRATHORACIC**	**OBSTRUCTIVE**	**RESTRICTIVE**	**OBSTRUCTIVE AND RESTRICTIVE**	**PLEURAL SPACE DISEASE**
Respiratory rate	Nl-↑	Nl-↑	↑↑↑	↑↑↑	↑↑↑	↑↑↑
Relative effort	↑↑↑Inspiration	↑↑Expiration	↑Expiration	↑↑Inspiration	No difference	↑Inspiration
Audible sounds	Inpiratory stridor, stertor	Expiratory cough/wheeze	Rarely expiratory wheeze	None	None	None
Auscultable sounds	Referred upper airway sounds; ↑↑breath sounds	End expiratory click; ↑↑breath sounds	Expiratory wheezes or ↑↑breath sounds; rarely, ↓breath sounds with air trapping	↑↑Breath sounds; ±crackles	↑↑Breath sounds, crackles, and/or wheezes	↓Breath sounds

↑, Slightly increased; ↑↑, increased; ↑↑↑, markedly increased; ↓, decreased; *Nl,* normal. Normal respiratory rates for dogs and cats at rest are ≤ 20/min. In the hospital setting, rates of ≤ 30/min are generally accepted as normal.

be increased (i.e., deep breaths are taken). Breath sounds are often increased.

Extrathoracic (Upper) Airway Obstruction

Patients with extrathoracic (upper) airway obstruction typically exhibit the greatest breathing effort during inspiration, which is generally prolonged relative to expiration. Stridor or stertor is usually heard, generally during inspiration. A history of voice change may be present with laryngeal disease.

Laryngeal paralysis and brachycephalic airway syndrome are the most common causes of upper airway obstruction

(see Chapter 18). Other laryngeal and pharyngeal diseases are listed in Boxes 16.1 and 16.2. Severe tracheal collapse can result in extrathoracic or intrathoracic large airway obstruction, or both. Rarely, other diseases of the extrathoracic trachea, such as foreign body, stricture, neoplasia, granuloma, and hypoplasia, result in respiratory distress.

Patients with extrathoracic airway obstruction often present with acute distress in spite of the chronic nature of most of these diseases, because of a vicious cycle of increased respirations leading to increased obstruction, as described in Chapter 16. This cycle can almost always be broken with medical management (Fig. 25.1). The patient is sedated (see Table 25.1) and provided a cool, oxygen-rich environment (e.g., oxygen cage). For dogs with brachycephalic airway syndrome, morphine is given. Otherwise, acepromazine is used. Subjectively, dogs with brachycephalic airway syndrome seem to have greater difficulty maintaining a patent airway when sedated with acepromazine compared with morphine. Short-acting corticosteroids (e.g., dexamethasone, 0.1 mg/kg intravenously) are thought by some to be effective in decreasing local inflammation.

In rare cases, sedation and oxygen supplementation will not resolve the respiratory distress, and the obstruction must be physically bypassed. Placement of an endotracheal tube is generally effective. A short-acting anesthetic agent is administered. Long and narrow endotracheal tubes with stylets should be available to pass by large or deep obstructions. If an endotracheal tube cannot be placed, a transtracheal catheter can be inserted distal to the obstruction (see later in this chapter). If a tracheostomy tube is needed, it can then be placed under controlled, sterile conditions. It is rarely necessary to perform a nonsterile emergency tracheostomy.

Intrathoracic Large Airway Obstruction

Respiratory distress caused by intrathoracic large airway obstruction is rare. Patients with intrathoracic large airway obstruction typically exhibit the greatest breathing effort during expiration, which is generally prolonged relative to inspiration. The most common cause of intrathoracic large airway obstruction is collapse of the mainstem bronchi and/or intrathoracic trachea (tracheobronchomalacia; see Chapter 21). A high-pitched, wheezing, cough-like sound is often heard during expiration in these patients, and crackles or wheezes may be auscultated. Other differential diagnoses include foreign body, advanced *Oslerus* infection, tracheal neoplasia, tracheal stricture, and bronchial compression by extreme hilar lymphadenopathy.

Sedation, oxygen supplementation, and minimization of stress as described for the management of extrathoracic airway obstruction are often effective in stabilizing these patients as well. High doses of hydrocodone or butorphanol will provide cough suppression and sedation (see Chapter 21). Dogs with chronic bronchitis may benefit from bronchodilators and corticosteroids.

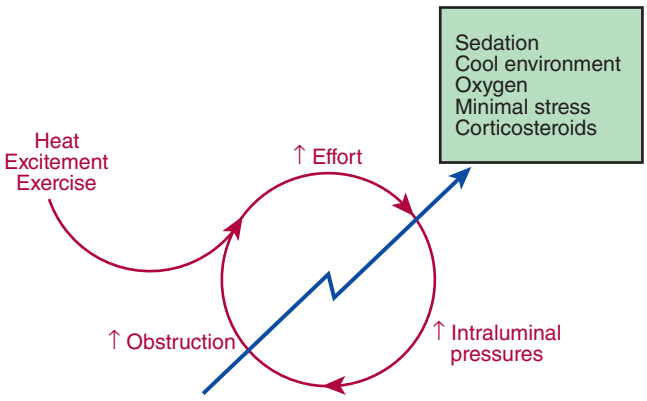

FIG 25.1
Patients with extrathoracic (upper) airway obstruction often present in acute respiratory distress because of progressive worsening of airway obstruction after an exacerbating event. Medical intervention is nearly always successful in breaking this cycle and stabilizing the patient's respiratory status.

PULMONARY PARENCHYMAL DISEASE

Diseases of the pulmonary parenchyma result in hypoxemia and respiratory distress through a variety of mechanisms, including obstruction of small airways (obstructive lung disease; e.g., idiopathic feline bronchitis); decreased pulmonary compliance (restrictive lung disease, "stiff" lungs; e.g., pulmonary fibrosis); and interference with pulmonary circulation (e.g., pulmonary thromboembolism). Most patients with pulmonary parenchymal disease, including those with pneumonia or pulmonary edema, develop hypoxemia through a combination of these mechanisms that contribute to $\dot{V}/\dot{Q}$ mismatch (see Chapter 20), including airway obstruction and alveolar flooding, and decreased compliance.

Animals that present in respiratory distress caused by pulmonary parenchymal disease typically have a markedly increased respiratory rate (see Table 25.2). Patients with primarily obstructive disease, usually cats with bronchial disease, may have prolonged expiration relative to inspiration with increased expiratory efforts. Expiratory wheezes are commonly auscultated. Patients with primarily restrictive disease, usually dogs with pulmonary fibrosis, may have prolonged inspiration relative to expiration and effortless expiration. Crackles are commonly auscultated. Occasionally, cats with severe bronchial disease will develop a restrictive breathing pattern in association with air trapping and hyperinflation of the lungs. Other patients, in which a combination of these processes is occurring, show increased effort during both phases of respiration; shallow breathing; and crackles, wheezes, or increased breath sounds on auscultation. Differential diagnoses for dogs and cats with pulmonary disease are provided in Box 19.1.

Oxygen therapy is the treatment of choice for stabilizing dogs or cats with severe respiratory distress believed to be caused by pulmonary disease. Bronchodilators, diuretics, or glucocorticoids can be considered as additional treatments if oxygen therapy alone is not adequate.

Bronchodilators, such as theophyllines or β-agonists, are used if obstructive lung disease is suspected because they

decrease bronchoconstriction. In combination with oxygen, they are the treatment of choice for cats with signs of bronchitis (see Chapter 21). Subcutaneous terbutaline (0.01 mg/kg, repeated in 5 to 10 minutes if necessary) or albuterol administered by metered dose inhaler (MDI) is most often used in emergency situations. Due to the airway obstruction, drug administered by MDI may not penetrate into deeper airways and often must be repeated numerous times before an effect is seen. Heart rate is used to monitor for toxicity. Bronchodilators are described in greater detail in Chapter 21.

Diuretics such as furosemide (2 mg/kg, administered intravenously) are indicated for the management of pulmonary edema. If edema is among the differential diagnoses of an unstable patient, a short trial of furosemide therapy is reasonable. However, potential complications of diuretic use resulting from volume contraction and dehydration should be taken into consideration. Continued use of diuretics is contraindicated in animals with exudative lung disease or bronchitis because systemic dehydration results in drying of airways and airway secretions. Mucociliary clearance of airway secretions and contaminants is decreased, and airways are further obstructed with mucus plugs.

Glucocorticoids decrease inflammation. Injectable formulations such as dexamethasone (0.1 to 0.5 mg/kg, administered intravenously) are indicated for animals in severe respiratory distress caused by the following conditions: idiopathic feline bronchitis, thromboembolism after adulticide treatment for heartworms, allergic bronchitis, pulmonary parasitism, and respiratory failure soon after initiation of treatment for pulmonary mycoses. Animals with other inflammatory diseases or acute respiratory distress syndrome (ARDS) may respond favorably to glucocorticoid administration. The potential negative effects of corticosteroids must be considered before their use. For example, the immunosuppressive effects of these drugs can result in exacerbation of an infectious disease. Although the use of short-acting corticosteroids for acute stabilization of such cases probably will not greatly interfere with appropriate antimicrobial therapy, long-acting agents and prolonged administration should generally be avoided. Glucocorticoid therapy potentially interferes with the results of future diagnostic tests, particularly if lymphoma or eosinophilic disease are differential diagnoses. Appropriate diagnostic tests are performed once the patient can tolerate the stress.

Broad-spectrum antibiotics are administered if there is evidence of sepsis (e.g., fever, neutrophilic leukocytosis with left shift, moderate to marked toxicity of neutrophils) or a high degree of suspicion of bacterial or aspiration pneumonia. Note that airway specimens (usually tracheal wash) should be obtained for culture if at all possible before broad-spectrum antibiotics are initiated to confirm the diagnosis of bacterial infection and to obtain susceptibility data. Specimens obtained after antibiotics are initiated may not be diagnostic, even with continued progression of signs. However, airway sampling may not be possible in these unstable patients. If sepsis is suspected, blood and urine cultures may be useful. The diagnosis and treatment of bacterial and aspiration pneumonia are described in Chapter 22.

If the dog or cat does not respond to this management, it may be necessary to intubate the patient and institute positive-pressure ventilation until a diagnosis can be established and specific therapy initiated.

PLEURAL SPACE DISEASE

Pleural space diseases cause respiratory distress by preventing normal lung expansion. Animals presenting in respiratory distress as a result of pleural space disease typically have a markedly increased respiratory rate (see Table 25.2). Relatively increased inspiratory efforts may be noted but are not always obvious. Decreased lung sounds on auscultation distinguish patients with tachypnea caused by pleural space disease from patients with tachypnea caused by pulmonary parenchymal disease. Increased abdominal excursions during breathing may be noted.

Paradoxical breathing refers to a breathing pattern in which the abdominal walls are "sucked in" during inspiration. Paradoxical breathing has been associated with pleural diseases in dogs and cats presented for respiratory distress (LeBoedec et al., 2012). The authors of this study attribute the paradoxical breathing to decreased inhibition of contraction of the intercostal muscles secondary to increased pleural pressure. The reported sensitivity and specificity of the finding as a predictor of pleural disease were 0.67 and 0.83 in dyspneic dogs, and 0.90 and 0.58 in dyspneic cats, respectively.

Most patients in respiratory distress resulting from pleural space disease have pleural effusion or pneumothorax (see Chapter 23). Other differential diagnoses are diaphragmatic hernia and mediastinal masses. If pleural effusion or pneumothorax is suspected to be causing respiratory distress, needle thoracocentesis (see Chapter 23) should be performed immediately before further diagnostic testing is conducted or any drugs are administered. Where available, ultrasonography can be used for rapid, minimally stressful assessment of the pleural space for fluid or air. The acronym for the examination is *TFAST,* which stands for *t*horacic *f*ocused *a*ssessment with *s*onography for *t*rauma. See the Lisciandro (2011) reference for probe positions and characteristic sonographic signs. Oxygen can be provided by mask while thoracocentesis is performed, but successful drainage of the pleural space will quickly improve the animal's condition. Occasionally, emergency placement of a chest tube is necessary to evacuate rapidly accumulating air (see Chapter 23).

As much fluid or air should be removed as possible. The exception is for animals with acute hemothorax. Hemothorax is usually the result of trauma or rodenticide intoxication. The respiratory distress associated with hemothorax is often the result of acute blood loss rather than an inability to expand the lungs. In this situation, as little volume as is needed to stabilize the animal's condition is removed. The remainder will be reabsorbed (autotransfusion) to the benefit of the animal. Aggressive fluid therapy is indicated.

OXYGEN SUPPLEMENTATION AND VENTILATION

OXYGEN SUPPLEMENTATION

Oxygen supplementation is generally indicated to maintain arterial blood oxygen pressures (Pa_{O_2}) at greater than 60 mm Hg. Oxygen supplementation is indicated in every dog or cat with signs of respiratory distress or labored breathing. Cyanosis is another clear indication. Whenever possible, the cause of hypoxemia should be identified and specific treatment initiated as well. Assisted ventilation is indicated for animals with an inadequate arterial oxygen concentration despite supplementation, and for animals with arterial carbon dioxide pressures exceeding 60 mm Hg (see Chapter 20).

The inhaled concentration of oxygen can be supplemented by the administration of 100% oxygen by mask, hood, nasal catheter, transtracheal catheter, endotracheal tube, tracheal tube, or oxygen cage. Administration of oxygen by nasal catheter is very well suited to most practices.

When administering 100% oxygen to an animal, the clinician must consider the anhydrous nature of pure oxygen and the toxic effects of oxygen in a high concentration. Because oxygen from tanks contains no water, drying of the airways can occur quickly, particularly if the nasal cavity has been completely bypassed by catheters or tubes. All animals with respiratory tract diseases should be systemically hydrated. Moisture must be added to the airways of animals who have been receiving oxygen by catheter or tube for longer than a few hours. Ventilators designed for long-term use have a heated humidifier incorporated into their design. Humidity exchange filters, which can also be attached to tracheal and endotracheal tubes, function by retaining moisture from exhaled air and adding it to inhaled air. These filters can support bacterial growth and must be replaced daily. Nebulization can also be used to add moisture to the airways. Less effective methods of hydration, such as instillation of sterile 0.9% sodium chloride solution directly into tubes or catheters, can be used if other options are not available. Some water vapor can also be added to the oxygen by incorporating pass-over or bubble humidifiers in the system.

Inhalation of air with greater than 50% oxygen is toxic to the pulmonary epithelium. Pulmonary function deteriorates, and death can result. Air with greater than 50% oxygen is therefore not provided for longer than 12 hours. If higher concentrations are necessary to maintain adequate arterial oxygen concentrations, ventilatory support is initiated.

Oxygen Masks

Oxygen masks are useful for short-term supplementation. The animal experiences minimal stress, and manipulations such as venous catheter placement and thoracocentesis can be performed. A snug fit is desirable to decrease the volume of dead space, and a relatively high flow rate is necessary (Table 25.3). Sterile eye ointment is applied to prevent desiccation of the corneas.

TABLE 25.3

Maximum Achievable Oxygen Concentrations and Associated Flow Rates for Various Methods of Supplementation

METHOD OF ADMINISTRATION	MAXIMUM OXYGEN CONCENTRATION (%)	FLOW RATE
Mask	50-60	8-12 L/min
Nasal catheter	50	6-8 L/min or 50-150 mL/kg/min
Transtracheal catheter	30-40	1-2 L/min
Endotracheal tube	100	0.2 L/kg/min
Tracheal tube	100	0.2 L/kg/min
Oxygen cage	60	2-3*

*After cage is filled, flow is adjusted on the basis of oxygen concentration as measured by oxygen sensor.
From Court MH et al.: Inhalation therapy: oxygen administration, humidification, and aerosol therapy, *Vet Clin North Am Small Anim Pract* 15:1041, 1985.

Oxygen Hoods

Oxygen hoods that can be placed over the animal's head are available. With some, the animals must be laterally recumbent and still, limiting the use of hoods to animals recovering from anesthesia, those that are severely depressed, and those that are heavily sedated (Fig. 25.2). Others are designed to completely surround the animal's head and are attached around the neck. One design is an adaptation of an Elizabethan collar (OxyHood, JorVet). In some situations, oxygen hoods may be better tolerated than oxygen masks, and it may take less manpower to care for an animal for which one is being used than an animal with an oxygen mask. A means for escape of exhaled air must always be provided to prevent the buildup of CO_2 within the hood.

Nasal Catheters

Nasal catheters can be used for long-term oxygen supplementation (Fig. 25.3). The animal is relatively free to move and is accessible for evaluation and treatment. Most animals tolerate the catheter well. Catheters can become obstructed with nasal secretions, however. Soft red rubber or infant feeding tubes or polyurethane catheters can be used. Tube size is based on patient size. In general, a 3.5 to 5F tube is used for cats, and a 5 to 8F tube is used for dogs.

Sedation is rarely necessary for catheter placement. First, the length of tubing to be inserted into the nasal cavity is measured against the head of the animal. The tubing should reach the level of the carnassial tooth. A water-soluble lubricant or 0.2% lidocaine jelly is applied to the length of the catheter that will be within the nasal cavity. Next, 0.2%

FIG 25.2
An oxygen hood can be used for recumbent animals as a substitute for an oxygen mask. In this patient, oxygen is being delivered through an opening in the top of the hood, and the light blue opening that will accommodate standard anesthesia tubing is left open for circulation of air. Regardless of the method used to increase the oxygen in inspired air, a means for escape of expired CO_2 is essential (Disposa-Hood, Utah Medical Products, Inc.).

FIG 25.3
Dog with intranasal catheter in place for delivery of oxygen. The catheter is sutured to the muzzle less than 1 cm from its exit from the naris and is further anchored with sutures to the face so that it exits behind the animal's head. An Elizabethan collar is routinely used to prevent the animal from removing the catheter.

lidocaine is dripped gently into the nasal cavity through the naris with the animal's nose pointed upward. The catheter is then passed through the naris and is initially aimed dorsomedially through the naris, then immediately ventromedially. Once the correct length of catheter has been inserted, it is gently bent beneath the lateral cartilage and sutured to the muzzle no farther than 1 cm caudal to the exit from the naris. The catheter can be further anchored to the face with sutures securing its path between the eyes to behind the animal's head. An Elizabethan collar is placed on the patient to prevent the animal from removing the catheter.

A sterile intravenous set can be connected to the catheter. The intravenous line can be attached to a half-filled bottle of sterile saline solution and positioned above the fluid level. Oxygen is then delivered through the bottle, below the fluid level, providing some moisture as the oxygen bubbles through the saline.

Transtracheal Catheters

Oxygen can be administered through a jugular catheter placed with sterile technique through the trachea. This approach is particularly useful for the emergency stabilization of animals with an upper airway obstruction. The catheter is placed as for transtracheal washing (see Chapter 20).

Endotracheal Tubes

Endotracheal tubes are used to administer oxygen during surgical procedures and cardiopulmonary resuscitation. They can be used to bypass most upper airway obstructions for emergency stabilization. Pure oxygen can be administered for short periods. Longer supplementation requires the mixing of 100% oxygen with room air. Ventilation can be provided with a cuffed endotracheal tube. Trauma to the trachea is decreased by using high-volume, low-pressure cuffs and by inflating the cuff with the least amount of pressure necessary to create a seal. If positive-pressure ventilation is not being used, the cuff can remain deflated.

Because endotracheal tubes are not tolerated by alert animals, tracheal tubes are preferred for long-term management. Conscious animals in which endotracheal tubes are used must be given sedatives, analgesics, paralyzing agents, or a combination of these drugs. The cuff should be deflated when possible to minimize tracheal damage. The tube must be cleaned periodically to remove secretions (see the recommendations for tracheal tube cleaning), and frequent flushing of the oral cavity is performed. Moisture must be added to the inspired gases, as previously discussed.

Tracheal Tubes

Tracheal tubes are placed through the tracheal rings and are readily tolerated by conscious animals. It is rare that an animal requires an emergency tracheostomy. Nearly all such animals can be stabilized by other techniques, allowing the tracheal tube to be subsequently placed using a careful, sterile surgical technique. Tracheal tubes are generally used for the management of animals with an upper airway obstruction. Room air often contains adequate oxygen for

use in animals with an upper airway obstruction once the obstruction has been bypassed.

The tube itself should have a diameter nearly as wide as the tracheal lumen and a length of 5 to 10 rings. It is necessary to use high-volume, low-pressure cuffs to prevent tracheal damage and subsequent stricture. Double-lumen tubes are ideal for this method. The inner tube can be removed for cleaning and can be replaced easily. Single-lumen tubes also work and may be necessary in small animals.

Tracheal tubes are usually placed with the animal anesthetized with a short-acting agent. The trachea is exposed through a ventral midline incision made just beneath the larynx. The trachea is entered through an incision made a few rings below the cricoid cartilage, parallel to the trachea and perpendicular to the rings, and through just enough rings to allow passage of the tube. Either end of the incision can be widened with a small transverse incision. Stay sutures are placed on each side of the incision to facilitate initial placement of the tube as well as later replacement if the tube is accidentally or intentionally removed. The tube is then inserted into the opening. With minimal pressure on the airway, it is tied with gauze around the neck of the animal. Few or no sutures are used to close the incision to prevent the collection of air subcutaneously. A gauze sponge with a slit cut in it and coated with antiseptic ointment can be placed over the incision and around the tube.

The tube must be monitored for obstruction and cleaned. The inner tube of double-lumen tubes can be easily removed for this purpose. The tube is cleaned every 30 to 60 minutes initially, with the interval increased as fewer secretions accumulate. Sterile technique is used when the tubes are handled, and they must be replaced if they become contaminated.

Single-lumen tubes are difficult to remove and replace safely for the first few days unless stay sutures are left in place. Periodic cleaning can be performed with the tube in place. Sterile saline solution is instilled into the tube for this purpose. To perform suctioning, a sterile urinary catheter with several openings at the end is attached to a suction unit and passed through the tube. The trachea and tracheal tube are then suctioned to remove secretions. Suctioning is performed for short intervals to allow the lungs to reinflate. Cleaning is performed every few hours initially, then less frequently if secretions are not accumulating.

A smaller tube can be used once the animal is able to oxygenate adequately with room air. The tube can be removed when the animal can oxygenate by breathing around a small tube with the lumen obstructed. The incision is allowed to heal without suturing. The tip of the tube is cultured for bacteria.

Antibiotics are not administered prophylactically. Any existing infection or infections that occur during therapy are treated on the basis of culture and sensitivity information.

Complications of tracheal tubes are common. In a report of temporary tracheostomy tubes by Nicholson and Baines (2012), complications occurred in 36 of 42 (86%) patients. Most of these complications were clinically insignificant (e.g., pneumomediastinum, subcutaneous emphysema) or correctable. The most common complications were tube obstruction (26%), dislodgment (21%), aspiration pneumonia (21%), and stoma swelling (21%). Overall, 34 of the dogs (81%) had a successfully managed temporary tracheostomy tube.

Oxygen Cages

Oxygen cages provide an oxygen-enriched environment with minimal stress to animals. However, the animal is isolated from direct contact, which can be a disadvantage. Other environmental factors, such as humidity, temperature, and carbon dioxide concentration, must be monitored and controlled, or extreme stress and even death can occur. The animal is totally dependent on proper cage function. The ability of the cage to maintain the correct environment varies with the specific cage as well as with each animal. Commercial cages are available for veterinary use. Incubators from human hospitals can be modified for small animals.

VENTILATORY SUPPORT

The purposes of ventilatory support are to decrease the retention of carbon dioxide and to improve oxygenation. Ventilatory support is labor intensive and associated with complications. It is used when other means of respiratory support are not adequate.

Retention of carbon dioxide, or hypercapnia, occurs in animals unable to ventilate adequately. Spontaneous ventilation can be impaired by neurologic dysfunction, such as that which occurs with severe head trauma, polyneuropathies, and some toxicities. Ventilatory support is recommended in such animals if the $Paco_2$ level increases to greater than 60 mm Hg. Hypoventilation caused by a pleural effusion or pneumothorax is treated by removing the fluid or air, not by positive-pressure ventilation. Hypoventilation caused by an upper airway obstruction is treated by establishing a patent airway.

Animals with severe lung disease may be unable to maintain adequate oxygenation without ventilatory support. Positive-pressure ventilation is routinely necessary for the management of patients with ARDS (see Pulmonary Edema, Chapter 22). As previously noted, long-term administration of air with an oxygen concentration greater than 50% results in serious lung damage. If the Pao_2 cannot be maintained at greater than 60 mm Hg without excessive oxygen supplementation, ventilatory support is indicated.

The delivery of air by positive pressure is different from normal inhalation of air by negative pressure. With positive pressure, the distribution of ventilation within the lungs is altered. The intrathoracic pressure increases each time the lungs are filled with air, which results in decreased venous return to the heart. Along with other effects, systemic hypotension results and can be severe enough to cause acute renal failure. Compliance of the lungs also decreases over time in animals receiving positive-pressure ventilation. As the lungs

become stiffer, greater pressures are necessary to expand them. Careful monitoring of animals is essential during ventilation. Important variables to monitor include blood gas values, compliance, mucous membrane color, capillary refill time, pulse quality, arterial blood pressure, central venous pressure, lung sounds, and urine output. The extensive nursing care and monitoring required for these patients usually limit the use of long-term ventilatory support to large referral hospitals.

