Proctoscopy or colonoscopy is indicated in dogs and cats with chronic large bowel disease unresponsive to appropriate dietary, antibacterial, or anthelmintic therapies as well as those that are losing weight, are hypoalbuminemic, or are at increased risk for specific diseases (e.g., histiocytic ulcerative colitis in Boxers). Colonoscopy plus biopsy is more sensitive and definitive for infiltrative diseases than imaging. Proctoscopy is used in animals with obvious rectal abnormalities (e.g., mass or stricture felt on digital rectal examination). Rigid biopsy forceps obtain excellent tissue samples that allow identification of most lesions, including submucosal ones. Biopsy instruments used with flexible endoscopes do not obtain as deep a tissue specimen but are adequate for sampling mucosal lesions.

Proctoscopy and colonoscopy are easier to perform, require less restraint, and do not always require the more expensive flexible equipment demanded by other endoscopic procedures. The colon must be clean to allow proper inspection of the mucosa. All food should be withheld for at least 36 and preferably 48 hours before the procedure, a mild laxative (e.g., bisacodyl) should be administered the night before the procedure, and several copious warm water enemas should be given the night before and the morning of the procedure. Proctoscopy requires less cleaning than colonoscopy. Commercial intestinal lavage solutions (e.g., GoLytely, CoLyte) clean the colon better than enemas and are particularly useful in larger dogs, those that will be undergoing ileoscopy (which necessitates a very clean ileocolic area), and animals in pain that resist enemas. The lavage solution is usually given to the animal twice the night before the procedure and perhaps once the morning of the procedure. In rare cases, it can cause gastric dilation or volvulus, and inadvertent aspiration can be devastating.

Occasional dogs with substantial colonic irritation strain so much that they essentially clean themselves out, and colonoscopy can be performed without cleansing enemas or lavage solutions. These same patients can sometimes be scoped with just manual restraint or mild sedation (Video 27.1). However, many animals undergoing colonoscopy have colonic or rectal irritation, and anesthesia is usually preferred.

Normal colonic mucosa is smooth and glistening, and submucosal blood vessels should be seen (Fig. 27.22). Enema tubes may cause linear artifacts. The colon should distend to a uniform diameter, but it may have bends. If a flexible scope is used, the clinician should identify and inspect the ileocolic valve and the cecum (Figs. 27.23 and 27.24). The clinician should always biopsy the mucosa. While some patients with neoplastic or inflammatory infiltrative diseases have obvious bruising (Video 27.2), normal gross findings do not rule out significant infiltrative disease. Strictured areas with relatively normal-appearing mucosa are usually caused by a

submucosal lesion, in which case biopsying must be aggressive enough to ensure that submucosal tissue is included in the specimen. Cytology can often detect histoplasmosis, protothecosis, some neoplasms, and eosinophilic colitis.

An adult or a pediatric human sigmoidoscope is usually adequate for rigid colonoscopy. The tip of the rigid biopsy forceps should have a shearing action (i.e., one part of the tip should fit into the other when it is closed, thus acting like a pair of scissors) instead of a clamshell (also called "double spoon") action in which the edges of the top and bottom jaws simply meet.

Ileoscopy is principally indicated in dogs with diarrhea and in cats with vomiting or diarrhea. It is performed during flexible colonoscopy and requires thorough colonic cleansing so that the ileocolic valve can be visualized. It is difficult or impossible to enter the ileum of most cats (because of size), but one can often pass biopsy forceps through the ileocolic valve and blindly biopsy the ileal mucosa

FIG 27.22

(Fig. 27.25; Video 27.3). Ileoscopy can be particularly valuable in diagnosing lymphoma in cats when the duodenal biopsies are nondiagnostic.

CAPSULE ENDOSCOPY

Recently capsule endoscopy has been introduced into veterinary medicine. It has primarily been used for looking for bleeding GI lesions but may be useful for diagnosing intestinal lymphangiectasia.

BIOPSY TECHNIQUES AND SUBMISSION

FINE-NEEDLE ASPIRATION BIOPSY

Fine-needle aspiration or core biopsy of enlarged lymph nodes, abdominal masses, and infiltrated abdominal organs

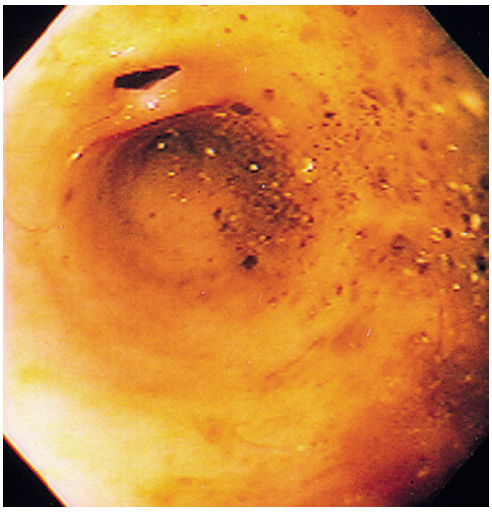

FIG 27.24
Endoscopic view of a normal ileocolic valve region from a cat. The blind pouch is the cecum, and the small opening above it is the ileocolic valve.