PART THREE ▪ Digestive System Disorders

Michael D. Willard

CHAPTER 26

Clinical Manifestations of Gastrointestinal Disorders

DYSPHAGIA, HALITOSIS, AND DROOLING

Dysphagia, halitosis, and drooling often coexists in animals with oral disease. Dysphagia (i.e., difficulty in eating) usually results from oral pain, masses, foreign objects, trauma, neuromuscular dysfunction, or a combination of these (Box 26.1). Halitosis typically signifies an abnormal bacterial proliferation secondary to tissue necrosis, tartar, periodontitis, or oral/esophageal retention of food (Box 26.2). Drooling occurs because animals are unable or unwilling to swallow (i.e., pseudoptyalism). Excessive salivation is often due to nausea; animals that are not nauseated rarely produce excessive saliva (Box 26.3). Although any disease causing dysphagia may have an acute onset, clinicians usually should first consider foreign objects or trauma as the cause in acutely dysphagic patients. The environmental and vaccination history should always be assessed to determine whether rabies is a reasonable possibility.

The next step is a thorough oral, laryngeal, and cranial examination. This examination is often the most important diagnostic step because most problems producing oral pain can be partially or completely defined at physical examination. Ideally, this is done without chemical restraint to facilitate detection of pain. However, many animals must be anesthetized for an adequate oral examination to search for anatomic abnormalities, inflammatory lesions, pain, and discomfort. If pain is found, the question is whether it occurs when the mouth is opened (e.g., retrobulbar inflammation), is associated with extraoral structures (e.g., muscles of mastication), or originates from the oral cavity. The clinician must search for fractures, lacerations, crepitus, masses, enlarged lymph nodes, inflamed or ulcerated areas, draining tracts, loose teeth, excessive temporal muscle atrophy, inability to open the mouth while the animal is under anesthesia, and ocular problems (e.g., proptosis of the eye, inflammation, or strabismus suggestive of retrobulbar disease). If oral pain is apparent but cannot be localized, retrobulbar lesions, temporomandibular joint disease, and posterior pharyngeal lesions should be considered. A concurrent clinicopathologic evaluation may be useful, especially if oral examination findings indicate systemic disease (e.g., lingual necrosis resulting from uremia, chronic infection secondary to hyperadrenocorticism).

Mucosal lesions (e.g., masses, inflamed or ulcerated areas) and painful muscles of mastication should be biopsied. Masses that do not disrupt the mucosa, especially those on the midline and dorsal to the larynx, can be difficult to discern and are often best found by digital palpation. Fine-needle aspiration and cytologic evaluation are reasonable first steps for diagnosing masses. Remember that fine-needle aspirates can only find disease; they do not exclude disease (i.e., they are not sensitive tests). Subtle masses or those dorsal to the larynx are often best aspirated with ultrasonographic guidance. Multiple aspirations are usually done before a wedge or punch biopsy is performed.

Incisional biopsy specimens must include generous amounts of submucosal tissues. Many oral tumors cannot be diagnosed with superficial biopsy specimens because normal oral flora cause superficial necrosis and inflammation obscuring the lesion. Clinicians are often afraid to biopsy aggressively because these lesions bleed profusely and are hard to suture. The clinician should avoid major vessels (e.g., the palatine artery) and use silver nitrate to stop hemorrhage. It is better to have difficulty stopping hemorrhage after obtaining an adequate biopsy specimen than to have less difficulty stopping hemorrhage after obtaining a nondiagnostic specimen. If diffuse oral mucosal lesions are noted, search carefully for vesicles (e.g., pemphigus); if found, remove them intact for histopathologic and immunofluorescent studies. If vesicles are not found, then at least two or three tissue samples representing a spectrum of new and old lesions should be obtained.

BOX 26.1

Causes of Dysphagia

Oral Pain

Fractured bones or teeth
Trauma
Periodontitis or caries (especially cats)
Mandibular or maxillary osteomyelitis
Other causes
  Retrobulbar abscess/inflammation
  Various other abscesses or granulomas of the oral cavity
  Temporal-masseter myositis
Stomatitis, glossitis, pharyngitis, gingivitis, tonsillitis, or sialoadenitis
  Immune-mediated disease
  Feline viral rhinotracheitis, calicivirus, leukemia virus, or immunodeficiency virus
  Lingual foreign objects, other foreign objects, or granulomas
  Tooth root abscess
  Uremia
  Electrical cord burn
  Miscellaneous causes
  - Thallium
  - Caustics
Pain associated with swallowing: esophageal stricture or esophagitis

Oral Mass

Tumor (malignant or benign)
Eosinophilic granuloma
Foreign object (oral, pharyngeal, or laryngeal)
Retropharyngeal lymphadenomegaly
Inflammatory polyp of middle ear (primarily cats)
Sialocele

Oral Trauma

Fractured bones (e.g., mandible, maxilla)
Soft tissue laceration
Hematoma

Neuromuscular Disease

Localized myasthenia
Temporal-masseter myositis
Temporomandibular joint disease
Oral, pharyngeal, or cricopharyngeal dysfunction
  Cricopharyngeal achalasia
Tick paralysis
Rabies
Tetanus
Botulism
Various cranial nerve dysfunctions/central nervous system disease

BOX 26.2

Causes of Halitosis

Bacterial Causes

Food retained in the mouth
  Anatomic defect allowing retention (exposed tooth roots, tumor, large ulcer)
  Neuromuscular defect allowing retention (pharyngeal dysphagia)
Food retained in the esophagus
Tartar or periodontitis
Damaged oral tissue
  Neoplasia/granuloma of mouth or esophagus
  Severe stomatitis/glossitis

Eating Noxious Substances

Necrotic or odoriferous food
Feces

BOX 26.3

Major Causes of Drooling

Ptyalism

Nausea
Hepatic encephalopathy (especially feline)
Seizure activity
Chemical or toxic stimulation of salivation (organophosphates, caustics, bitter drugs [e.g., atropine, metronidazole])
Behavior
Hyperthermia
Salivary gland hypersecretion

Pseudoptyalism

Oral pain, especially stomatitis, glossitis, gingivitis, pharyngitis, tonsillitis, or sialoadenitis (see Box 26.1)
Oral or pharyngeal dysphagia (see Box 26.1)
Facial nerve paralysis

If oral examination findings are not helpful, plain oral and laryngeal radiographs are usually the best next steps. Oral cultures are rarely helpful because normal oral flora makes interpretation of results difficult. Even animals with severe halitosis or stomatitis secondary to bacterial infection rarely benefit from bacterial culture, unless there is a draining tract or abscess.

Halitosis often accompanies dysphagia, in which case it is usually more productive to determine the cause of the dysphagia. If halitosis occurs without dysphagia, the clinician should first be sure that the odor is abnormal and then check for the ingestion of odoriferous substances (e.g., feces). A thorough oral examination is still the most important test. Halitosis not attributable to an oropharyngeal lesion may be

originating from the esophagus. Radiographs (plain and/or contrast) or esophagoscopy may reveal a tumor or retained food secondary to stricture or weakness. If the history and oral examination are unrevealing except for mild to moderate tartar accumulation, the teeth should be cleaned to try to resolve the problem.

Drooling is usually caused by nausea, oral pain, or dysphagia. The approach to the diagnosis of oral pain and dysphagia is described under the appropriate headings. Nausea is considered in the section on vomiting.

Dysphagic animals without demonstrable lesions or pain may have neuromuscular disease. Dysphagia of muscular origin usually results from atrophic myositis (see Chapter 67). Finding swollen, painful temporal muscles suggests acute myositis. Finding severe temporal-masseter muscle atrophy plus difficulty opening the mouth (even when the animal is anesthetized) suggests chronic temporal-masseter myositis. Biopsy of affected muscles is indicated. It is critical that muscle tissue be retrieved; it is easy to obtain only fibrous scar tissue. A positive test for antibodies to type 2M muscle fibers is consistent with masticatory muscle myositis but not polymyopathy.

Neurogenic dysphagia is caused by disorders in the oral (i.e., also called *prehensile*), pharyngeal, or cricopharyngeal phases of swallowing (disorders of the latter two phases are discussed in the section on regurgitation). Rabies should always be considered, despite its relative rarity. After rabies is presumptively ruled out, cranial nerve deficits (especially deficits of cranial nerves V, VII, IX, XII) should be considered. Because clinical signs vary depending on the nerve (or nerves) affected, a careful neurologic examination is indicated.

Inability to pick up food or having food drop from the mouth while eating usually indicates a prehensile disorder. Dysphagia may be noticeable in dogs and cats with pharyngeal and cricopharyngeal dysfunction, but regurgitation is often more prominent. Dynamic contrast-enhanced cinefluoroscopy or fluoroscopy is best for detecting and defining neuromuscular dysphagia. Localized myasthenia is an important cause of pharyngeal dysphagia and should be ruled out with serology. If neuromuscular problems are seemingly ruled out by imaging and serology, then anatomic lesions and occult causes of pain (e.g., soft tissue inflammation or infection) must be reconsidered.

DISTINGUISHING REGURGITATION FROM VOMITING FROM EXPECTORATION

Regurgitation is expulsion of material (i.e., food, water, saliva) from the mouth, pharynx, or esophagus and must be differentiated from vomiting (expulsion of material from the stomach and/or intestines) and expectoration (expulsion of material from the respiratory tract). Historical and physical examination findings sometimes allow differentiation (Table 26.1). Expectoration is generally associated with coughing at the time of the event. However, because dogs that cough and gag excessively may stimulate themselves to vomit as well, careful history taking is important. Animals that regurgitate and some that vomit may cough due to aspiration.

TABLE 26.1

Aids to Differentiate Regurgitation From Vomiting*

SIGN	REGURGITATION	VOMITING
Prodromal nausea†	No	Usually
Retching‡	No	Usually
Material produced		
Food	±	±
Bile	No	±
Blood	± (undigested)	± (digested or undigested)
Amount of material	Any amount	Any amount
Time relative to eating	Anytime	Anytime
Distention of cervical esophagus	Rare	No
Dipstick analysis of material		
pH	≥7	≤5 or ≥8
Bile	No	±

*These are *guidelines* that often help distinguish vomiting from regurgitation. However, occasional animals will require plain and/or contrast-enhanced radiographs to distinguish between the two. In particular, animals that are vomiting may appear to be regurgitating. The reverse is less common.
†May include salivation, licking lips, pacing, and an anxious expression. The owner may simply state that the animal is aware that it will soon "vomit."
‡These are usually forceful, vigorous abdominal contractions or dry heaves. This is not to be confused with gagging, which is common in regurgitation.

The criteria in Table 26.1 are guidelines. Some animals that appear to be regurgitating are vomiting and vice versa. In particularly severe cases of esophageal weakness, one may see the cervical esophagus balloon in and out during respiration (Video 26.1). If the clinician cannot distinguish between two based on history and physical examination findings, a urine dipstick may be used to determine pH and whether there is bilirubin in *freshly* "vomited" material. If the pH is 5 or less, the material is probably gastric in origin, resulting from vomiting. A pH of 7 or greater without evidence of bilirubin is most consistent with regurgitation. Finding bilirubin means the material is duodenal in origin (i.e., vomiting). Finding blood in the urine dipstick test is not helpful.

If vomiting and regurgitation still cannot be distinguished, plain thoracic radiographs ± a barium-contrast esophagram will detect most esophageal lesions. However, some esophageal disorders (e.g., hiatal hernia, partial stricture, segmental motility defects) are easily missed unless a careful radiographic technique and/or fluoroscopy is used. Endoscopy is sometimes required to detect esophageal lesions missed by imaging (e.g., esophagitis).

REGURGITATION

If regurgitation is confirmed, the disease should be localized to the oropharynx or esophagus (Fig. 26.1). History or observing the pet eating should allow the clinician to detect dysphagia (e.g., undue stretching or flexing of the neck during swallowing, repeated efforts at swallowing, food falling from the mouth during swallowing). Some animals with dysphagia associated with neuromuscular disorders have more difficulty swallowing liquids than solid foods, probably because it is easier to aspirate liquids. Oropharyngeal dysphagic animals in particular often cough when swallowing water.

If a regurgitating animal is dysphagic, then oral, pharyngeal, and cricopharyngeal dysfunctions must be considered; the latter two clinically mimic each other. Fluoroscopic evaluation of swallowing a barium meal is necessary to differentiate pharyngeal from cricopharyngeal dysfunction. If they are not accurately differentiated, inappropriate therapy may cause morbidity or mortality.

Two main reasons for esophageal regurgitation are obstruction and muscular weakness. Plain thoracic radiographs are the initial step for defining these problems. Barium-contrast esophagrams are often necessary because plain films do not detect many esophageal lesions. Using liquid barium sulfate can miss partial strictures, but mixing barium with canned food or kibble typically reveals these lesions. Fluoroscopy may be necessary to detect partial loss of peristalsis, segmental aperistalsis, gastroesophageal reflux, or sliding hiatal hernias. Sometimes the lower esophageal sphincter must be fluoroscopically observed for several minutes to detect frequency and severity of gastroesophageal reflux (normal animals may show occasional reflux). If the animal seems to be regurgitating but contrast-enhanced radiographs fail to reveal esophageal dysfunction, either the assessment of regurgitation is wrong or there is occult esophageal disease requiring esophagoscopy for diagnosis (e.g., esophagitis, gastroesophageal reflux).

Esophageal obstruction is principally caused by foreign objects, vascular anomalies, cicatrix, and tumors. Achalasia

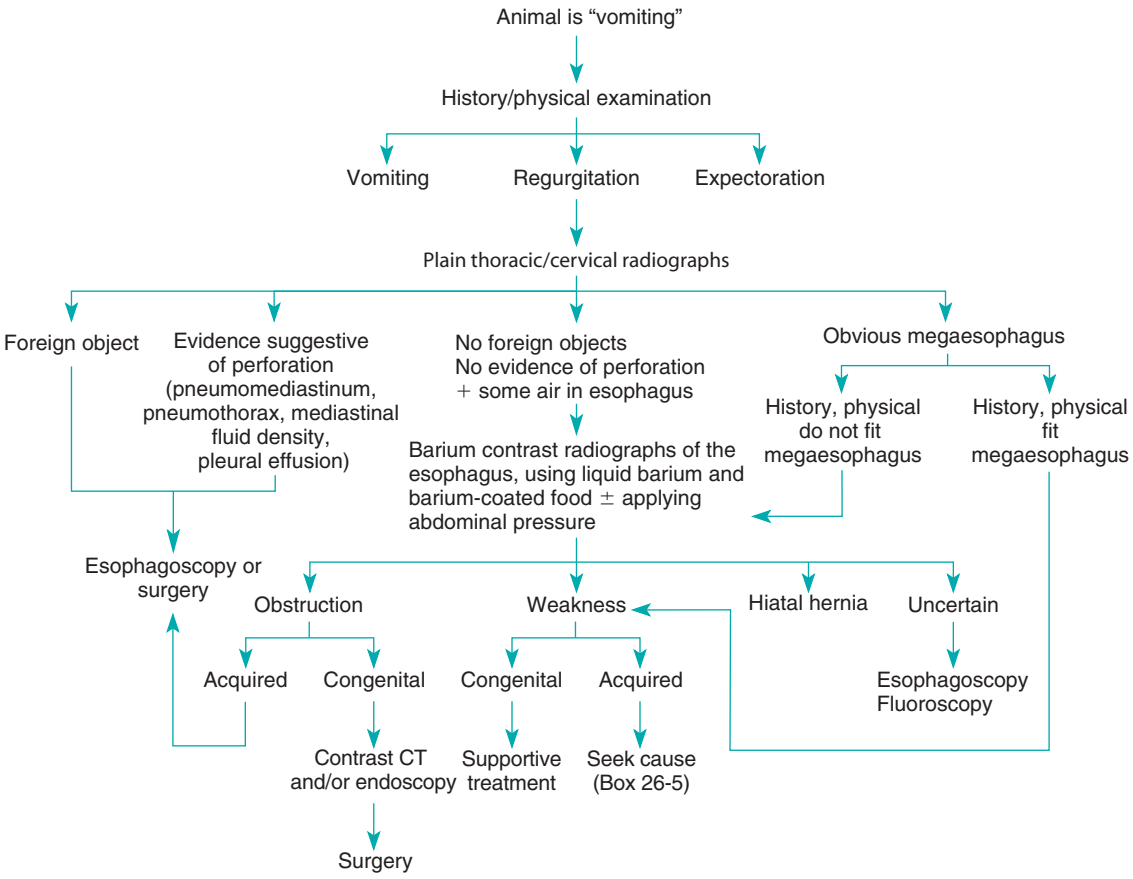

FIG 26.1
General diagnostic approach to regurgitation in the dog and cat.

of the lower esophageal sphincter may sometimes be responsible (Box 26.4). Obstruction should be characterized as congenital or acquired and as intraluminal, intramural, or extraesophageal. Congenital obstructions are usually extraesophageal vascular ring anomalies. Acquired intraluminal obstructions are usually foreign objects or cicatrix secondary to esophagitis. The clinician should always determine whether animals with esophageal foreign objects (especially small foreign objects that would have been expected to have passed) have a partial esophageal stricture that predisposed them to obstruction. Endoscopy may be both diagnostic and therapeutic in these animals; thoracotomy is seldom needed for management of cicatrix or intraluminal foreign objects.

Esophageal weakness may be congenital or acquired. Congenital weakness is typically idiopathic, and further diagnostics are unfruitful. Acquired esophageal weakness usually results from an underlying neuromuscular problem. Although an underlying cause is infrequently diagnosed, finding one may lead to a permanent cure as opposed to supportive therapy of the symptoms. A complete blood count (CBC), serum biochemistry profile, determination of serum antibody titers to acetylcholine receptors, resting serum cortisol (see Chapter 50), serum creatine kinase, and/or fecal examination for *Spirocerca lupi* ova are performed to look for causes of acquired esophageal weakness (Box 26.5). One may also consider searching for lead intoxication (nucleated red blood cells and basophilic stippling in the CBC, serum and urine lead concentrations), canine distemper (retinal lesions), and various neuropathy-myopathies (electromyography, nerve biopsy, muscle biopsy). Chagas disease causes esophageal disease in people but has not been reported to cause esophageal weakness in dogs. Lower esophageal achalasia-like syndrome has been identified in dogs with congenital and acquired weakness. The prevalence of this syndrome is currently uncertain, but assumed to be low. Fluoroscopic examination is necessary for diagnosis.

Esophagoscopy may detect esophagitis or small lesions (e.g., partial strictures) that contrast-enhanced esophagrams do not reveal. If esophagitis is found, the clinician should look carefully for a cause (e.g., hiatal hernia, gastric outflow obstruction). After entering the stomach, the endoscopist must retroflex the tip of the endoscope and examine the gastric side of the lower esophageal sphincter for leiomyomas or malformation (e.g., hiatal hernia). Gastroduodenoscopy is performed concurrently to look for gastric and duodenal reasons for gastroesophageal reflux or vomiting.

BOX 26.4

Causes of Esophageal Obstruction

Congenital Causes

Vascular ring anomaly
- Persistent fourth right aortic arch (most common type)
- Other vascular rings

Esophageal web (rare)

Acquired Causes

Foreign object (especially when there is a sudden onset)
Cicatrix/stricture (not common but very important)
Neoplasia
- Esophageal tumors
  - Carcinoma
  - Sarcoma caused by *Spirocerca lupi*
  - Leiomyoma of lower esophageal sphincter
- Extraesophageal tumors
  - Thyroid carcinoma
  - Pulmonary carcinoma
  - Mediastinal lymphosarcoma

Achalasia of the lower esophageal sphincter (sometimes found in dogs)
Gastroesophageal intussusception (very rare)

BOX 26.5

Causes of Esophageal Weakness

Congenital Causes

Idiopathic
Achalasia-like syndrome (not sure how common)

Acquired Causes

Myasthenia (generalized or localized) (important)
Hypoadrenocorticism (uncommon but important)
Severe esophagitis
- Gastroesophageal reflux
  - Hiatal hernia
  - Anesthesia-associated reflux (uncommon but important)
  - Spontaneous reflux
- Foreign body (uncommon but important)
- Caustic ingestion
  - Iatrogenic (e.g., doxycycline, clindamycin, ciprofloxacin, nonsteroidal anti-inflammatory drugs [NSAID])
  - Disinfectants, chemicals, etc.
- Persistent vomiting
- Excessive gastric acidity
  - Gastrinoma
  - Mast cell tumor
- Fungal organisms (e.g., pythiosis)

Myopathies (including muscular dystrophy)/neuropathies
Miscellaneous causes
- Achalasia-like syndrome
- Dysautonomia
- *Spirocerca lupi*
- Dermatomyositis (principally in Collies)
- Botulism
- Tetanus
- Lead poisoning
- Canine distemper

Idiopathic

VOMITING

Vomiting is usually caused by (1) motion sickness, (2) ingestion of emetogenic substances (e.g., drugs), (3) gastrointestinal (GI) tract obstruction, (4) abdominal (especially alimentary tract) inflammation or irritation, and (5) extragastrointestinal tract diseases that may stimulate the medullary vomiting center region or the chemoreceptor trigger zone (Box 26.6). Occasionally, central nervous system (CNS) disease, behavior, and learned reactions to specific stimuli may cause vomiting. If the cause of the vomiting is inapparent on history and physical examination, the next step depends on whether the vomiting is acute or chronic and whether there is hematemesis (Figs. 26.2 and 26.3). Remember that blood in vomitus may be fresh (i.e., red) or digested to varying degrees (i.e., "coffee grounds" or "dregs").

In animals with acute vomiting without hematemesis, clinicians should first search for obvious causes (e.g., ingestion of a foreign body, intoxication, organ failure, parvovirus) as well as for secondary fluid, electrolyte, or acid-base abnormalities or sepsis that require prompt, specific therapy. If the animal appears stable and there is no obvious cause, symptomatic treatment is often first tried for 1 to 2 days. If the animal is too sick for the clinician to take a chance on

BOX 26.6

Causes of Vomiting

- Motion Sickness (Acute) (Important)
- Diet (Important)
  - Dietary indiscretion
  - Dietary intolerance
- Emetogenic Substances (Acute)
  - Drugs: almost any drug can cause vomiting (especially drugs administered orally [PO]), but the following drugs seem especially likely to cause vomiting:
    - Digoxin
    - Chemotherapeutics (e.g., cyclophosphamide, cisplatin, dacarbazine, doxorubicin)
    - Selected antibiotics (e.g., erythromycin, tetracycline/doxycycline, amoxicillin plus clavulanic acid)
    - Penicillamine
    - Nonsteroidal antiinflammatory drugs
    - Apomorphine
    - Xylazine
  - Toxic chemicals
    - Strychnine
    - Heavy metals
- Gastrointestinal Tract Obstruction (Acute or Chronic) (Important)
  - Gastric Outflow Obstruction
    - Benign pyloric stenosis (uncommon)
    - Foreign object (common)
    - Gastric antral mucosal hypertrophy
    - Neoplasia
    - Nonneoplastic infiltrative disease (e.g., pythiosis)
    - Gastric malpositioning
      - Gastric dilation or volvulus (see nonproductive retching)
      - Partial gastric dilation/volvulus (does not always cause clinical signs)
  - Intestinal Obstruction
    - Foreign object (very common)
      - Nonlinear objects
      - Linear objects
    - Neoplasia
    - Intussusception
    - Cicatrix (rare)
    - Torsion/volvulus (very rare)
- Gastrointestinal/Abdominal Inflammation (Acute or Chronic) (Important)
  - Gastritis (common)
    - Without ulcers/erosions
    - With ulcers/erosions
    - Non-obstructing foreign body
    - Parasitic (i.e., *Physaloptera, Ollulanus*)
  - Enteritis (acute)
    - Parvovirus (common)
    - Acute hemorrhagic diarrheal syndrome (common)
    - Parasites (acute or chronic)
    - Inflammatory bowel disease (IBD) (more common in cats)
  - Pancreatitis (common and very important in dogs)
  - Peritonitis (acute or chronic; septic or nonseptic)
  - Colitis (acute or chronic)
  - Splenitis
- Extraalimentary Tract Diseases (Acute or Chronic) (Important)
  - Uremia (common)
  - Adrenal insufficiency (uncommon but important)
  - Hypercalcemia
  - Hepatic insufficiency or disease (Important)
  - Cholecystitis
  - Diabetic ketoacidosis
  - Pyometra
  - Endotoxemia/septicemia
- Miscellaneous Causes (Acute or Chronic)
  - Dysautonomia
  - Feline hyperthyroidism (Important)
  - Postoperative nausea/ileus (uncommon)
  - Overeating
  - Idiopathic hypomotility
  - Central nervous system disease
    - Tumor
    - Meningitis
    - Increased intracranial pressure
  - Sialoadenitis/sialoadenosis*
  - Behavior
  - Physiologic (epimeletic in female dogs)

*It is important to determine whether this is the cause of vomiting or an effect of vomiting.