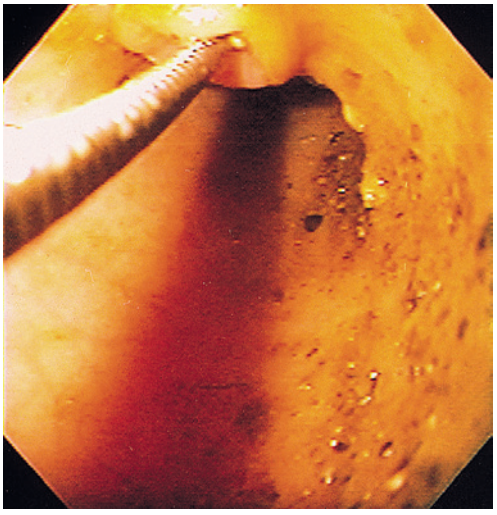

FIG 27.25

may be guided by abdominal palpation or ultrasonography. A 23- to 25-gauge needle is typically used so that any inadvertent intestinal or vascular perforation is not harmful (see Chapter 74).

ENDOSCOPIC BIOPSY

Rigid endoscopy usually provides excellent biopsy samples of the descending colon (i.e., large specimens that include the full thickness of the mucosa, including some muscularis mucosa), but the stomach and small intestine cannot be biopsied with this equipment. Flexible endoscopes can reach more of the alimentary tract, but the tissue samples obtained with these scopes may not always be deep enough to allow submucosal lesions to be diagnosed. Ideally, the tissue to be

biopsied is visualized, but the clinician may blindly pass the biopsy forceps through the ileocolic valve to biopsy the ileum if the tip of the endoscope cannot be advanced into these areas.

Not all laboratories are adept at processing and interpreting endoscopic samples of intestinal tissue. Endoscopes with 2.8-mm biopsy channels are generally preferred to those with a 2.0- or a 2.2-mm channel because the larger forceps allow retrieval of substantially larger and deeper tissue samples.

When intestinal or gastric mucosa is biopsied, the tissue sample must be handled carefully to minimize artifacts and distortion. The tissue should be carefully removed from the biopsy forceps with a 25-gauge needle. A squash preparation of one tissue specimen can be evaluated cytologically, and the remaining samples are fixed in formalin and evaluated histologically. The cytology slides should be evaluated by a pathologist familiar with GI cytology. Cytologic preparations of the gastric mucosa may show adenocarcinoma, lymphoma, various inflammatory cells, or spirochetes (see Fig. 30.1). Cytologic studies of the intestinal mucosa may show eosinophilic enteritis, lymphoma, histoplasmosis, or protothecosis, and occasionally giardiasis, bacteria, or *Heterobilharzia* ova. Cytology is specific but insensitive (i.e., failing to find something does not allow the clinician to eliminate it).

The laboratory should be consulted regarding the proper way to submit endoscopic tissue samples. To simply submit intestinal tissues floating freely in formalin almost guarantees that few if any pieces will be optimally oriented on the histopathology slide. The clinician should place tissues from different locations in different vials of formalin; each vial should be properly labeled. Small tissue samples should not be allowed to dry out or be damaged before placement in formalin.

Two common problems with endoscopically obtained tissue samples are that the sample is too small or there is excessive artifact. Lymphomas are sometimes relatively deep in the mucosa (or are submucosal), and a superficial biopsy specimen may then show only a tissue reaction above the tumor, resulting in a misdiagnosis of inflammation. Multiple biopsy specimens should be obtained until there are at least six to eight samples of excellent size and depth (i.e., the full thickness of mucosa). It is important for the pathologist to inform the clinician whether or not the quality of the tissue samples was adequate for evaluation and if the severity of the histologic lesions found is consistent with the severity of clinical signs.