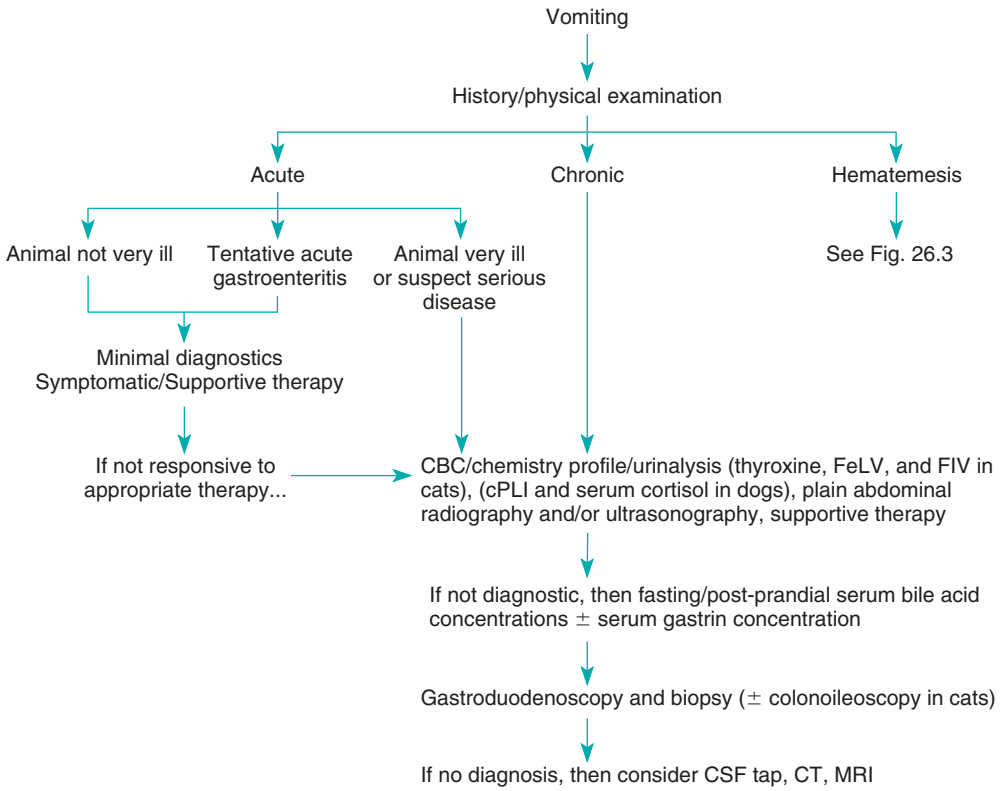

FIG 26.2
General diagnostic approach to vomiting in the dog and cat. *CBC,* Complete blood count; *cPLI,* canine pancreatic lipase immunoreactivity; *CSF,* cerebrospinal fluid; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *MRI,* magnetic resonance imaging.

guessing wrong, if the vomiting persists for 2 to 4 days after the start of symptomatic therapy, or if the condition worsens during this initial time, then more aggressive diagnostic testing is usually appropriate.

The clinician should search for historical evidence of ingested foreign objects, toxins, inappropriate food, or drugs. Physical examination is used to look for abdominal abnormalities (e.g., masses, pain) and evidence of extraabdominal disease (e.g., uremic glossitis, a thyroid nodule indicative of hyperthyroidism). Clinicians should always look for linear foreign bodies in vomiting cats and carefully examine the base of the tongue; chemical restraint (e.g., ketamine HCl, 2.2 mg/kg of body weight given intravenously) may be necessary to examine this area properly. The abdomen is palpated to search for masses or pain, but even careful palpation may miss short ileocolic intussusceptions in the craniodorsal abdomen. It is reasonable to perform fecal examination for parasites because they can cause vomiting. If a cause cannot be found and the animal is not unduly ill, the clinician may prescribe a therapeutic trial (e.g., pyrantel and a dietary trial; see Table 28.7). Therapeutic trials should be designed so that failure of the therapy allows the clinician to exclude at least one disease.

If acute vomiting does not respond to symptomatic therapy or if the animal is so sick that the clinician cannot take a chance on symptomatic therapy being ineffective, aggressive diagnostic testing is appropriate. Animals with acute or chronic vomiting without hematemesis should undergo abdominal radiography and/or ultrasonography to look for intestinal obstruction, foreign objects, masses, pancreatitis, peritonitis, poor serosal contrast, alimentary tract ileus, free abdominal fluid, or free abdominal gas. Abdominal ultrasonography can be more revealing than plain radiographs, but radiographs may be more sensitive in revealing free air and some foreign bodies. A CBC, serum biochemistry profile, and urinalysis are also indicated. Cats should be tested for feline leukemia virus, feline immunodeficiency virus, and hyperthyroidism. It may be necessary to measure serum bile acid concentrations (or blood ammonia concentrations) or resting serum cortisol concentrations to screen for hepatic or adrenal insufficiency, respectively, that can be unsuspected based on serum biochemistry profiles. Immunoreactive pancreatic lipase activity can be helpful in diagnosing otherwise occult canine pancreatitis, but it must be remembered that the test cannot be used as a simple litmus test for clinically important pancreatitis.

If results of extensive clinical pathology testing and abdominal imaging are not diagnostic in a patient with chronic vomiting, the next diagnostic step is usually upper GI endoscopy. If endoscopy is not available, then exploratory laparotomy may be substituted, but surgery can miss gastric lesions that will be picked up endoscopically. Contrast gastrograms

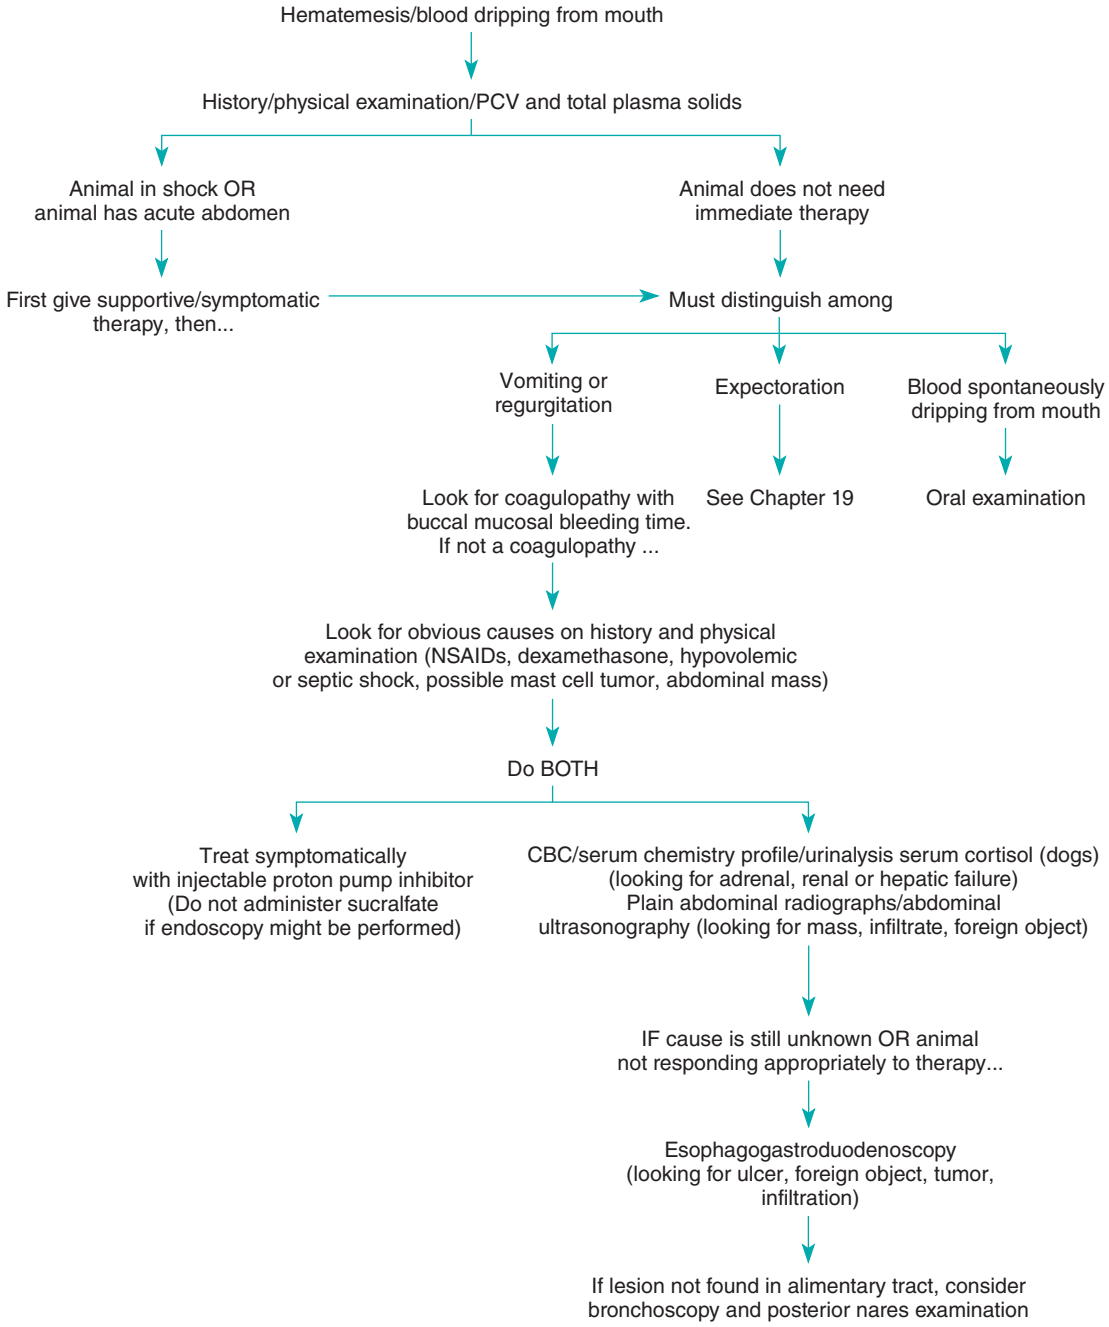

FIG 26.3
General diagnostic approach to hematemesis in the dog and cat. *CBC,* Complete blood count; *PCV,* packed cell volume.

are occasionally helpful; however, endoscopy is usually more cost-effective. During endoscopy, the clinician should biopsy the stomach and duodenum, regardless of normal gross mucosal appearance. In cats, endoscopic biopsy of the ileum and ascending colon may occasionally be required to find the cause of vomiting. If laparotomy is chosen over endoscopy, the entire abdomen should be examined. The stomach, duodenum, jejunum, ileum, mesenteric lymph nodes, liver, and, in cats, the pancreas should typically be biopsied.

If the cause of vomiting is undiagnosed after biopsy, the basis for previously excluding the different diseases should be reviewed. Diseases may be inappropriately ruled out (or diagnosed) because the clinician does not understand the limitations of certain tests. For example, dogs with hypoadrenocorticism may have normal electrolyte concentrations; inflammatory gastric and bowel disease may be localized to one area of the stomach or intestine and rarely causes significant changes in the white blood cell count; hyperthyroid cats may have normal serum thyroxine concentrations; dogs and cats with hepatic failure may have normal serum bilirubin concentrations as well as normal serum alanine aminotransferase and alkaline phosphatase activities; dogs

and cats with pancreatitis may have normal immunoreactive pancreatic lipase activities and normal abdominal ultrasound examinations; and *Physaloptera* infections are almost never diagnosed by fecal examination. Finally, the clinician may have to consider uncommon diseases that are more difficult to diagnose (e.g., idiopathic gastric hypomotility, occult CNS disease).

HEMATEMESIS

Clinicians must often use history and physical examination to help identify hematemesis as well as distinguish it from other problems. Hematemesis is expulsion of digested (i.e., "coffee grounds") or fresh blood. Animals with oral lesions that have blood dripping from their lips do not have hematemesis. Likewise, hemoptysis (i.e., coughing up blood) is not hematemesis.

Clinicians should distinguish vomiting that produces specks of blood from vomiting in which there is substantial blood present. The former may be caused by gastric mucosal trauma secondary to vigorous vomiting from any cause, and animals with such "hematemesis" should generally be treated as described in the previous section on vomiting. Patients that produce more substantial amounts of blood generally should be approached differently. Although hematemesis is usually caused by gastroduodenal ulceration and erosion (GUE), clinicians should not make this assumption and automatically treat for such. The clinician should first check the hematocrit and plasma total protein concentration to determine whether a blood transfusion is necessary (see Fig. 26.3). The clinician should next try to determine whether there is a coagulopathy (uncommon but important), ingestion of blood from another site (including the respiratory tract), or a gastrointestinal tract (GIT) lesion (e.g., GUE) (Box 26.7). Platelet counts and a measure of clotting capability (e.g., buccal mucosal bleeding time) are strongly recommended. The clinician should next look for obvious causes of GIT hemorrhage (e.g., acute gastritis, acute hemorrhagic diarrheal syndrome [used to be called *hemorrhagic gastroenteritis*], or GUE due to ulcerogenic drugs [e.g., nonsteroidal

BOX 26.7

Causes of Hematemesis

Coagulopathy (Uncommon)

Thrombocytopenia/platelet dysfunction
Clotting factor deficiency
Disseminated intravascular coagulation

Alimentary Tract Lesion

Gastrointestinal tract ulceration/erosion (common and important)
  Infiltrative disease (important)
  - Neoplasia
    - Leiomyoma
    - Carcinomas
    - Lymphomas
  - Pythiosis (especially younger dogs in the southeastern United States)
  - Inflammatory bowel disease (uncommon)

  "Stress" ulceration
  - Hypovolemic shock
  - Septic shock (i.e., systemic inflammatory response syndrome)
  - After gastric dilation or volvulus
  - Neurogenic "shock"
  - Extreme or sustained exertion (common in select working animals)

  Hyperacidity
  - Mast cell tumor
  - Gastrinoma (rare)

  Iatrogenic causes
  - Nonsteroidal antiinflammatory drug (common and important)
  - Glucocorticoids (especially dexamethasone) (important)

  Other causes
  - Hepatic disease (common and important)
  - Hypoadrenocorticism (uncommon but important)
  - Pancreatitis (common disease but uncommonly causes ulceration or hematemesis)
  - Renal disease (common disease but uncommonly causes ulceration or hematemesis)
  - Inflammatory diseases

  Foreign objects (rarely a primary cause of hematemesis, but will worsen preexisting ulceration or erosion)

Gastritis
  Acute gastritis (common)
  Acute hemorrhagic diarrheal syndrome (common)
  Chronic gastritis (uncommon in dogs)
  Helicobacter-associated disease (doubtful association with hematemesis in dogs and cats)

Gastric mucosal trauma from vigorous vomiting*
Gastric polyps
Esophageal disease (uncommon)
  Tumor
  Severe esophagitis
  Trauma

Bleeding oral lesion
Gallbladder disease (especially tumors) (rare)

Extraalimentary Tract Lesion (Blood Is Swallowed and Then Vomited) (Rare)

Respiratory tract disorders
  Lung lobe torsion
  Pulmonary tumor
  Posterior nares lesion

Dietary indiscretion

*Hematemesis caused by vigorous vomiting usually consists of specks of blood as opposed to larger quantities.

antiinflammatory drugs, dexamethasone] or recent severe hypovolemic shock or systemic inflammatory response syndrome or abdominal masses that may involve the gastric mucosa or cutaneous mast cell tumors). Remember: mast cell tumors can grossly mimic almost any other benign or malignant neoplasm, especially lipomas.

If acute gastritis, acute hemorrhagic diarrheal syndrome, nonsteroidal antiinflammatory drug or dexamethasone–induced GUE, or GUE resulting from shock is strongly suspected, the clinician may elect a limited diagnostic workup (e.g., CBC, serum biochemistry panel) to define the degree of blood loss and look for evidence of renal, hepatic, or adrenal failure. Then the animal can be treated symptomatically for 3 to 5 days (see Chapter 28, pp. 437-440) to see what effect this has in controlling clinical signs. Endoscopy is not necessary or helpful in many of these cases because it cannot reliably distinguish between ulcers that will heal with medical therapy and those that will require surgical resection. However, if the cause of hematemesis or GUE is unknown, more aggressive diagnostic tests (e.g., abdominal ultrasound and gastroduodenoscopy) should be considered (see Fig. 26.3). The stomach and duodenum should be imaged, preferably by ultrasonography, to look for alimentary tract infiltrations, foreign objects, and masses. Endoscopy is the most sensitive and specific means of finding and evaluating GUE. The principal indications for endoscopy in animals with upper GI blood loss include (a) distinguishing potentially resectable ulcers from widespread, unresectable erosions in patients with life-threatening GI bleeding; (b) localizing ulcers when considering surgical resection; and (c) determining the cause of GUE in patients with upper GI blood loss of unknown cause. Abdominal exploratory surgery may be performed instead of endoscopy, but it is easy to miss bleeding mucosal lesions when examining the serosal surface of the GIT. Intraoperative endoscopy (i.e., endoscopic examination of the mucosal surface of the stomach and duodenum while the abdomen is opened) may sometimes be useful in finding lesions that the surgeon cannot discern from the serosal surface.

If the source of bleeding cannot be found using gastroduodenoscopy, the clinician should consider possible bleeding sites beyond the reach of the endoscope; blood being swallowed from a lesion in the mouth, posterior nares, trachea, or lungs; hemorrhage from the gallbladder; or an intermittently bleeding gastric or duodenal lesion. Capsule endoscopy has recently become available for dogs and can also be used to look for bleeding lesions throughout the GI tract. It can be used when endoscopy is not available or when the bleeding lesion is suspected to be beyond the reach of the endoscope. Endoscopy of the trachea and choana can be diagnostic in some cases of occult respiratory hemorrhage.

DIARRHEA

Diarrhea is nothing more than excessive fecal water. This explains why many animals with severe small bowel disease do not have diarrhea. When diarrhea is present, one should first distinguish acute from chronic problems.

Acute diarrhea is usually caused by diet, parasites, or infectious diseases (Box 26.8). Dietary problems are often detected by history; parasites by fecal examination; and infectious diseases by history (i.e., evidence of contagion or exposure), CBC, fecal enzyme–linked immunosorbent assay for canine parvoviral antigen, and exclusion of other causes.

BOX 26.8

Causes of Acute Diarrhea

Diet (Common and Important)

Intolerance/allergy
Poor-quality food
Rapid dietary change (especially in puppies and kittens)
Bacterial food poisoning
Dietary indiscretion

Parasites (Common and Important)

Helminths
Protozoa
- *Giardia*
- *Tritrichomonas* (feline)
- *Coccidia*

Infectious Causes

Viral causes
- Parvovirus (canine, feline) (dogs: common and important)
- Coronavirus (canine, feline) (infrequent, not important)
- Feline leukemia virus (including infections secondary to it)
- Feline immunodeficiency virus (specifically infections secondary to it)
- Various other viruses (e.g., rotavirus, canine distemper virus)

Bacterial causes
- *Salmonella* spp. (uncommon)
- *Clostridium perfringens* (common and important in large bowel diarrheas)
- Verotoxin-producing *Escherichia coli*
- *Campylobacter jejuni* (uncommon)
- *Yersinia enterocolitica* (questionable)
- Various other bacteria

Rickettsial infection
- Salmon poisoning (regionally important)

Other Causes

Acute hemorrhagic diarrheal syndrome
Intussusception
Ingestion of "toxins"
- "Garbage can" intoxication (spoiled foods)
- Chemicals
- Heavy metals
- Various drugs (antibiotics, antineoplastics, anthelmintics, antiinflammatories, digitalis, lactulose)

Acute pancreatitis (diarrhea is usually a modest component of clinical signs but it can be major)
Hypoadrenocorticism

If acute diarrhea becomes unduly severe or persistent (i.e., chronic), then additional diagnostic tests are recommended.

Animals with chronic diarrhea should be examined for parasites. Typically multiple fecal examinations looking for nematodes, *Giardia,* and *Tritrichomonas* are indicated. The in-house enzyme-linked immunosorbent assay (ELISA) "snap" tests for Giardia are more sensitive than fecal examination and have excellent negative predictive values. The indirect fluorescent antibody test (IFA) test for *Giardia* is considered the "gold standard" test, but requires feces to be sent off to a laboratory. Next, the clinician should determine whether the diarrhea originates from the small or large intestine. History is often the best tool (Table 26.2). Failure to lose weight or body condition despite chronic diarrhea almost always indicates large bowel disease. Weight loss usually indicates small bowel disease although severe large bowel diseases (e.g., pythiosis, histoplasmosis, protothecosis, malignancy) may cause weight loss; however, animals with large bowel disease causing weight loss usually have obvious signs of colonic involvement (e.g., fecal mucus, tenesmus, hematochezia). Whenever tenesmus is present, the clinician should ascertain whether or not it was present when the disease began. If tenesmus did not begin until late in the course of the diarrhea, it may be due simply to perineal scalding or anal soreness resulting from chronic irritation.

Chronic small intestinal diarrhea can be categorized as maldigestion, nonprotein-losing malabsorptive disease, and protein-losing enteropathy. Maldigestion is principally caused by exocrine pancreatic insufficiency (EPI) and infrequently causes marked hypoalbuminemia (i.e., < 2.0 g/dL with a normal range 2.5-4.4 g/dL). Film digestion tests for fecal trypsin activity, Sudan staining of feces for undigested fats, and fat absorption tests yield many false-negative and false-positive results. The most sensitive and specific test for EPI is the serum trypsin-like immunoreactivity (TLI; see Chapter 27, p. 423), which is indicated in patients with chronic small intestinal diarrhea.

Attempting to diagnose EPI by supplementing pancreatic enzymes is strongly discouraged. If a dog's diarrhea ameliorates in response to pancreatic enzyme supplementation, it might be due to EPI or antibiotic-responsive enteropathy (ARE; i.e., dysbiosis) or it might just be a fortuitous, temporal effect. A false-positive diagnosis of EPI results in the unnecessary supplementation of expensive enzymes. Up to 15% of dogs with EPI do not respond when enzymes are added to their diet; therefore if EPI is incorrectly ruled out in such a case, unnecessary endoscopies or operations often result. Therefore the clinician should definitively diagnose or rule out EPI before proceeding with other diagnostic tests or treatments.

Malabsorptive intestinal disease may be protein-losing enteropathy (PLE) or nonprotein-losing (Fig. 26.4). Diarrhea occurs only if the absorptive capacity of the colon is exceeded. Therefore a dog or cat can be losing weight and/or albumin because of small intestinal disease and not have diarrhea (see the section on Weight Loss). The serum albumin concentration can be mildly or markedly decreased (i.e., 2.0 g/dL or less [normal range 2.5-4.4 g/dL]) in patients with PLE. If an animal has marked hypoalbuminemia not caused by protein-losing nephropathy, hepatic insufficiency, or skin lesions, then PLE is diagnosed by process of exclusion. If the serum albumin is mildly decreased (i.e., 2.1-2.4 g/dL), then other causes (e.g., sequestration in third space, nutrition) should also be considered. Hypoglobulinemia sometimes develops in patients with PLE, but many patients with PLE do not have panhypoproteinemia. In general, dogs with PLE are preferably approached with aggressive diagnostics.

In patients with nonprotein-losing malabsorptive disease, the clinician may perform additional diagnostic tests (e.g., intestinal biopsy) or perform therapeutic trials. If the patient

TABLE 26.2

Differentiation of Chronic Small Intestinal From Large Intestinal Diarrheas

SIGN	SMALL INTESTINAL DIARRHEA	LARGE INTESTINAL DIARRHEA
Weight loss*	Expected	Uncommon*
Polyphagia	Sometimes	Rare to absent
Frequency of bowel movements	Often near normal	Sometimes very increased but often normal
Volume of feces	Often increased, but can be normal volume	Sometimes decreased (because of the increased frequency) but can be normal
Blood in feces	Melena (rare)	Hematochezia (sometimes†)
Mucus in feces	Uncommon	Sometimes
Tenesmus	Uncommon (but may occur later in chronic cases)	Sometimes
Vomiting	May be seen	May be seen

*Failure to lose weight or condition is the most reliable indication that an animal has large bowel disease. However, animals with colonic histoplasmosis, pythiosis, lymphoma, protothecosis, or similar severe infiltrative diseases may have weight loss due to large bowel disease.
†Hematochezia becomes much more important as a differentiating feature in animals that are losing weight. Its presence in such animals confirms the presence of large bowel involvement (either by itself or in combination with small bowel disease) despite weight loss.

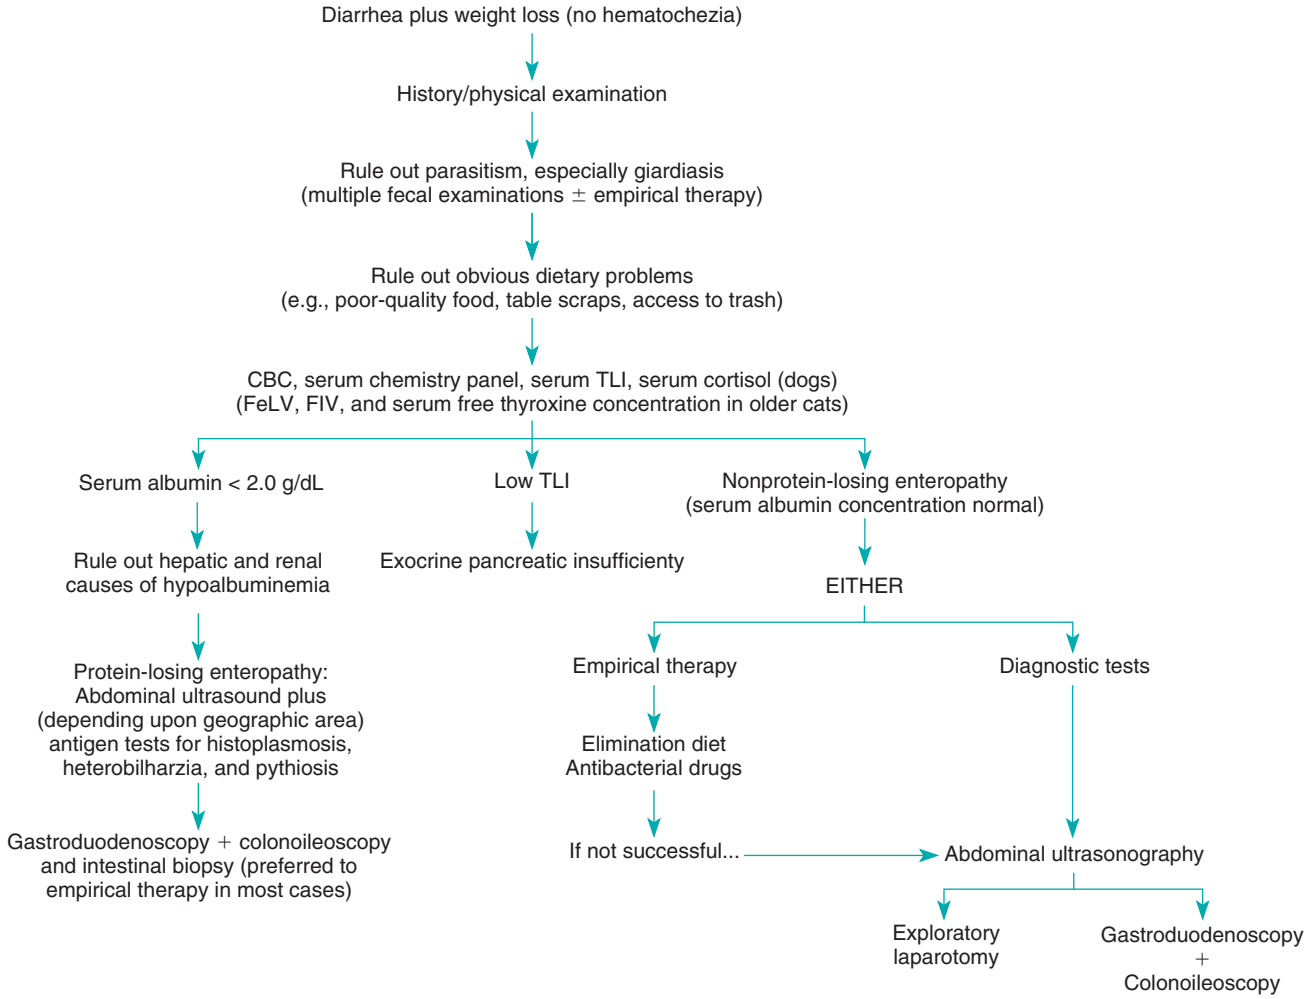

FIG 26.4
General diagnostic approach to small intestinal diarrhea in the dog and cat. *CBC,* Complete blood count; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus, *TLI,* trypsin-like immunoreactivity.

is not emaciated or rapidly losing weight and is not hypoalbuminemic, then biopsy is seldom the best next step. Screening for atypical hypoadrenocorticism with resting serum cortisol concentrations is appropriate. Testing for histoplasmosis, pythiosis, and heterobilharziasis can be appropriate, depending upon geographical location. Therapeutic trials are the best way to diagnose dietary-responsive diarrhea and ARE (also called *antibiotic-responsive diarrhea* and/or *dysbiosis*), which are two of the most common causes of chronic small bowel diarrhea in dogs. ARE cannot be diagnosed by measuring serum cobalamin and folate concentrations. If a therapeutic trial is performed, the clinician must be sure that it is done properly (e.g., long enough, correct dose) so that it has a high likelihood of succeeding if the animal has the suspected disease. If the patient seems particularly ill (e.g., severe or rapid weight loss), or is hypoalbuminemic, or has failed well-implemented clinical trials and is negative for infectious causes (i.e., histoplasmosis, heterobilharziasis, pythiosis) and atypical hypoadrenocorticism, then abdominal ultrasonography is the next step. Ultrasonography should always precede biopsy because it may be diagnostic if it shows dilated lymphatics in the intestinal mucosa (i.e., lymphangiectasia) or lymphadenopathy or intestinal infiltrates that can be aspirated percutaneously. If ultrasonography is not diagnostic, then biopsy is the next step (Boxes 26.9 and 26.10). Either laparotomy or endoscopy can be performed to biopsy the bowel. If ultrasonography reveals a localized lesion that cannot be reached with an endoscope, then laparotomy is indicated. Otherwise, endoscopy is quicker and safer than laparotomy and may allow the clinician to biopsy lesions not discernable from the serosal surface. Endoscopic biopsy specimens can easily be nondiagnostic if the endoscopist has not been carefully trained in biopsy techniques. If laparotomy is performed in hypoalbuminemic animals, it may be prudent to use nonabsorbable suture material and/or perform intestinal serosal patch grafting. Distended intestinal lymphatics or lipogranulomas in the intestinal wall are suggestive of lymphangiectasia. If intestinal biopsy specimens are not helpful, the main possibilities are that the tissue specimens were inadequate (e.g., not deep enough, from

BOX 26.9

Major Causes of Malabsorptive Disease

Dog

Parasitism: giardiasis, nematodes (common and important)
Dietary responsive (food intolerance or allergy; common and important)
Antibiotic-responsive enteropathy (also called "dysbiosis") (common and important)
Inflammatory bowel disease
Neoplastic bowel disease (especially lymphoma; important but not common)
Fungal infections (regionally important)
- Pythiosis
- Histoplasmosis

Cat

Dietary responsive (food intolerance or allergy; common and important)
Parasitism: giardiasis
Inflammatory bowel disease: lymphocytic-plasmacytic enteritis (common and important)
Neoplastic bowel disease (especially lymphoma; common and important)

BOX 26.10

Major Causes of Protein-Losing Enteropathy*

Dog

Intestinal lymphangiectasia (common and important)
Alimentary tract lymphoma (important)
Severe inflammatory bowel disease
Alimentary tract fungal infections
- Histoplasmosis (regionally important)
- Pythiosis (regionally important)

Chronic intussusception (especially young dogs)
Alimentary tract hemorrhage (e.g., ulceration or erosion, neoplasia, parasites)
Unusual enteropathies (e.g., chronic purulent enteropathy, severe ectasia of mucosal crypts)
Massive hookworm or whipworm infestation (regionally important)

Cat

Alimentary tract lymphoma (important)
Severe inflammatory bowel disease (common and important)
Alimentary hemorrhage (e.g., neoplasia, duodenal polyps, idiopathic ulceration)

*Any gastrointestinal disease can cause protein-losing enteropathy, but these are the most common causes. Except for lymphangiectasia, these diseases do not consistently produce protein-losing enteropathy.

BOX 26.11

Major Causes of Chronic Large Intestinal Diarrhea

Dog

Dietary responsive (intolerance or allergy; important and common)
Fiber-responsive (important and common)
Parasitism
- Whipworms (regionally important and common)
- *Heterobilharzia* (regionally important)

Bacterial diseases
- "Clostridial" colitis (important and common)
- Histiocytic ulcerative colitis (usually Boxers and French Bulldogs)

Fungal infections (regionally important and common)
- Histoplasmosis
- Pythiosis

Inflammatory bowel disease (uncommon in dogs)
Neoplasia
- Lymphoma
- Adenocarcinoma

Cat

Dietary responsive (intolerance or allergy; important and common)
Fiber-responsive (important and common)
Inflammatory bowel disease (important)
Tritrichomonas (especially important in exotic cats and in catteries)
Feline leukemia virus infection (including infections secondary to it)
Feline immunodeficiency virus infection (specifically infections secondary to it)

the wrong place, too much artifact), the pathologist did not recognize the lesion, the animal has occult giardiasis or ARE or dietary intolerance, or there is disease (e.g., lymphangiectasia, neoplasia, inflammation) localized to where the clinician did not biopsy.

There are some differences in cats with chronic small bowel disease compared with dogs. PLE is less common in cats, and when present typically indicates severe infiltrative disease (usually not lymphangiectasia) and the need for biopsy. Nematode infections causing chronic diarrhea are much less common in cats than in dogs.

Dogs with chronic large intestinal diarrhea (Box 26.11) should first undergo a digital rectal examination to search for mucosal thickening or proliferation. The rectum is the most common site of canine colonic neoplasia, and finding obvious mucosal lesions indicates the need for biopsy. If the rectal mucosa seems normal, the animal has not lost weight,

and the serum albumin is well within the normal range (a serum albumin at the lower end of the reference range may not be "normal" enough), then it is often most appropriate to try therapeutic trials after a few basic diagnostic tests. Fecal examination to detect whipworms, fecal ELISA to detect *Giardia* (a small bowel problem that can mimic large bowel disease), and fecal PCR to detect *Tritrichomonas* (cats) are indicated. Therapeutic trials usually consist of high-fiber diets, elimination diets, antibacterials to control "clostridial" colitis, and/or treatment for parasites.

Additional diagnostic tests that may be done instead of therapeutic trials principally include biopsying colonic mucosa by colonoscopy, and fecal assays for toxins (e.g., clostridial toxin) and/or specific organisms (e.g., *Campylobacter, Salmonella*). Fecal cultures and antigen tests for specific pathogens should be considered if history indicates a strong likelihood of a contagious disorder. Fecal ELISA and PCR assays should be done before performing enemas or administering lavage solutions. Unless there is a good epidemiologic reason to strongly suspect infectious bacteria, fecal cultures and antigen/DNA tests tend to be very low-yield procedures that are difficult to interpret. Colonoscopy/biopsy is principally useful to diagnose histoplasmosis, histiocytic ulcerative colitis, protothecosis, Heterobilharzia, or neoplasia in dogs, whereas cats are often diagnosed with colonic inflammatory bowel disease.

If the results of these tests are not diagnostic, the clinician must consider three main possibilities. First, the biopsy specimens may not be representative of the entire colonic mucosa. For example, if the disease is localized to the region of the ileocolic valve, it will be necessary to use a flexible endoscope to reach the area. Second, the pathologist may not have recognized the lesions. Third, there may be no mucosal lesions. This typically occurs in animals with a dietary intolerance or allergy, "clostridial" colitis, or fiber-responsive diarrhea, all common problems in dogs.

HEMATOCHEZIA

If the patient has hematochezia (fresh blood in the feces) and diarrhea, the problem should usually be approached in the same manner as for animals with large bowel diarrhea (see Chapter 26, pp. 401-402). The patient with normal stools plus hematochezia is approached slightly differently. Streaks of blood on the outside of otherwise normal feces usually indicates a distal colonic or rectal lesion, whereas blood mixed into feces suggests that bleeding is occurring higher in the colon. Coagulopathies rarely cause bleeding from the rectum only. Focal bleeding lesions in the distal colon, rectum, or perineal region (Box 26.12) are especially important. Acute hematochezia may also result from trauma (e.g., passing a foreign body).

A thorough digital rectal examination is the best initial step (even if anesthesia is necessary). The clinician should express each anal sac repeatedly and examine the contents. If the problem is chronic and digital rectal examination is not helpful, then colonoscopy and biopsy are indicated. Barium enema is not recommended. Biopsy specimens of masses must include submucosa or many neoplastic lesions will be missed. Hematochezia is rarely severe enough to cause anemia; however, a CBC can be performed to look for and characterize anemias.

BOX 26.12

Major Causes of Hematochezia*

Dog

Anal-rectal disease

Anal sacculitis (important and common)
Neoplasia
- Rectal adenocarcinoma (important)
- Rectal polyp (important)
- Colorectal leiomyoma or leiomyosarcoma

Perianal fistulas (important)
Anal foreign body
Rectal prolapse
Anal-rectal trauma (e.g., foreign body, thermometer, enema tube, fecal loop, pelvic fractures)

Colonic/intestinal disease

Parasitism
- Whipworms (important and common)
- Hookworms (severe infections can involve the colon)

Dietary responsive (intolerance or allergy; common)
"Clostridial" colitis (common disease but uncommonly causes hematochezia)
Acute hemorrhagic diarrheal syndrome (important and common)
Parvoviral enteritis (important and common)
Histoplasmosis (regionally important and common)
Pythiosis (regionally important)
Intussusception (more common in young animals)
- Ileocolic
- Cecocolic

Inflammatory bowel disease
Colonic trauma
Coagulopathy
Colonic vascular ectasia

Cat

Dietary responsive (intolerance or allergy)
Inflammatory bowel disease (important)
Coccidia
Rectal tumors (uncommon)

*These diseases do not consistently produce hematochezia, but when hematochezia is present, these are the most common causes.

MELENA

Melena is caused by digested blood and is seen as "coal tar"-black (not just "dark") feces. Clinicians must distinguish melena from stools that are intensely dark green. Melena is strongly suggestive of upper alimentary tract bleeding or

ingestion of blood (Box 26.13). However, a lot of blood must enter the GI tract in a relatively short time to produce melena, which is why most animals with upper GI hemorrhage do not have melena. A CBC is indicated to look for iron deficiency anemia (i.e., microcytosis, hypochromasia). Measuring total serum iron concentration and total iron-binding capacity plus staining the bone marrow for iron are more definitive tests for iron deficiency anemia. Ultrasonography is helpful when looking for infiltrated, bleeding lesions (e.g., an intestinal tumor). Gastroduodenoscopy is the most sensitive test for GUE (which is often missed by ultrasonography). If ultrasound and gastroduodenoscopy are nonrevealing, then one must suspect small intestinal lesions beyond the reach of the endoscope. If imaging reveals a lesion beyond the reach of the endoscope, exploratory laparotomy is required. The clinician may elect to perform exploratory surgery immediately, but it is easy to miss bleeding mucosal lesions when examining the serosa or palpating the bowel. Intraoperative endoscopy (i.e., having the surgeon manually advance the tip of the endoscope while pushing the intestines onto the endoscope) may be helpful if no lesion is detected at surgery. Capsule endoscopy may be helpful in confirming that there is a bleeding lesion in the distal small intestines before laparotomy (or in finding a more orad lesion previously missed). Contrast radiographs rarely detect bleeding lesions and are not recommended

TENESMUS

Tenesmus (i.e., ineffectual or painful straining at urination or defecation) and dyschezia (i.e., painful or difficult elimination of feces from the rectum) are principally caused by obstructive or inflammatory distal colonic or urinary bladder or urethral lesions (Box 26.14). Colitis, constipation, perineal hernias, perianal fistulas, prostatic disease, and cystic/urethral disease are the most common causes of tenesmus. Most rectal masses and strictures cause hematochezia; however, some do not disrupt the colonic mucosa and cause only tenesmus.

The first goal (especially in cats) is to distinguish lower urinary tract from alimentary tract disease. In cats tenesmus secondary to a urethral obstruction is often misinterpreted as constipation. By observing the patient, the clinician may be able to determine whether the animal is attempting to urinate or defecate. Palpating the bladder is important; a distended urinary bladder often indicates an obstruction whereas a small, painful bladder often indicates cystitis. A urinalysis can also be helpful. If necessary, one can catheterize the urethra to determine if it is patent.

If the clinician suspects tenesmus resulting from alimentary tract disease, the next steps are to palpate the abdomen, perform a digital rectal examination, and visualize the anus and perineal areas even if this requires sedation/anesthesia.

BOX 26.13

Major Causes of Melena*

Dog

- Hookworms (important)
- Gastroduodenal tract ulceration/erosion (see Box 26.7) (important)
- Gastric or small intestinal tumor (important)
  - Lymphoma
  - Adenocarcinoma
  - Leiomyoma or leiomyosarcoma
  - Polyp
- Ingested blood
  - Oral lesions
  - Nasopharyngeal lesions
  - Pulmonary lesions
  - Diet
- Hypoadrenocorticism (uncommon but important)
- Coagulopathies (uncommon but important)

Cat (Rare)

- Gastrointestinal tumor
  - Lymphoma
  - Duodenal polyps
  - Other tumors (adenocarcinoma, mast cell tumor)
- Coagulopathies: vitamin K deficiency (intoxication or resulting from malabsorption)

*These diseases do not consistently produce melena, but if melena is present, these are the most common causes.

BOX 26.14

Major Causes of Tenesmus and/or Dyschezia

Dog

- Perineal inflammation or pain: anal sacculitis (common and important)
- Rectal inflammation/pain
  - Perianal fistulae (important)
  - Tumor (important)
  - Proctitis (either primary disease or secondary to diarrhea or prolapse)
  - Histoplasmosis/pythiosis
- Colonic/rectal obstruction
  - Rectal neoplasia
  - Rectal granuloma
  - Perineal hernia (important)
  - Constipation
  - Prostatomegaly (common and important)
  - Pelvic fracture
  - Other pelvic canal masses
  - Rectal foreign object

Cat

- Urethral obstruction (common and very important)
- Rectal obstruction
  - Pelvic fracture
  - Perineal hernia
- Constipation
  - Abscess near rectum

The clinician should not assume that constipation, if present, is causing the tenesmus. Severe pain (e.g., that resulting from proctitis) may make the animal refuse to defecate and cause secondary constipation. Most rectal strictures, perineal hernias, masses, enlarged prostates, pelvic fractures, and rectal tumors can be detected during a digital rectal examination. The clinician may need to use two fingers to detect partial strictures when examining large dogs. Perianal fistulae are usually visible but may be detected only as perirectal thickenings. Next, the clinician expresses the anal sacs and examines their contents. Finally, the clinician evaluates the feces to determine whether they are excessively hard or have abnormal contents (e.g., hair, trash).

A biopsy should be done of any mass, stricture, or infiltrative lesion found by rectal examination. A rectal scraping is sometimes sufficient (e.g., histoplasmosis), otherwise biopsy specimens taken with rigid biopsy forceps that include submucosa are preferred. Fine-needle aspiration should be performed on extracolonic masses because abscesses occasionally occur.

If the clinician is confused by physical examination findings, observing the animal defecate may help define the underlying process. Animals with inflammation often continue to strain after defecating, whereas a constipated animal strains before feces are produced. Tenesmus that occurs when an animal is in a squatting position often results from colitis, whereas tenesmus that occurs when an animal is in a semiwalking or partial squatting position usually results from constipation.

CONSTIPATION

Constipation (infrequent and difficult evacuation of feces) and obstipation (intractable constipation) have several causes (Box 26.15). The initial use of symptomatic therapy is often successful, but it is important to look for causes because some problems may become harder to treat if symptomatic therapy masks signs while the underlying disease progresses.

Iatrogenic, dietary, environmental, or behavioral causes should be sought on history. Feces should be examined to determine whether they contain plastic, bones, hair, popcorn, or other such material. Physical and digital rectal examinations are done to search for rectal obstruction or infiltration. Plain pelvic radiographs can help show whether the animal has anatomic abnormalities or a previously undetected

BOX 26.15

Causes of Constipation

Iatrogenic Causes

Drugs
- Opiates
- Anticholinergics
- Carafate (sucralfate)
- Barium sulfate

Behavioral/Environmental Causes

Change in household/routine (especially cats)
Soiled litter box/no litter box (especially cats)
House training
Inactivity

Refusal to Defecate

Behavioral
Pain in rectal/perineal area (see Box 26.14)
Inability to assume position to defecate
- Orthopedic problem
- Neurologic problem

Dietary Causes

Excessive fiber in dehydrated animal
Abnormal diet (especially dogs)
- Hair
- Bones
- Indigestible material (e.g., plants, plastic)

Colonic Obstruction

Pseudocoprostasis
Deviation of rectal canal: perineal hernia (important)
Intraluminal and intramural disorders
- Tumor
- Granuloma
- Cicatrix
- Rectal foreign body
- Congenital stricture

Extraluminal disorders
- Tumor
- Granuloma
- Abscess
- Healed pelvic fracture
- Prostatomegaly (common and important)
- Prostatic or paraprostatic cyst
- Sublumbar lymphadenopathy

Colonic Weakness

Systemic disease
- Hypothyroidism (important)
- Hypercalcemia
- Hypokalemia

Localized neuromuscular disease
- Spinal cord trauma
- Pelvic nerve damage
- Dysautonomia
- Chronic, massive dilation of the colon causing irreversible stretching of the colonic musculature

Miscellaneous Causes

Severe dehydration
Idiopathic megacolon (especially cats)

colonic obstruction (e.g., prostatomegaly, enlarged sublumbar lymph node). Ultrasonography is the preferred technique when looking for infiltrates. A serum biochemistry panel may reveal causes of colonic inertia (e.g., hypothyroidism, or rarely hypercalcemia or hypokalemia,).

Colonoscopy is indicated if the clinician suspects an obstruction too orad to be detected by digital examination. Ultrasound-guided fine-needle aspiration of infiltrative colonic lesions sometimes yields diagnostic findings, but colonoscopy (especially rigid) allows a more reliable biopsy specimen to be obtained. If a thorough diagnostic workup fails to identify a cause in a patient with a grossly dilated colon, idiopathic megacolon may be present.

FECAL INCONTINENCE

Fecal incontinence is typically caused by lower motor neuron disease (e.g., cauda equina syndrome, lumbosacral stenosis) or a partial rectal obstruction. Severe irritative proctitis may cause urge incontinence. Animals with rectal obstructions continually try to defecate because the anal canal is filled with feces. Proctitis is suspected on the basis of rectal examination findings and confirmed by proctoscopy and biopsy findings. Neuromuscular disease is suspected if an abnormal anal reflex is found, usually in conjunction with other neurologic defects in the anal, perineal, hindlimb, or coccygeal region. Defects in the coccygeal region are discussed in Chapter 65.

WEIGHT LOSS

Weight loss may be due to any of several categories of problems (Box 26.16). If other problems with more restrictive lists of differentials (e.g., ascites, vomiting, diarrhea, polyuria/polydipsia) are also present, they should usually be investigated first because it may be easier to find the cause. If there are no other concurrent problems that facilitate localization of the disease, then the clinician should determine what the animal's appetite was when the weight loss *began* (Fig. 26.5). Almost any disease can eventually cause anorexia/hyporexia. Weight loss despite an adequate caloric intake (or failure to gain weight despite an excessive caloric intake) usually indicates maldigestion, malabsorption, excessive utilization (e.g., hyperthyroidism, lactation) or inappropriate loss (e.g., diabetes mellitus) of calories. If the patient is hyporexic, it is important to determine if the hyporexia is severe enough that the weight loss can reasonably be attributed to the decreased caloric intake.

The animal's history should be reviewed for evidence of dietary problems, dysphagia, regurgitation, vomiting, or increased use of calories (e.g., lactation, strenuous work, extreme temperatures). Signalments suggestive of particular diseases (e.g., hyperthyroidism in older cats, hepatic failure in young Yorkshire Terriers with signs of portosystemic shunts) should be recognized. It is important to remember that diarrhea may be absent in animals with severe small intestinal disease.

BOX 26.16

Causes of Weight Loss

- **Food**
  - Not enough (especially if there are multiple animals)
  - Poor quality food or low-caloric-density food
  - Inedible
- **Anorexia** (see Box 26.17)
- **Dysphagia** (see Box 26.1)
- **Regurgitation/Vomiting** (i.e., must be losing enough calories to account for weight loss; see Boxes 26.4 to 26.6)
- **Maldigestive Disease**
  - Exocrine pancreatic insufficiency (usually but not always associated with diarrhea)
- **Malabsorptive Disease** (see Box 26.9)
  - Small intestinal disease (may be associated with normal stools)
- **Malassimilation**
  - Organ failure
    - Cardiac failure
    - Hepatic failure
    - Renal failure
    - Adrenal failure
- **Excessive Utilization of Calories**
  - Lactation
  - Increased work
  - Extremely cold environment
  - Pregnancy
  - Increased catabolism resulting from fever/inflammation
  - Hyperthyroidism
- **Increased Loss of Nutrients**
  - Diabetes mellitus
  - Protein-losing nephropathy
  - Protein-losing enteropathy
- **Neuromuscular Disease**
  - Lower motor neuron disease
- **Cancer Cachexia**

Physical examination might identify abnormalities that localize the problem to a particular body system (e.g., nasal disease preventing normal olfaction, dysphagia, arrhythmia suggestive of cardiac failure, weakness suggestive of neuromuscular disease, abnormally sized or shaped organs, abnormal fluid accumulations). Retinal examination may identify inflammatory or infiltrative diseases, especially in cats.