FULL-THICKNESS BIOPSY

If endoscopy is not available, abdominal surgery may be needed to perform gastric and intestinal biopsies. Full-thickness biopsy specimens obtained surgically can have fewer artifacts than those obtained endoscopically; however, the clinician must consider the pros and cons of surgery in a potentially debilitated or ill animal. Endoscopy allows the clinician to direct the biopsy forceps to lesions that cannot be seen from the serosal surface. If surgery is performed, the entire abdomen should be examined (i.e., literally from the beginning of the stomach to the end of the colon along with all parenchymal organs). Biopsy specimens of the stomach, duodenum, jejunum, ileum, mesenteric lymph nodes, and liver (and the pancreas in cats) should be obtained, regardless of how normal these organs appear, unless an obvious lesion (e.g., a large tumor) is found. The colon is more likely to dehisce than the small intestine, and full thickness colonic biopsies should be avoided unless there is an overriding reason to do them. It is wise not to assume that a grossly impressive lesion is responsible for the clinical signs; rather, the clinician usually should perform a biopsy even when the diagnosis seems obvious. Dehiscence is a major risk if biopsy is occurring in an abdomen that already has septic peritonitis present. It is a concern if the serum albumin concentration is less than 1.5 g/dL, but excellent technique minimizes the risk. The clinician should consider whether esophagostomy, gastrostomy, or enterostomy feeding tubes should be placed in emaciated animals before exiting the abdomen.

CHAPTER 28

General Therapeutic Principles

FLUID THERAPY

Fluid therapy is primarily used to treat shock, dehydration, and electrolyte and acid-base disturbances. Accurately predicting electrolyte and acid-base changes on the basis of clinical parameters is impossible, hence serum electrolyte concentrations typically must be measured in significantly ill patients. Vomiting gastric contents classically but inconsistently produces hypokalemic, hypochloremic, metabolic alkalosis. Loss of intestinal contents classically produces hypokalemia with or without acidosis, but hypokalemic metabolic alkalosis may occur. Vomiting animals are often hypokalemic, but patients with hypoadrenocorticism or severe renal failure may be hyperkalemic. Electrolyte concentrations can quickly be determined by point-of-care methodology. If fluid therapy must be started in a severely ill vomiting patient before electrolyte concentrations are known, physiologic saline solution plus 20 mEq potassium chloride per liter is typically a reasonable choice (Table 28.1), assuming the fluids are administered at one to two times maintenance requirement. If point-care-methodology is unavailable, a lead II electrocardiographic (ECG) tracing may be evaluated to look for evidence of hyperkalemia (see Chapter 53).

Reexpanding the vascular compartment and improving peripheral perfusion alleviates lactic acidosis. Hence, bicarbonate administration is almost never needed, and may in fact be detrimental. Bicarbonate is primarily administered to patients with extreme acidosis (e.g., pH < 7.05 or bicarbonate < 10 mEq/L) that are in imminent danger of dying. Bicarbonate, lactated Ringer's solution, and Normosol-R should not be used if alkalosis seems likely (e.g., vomiting of gastric origin).

Parenteral fluid administration is indicated if the animal is significantly hypovolemic or if absorption of enteral fluids is questionable (e.g., severe intestinal disease, obstruction, vomiting, or ileus). Subcutaneous (SC) fluid administration is acceptable if the animal is not severely dehydrated or in shock, absorbs the fluids, and tolerates repeated SC administration. Multiple SC depots of 10 to 50 mL each are given, depending on the animal's size. Dependent areas should be checked for unabsorbed fluids before administering more fluid SC. Severely dehydrated animals often absorb SC fluids very slowly, making initial intravenous (IV) administration preferred. IV fluid administration is required in patients that are severely dehydrated or are in shock, even if a venous cutdown is necessary. Intramedullary administration may be used if an IV catheter cannot be established. To do this, a large-bore hypodermic needle or a bone marrow aspiration needle (preferable) can be inserted into the femur (trochanteric fossa), tibia, wing of the ilium, or humerus. Fluids can be administered by the intramedullary route at a maintenance rate or faster. Intraperitoneal administration repletes the intravascular compartment more slowly than IV or intramedullary techniques and is not recommended.

Dogs in hypovolemic shock typically have tachycardia, poor peripheral perfusion, cool extremities, prolonged capillary refill time, weak femoral pulse, and/or tachypnea, while dogs in early systemic inflammatory response syndrome (SIRS) initially have red oral mucous membranes, warm extremities, and a strong, bounding femoral pulse before classic signs of shock occur. Treatment of severe shock does not consist of giving a fixed amount of fluids; rather, the clinician gives fluids to effect. This often consists of an initial IV bolus of 10 to 20 mL/kg of an isotonic crystalloid (e.g., lactated Ringer's, Normosol R or Physiologic saline, all typically without supplemental potassium) over 15 to 30 minutes. Next, instead of "blindly" giving a fixed, calculated amount, fluids are administered until the patient is hemodynamically stable, remembering that it is easy to overhydrate cats. Ultimately, one blood volume (i.e., 90 mL/kg for the dog; 50 mL/kg for the cat) is usually administered over the first 1 to 2 hours. However, additional fluids are typically needed 30 to 60 minutes later because the initial crystalloids quickly redistribute into the interstitial compartment. Large dogs in severe shock (e.g., gastric dilation/volvulus) may require two simultaneous 16- to 18-gauge cephalic catheters and IV bags placed in pneumatic compression devices to achieve an adequate flow rate.