A CBC, serum biochemistry profile, and urinalysis should be done next to search for evidence of inflammation, organ failure, or a paraneoplastic syndrome. Cats should be tested for circulating feline leukemia virus antigen and antibodies to feline immunodeficiency virus. Serum T_4 (and sometimes fT_4) concentrations should be determined in middle-aged to older cats. If clinical pathology data are not helpful, imaging is usually the next step. Thoracic radiographs (ventrodorsal and both lateral views) are important because significant

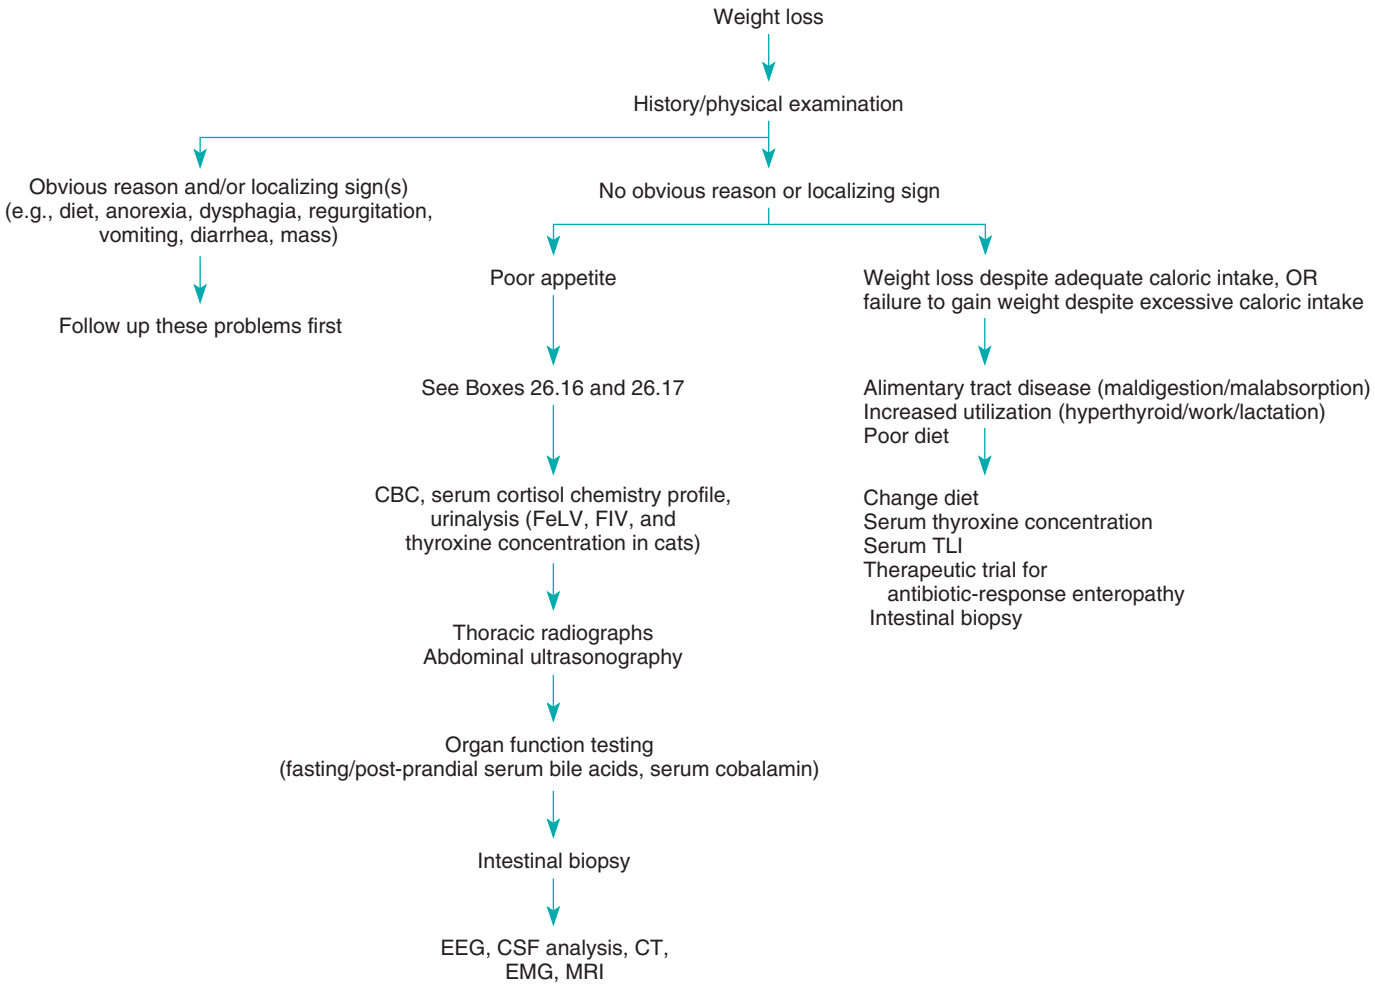

FIG 26.5
General diagnostic approach to weight loss in the dog and cat. *ACTH,* Adrenocorticotropic hormone; *CBC,* complete blood count; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *EEG,* electroencephalography; *EMG,* electromyography; *FeLV,* feline leukemia virus; *FIV,* feline immunodeficiency virus; *MRI,* magnetic resonance imaging.

thoracic disease cannot be ruled out because of normal physical examination findings. Computed tomography (CT) is more sensitive for thoracic disease than plain radiographs, but three-view radiographic examinations are usually adequate. Most cats and some dogs can be palpated well enough that abdominal radiographs are not cost-effective early in the workup. However, abdominal ultrasonography may reveal infiltrative lesions that cannot be palpated or seen radiographically.

If the cause of weight loss remains unknown after these tests, additional diagnostics are necessary. Daily physical examinations can be an important means of localizing the problem. Fever of unknown origin may be noted (see Chapter 90). Organ function testing (e.g., serum bile acid concentrations, serum cortisol, serum TLI, serum cobalamin) is reasonable. Likewise, if serum T_4 concentrations are normal in a cat with suspected hyperthyroidism, the serum fT_4 concentration should be determined or other tests (e.g., nuclear scintigraphy) performed (see Chapter 48).

If the cause of weight loss still remains undiagnosed, the clinician should consider performing therapeutic trials (e.g., for ARE) or gastric/intestinal biopsy. If a laparotomy is performed instead of endoscopy, the entire abdomen should be examined and multiple biopsy samples of the alimentary tract, liver, and mesenteric lymph nodes obtained. Pancreatic biopsy should be considered in cats.

Other possible diagnostic tools include tests to evaluate the CNS (i.e., cerebrospinal fluid analysis, CT, magnetic resonance imaging). Animals that are hyporexic due to CNS disease do not always have obvious cranial nerve deficits or seizures. Peripheral nerves and muscles may be evaluated by serum creatine kinase, electromyography, and muscle/nerve biopsies. Sometimes the weakness associated with neuropathies and myopathies is mistaken for lethargy; see Chapter 59). If the cause of the weight loss still remains undiagnosed and the history and physical examination findings are still noncontributory, occult cancer becomes a major differential diagnosis. In such cases, the clinician may have to wait and

retest later with the hope that the disease will progress enough to be detected.

Causes of weight loss that can be particularly difficult to diagnose include gastric disease not causing vomiting, intestinal disease not causing vomiting or diarrhea, hepatic disease with normal serum chemistries, occult inflammatory disease, atypical hypoadrenocorticism with normal serum electrolyte concentrations, occult cancer, "dry" feline infectious peritonitis, and CNS disease without cranial nerve deficits or seizures.

ANOREXIA/HYPOREXIA

The diagnostic approach and differential diagnoses for animals with hyporexia of uncertain cause is similar to that for animals with weight loss (see Fig. 26.5) (Box 26.17). Inflammatory disease is often detected by the CBC or by finding fever. GI disease may produce hyporexia without vomiting or diarrhea. Cancer cachexia (with anorexia as the predominant sign) may stem from relatively small tumors that are not grossly detectable, although this is rare. Finally, CNS disease must be considered, especially if there is altered mentation. However, altered mentation may resemble the depression and lethargy commonly seen in animals with other diseases.

ABDOMINAL EFFUSION

Abdominal effusion is usually caused by hypoalbuminemia, portal hypertension, and/or increased vascular/lymphatic permeability (i.e., inflammation). Effusions resulting from alimentary tract disorders are primarily caused by PLE (pure low protein transudate due to severe hypoalbuminemia) or alimentary tract rupture (i.e., septic peritonitis). Some animals with PLE have normal stools, ascites being the only abnormality on history or physical examination. Malignant tumors may obstruct lymphatic flow or increase vascular permeability, causing transudates, modified transudates or nonseptic peritonitis. Modified transudates usually result from hepatic or cardiac disease or from abdominal malignancies. For further information on abdominal effusions, see Chapters 33 and 34.

ACUTE ABDOMEN

Acute abdomen refers to various abdominal disorders producing shock (hypovolemic or septic), sepsis, and/or severe pain (Box 26.18). Causes may include alimentary tract obstruction or leakage, vascular compromise (e.g., congestion, torsion, volvulus, ischemia), inflammation, neoplasia, or sepsis. The approach to this problem is determined by the severity of clinical signs (Fig. 26.6).

Shock and gastric dilation or volvulus (GDV) must be identified and treated immediately. Once these conditions are eliminated, the next major decision is whether to perform exploratory surgery or initiate medical therapy. Animals with abdominal masses, foreign objects, bunched-up loops of painful small intestine suggestive of linear foreign body, or spontaneous septic peritonitis should typically undergo surgery as soon as they are acceptable anesthetic risks. If the cause of the acute abdomen is uncertain, it can be difficult to decide whether to do surgery. Surgery is not necessarily beneficial and may be detrimental to animals with pancreatitis, parvoviral enteritis, pyelonephritis, or prostatitis. Typically, abdominal imaging (i.e., plain abdominal radiography,

BOX 26.17

Major Causes of Anorexia/Hyporexia

Inflammatory Disease (Anywhere in Body) (Common and Important)

- Bacterial infections
- Viral infections
- Fungal infections
- Rickettsial infections
- Protozoal infections
- Sterile inflammation
  - Immune-mediated disease
  - Neoplastic disease
  - Necrosis
  - Pancreatitis
- Fever of unknown origin

Dysphagia (Especially Resulting From Pain)

- Nausea (common and important)
  - Stimulation of the medullary vomiting center for any reason but especially gastric or intestinal disease, even if it is not sufficient to cause vomiting (common with gastric disease; see Box 26.6)
- Metabolic Disease
  - Organ failure (e.g., kidney, adrenal, liver, heart)
  - Hypercalcemia
  - Diabetic ketoacidosis
  - Hyperthyroidism (usually causes polyphagia, but some cats have apathetic hyperthyroidism)
- Central Nervous System Disease (often without obvious neurologic abnormalities)
- Cancer Cachexia
- Anosmia (rare)
- Psychological Causes

BOX 26.18

Major Causes of Acute Abdomen

Septic Inflammation

Septic peritonitis (common and important)
- Perforated gastric ulcer (NSAIDs, tumor) (important)
- Perforated intestines (tumor, post-op dehiscence, linear foreign body, severe inflammation) (common and important)
- Devitalized intestines (intussusception, thrombosis/infarct)
- Ruptured gallbladder (e.g., septic cholecystitis, mucocele) (uncommon but important)
- Abscess/infection
  - Splenic
  - Hepatic
  - Cholecystitis
  - Prostatic
  - Renal
- Pyometra (ruptured) (important)

Nonseptic Inflammation

Pancreatitis (common and important)
Uroabdomen (important)
Pansteatitis

Organ Distention or Obstruction

Gastric dilation or volvulus (common and important)
Intestinal obstruction resulting from many causes (common and important)
Intussusception (important, especially younger animals)
Dystocia
Mesenteric volvulus (rare)
Incarcerated obstruction (rare)

Ischemia

Torsion of spleen, liver lobe, testicle, or other organ (rare)
Thromboembolism of abdominal organ(s) (rare)

Other Causes of Abdominal Pain (see Box 26.19)

Abdominal Hemorrhage

Abdominal neoplasia (hemangiosarcoma, hepatocellular carcinoma) (common and important)
Trauma
Coagulopathy (important)

Abdominal Neoplasia

NSAIDs, Nonsteroidal antiinflammatory drugs.

ultrasonography) and clinical pathologic studies (i.e., CBC, chemistry panel) should be performed before a laparotomy is performed. Ultrasound can reveal infiltrates that radiographs cannot detect, sometimes allowing diagnosis via aspiration. However, radiographs occasionally detect lesions (e.g., small foreign bodies, free abdominal gas) that were missed ultrasonographically. Imaging may reveal spontaneous pneumoperitoneum, abdominal masses, foreign objects, alimentary tract obstruction, gastric or mesenteric torsion (these require surgical treatment), or free peritoneal fluid (this requires abdominocentesis and fluid analysis for management). Radiographic contrast series are seldom appropriate and may complicate later therapy/surgery.

If optimal medical therapy is being given and the animal's condition is clearly deteriorating or does not improve after 2 to 5 days of therapy, or if the animal continues to have excruciating pain, it is often appropriate to recommend exploratory surgery. Inform the client that you may discover the animal has a disorder not surgically correctable (e.g., pancreatitis) or that nothing abnormal may be found. In the latter case, the clinician should biopsy various abdominal organs and then treat the animal's symptoms while awaiting biopsy results.

ABDOMINAL PAIN

"Abdominal" pain must first be determined to be abdominal and not extraabdominal in origin (e.g., thoracolumbar pain is often erroneously assessed as being abdominal in origin). An animal with true abdominal pain may show obvious discomfort (e.g., it paces or repeatedly assumes different positions, repeatedly looks at or licks its abdomen) and may whine, growl, or snap if the abdomen is touched. Some dogs stretch out and assume a "praying" position (i.e., the "position of relief"). Other animals have inconspicuous signs (e.g., the animal grunts or tries to walk away when palpated, the abdomen is tensed) that are easily missed. On the other hand, rough abdominal palpation technique in normal animals may elicit a guarding response that can mimic abdominal pain. Main causes of abdominal pain are listed in Box 26.19.

If the patient has abdominal pain, the goal is to determine the source. If the pain is originating from within the abdominal cavity, the diagnostic approach depends on its severity, progression of disease, and whether there are any obvious causes. The steps taken in diagnosing the cause of abdominal pain are similar to those taken in an animal with acute abdomen. Some causes of abdominal pain can be difficult to diagnose (e.g., acute pancreatitis, localized peritonitis).

ABDOMINAL DISTENTION OR ENLARGEMENT

Abdominal distention or enlargement may be associated with an acute abdomen, but these conditions are typically separate problems. It is best to believe clients who claim

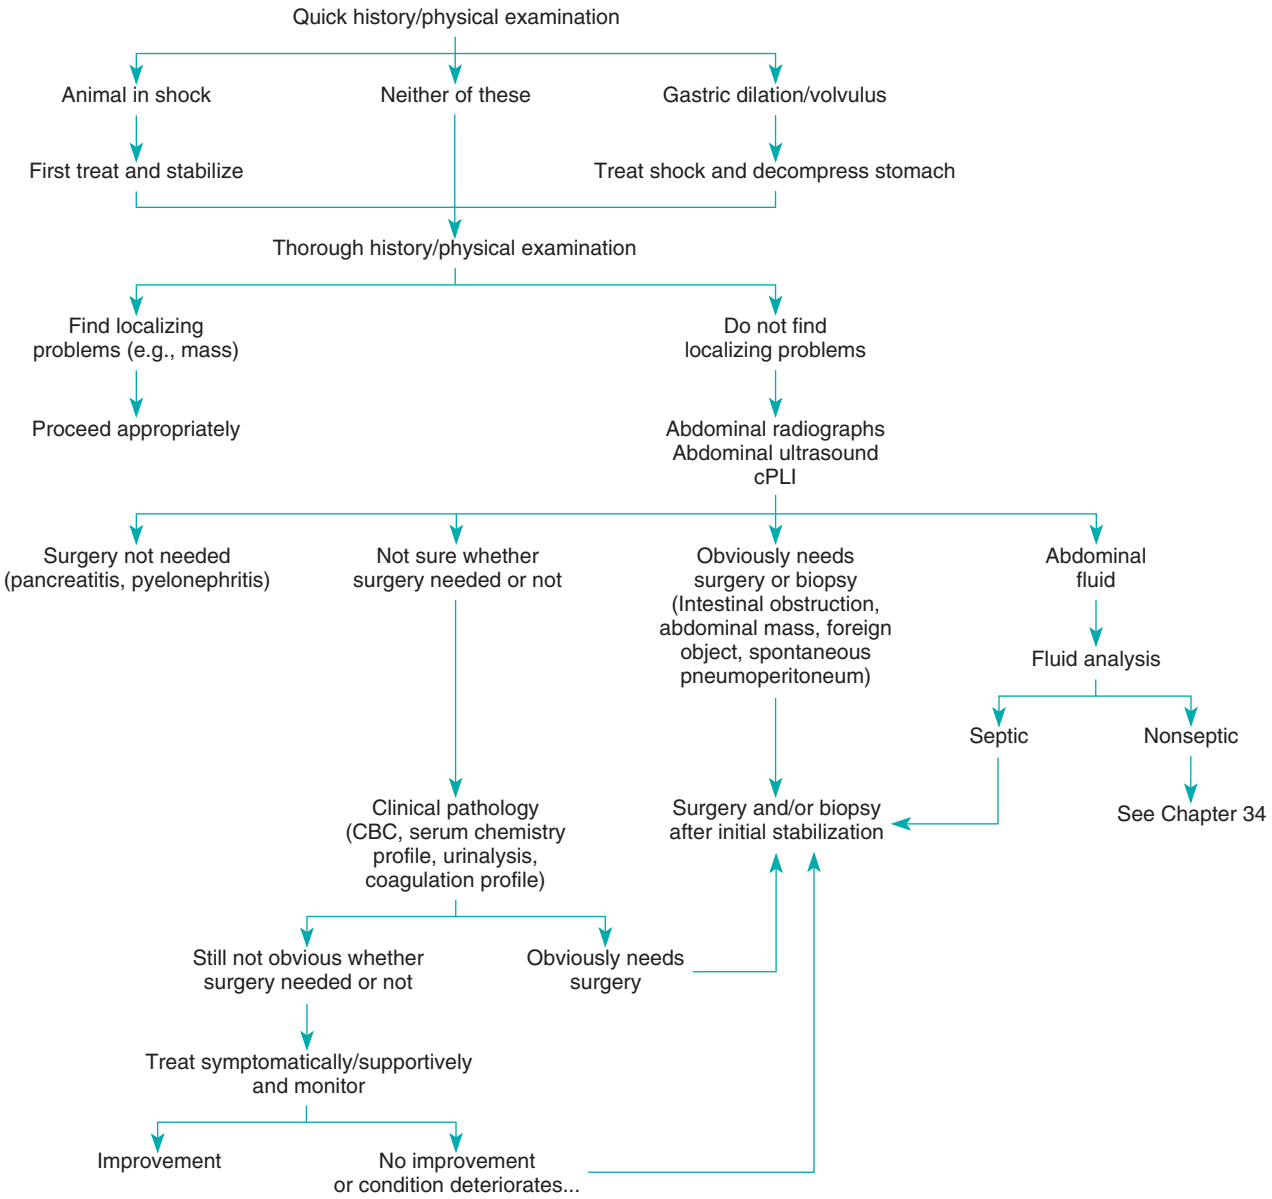

FIG 26.6
General diagnostic approach to acute abdomen in the dog and cat. *CBC,* Complete blood count; *PLI,* pancreatic lipase immunoreactivity.

there is abdominal enlargement until good cause is found to believe otherwise. There are six main causes of abdominal distention (Box 26.20).

The first concern is whether an acute abdomen is present (e.g., GDV, septic peritonitis, hemoabdomen plus shock). After an acute abdomen is ruled out, it should be possible to classify enlargement on the basis of physical examination and abdominal imaging (i.e., radiography or ultrasonography), according to the criteria in Box 26.20. Obesity and pregnancy should be obvious. Specimens of free abdominal fluid should be obtained and analyzed as described in Chapter 34. Biopsy should be performed on abdominal masses and enlarged organs, unless there is a reason not to (e.g., hepatomegaly caused by severe right-sided heart failure). Fine-needle aspiration is typically safe, although leakage of septic contents or implantation of neoplastic cells may rarely occur. Ultrasonography helps determine potential for hemorrhage or leakage (e.g., cyst, mass with ultrasonographic characteristics of hemangiosarcoma). Finding spontaneous pneumoperitoneum suggests alimentary tract rupture or septic peritonitis and is usually an indication for prompt surgical exploration. A hollow viscus dilated with gas may indicate obstruction (i.e., gastric dilation, intestinal obstruction) or physiologic ileus (see p. 420 and pp. 467-468; Figs. 27.5 and 30.3. Surgery is indicated if an obstruction seems likely. If abdominal musculature weakness is suspected, hyperadrenocorticism may be considered. Results of a CBC, serum biochemistry panel, and urinalysis are used to

BOX 26.19

Causes of Abdominal Pain

- Poor Palpation Technique ("Pseudo-pain")
- Musculoskeletal System (Mimics Abdominal Pain)
  - Fractures
  - Intervertebral disk disease (common and important)
  - Diskospondylitis (important)
  - Abscesses
- Peritoneum
  - Peritonitis
    - Septic (common and important)
    - Nonseptic (e.g., uroabdomen) (important)
  - Adhesions (rare)
- Gastrointestinal Tract
  - Gastrointestinal ulcer
  - Foreign object (especially linear)
  - Neoplasm
  - Adhesions (rare)
  - Intestinal ischemia (rare)
  - Intestinal spasm (rare)
  - See also Box 26.18, under Organ Distention or Obstruction
- Hepatobiliary Tract
  - Hepatitis
  - Cholelithiasis or cholecystitis
- Pancreas
  - Pancreatitis (common and important)
- Spleen
  - Torsion (rare)
  - Rupture
  - Neoplasm
  - Infection (rare)
- Urogenital System
  - Pyelonephritis (important)
  - Lower urinary tract infection
  - Prostatitis (important in dogs)
  - Nonseptic cystitis (common and important in cats)
  - Cystic or ureteral obstruction or rupture (common, especially after trauma)
  - Urethritis or obstruction (common)
  - Metritis
  - Uterine torsion (rare)
  - Neoplasm
  - Testicular torsion (rare)
  - Mastitis (does not cause true abdominal pain but mimics abdominal pain)
- Miscellaneous Causes
  - Postoperative pain (especially if animal has a tight suture line)
  - Iatrogenic causes
  - Drugs (e.g., misoprostol, bethanechol)
  - Adrenalitis (associated with hypoadrenocorticism) (rare)
  - Heavy metal intoxication (rare)
  - Vasculopathy (rare)
    - Rocky Mountain spotted fever vasculitis
    - Infarct

BOX 26.20

Causes of Abdominal Enlargement

- Tissue
  - Pregnancy (common and important)
  - Hepatomegaly (infiltrative or inflammatory disease, lipidosis, neoplasia)
  - Splenomegaly (infiltrative or inflammatory disease, neoplasia, hematoma)
  - Renomegaly (neoplasia, infiltrative disease, compensatory hypertrophy)
  - Miscellaneous neoplasia
  - Granuloma (e.g., pythiosis)
- Fluid
  - Contained in organ(s)
  - Congestion resulting from torsion, volvulus, or right-sided heart failure
  - Spleen
  - Liver
  - Cysts
  - Paraprostatic cyst
  - Perinephric cyst
  - Hepatic cyst
  - Hydronephrosis
  - Intestines or stomach (resulting from obstruction or ileus)
  - Pyometra
  - Free in abdomen (common and important)
    - Transudate, modified transudate, exudate, blood, chyle
- Gas
  - Contained in organ(s)
  - Stomach (gastric dilation or volvulus) (common and important)
  - Intestines (resulting from obstruction)
  - In parenchymatous organs (e.g., liver) resulting from infection with gas-producing bacteria
  - Free in abdomen
  - Iatrogenic (after laparoscopy or laparotomy)
  - Alimentary tract or female reproductive tract rupture
  - Bacterial metabolism (peritonitis)
- Fat
  - Obesity
  - Lipoma
- Weak Abdominal Muscles
  - Hyperadrenocorticism (important)
- Feces

look for specific organ involvement (e.g., hyperadrenocorticism). Contrast-enhanced alimentary or urinary tract radiographs are generally not appropriate; ultrasonography typically makes such techniques unnecessary. Sometimes abdominal CT examination will be required.

CHAPTER 27

Diagnostic Tests for the Alimentary Tract

PHYSICAL EXAMINATION

Routine physical examination is the first step in evaluating animals with alimentary tract disease. If oral, abdominal, or rectal disease is a concern and the patient refuses to allow examination of the area, it is usually appropriate to use chemical restraint to adequately examine the area. A common example is a vomiting cat with a possible linear foreign body lodged under the tongue; the clinician should thoroughly examine the mouth and base of the tongue, even if it requires strong sedation.

The clinician should methodically identify individual organs during abdominal palpation. In dogs the small intestine, large intestine, and urinary bladder can usually be found (unless there is pain, effusion, or obesity). In cats both kidneys are usually palpable. In both species clinicians should usually be able to detect substantial splenomegaly, hepatomegaly, intestinal or mesenteric masses, and intestinal foreign objects. Abdominal pain may be subtle; some animals cry out during gentle palpation, whereas others just tense their abdomen (i.e., guarding) or try to move away. Rough palpation technique can cause a normal animal to tense up or vocalize during palpation, mimicking abdominal pain. Light, careful palpation permits the definition of more of the abdominal contents. If there is sufficient abdominal fluid to prevent meaningful abdominal palpation, ballottement of the abdomen should produce a fluid wave.

During digital rectal examination, the examiner should be able to identify and evaluate the colonic mucosa, anal sphincter, anal sacs, pelvic canal bones, muscular support for the rectum, urogenital tract, and luminal contents. It is easy to misinterpret small mucosal polyps as mucosal folds and to miss partial strictures large enough to allow a single digit to pass through easily.

ROUTINE LABORATORY EVALUATION

COMPLETE BLOOD COUNT

Complete blood counts are important in animals at risk for neutropenia (e.g., parvoviral enteritis, severe sepsis), infection (e.g., aspiration pneumonia), or anemia (e.g., pale mucous membranes, melena, hematemesis) and also in those that have fever, severe weight loss, or hyporexia of occult cause. The clinician should always consider absolute numbers of the different types of white blood cells. If the animal is anemic, the clinician should look for evidence of regeneration (i.e., reticulocytes, polychromasia) and iron deficiency (e.g., hypochromasia, microcytosis, increased red blood cell distribution width).

COAGULATION

Platelet numbers can be estimated from a blood smear. A dog should have 8 to 30 platelets per oil immersion field; finding 1 platelet per field suggests a platelet count of approximately 15,000 to 20,000/µL. Coagulation panels may detect unsuspected coagulopathies (e.g., disseminated intravascular coagulation). Activated clotting times are crude estimates of the intrinsic clotting pathway; partial thromboplastin times are more sensitive. Mucosal bleeding time is an excellent screening test for coagulopathies severe enough to cause clinical bleeding.

SERUM BIOCHEMISTRY PROFILE

Serum alanine transaminase, alkaline phosphatase, blood urea nitrogen, creatinine, total protein, albumin, sodium, potassium, chloride, total CO_2, cholesterol, calcium, phosphorus, bilirubin, and glucose concentrations are important to evaluate in animals with severe vomiting, diarrhea, ascites, unexplained weight loss, or hyporexia. Clinicians cannot predict changes that will occur or the magnitude of changes in a particular animal, even when the cause of the disease is known. The total CO_2 concentration is not as definitive as blood gas analysis for defining acid-base, but it typically suffices.

The serum albumin concentration is more useful than serum total protein concentration. Hyperglobulinemia has many causes (e.g., heartworms, chronic dermatitis, ehrlichiosis) and can cause the serum total protein concentration to be normal in hypoalbuminemic patients. Severe hypoalbuminemia (i.e., <2.0 g/dL) is important diagnostically; it is more commonly found in animals with intestinal

lymphangiectasia, gastrointestinal (GI) blood loss, severe infiltrative alimentary tract disease, parvoviral diarrhea, or ascites. It is important to measure the serum albumin using technology designed for canine and feline albumin; some techniques used for measuring human albumin produce falsely low measurements of canine albumin. It is important to use the same lab when repeating the serum albumin concentration; different labs often have slightly different normal ranges, which causes confusion when monitoring hypoalbuminemic patients.

Ill animals (especially those receiving multiple drugs) are at risk for secondary renal or hepatic failure. Very young and very small animals easily become hypoglycemic if they cannot eat or absorb ingested nutrients. Finding hypercalcemia or hypoalbuminemia may provide a clue to the underlying problem in animals with weight loss or hyporexia.

SERUM CORTISOL

Atypical hypoadrenocorticism is more common in dogs than many clinicians realize. Measuring resting serum cortisol as a screening test to decide whether or not to perform an ACTH-stimulation test has become standard practice in patients with difficult to diagnose/control vomiting, diarrhea, or hyporexia.

URINALYSIS

Urinalysis is required to accurately evaluate renal function and, in conjunction with the urine protein/creatinine ratio, to help determine the cause of hypoalbuminemia. Urine should always be obtained before fluid therapy is begun.

FECAL PARASITIC EVALUATION

Fecal flotation is indicated in most animals with alimentary tract disease or weight loss, especially puppies and kittens. Even if parasitism is not the primary problem, it may cause additional debilitation. Concentrated salt or sugar solutions are typically used for fecal flotation. The former are usually superior, although incorrectly made solutions may not force heavier ova (e.g., whipworms) to float. Moreover, concentrated salt solutions can distort *Giardia* cysts, making identification difficult. Zinc sulfate flotation solution is preferred for detecting nematode ova and *Giardia* cysts. Centrifugation promotes separation of cysts from the fecal matter and results in a more sensitive fecal examination. Some parasites intermittently shed small numbers of ova or cysts, necessitating repeated fecal analyses for diagnosis. Whipworm and *Giardia* infections can be especially difficult to diagnose with fecal flotation.

The ova of the most common tapeworm species are contained in segments and are not found by flotation techniques. *Nanophyetus salmincola* (the fluke that transmits salmon poisoning) is detected by many flotation solutions, although sedimentation examinations are required to detect most other fluke ova. Cryptosporidiosis is difficult to detect by routine flotation techniques. The clinician should send the feces to a laboratory familiar with this coccidium and is able to perform special procedures to detect it. Enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), and indirect fluorescent antibody (IFA) methodologies are more sensitive than fecal flotation for finding cryptosporidia (see later).

Direct fecal examination, although convenient, is not sensitive for nematodes and should not replace flotation techniques. However, occasionally amebiasis, strongyloidiasis, and whipworm infections missed by flotation procedures can be detected by direct examination. Motile *Giardia* and *Tritrichomonas* trophozoites may be found if the feces are very fresh and the smear is adequately diluted with saline solution. Direct examination is much less sensitive than zinc sulfate flotation, IFA, PCR, and ELISA techniques in detecting giardiasis (see later).

Fecal sedimentation is time consuming and offers no advantage in detecting common GI tract parasites. However, it does detect fluke ova missed by other techniques, especially the ova of *Eurytrema* spp., *Platynosomum* spp., *Amphimerus* spp., and *Heterobilharzia* spp.

Feces may be preserved by mixing equal volumes of feces and 10% neutral buffered formalin or by using commercially available kits. Polyvinyl alcohol is used in the latter, and feces preserved in this manner can be examined weeks to months later. These techniques are especially useful if one cannot immediately examine feces for protozoal cysts.

PCR analysis on feces can detect *Heterobilharzia* spp. (GI Lab, Texas A&M University, College Station, TX). It appears to be at least as sensitive as fecal sedimentation.

FECAL DIGESTION TESTS

Examining feces for undigested food particles by staining thin fecal smears with the Sudan stain (for fat) or iodine (for starch and muscle fibers) is discouraged. Finding excessive amounts of undigested fecal fat is supposedly suggestive of exocrine pancreatic insufficiency (EPI), but this test has many false-positive and false-negative results. If EPI is a differential diagnosis, a species-specific serum trypsin-like immunoreactivity (TLI) is the recommended test (see the section on digestion and absorption tests).

Fecal analysis for proteolytic activity (i.e., the fecal trypsin content) also tests for EPI. Qualitative estimates (e.g., fecal film digestion, fecal gelatin digestion) are unreliable. Quantitative analysis is seldom needed because the TLI test is easier to perform. It is rarely necessary to quantitate fecal proteolytic activity to diagnose EPI caused by pancreatic duct obstruction (exceedingly rare), something TLI does not detect. In this test, feces are collected for 3 consecutive days and stored frozen until sent to the laboratory. Quantitated fecal fat analysis is almost never indicated.

Fecal occult blood analyses are seldom useful because most pets eat meat by-products that cause a positive reaction. False-positive reactions may also be produced by cimetidine, oral iron preparations, and some vegetables. The

sensitivity of different techniques varies, making it difficult to accurately compare results. Finally, blood is often not distributed homogeneously throughout the feces, and a negative result could stem from a sampling error (especially in animals with lower intestinal tract problems).

If fecal occult blood analysis is desired, one should feed the animal a meat-free diet for 3 to 4 days before performing the test. Tests using the reagents benzidine or orthotoluidine to detect hemoglobin tend to be very sensitive (and hence less specific), whereas those using guaiac are less sensitive (and thus more specific). A sensitive and specific fluorometric method has been validated in dogs. Repeated testing may be necessary to demonstrate intermittent bleeding.

BACTERIAL FECAL CULTURE

Fecal culture is seldom indicated in small animals unless a contagious bacterial disease is strongly suspected, and even then simply finding a "pathogenic" bacteria in an animal's feces does not confirm that it is causing disease. Culture results must be correlated with clinical signs and the results of other laboratory tests. The clinician should always contact the laboratory before collecting/submitting feces, informing them specifically what bacteria to attempt to grow; there are specific techniques for collection, submission, and culture for most fecal pathogens. Fecal culture cannot be used to diagnose small intestinal antibiotic-responsive enteropathy (ARE), also called *dysbiosis*.

Potential pathogens most commonly cultured from feces from small animals include *Clostridium perfringens, Salmonella* spp., *E. coli,* and *Campylobacter jejuni.* Confirmation of toxin production by specific bacteria can be performed using PCR techniques or bioassay. *Salmonella* spp. are best cultured by inoculating at least 1 g of fresh feces into an enrichment medium and subsequently a selective medium specific for *Salmonella* spp. *Salmonella* can also be grown from colonic mucosa. To culture *C. jejuni,* very fresh feces must be inoculated onto selective media and incubated at approximately 40° C instead of 37° C. If inoculation is to be delayed, special transport media should be used, not routine commercial transport devices (e.g., culturette swabs). *Candida* spp. are occasionally cultured from feces. Growing *Candida* is often hard to interpret, but the organisms might cause problems in some animals (e.g., those receiving chemotherapy).

There is a culture technique (InPouch TF, BioMed Diagnostics) for *Tritrichomonas blagburni* in feline feces. The culture technique can be done in the practice and appears to be more sensitive than direct fecal examination but less sensitive than PCR.

ELISA, IFA, AND PCR FECAL ANALYSES

ELISA can be used to detect antibodies or antigens. The test for canine parvovirus is very specific. However, parvovirus may not be excreted in the feces for the first 24 to 48 hours after onset of clinical signs; therefore, it may be necessary to repeat the test in 2 to 3 days if initial results are negative in a dog strongly suspected of having parvoviral infection. Additionally, although dogs with parvoviral diarrhea initially shed large amounts of virus, fecal shedding decreases substantially during the ensuing 7 to 14 days. A repeatedly negative test result therefore does not rule out parvoviral infection, but it does necessitate a consideration of other acute, febrile gastroenteritides (e.g., salmonellosis). This test is particularly valuable if there are epidemiologic considerations (e.g., breeding kennel).

ELISAs for detecting a *Giardia*-specific antigen in human (ProSpecT/Microplate ELISA assay for Giardia, Alexon, Inc.) and canine/feline feces (SNAP Giardia Test, Idexx Laboratories) are available. The SNAP *Giardia* test appears to be sensitive with good negative predictive value, but it has poor positive predictive value at typical low prevalence rates when compared with IFA testing of feces. It has the advantage of being able to be performed in the practice. An IFA test (MERIFLUOR *Cryptosporidium/Giardia* direct immunofluorescent kit, Meridian Bioscience, Inc.) is probably the most sensitive and specific test for giardiasis but requires that feces be sent to a commercial laboratory.

ELISAs for detecting cryptosporidial antigens in feces (ProSpecT Cryptosporidium Microplate Assay, Meridian Diagnostics, Inc. and ProSpecT Cryptosporidium Microplate Assay, Remel, Inc.) are more sensitive than routine fecal examinations. Special staining of fecal smears with a modified Ziehl-Neelsen acid-fast technique is also sensitive, albeit more labor intensive. An IFA test (MERIFLUOR *Cryptosporidium/Giardia* direct immunofluorescent kit, Meridian Bioscience, Inc.) is not as sensitive as ELISA when looking for cryptosporidia.

Assays for bacterial toxins in feces are typically valuable for implicating specific bacteria as causing diarrhea in people, but a positive test in a dog or cat is not *prima facia* evidence it is causing disease. *C. difficile* in particular is of uncertain pathogenic significance in dogs and cats. ELISA tests (*C. perfringens* Enterotoxin Test, TechLab) and reverse passive latex agglutination tests (Oxoid PET-RPLA, Unipath Co.) for *C. perfringens* enterotoxin are available, but the results do not clearly correlate with clinical disease.

PCR testing for antigens in feces has become popular because of its sensitivity and specificity, but finding any of numerous agents in feces does not guarantee that the agent is responsible for disease. There are fecal PCR panels that can detect *Giardia, Cryptosporidium, Salmonella, C. perfringens* enterotoxin A, enteric coronavirus, parvovirus, and/or distemper virus in canine feces. Likewise there are fecal PCR panels that detect *Tritrichomonas blagburni, Giardia, Cryptosporidium, Toxoplasma gondii, Salmonella, C. perfringens* enterotoxin A, coronavirus, and/or panleukopenia virus in feline feces. The GI Lab (Texas A&M University) also offers PCR testing for *C. jejuni* and *C. coli*. In all cases, a positive PCR does not guarantee that the agent is producing clinical disease.

CYTOLOGIC EVALUATION OF FECES

Fecal cytologic evaluations may identify etiologic agents or inflammatory cells. In this method a thin, air-dried smear is stained with Gram or a Romanowsky-type stain (e.g., Diff-Quik). The latter identifies cells better than Gram stain does.

Finding excessive numbers of spore-forming bacteria (e.g., >3-4 per 1000× field) was once thought to strongly suggest clostridial colitis (see Fig. 31.1). However, the presence of spores is neither specific nor sensitive for clostridial colitis. Finding that the bacterial population is relatively uniform morphologically is of uncertain value, other than to show that the normal bacterial flora is disrupted. However, no comments can be made relative to cause or effect.

Short, curved, gram-negative rods (i.e., "commas" or "seagull wings") are supposedly suggestive of campylobacteriosis, but the value of this test in dogs and cats is doubtful. The larger spirochetes, which are often plentiful in diarrheic feces, are not *C. jejuni* and are of uncertain pathogenicity. Fungal organisms (e.g., *Histoplasma capsulatum, Cyniclomyces guttulatus, Candida* spp.) are rarely found by fecal examination; cytologic examination of mucosal scrapings or histologic examination of biopsy specimens is usually necessary to diagnose histoplasmosis.

Leukocytes in feces indicate a transmural colonic inflammation instead of just superficial mucosal inflammation. However, a definitive diagnosis of a particular cause is not possible.

ELECTRON MICROSCOPY

Electron microscopy can be used to find various viral particles (e.g., coronavirus, parvovirus, astrovirus) in feces. Because ELISA is usually adequate for detecting parvovirus, electron microscopy is rarely necessary. However, it is reasonable to choose this technique if other test results are not diagnostic and there are epidemiologic considerations. Fecal samples for electron microscopy analysis should be obtained early in the disease because fecal viral concentrations may decrease dramatically within 7 to 14 days after the onset of signs. Furthermore, some delicate viruses (e.g., coronavirus) degenerate quickly, and the feces from animals suspected of having such an infection must be handled appropriately if meaningful results are to be obtained. It is important that clinicians contact their laboratory for instructions on sample handling.

RADIOGRAPHY OF THE ALIMENTARY TRACT

Radiography allows evaluation of structures that cannot be adequately assessed during physical examination (e.g., esophagus, stomach) and may detect abnormalities missed by abdominal palpation (e.g., gastric mass, foreign object, splenic parenchymal mass). Plain radiographs should always be obtained before contrast-enhanced radiographs because (1) the former may be diagnostic and eliminate the need for contrast studies, (2) contrast-enhanced radiographs may be found to be contraindicated (e.g., evidence of GI tract leakage), and (3) plain radiographs are needed to ensure a correct radiographic technique during the contrast procedure. Contrast-enhanced radiographs may be able to detect abnormalities (e.g., a gastric outflow tract obstruction) that plain radiographs cannot.

Radiographs are generally useful in the diagnostic workup of animals with dysphagia, regurgitation, vomiting, abdominal mass or distention, abdominal pain, or acute abdomen. They are occasionally helpful in animals with constipation, weight loss, or hyporexia of unknown cause, but other tests are usually indicated first in such animals and often render radiographs unnecessary. Radiographic findings are rarely diagnostic in dogs or cats with diarrhea or copious abdominal effusion.

ULTRASONOGRAPHY OF THE ALIMENTARY TRACT

Ultrasonography may be done in combination with or instead of radiography. It is extremely operator dependent. It is often useful in animals with an acute abdomen, abdominal effusion, vomiting, chronic diarrhea, weight loss, or hyporexia of unknown cause and also in those with an abdominal mass, distention, or pain. Ultrasonography often identifies pancreatitis, infiltrations in various organs, and intussusceptions that radiography misses. Furthermore, while effusions render radiographs useless, they enhance ultrasonographic contrast. Ultrasonography is often more informative than radiography for determining whether an animal with an acute abdomen requires surgery. Finally, ultrasonography can be used to guide percutaneous aspiration and biopsy of intraabdominal lesions that would otherwise necessitate surgery or laparoscopy.

Techniques

A 5-MHz probe is probably the most utilitarian. Hair is often clipped so that there is no trapped air that could compromise image quality.

Findings

The thickness, echodensity, and homogeneity of organs (e.g., liver, spleen, intestine, stomach, mesenteric lymph nodes, masses) may be assessed. Intraparenchymal infiltrates that cannot be detected radiographically may also be found. The particular ultrasonographic findings seen in specific disorders of the alimentary tract are discussed in subsequent chapters dealing with the disorders.

IMAGING OF THE ORAL CAVITY, PHARYNX, AND ESOPHAGUS

INDICATIONS

Animals with dysphagia, oral pain, halitosis of unknown cause, or a swelling or mass should generally undergo imaging. If dysphagia of neuromuscular origin is suspected, dynamic contrast studies (i.e., fluoroscopy) are recommended. Ultrasonography can be useful for evaluating infiltrates or masses, but magnetic resonance imaging (MRI) offers even more detail.

Techniques

Anesthesia is necessary so that animals can be properly positioned for cranial radiographs. Lateral, dorsoventral (DV), and oblique radiographs are used to detect foreign objects or fractures. Open-mouth ventrodorsal (VD) views and end-on views of the nose may also be helpful. Computed tomography (CT) is superior to radiographs (and easier) for finding fractures, and a helical CT can perform the examination so quickly that deep sedation may be all that is needed. MRI is superior to CT for detecting soft tissue lesions. Dynamic studies (i.e., fluoroscopy, cinefluoroscopy) are necessary to evaluate for dysphagia of neuromuscular origin. Dynamic studies are performed by feeding conscious animals various forms of barium (i.e., liquid, paste, and mixed with food). Performing dynamic studies in sternal recumbency is preferred because lateral recumbency might increase transit time and change the type of peristaltic waves.

Findings

Foreign objects, fractures, bone lysis, soft tissue masses or densities, and emphysema are the most common findings. Bone surrounding the tooth roots should be examined for lysis and the temporomandibular joints for arthritis. It is important to consider the bilateral symmetry of the skull; one side should be compared with the other when evaluating the VD projection. When performing contrast-enhanced or dynamic studies, the clinician should watch for aspiration of barium, the strength with which the bolus is propelled into the esophagus, and synchronization of the opening of the cricopharyngeal muscle with the pharyngeal phase of swallowing.

INDICATIONS FOR IMAGING OF THE ESOPHAGUS

Indications for evaluating the esophagus include any type of neuromuscular dysphagia, regurgitation, pain when swallowing, unexplained recurrent pneumonia or cough, radiographic thoracic "masses" of undetermined origin, and before surgical lateralization of arytenoids for laryngeal paralysis. A barium contrast esophagram is often necessary to define esophageal pathology unless plain films reveal obvious megaesophagus, a foreign object, evidence of esophageal perforation (e.g., a pleural effusion, pneumothorax, pneumomediastinum), or an obvious hiatal hernia. Be sure to include the cervical esophagus. Finding obvious megaesophagus on plain radiographs is usually sufficient, but rare dogs with apparent megaesophagus on plain radiographs demonstrate normal function when barium is administered. Ultrasonography, CT, and MRI are seldom helpful for dogs and cats with esophageal disease, unless there is a thoracic mass.

Techniques

Liquid barium is the best contrast agent for esophageal studies. It provides excellent detail and is not problematic if aspirated unless there is preexisting pneumonia. The clinician must not administer drugs that affect esophageal motility (e.g., xylazine, ketamine, anesthesia). The animal should take several swallows of dilute barium from a syringe, shortly after which right lateral and VD radiographs are obtained. Barium paste does not offer any substantive advantages over liquid barium. Hypertonic iodine contrast agents do not achieve as good a contrast as barium and cause severe problems if aspirated; isotonic water-soluble iodine contrast agents are better but still provide mediocre contrast. If radiographic studies performed with liquid contrast agents do not detect an abnormality in an animal in which esophageal disease is strongly suspected, the study should be repeated using a mixture of barium and food (both canned food and dry kibble). Such studies may detect partial strictures or muscular weakness not found with previous studies.

If barium is retained in the esophagus but little or none enters the stomach, the animal should be held in a vertical position so that gravity facilitates migration of barium into the stomach. If barium readily enters the stomach, this indicates that there is no lower esophageal sphincter obstruction. If a hiatal hernia is suspected but not seen, a lateral radiograph of the caudal thorax may be taken while the abdomen is manually compressed. This is done in an attempt to force the contrast-filled stomach to herniate into the thorax, allowing diagnosis.

If esophageal disease seems likely but is not found by static radiographs, fluoroscopic studies are indicated next. If possible, the clinician should perform fluoroscopy as the animal swallows the barium to assess esophageal motility and look for partial esophageal obstruction, segmental esophageal weakness, gastroesophageal reflux, and esophageal-pharyngeal reflux (i.e., cricopharyngeal incompetence). Having the patient in sternal recumbency is preferred for dynamic studies. It may be necessary to observe the esophagus for several minutes (or longer) before some abnormalities (e.g., gastroesophageal or esophageal-pharyngeal reflux) occur. In animals with marginal esophageal disease, fluoroscopy may be necessary to document that primary or secondary esophageal waves are present but are either weak or not readily stimulated. If fluoroscopy is unavailable, multiple radiographs (usually lateral projections) taken in rapid succession beginning very shortly (i.e., 5-10 seconds) after swallowing are sometimes adequate.

If an esophageal perforation is suspected (e.g., septic pleuritis or mediastinitis, pneumomediastinum, or

pneumothorax), an isotonic iodine contrast medium should be used. However, the only purpose of such a study is to localize the perforation. If the clinician already knows where the leakage is likely to be (e.g., there is a bone foreign body in the esophagus), contrast radiographs are of dubious value. Perforations may not be obvious if the foreign body that caused them is filling and occluding the defect.

Findings

Esophageal dilation, foreign objects, soft tissue densities, spondylosis suggestive of spirocercosis, and hiatal hernia may often be identified on plain films. An air-filled esophagus is not always diagnostic of pathologic esophageal weakness. Although it is tempting to use plain radiograph findings as the basis for the diagnosis of esophageal disease when there is an "obvious" abnormality, it is possible to misinterpret plain films or miss abnormalities that a barium contrast–enhanced study would reveal. Rarely, animals with a dilated, air-filled esophagus on plain films have normal esophageal function when evaluated with a barium contrast esophagram (Fig. 27.1, *A*). In contrast, many animals with relatively minor changes on plain radiographs have substantial esophageal dysfunction (see Fig. 27.1, *B*). Occasionally, accumulation of food in the classic location for a vascular ring anomaly may be caused by localized esophageal weakness or a thymic cyst.

Almost all esophageal foreign objects can be seen on plain radiographs. However, excellent radiographic technique is necessary because some foreign objects (e.g., poultry bones, rawhide treats) are relatively radiolucent (Fig. 27.2). An esophageal perforation sometimes causes pneumothorax, pneumomediastinum, or a pleural/mediastinal effusion.

Contrast-enhanced esophagrams should be considered in animals with unidentified thoracic masses because many esophageal tumors radiographically resemble pulmonary parenchymal masses (see Fig. 29.8). Contrast-enhanced esophagrams may also show that structures that seemingly involve the esophagus actually do not. An obstruction is suggested on contrast-enhanced esophagrams if the barium column terminates abruptly as it travels caudally; weakness usually causes contrast to be retained throughout the esophagus or the weakened segment of the esophagus (Fig. 27.3). A partial obstruction is suggested by retention of barium-impregnated food but not liquid barium (see Fig. 29.7).

A barium contrast study will not always reveal a hiatal hernia (Fig. 29.4). Some hiatal hernias slide in and out of the diaphragm and may be normally positioned when the radiograph is taken. Gastroesophageal reflux and esophagitis also may be difficult to diagnose radiographically. Barium may adhere to a severely diseased mucosa, but less severe esophagitis may not be detected. Normal dogs may have an episode of gastroesophageal reflux during a contrast study, whereas dogs with pathologic gastroesophageal reflux may not have reflux during a short examination.

If the animal is believed to be regurgitating but the barium contrast–enhanced radiographs are unrevealing, either the assessment of regurgitation is wrong or there is occult disease

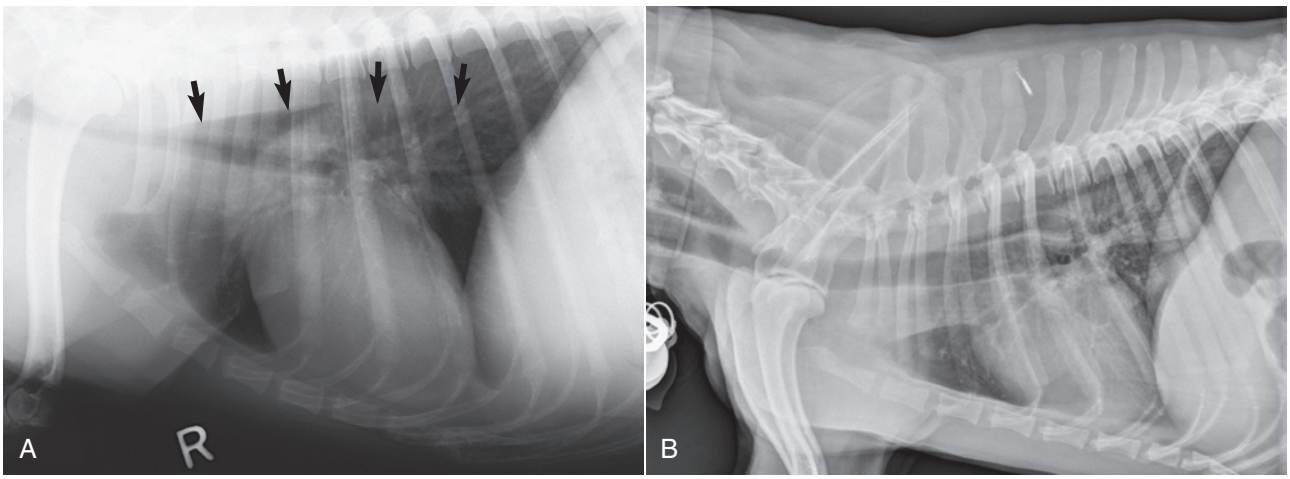

FIG 27.1
(A) Lateral thoracic radiograph from a dog that was seen because of coughing. Note the dilated, air-filled esophagus *(arrows)*. Contrast-enhanced esophagram (with fluoroscopy) obtained 2 days later documented normal esophageal size and function. **(B)** Lateral thoracic radiograph from a dog that is coughing and spitting up food occasionally. There is minimal air accumulation in the thoracic esophagus, but there is substantial air accumulation in the cervical esophagus immediately behind the cricopharyngeous sphincter. The dog has major esophageal dysfunction, primarily in the cervical esophagus. This image shows how easy it is to miss segmental esophageal weakness of the cervical esophagus on plain radiographs.

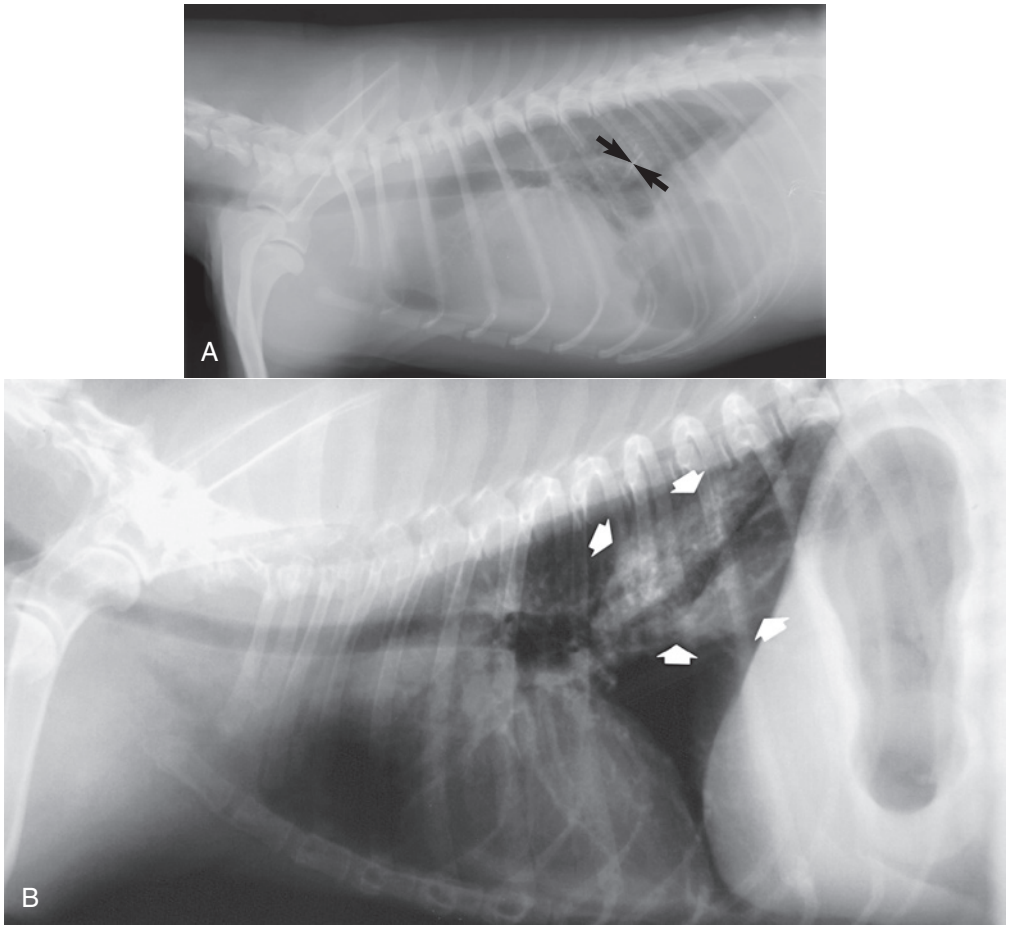

FIG 27.2
(A) Lateral thoracic radiograph from a dog with a foreign object in the esophagus *(arrows)*. Note the concomitant pleural effusion. A chicken bone had perforated the esophagus, and septic pleuritis was present. **(B)** Lateral thoracic radiograph from a dog with a rawhide treat in the esophagus. The density representing the bone *(arrows)* is more diffuse than was seen in **(A)** and looks more like a pulmonary parenchymal density than a bone. (**A** from Allen D, ed.: *Small animal medicine,* Philadelphia, 1991, JB Lippincott.)

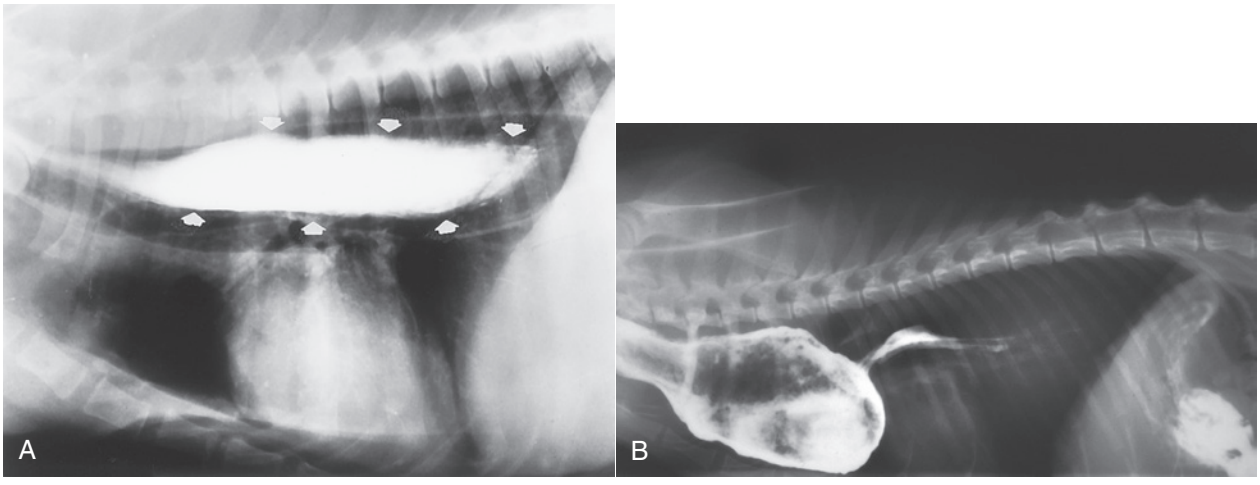

FIG 27.3

Note that barium is retained throughout the length of the esophagus *(arrows)*. **(B)** Lateral thoracic contrast-enhanced radiograph of a cat with an esophageal obstruction caused by a vascular ring anomaly.

in which case reexamination of the esophagus with endoscopy or fluoroscopy or both are required.

IMAGING OF THE STOMACH AND SMALL INTESTINE

INDICATIONS FOR RADIOGRAPHIC IMAGING OF THE ABDOMEN WITHOUT CONTRAST MEDIA

Common indications for plain abdominal radiography include vomiting, acute abdomen, constipation, hyporexia, abdominal pain, abdominal enlargement, abdominal distention, or a mass. Plain radiographs are rarely beneficial in animals with a marked abdominal effusion (the fluid obliterates serosal detail) or with chronic diarrhea. Plain abdominal radiographs can be especially helpful in detecting radiodense foreign objects and alimentary tract dilation caused by obstruction.

Techniques

The clinician always should obtain at least two radiographic views, usually right lateral and VD projections. Cleansing enemas may improve the diagnostic usefulness of radiographs in patients with a great deal of feces; however, a critically ill animal or one with an acute abdomen generally should not have an enema unless plain radiographs show it is necessary.

Findings

Plain abdominal radiographs may detect masses, foreign objects, a gas- or fluid-distended hollow viscus, misshapen or emphysematous parenchymal organs, pneumoperitoneum, abdominal effusions, and displaced organs suggestive of a mass or adhesion.

Gastric outflow tract obstruction is easy to diagnose when there is marked gastric distention (Fig. 27.4). However, if the patient has recently vomited, the stomach may be empty and contracted. Gastric dilation, especially with volvulus, is easily recognized (see Fig. 30.3). Radiodense foreign objects are easily seen, but radiolucent foreign objects are seen only if they are outlined by swallowed air.

Intestinal obstructions are typically easier to diagnose with plain radiographs than are gastric obstructions. Obstructed intestines distended with air, fluid, or ingesta are not readily emptied when the patient vomits (unless it is a high duodenal obstruction) in contrast to an obstructed stomach, which is relatively easy to empty. Intestinal distention (i.e., ileus) may be caused by inflammation (i.e., adynamic or physiologic ileus) as well as obstruction (i.e., mechanical, occlusive, or anatomic ileus). Anatomic ileus (i.e., obstruction) typically produces a non-uniform intestinal distention with a greater degree of distention than is seen with physiologic ileus (Fig. 27.5). If "stacking" of the distended intestines or sharp bends and turns in the dilated intestines are seen, this also suggests anatomic ileus. Standing lateral radiographs rarely aid in differentiating anatomic from physiologic ileus. Even experienced radiologists occasionally confuse physiologic ileus with obstruction. Thus diseases producing severe inflammation (e.g., parvoviral enteritis) may closely mimic intestinal obstruction.

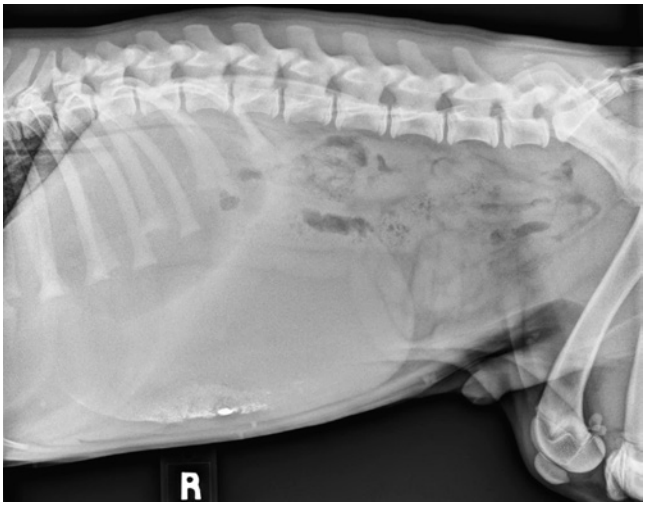

FIG 27.4
Plain lateral radiograph from a dog with gastric outflow obstruction. Note the dilated stomach protruding past the costal arch. This radiographic pattern is not sensitive for outflow obstruction, but it is relatively specific.

Special types of intestinal obstructions are associated with unique radiographic findings. If the entire intestinal tract is uniformly distended with gas (Fig. 27.6) and the clinical signs fit, mesenteric volvulus may be diagnosed. If marked intestinal distention is very localized and seems out of place (e.g., has herniated), a strangulated or incarcerated intestinal obstruction (see Fig. 31.11) should be considered.

Linear foreign bodies rarely produce gas-distended bowel loops. Instead, they tend to cause the intestines to bunch together; sometimes small gas bubbles are present (see Fig. 31.12). This occurs because the intestines "gather" around the linear foreign object as they try to propel it aborad. This "gathering" or "bunching" plus the fact that linear foreign bodies tend primarily to affect the upper small intestines (i.e., duodenum) mean that it is rare that they cause severely gas-distended loops of bowel. Sometimes pleated (i.e., "accordion-like") intestines can be seen on plain radiographs (see Fig. 31.12).

It is difficult to determine the thickness of intestines on plain radiographs. Animals with diarrhea and an increased amount of intestinal fluid are often misdiagnosed as having thickened intestinal walls.

Decreased serosal contrast is due to either lack of fat or excessive abdominal fluid (see Chapter 34). Displacement of an organ (Fig. 27.7) often means there is a mass present. Pneumoperitoneum is diagnosed if both the thoracic and abdominal surfaces of the diaphragm or if the serosal surfaces of the liver, stomach, or kidneys are easily seen (see Fig. 32.1, *A*). However, perforation sometimes causes only

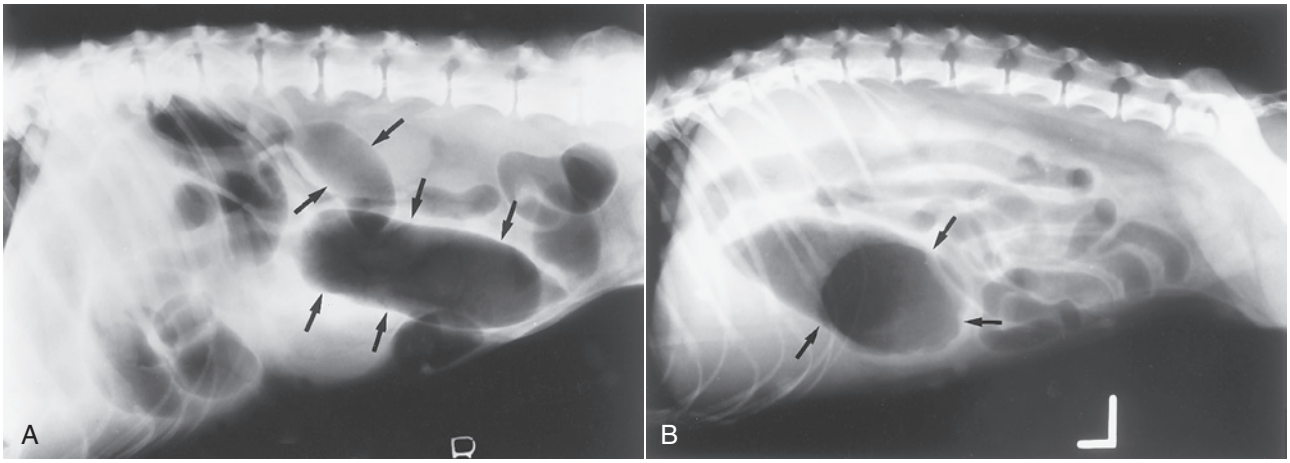

FIG 27.5
(A) Plain lateral abdominal radiograph from a dog with an intestinal obstruction causing intestinal distention. Note the markedly increased diameter of the small intestinal lumen *(arrows)*. **(B)** Plain lateral abdominal radiograph from a dog with peritonitis causing physiologic ileus. Note the lesser degree of small intestinal distention compared with that in **A.** The large gas-filled structure is the gastric pylorus *(arrows)*. (Courtesy Dr. Kenita Rogers, Texas A&M University, College Station, TX.)

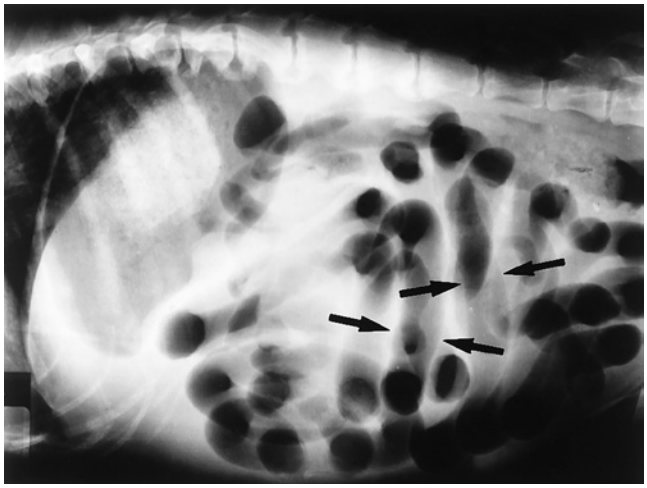

FIG 27.6
Lateral abdominal radiograph from a dog that had an acute onset of vomiting, abdominal pain, and shock. There is a uniform intestinal distention that is not as great as that in Fig. 27.5, *A*. However, distention is more than that seen in Fig. 27.5, *B*. Some intestinal loops have assumed a vertical orientation *(arrows)*, which suggests the existence of an obstruction. This dog had a mesenteric volvulus. (Courtesy Dr. Susan Yanoff, U.S. Military.)

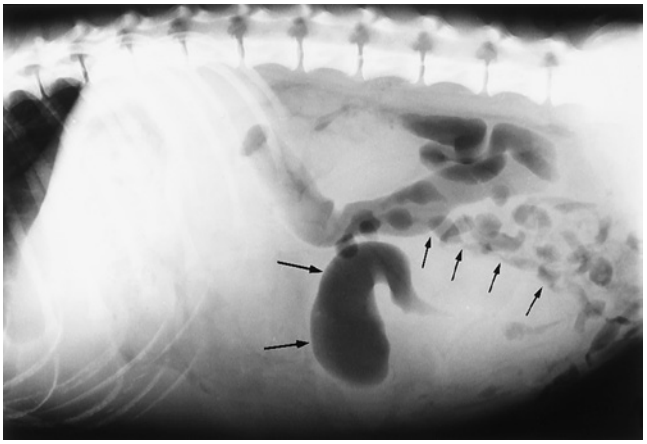

FIG 27.7
Lateral abdominal radiograph from a dog with a large granuloma caused by pythiosis. Small intestinal loops are displaced dorsally and caudally *(small arrows)*. The border of the mass is not discernible except where it displaces small intestinal loops. The finding of a dilated intestinal loop *(long arrows)* is consistent with obstruction.

there to be a few gas bubbles in the peritoneal cavity (see Fig. 32.1, *B*).

INDICATIONS FOR ULTRASONOGRAPHY OF THE STOMACH AND SMALL INTESTINES

Ultrasonography is particularly useful for detecting intussusceptions, pancreatitis, abdominal infiltrative disease, and small amounts of effusion not seen radiographically; evaluating the hepatic parenchyma; and identifying abdominal neoplasia in animals with abdominal effusion. Ultrasonography is much more revealing than radiography in animals with minimal body fat that have little or no radiographic contrast in the abdomen. However, very dehydrated animals may be difficult to image with ultrasound, and it is easy to miss small foreign objects (especially in the stomach/intestines if food and gas are present). Ultrasonography will not detect bony changes and modest microhepatica that are

detected by radiographs. The skill of the ultrasonographer determines the usefulness of the technique.

Technique

Before ultrasonography is performed, the abdominal hair is usually clipped to improve the quality of the examination. This is not necessary in animals with minimal hair. Because air in the stomach or intestines limits the usefulness of ultrasonography, exercise, drugs (e.g., some narcotics) that cause hyperventilation, and enemas should be avoided before the examination. The clinician should not hesitate to sedate the dog if it is hyperactive or hyperventilating.

Findings

Ultrasonography detects almost any soft tissue change that plain radiographs detect, plus gastric and intestinal infiltrates (Fig. 27.8, *A*), intussusceptions (see Fig. 27.8, *B*), enlarged lymph nodes (see Fig. 27.8, *C*), masses (see Fig. 27.8, *D*), some radiolucent foreign objects, and small amounts of free peritoneal fluid that radiographs cannot detect. If

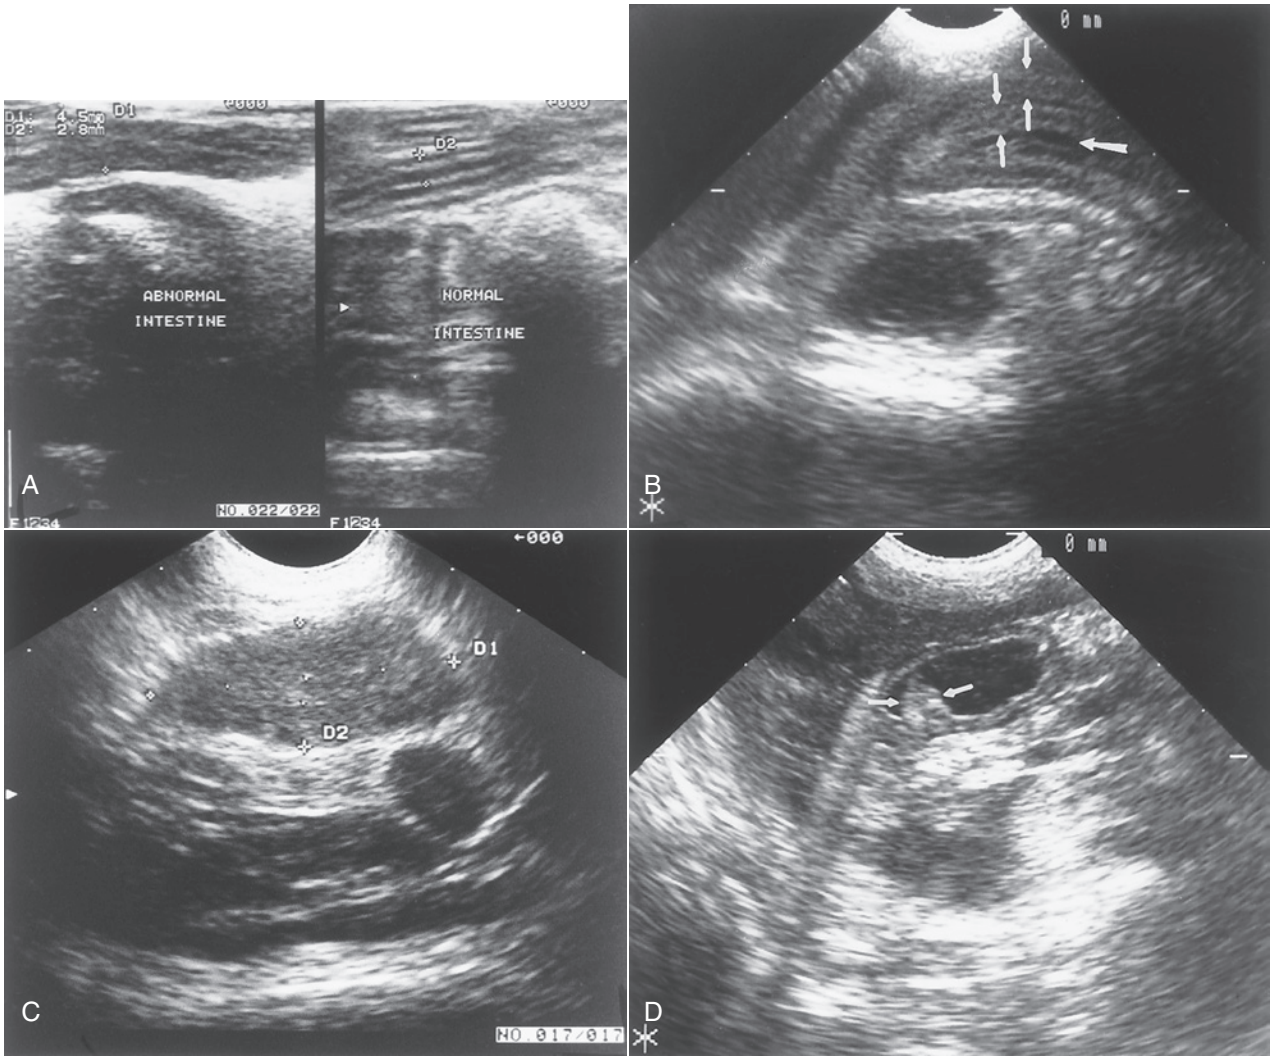

FIG 27.8
(A) Ultrasonographic image of two sections of small intestine from a cat with an alimentary tract lymphoma. The normal intestine on the right is 2.8 mm thick (see the two "+'s" noted as D2), whereas the abnormal intestine on the left is 4.5 mm thick (D1) because of neoplastic infiltrates. **(B)** Ultrasonographic image of an ileocolic intussusception that was not obvious on plain abdominal radiographs. There are two intestinal walls *(small arrows)* seen on each side of the lumen *(large arrow)*. **(C)** An enlarged mesenteric lymph node in a dog caused by lymphoma, seen by ultrasonography. The lymph node was not detected on radiographs or by abdominal palpation. **(D)** Ultrasound image of the gastric antrum from a dog with benign gastric polyps. One polyp can be seen *(arrows)* protruding into the gastric lumen. (Courtesy Dr. Linda Homco, Cornell University, Ithaca, NY.)

tissue infiltrates are found, they can sometimes be aspirated by the fine-needle technique.

INDICATIONS FOR CONTRAST-ENHANCED GASTROGRAMS

Since the advent of ultrasonography, contrast gastrograms are seldom required. However, they may be considered in vomiting animals when ultrasound studies and plain abdominal radiographs are unrevealing. It is primarily useful to detect gastric masses/foreign bodies and gastric motility problems. Endoscopy is usually a better choice to examine the stomach unless there is a primary motility problem (rare).

Technique

The animal should not be allowed to eat for at least 12 hours (preferably 24 hours) before the procedure, and feces should be removed with enemas. Plain radiographs should be obtained immediately before the contrast-enhanced films to verify that the abdomen has been properly prepared, that the radiographic technique is correct, and that the diagnosis cannot be made on the basis of the plain radiographic findings alone. Liquid barium sulfate is then administered orally (8-10 mL/kg in small dogs and cats and 5-8 mL/kg in large dogs). Iohexol can be administered orally (i.e., 700-875 mg I/kg, which is usually about 1¼ to 1½ mL/kg). The agent should be administered via a stomach tube to ensure adequate gastric filling and optimal evaluation of the stomach. The animal should not receive motility-altering drugs (e.g., xylazine, ketamine, parasympatholytics) that delay outflow.

Immediately after barium administration, radiographs are taken in left and right lateral plus DV and VD projections. Lateral and DV projections should be obtained again at 15 and 30 minutes and perhaps hourly from 1 to 3 hours. The right lateral view causes barium to pool in the pylorus, the left lateral view causes it to pool in the gastric body, the DV view causes it to pool along the greater curvature, and the VD view allows better evaluation of the pylorus and antrum. Double-contrast gastrograms provide more detail than single-contrast gastrograms. They are performed by administering and immediately removing barium via a stomach tube and then insufflating the stomach with gas until it is mildly distended.

If available, fluoroscopy is best performed immediately after administration of the barium. It can be used to evaluate gastric motility, gastric outflow, and the maximal opening size of the pylorus. If the animal is fed barium mixed with food (recommended only if gastric outflow tract obstruction is suspected despite normal liquid barium study findings), gastric emptying will be markedly delayed compared with that seen when the animal is fed liquid barium.

Findings

Gastric emptying is considered delayed if liquid barium does not enter the duodenum within 15 to 30 minutes after administration or if the stomach fails to almost completely empty the liquid barium within 3 hours. Luminal filling defects (e.g., growths and radiolucent foreign objects), pyloric lesions preventing gastric emptying, and infiltrative lesions may be seen using this method. However, normal peristalsis, ingesta, or gas bubbles may resemble an abnormality, so a change must be seen on *at least* two separate films before the clinician can diagnose disease.

Contrast-enhanced gastrograms are very insensitive for detecting ulcers and useless for erosions. Ulcers are documented radiographically if barium is seen to enter the gastric or duodenal wall or if a persistent spot of barium is identified in the stomach long after the organ has emptied itself of the contrast agent. The duodenum should be scrutinized in a search for constrictions and infiltrative lesions because many vomiting animals have disease there (e.g., inflammatory bowel disease, tumors) rather than in the stomach (see Chapter 31).

INDICATIONS FOR CONTRAST-ENHANCED STUDIES OF THE SMALL INTESTINE

Vomiting is the principal albeit rare reason for performing contrast studies of the upper small intestine. Contrast-enhanced radiographs can typically distinguish anatomic from physiologic ileus but are almost never needed for that purpose. Orad obstructions are easier to demonstrate than aborad ones. If a very aborad obstruction is suspected (e.g., ileocolic intussusception), a barium enema (or preferably ultrasonography) is often better than an upper GI contrast series. Although linear foreign objects usually produce subtle findings on plain radiographs, they often cause a classic "pleating" or "bunching" of the intestines on contrast films (see Fig. 31.12, *C*).

Animals with diarrhea seldom benefit from contrast studies of the intestines because normal radiographic findings do not exclude severe intestinal disease. Even if radiographic findings indicate infiltrative disease, it is still necessary to obtain a biopsy specimen to determine the cause. It is usually more cost-effective to skip contrast-enhanced radiographs and perform endoscopy or surgery.

Use of iodinated contrast agents (preferably iohexol) is reasonable if an alimentary tract perforation is suspected. However, if spontaneous septic peritonitis is strongly suspected, it can usually be definitively diagnosed by ultrasound-guided abdominocentesis and fluid analysis, which reveals septic peritonitis. If ultrasound is unavailable and blind abdominocentesis is unrevealing in such a patient, it is often better to perform a thorough exploratory laparotomy than contrast-enhanced radiography.

Contrast CT of the GI tract is possible but is seldom needed and can be difficult to critically evaluate.

Technique

Liquid barium sulfate is administered as described for contrast-enhanced gastrography. Lateral and VD radiographs should be obtained immediately and then 30, 60, and 120 minutes after barium administration. Additional films are obtained as necessary. The study is completed once

contrast has reached the colon. If chemical restraint is absolutely necessary, acetylpromazine may be used. Fluoroscopy is rarely needed for these studies.

Hypertonic iodinated contrast agents are inferior to barium for small intestinal studies because they decrease the intestinal transit time and can cause considerable fluid shifts by osmotically drawing fluid into the GI tract. Their potential advantages rarely outweigh their disadvantages. Isotonic iodinated contrast agents are safer and produce better detail than the hypertonic iodinated compounds but are still less diagnostic than barium.

Findings

In a complete intestinal obstruction, the barium column cannot advance beyond a certain point, and the intestines orad to this point are typically dilated. A partial obstruction may be denoted by delayed passage past a certain point (there may or may not be dilation of the intestines orad to this point) or constriction of the lumen. Because it is easy to overinterpret contrast-enhanced radiographs of the intestines, changes must be seen on *at least* two different films taken at different times before a disease is diagnosed.

"Enteritis" is often incorrectly diagnosed if a fine "brush border" in the lumen is found. However, this finding actually results from the barium normally distributing itself among villi, not from enteritis. Infiltration from neoplasia or inflammatory infiltrates classically causes scalloped margins (sometimes called *thumb-printing*). However, its absence does not rule out infiltrative disease. Focal dilations not caused by obstruction (i.e., diverticula) are rare and usually represent a localized neoplastic infiltrate. In rare instances, unsuspected intestinal blind loops or short-bowel syndromes may be detected. Motility problems may cause slowed passage of the contrast through the alimentary tract, but hypomotility is usually due to obstruction or abdominal inflammation.

INDICATIONS FOR BARIUM CONTRAST ENEMAS

This is a largely outdated procedure that is almost never done anymore. It might be useful if there is a severe colonic lesion and ultrasound and colonoscopy are not available. The reader is referred to earlier editions of this text for more information on barium contrast enhanced enemas.

PERITONEAL FLUID ANALYSIS

Fluid analysis is discussed in detail in Chapter 34. The fluid is obtained by performing abdominocentesis with a syringe and needle. If this technique fails, a multifenestrated catheter (e.g., dialysis catheter) may be successful. It is sometimes best to allow fluid to spontaneously drain out of the catheter without applying negative pressure.

If peritoneal inflammation is suspected but abdominal fluid cannot be retrieved, a diagnostic peritoneal lavage may be performed. In this method a sterile catheter (preferably with multiple fenestrations) is inserted into the abdomen and warm, sterile physiologic saline solution (20 mL/kg) is administered rapidly. The abdomen is massaged vigorously for 1 to 2 minutes, and then some of the fluid is aspirated. The aspirate is evaluated cytologically.

DIGESTION AND ABSORPTION TESTS

Exocrine pancreatic function may be tested by measuring fecal proteolytic activity (not recommended), fat absorption with and without pancreatic enzymes (not recommended), or serum TLI (recommended).

Serum TLI is the most sensitive and specific test for EPI and is convenient (i.e., submit 1 mL of refrigerated serum obtained after an overnight fast) and readily available. The TLI assay detects circulating proteins produced by a normally functioning exocrine pancreas and is even valid in animals receiving pancreatic enzyme supplements orally. It is important to use an assay that is specifically designed for the species being tested. Pancreatitis, renal failure, and severe malnutrition may increase the serum TLI concentrations, but this rarely causes results to be misinterpreted. However, if EPI is caused by obstruction of the pancreatic ducts (rare) as opposed to acinar cell atrophy or destruction (common), the serum TLI test may not detect maldigestion. In such cases, a quantitative fecal proteolytic assay is required.

Normal dogs have serum TLI activities of 5.2 to 35 µg/L. Values of less than 2.5 µg/L confirm a diagnosis of EPI. Values between 2.5 to 5.2 ug/L should be rechecked later. Normal cats have higher values (28-115 µg/L). The serum TLI assay is primarily indicated in patients with chronic small intestinal diarrhea or chronic weight loss of unknown origin. Feline EPI is less common than canine EPI, but the test is still a good idea in cats. Although principally used to detect EPI, serum TLI values substantially greater than normal are suggestive of pancreatitis.

SERUM CONCENTRATIONS OF VITAMINS

Serum concentrations of cobalamin and folate are sometimes helpful in animals with chronic small intestinal diarrhea or chronic weight loss. These tests may provide evidence of severe small intestinal mucosal disease; however, they are insensitive for small intestinal disease and not specific for any particular intestinal disease. Dietary cobalamin is absorbed in the intestine, principally the ileum; hence, ileal disease is thought to be particularly likely to cause hypocobalaminemia ostensibly because of malabsorption of the vitamin. Cobalamin concentrations are usually decreased in dogs with EPI, possibly because of the abnormalities in small intestinal bacterial populations in such animals. Severe mucosal disease, especially in the region of the ileum, may also cause serum cobalamin concentrations to be decreased. Perhaps the major indications for measuring serum cobalamin are to look for evidence of intestinal disease in patients

with weight loss of uncertain cause and to better define cats with known small intestinal disease (cobalamin-deficient cats can experience metabolic complications). If the serum cobalamin is low in a patient with weight loss of unknown cause, small intestinal disease may be responsible. B-complex vitamin supplementation may cause an increased serum cobalamin concentration.

Dietary folate is absorbed in the small intestine. Excessive numbers of bacteria in the upper small intestine sometimes synthesize and release folate, causing the serum concentrations to be increased. Likewise, severe intestinal mucosal disease may decrease absorption, causing lower serum concentrations. B-complex vitamin supplementation may increase serum folate concentrations. Like cobalamin, folate concentrations are insensitive for intestinal disease and not specific for any particular intestinal disease. Because bright light degrades cobalamin, samples should be frozen and kept in the dark during storage and transport.

OTHER SPECIAL TESTS FOR ALIMENTARY TRACT DISEASE

Antibodies to acetylcholine receptors should be measured if the clinician is looking for localized myasthenia, which is a potential cause of dysphagia or esophageal weakness (see p. 454). Increased titers to such antibodies are strongly suggestive of myasthenia gravis, even if there are no systemic signs. False-positive results are rare. Serum can be sent to Dr. Diane Shelton (Comparative Neuromuscular Laboratory, Basic Science Building, University of California at San Diego, La Jolla, CA 92093-0612) for this analysis.

Measurement of antibodies to 2M muscle fibers can be helpful in dogs with suspected masticatory muscle myositis (see p. 451). These antibodies are typically not found in dogs with polymyositis, whereas most dogs with masticatory myositis do have them. Serum is required for the test and can be sent to Dr. Diane Shelton for testing.

Serum gastrin concentrations are measured in animals with signs suggestive of gastrinoma (i.e., chronic vomiting, weight loss, and diarrhea in older animals, especially if there is concurrent esophagitis or duodenal ulceration). Gastrin stimulates gastric acid secretion and is trophic for gastric mucosa. Serum for assay of gastrin is harvested from an animal after an overnight fast and rapidly frozen. The serum gastrin concentration may be increased in animals with gastrinoma, a gastric outflow tract obstruction, renal failure, short-bowel syndrome, or atrophic gastritis and those receiving proton pump inhibitors (histamine-2 [H_2] receptor antagonists cause a lesser increase). Resting serum gastrin concentrations may vary, with occasional values in the normal range in animals with gastrinoma. Provocative testing should be considered in dogs strongly suspected of having gastrinoma but with normal baseline serum gastrin concentrations (see Chapter 49).

Testing for urease activity in gastric mucosa for *Helicobacter* spp. is rarely done anymore. *Helicobacter* spp. can usually be found easily by histology. For more information on urease activity, please see prior editions of this textbook.

Fecal α_1-protease inhibitor can be measured in feces and is a marker for GI protein loss. Clinically this test is rarely indicated but could be helpful when trying to distinguish whether hypoalbuminemia is at least partly due to a protein-losing enteropathy in a patient with known renal protein loss or hepatic insufficiency. The test is performed by the GI Lab at Texas A&M University.

Tests for *Pythium insidiosum* are available. ELISA tests for antibodies and PCR testing for antigen can be done at the College of Veterinary Medicine, Louisiana State University, Baton Rouge, LA 70803.

ENDOSCOPY

Endoscopy can be cost effective in animals with chronic vomiting, diarrhea, or weight loss if cases are selected carefully and the endoscopist is accomplished. It permits rapid exploration of selected sections of the alimentary tract and mucosal biopsy without the need for a thoracotomy or laparotomy. Although excellent for detecting morphologic changes (e.g., masses, ulcers, obstruction), it is insensitive for revealing abnormal function (e.g., esophageal weakness).

Rigid endoscopy of the colon is easier to perform and less expensive than flexible endoscopy, and it provides excellent biopsy samples. Flexible endoscopes allow one to examine the ileocolic and cecocolic valve areas as well as the ascending and transverse colons, areas that cannot be inspected with a rigid endoscope. Flexible instruments are expensive and require time and commitment to become proficient in their use. One is limited by how far the instrument can be advanced. Expertise is required to obtain diagnostic tissue samples without excessive artifacts.

Esophagoscopy is useful in looking for esophageal tumors (Fig. 27.9), foreign objects (Fig. 27.10), inflammation (Fig. 27.11), and obstruction (Fig. 27.12). Foreign objects and cicatrix are preferentially treated endoscopically. It is important to enter the stomach and retroflex the scope's

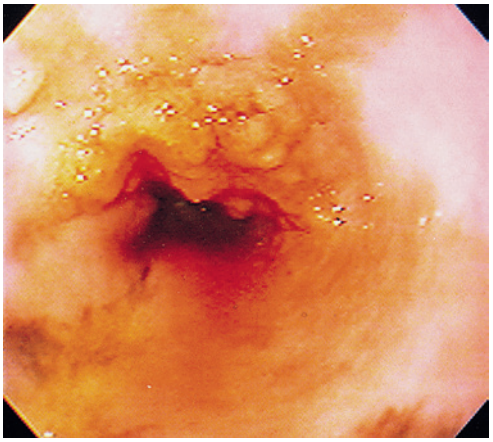

FIG 27.9

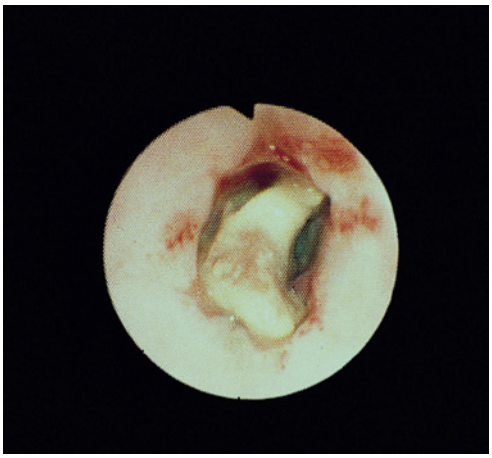

FIG 27.10
Endoscopic view of the esophagus of a dog with a chicken neck bone lodged in it. The bone was ultimately removed with a rigid scope and alligator forceps.

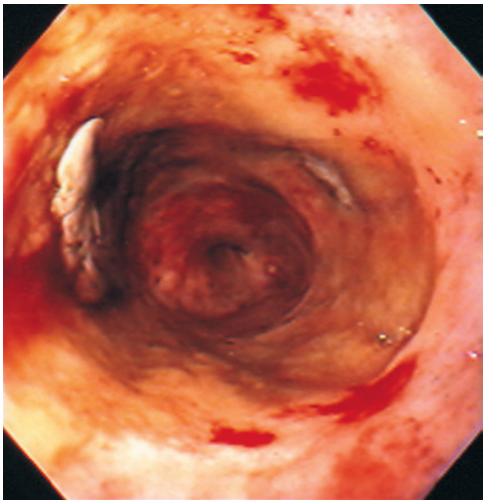

FIG 27.11
Endoscopic view of the distal esophagus of a dog with severe esophagitis secondary to a bone foreign body. Note the white plaque in the 9 o'clock position that is due to pressure necrosis from the foreign body.

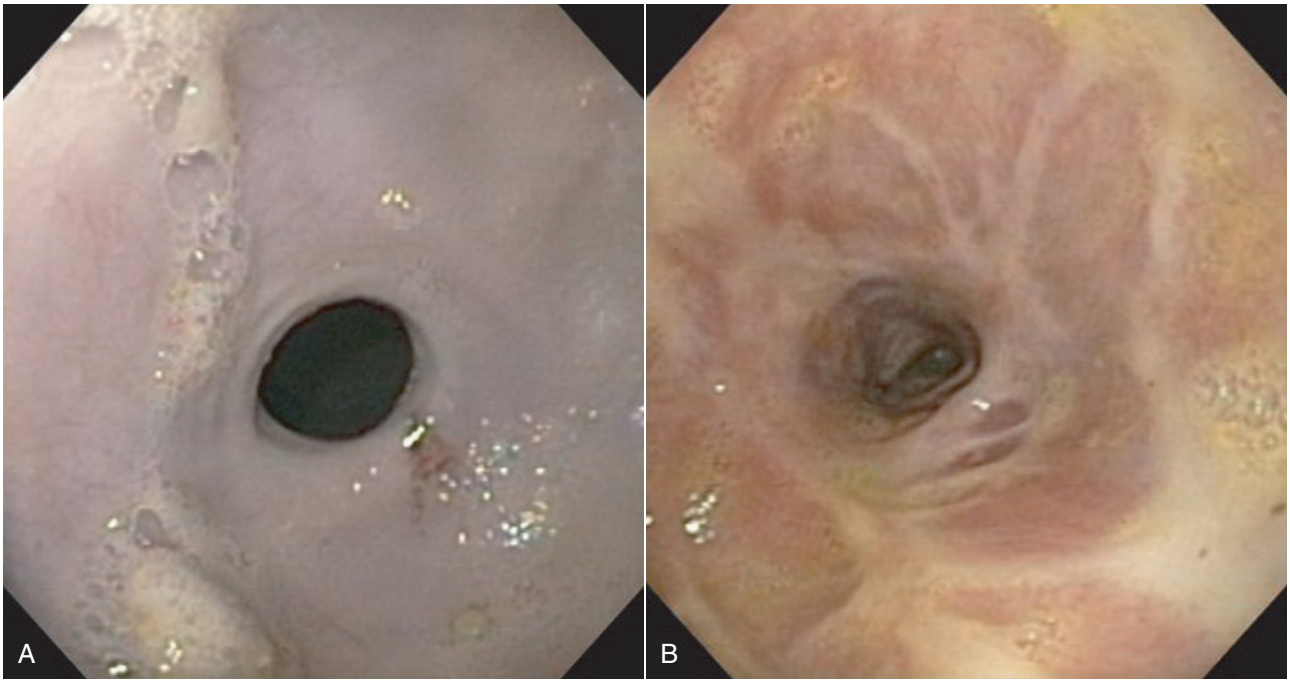

FIG 27.12
(A) Endoscopic view of a dog with an esophageal stricture. Note the obvious, circumferential narrowing. **(B)** Another endoscopic view of a dog's esophagus with an obvious narrowing. In this case, there are numerous, pale scars demonstrating that severe esophagitis was present at one time.

tip to view the lower esophageal sphincter area to detect leiomyomas (Fig. 27.13). The esophageal lumen is covered with squamous epithelium that cannot readily be pulled off with typical flexible endoscopic forceps. Therefore if esophageal mucosal biopsy specimens are desired, flexible endoscopes are typically inadequate unless the distal feline esophagus is being biopsied or there is a tumor or severe inflammation.

Although esophagoscopy may occasionally detect esophageal weakness, it is insensitive. Not all foreign objects can be safely removed endoscopically, and the clinician must guard against rupturing a diseased esophagus while trying

FIG 27.13
View of the lower esophageal sphincter (as seen from the stomach) of a dog with a leiomyoma (mass covered with normal-appearing mucosa). This tumor was causing vomiting and regurgitation.

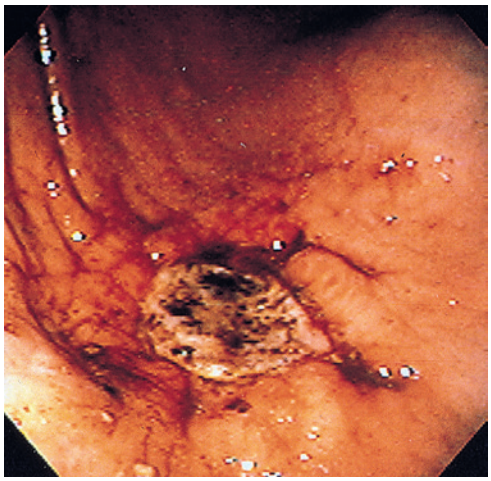

FIG 27.14
Endoscopic view of a gastric ulcer on the greater curvature in a Chow. Note that it is obvious that the mucosa is eroded to the level of the submucosa.

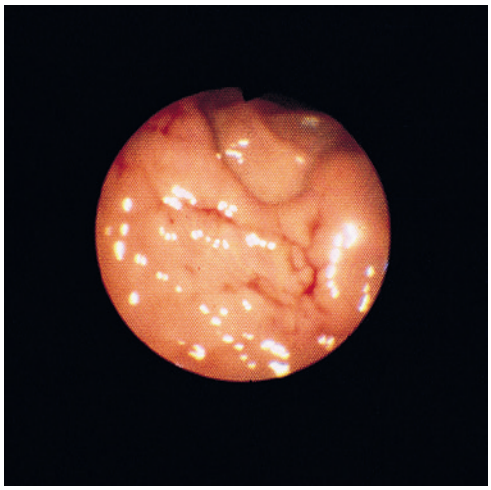

FIG 27.15
Endoscopic view of the gastric mucosa of a dog's stomach that has obvious bleeding. This dog had received nonsteroidal drugs, and the bleeding represented erosions that could not be detected with radiographs or ultrasonography. (From Fossum T, ed.: *Small animal surgery,* St Louis, 1997, Mosby.)

to extract a foreign object. Finally, care must be taken to avoid creating gastric distention in patients with esophageal strictures or tension pneumothorax in animals with an esophageal perforation.

Rigid endoscopy is often more useful than flexible endoscopy in removing esophageal foreign objects. Rigid endoscopes can protect the esophagus during extraction of the object and allow use of rigid forceps that permit the endoscopist greater control. Care must be taken to maintain the animal's esophagus as straight as possible when using a rigid endoscope. If a flexible endoscope is used to remove a foreign body, it is sometimes helpful to pass it through a rigid scope or tube that has been passed through the cricopharyngeal sphincter; this may facilitate retrieval of the foreign object through the sphincter.

Gastroduodenoscopy and biopsy are indicated in selected animals with vomiting, apparent upper GI blood loss, suspected gastroduodenal reflux, or small intestinal disease. It is more sensitive and specific than radiography for detecting mucosal ulcers (Fig. 27.14), erosions (Fig. 27.15), tumors (Fig. 27.16), and inflammatory lesions (Figs. 27.17 to 27.19). Endoscopy is also quicker and less stressful to the animal than exploratory laparotomy. Many foreign objects in the upper GI tract (Fig. 27.20) can be removed endoscopically, and multiple biopsy specimens can be obtained. Occasionally, unexpected diagnoses (e.g., *Physaloptera* infection; Fig. 27.21) may be found. It may be necessary to use endoscopes with outer diameters of 9 mm or less in dogs and cats weighing less than 4 to 5 kg. Whenever possible, a scope with a 2.8-mm biopsy channel should be used to obtain larger tissue specimens and allow the use of better foreign object retrieval devices.

The stomach must be as empty as possible when gastroduodenoscopy is performed, which usually necessitates at least a 24-hour fast; many animals undergoing gastroscopy may not empty their stomachs as rapidly as would a dog without abdominal disease. During the procedure the stomach must be adequately inflated with air to allow thorough evaluation of its mucosa. Suction must be available to remove secretions or air. The endoscopist must inspect the mucosa methodically. It is particularly easy to miss lesions (e.g., ulcers or *Physaloptera*) just inside the pylorus. Biopsy

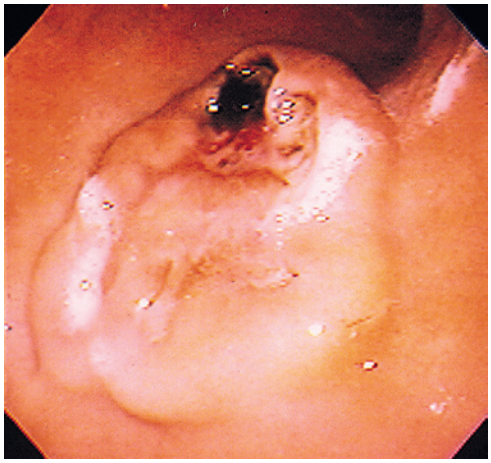

FIG 27.16
Endoscopic view of the stomach of a dog with an obvious mass in the greater curvature. This is an ulcerated leiomyosarcoma that was successfully removed.

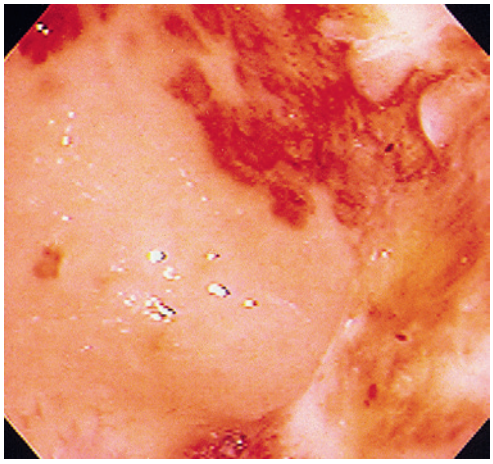

FIG 27.17
Endoscopic view of the stomach of a cat with diffuse inflammation, erosion, and ulceration of unknown cause.

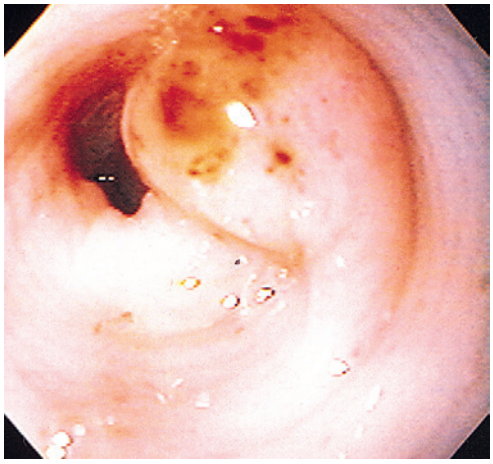

FIG 27.18

specimens of the gastric and duodenal mucosa should always be obtained because normal gross findings do not rule out severe mucosal disease. Like esophagoscopy, gastroduodenoscopy is not sensitive in identifying functional problems (i.e., gastric hypomotility).