Hypertonic saline and/or colloids allow small volume resuscitation, which is easier than administering large

TABLE 28.1

General Guidelines for Initial Potassium Supplementation of Intravenous Fluids

PLASMA POTASSIUM CONCENTRATION (mEq/L)	AMOUNT OF POTASSIUM CHLORIDE (KCl) TO ADD TO FLUIDS GIVEN AT MAINTENANCE RATES* (mEq/L)
3.7-5.0	10-20
3.0-3.7	20-30
2.5-3.0	30-40
2.0-2.5	40-60
≤2.0	60-70

*Do not exceed 0.5 mEq/kg/h potassium except in animals in hypokalemic emergencies, and then only with constant close electrocardiographic monitoring. Be sure to routinely monitor plasma potassium concentrations whenever administering fluids with more than 30 to 40 mEq of potassium per liter.

volumes of crystalloids to large animals. Four to five mL/kg of hypertonic saline solution (i.e., 7%) given IV over 10 to 20 minutes (do not exceed 1 mL/kg/min) is effective for approximately 30 minutes. Hypertonic solutions generally should not be used in animals with hypernatremic dehydration, cardiogenic shock, or renal failure and probably in those with uncontrolled hemorrhage. If necessary, hypertonic saline may be readministered in 2 mL/kg aliquots until a total of 10 mL/kg has been given or until the serum sodium concentration is 160 mEq/L. However, because the volume expansive effects of hypertonic saline last only for approximately 30 minutes, the clinician needs to administer other fluids (usually at a reduced rate until shock is controlled). A mixture of 23.4% saline solution plus 6% hetastarch or pentastarch in a 1:2 ratio administered at 3 to 5 mL/kg gives a longer duration of action than hypertonic saline solution alone.

Colloids (e.g., hetastarch or pentastarch) also draw water from the interstitial compartment into the vascular compartment, but their effects last longer than hypertonic saline and do not increase the total body sodium load. Relatively small volumes can be administered quickly (i.e., in dogs, 5-10 mL/kg slow IV bolus with a maximum of 20 mL/kg/day; in cats, 5-10 mL/kg/day), and the clinician must reduce the subsequent rate of IV fluid administration to prevent hypertension. Colloids should be used with caution in animals with bleeding tendencies. In rare cases, the colloid may go into extravascular compartments, drawing fluid out of the vascular compartment complicating the shock; therefore, close monitoring is required.

Maintenance fluid requirements for dogs weighing between 10 and 50 kg are 44 to 66 mL/kg/day with larger dogs needing less per kilogram than smaller dogs. Dogs weighing less than 5 kg may need 80 mL/kg/day. Cats weighing more than 3 kg need 53 to 61 mL/kg/day. It is important to choose the correct fluid to prevent electrolyte imbalances, especially hypokalemia. In general, potassium should be supplemented if the animal is hyporexic or vomiting, has diarrhea, or is receiving prolonged or intense fluid therapy (see guidelines for administration in Table 28.1). The animal should be monitored for iatrogenic hyperkalemia. Generally, no more than 0.5 mEq K/kg/h should be administered IV. If the animal is not vomiting, oral (PO) potassium supplementation is often more effective than parenteral supplementation. Cats receiving IV fluids often show an initial decrease in their serum potassium concentrations, even if the fluids contain 40 mEq or more of potassium chloride per liter; therefore, severely hypokalemic cats should initially receive oral potassium gluconate, if possible.

Dehydrated animals not in shock are treated by replacing the estimated fluid deficit. First, the degree of dehydration must be estimated. Prolonged skin tenting is usually first noted at 5% to 6% dehydration, but any patient with substantial weight loss may show skin tenting. Obese animals and those with peracute dehydration often do not show skin tenting even with severe dehydration. Dry, tacky oral mucous membranes usually indicate 6% to 7% dehydration. However, well-hydrated, panting, or dyspneic animals can have dry mouths. Multiplying the estimated percentage of dehydration by the animal's weight (in kilograms) determines the liters required to replace deficit. This amount is typically replaced over 2 to 8 hours, depending on the animal's condition. Fluid delivery rate should generally not exceed 88 mL/kg/h. In general, it is better to slightly (not grossly) overestimate rather than underestimate the fluid deficit, unless the animal has congestive heart failure, anuric/oliguric renal failure, severe hypoproteinemia, or pulmonary edema. In general, cats are more easily harmed by excessive fluid administration than are dogs.

Ongoing losses are typically estimated from observations of vomiting, diarrhea, and urination, but it is common to underestimate losses. Weighing the animal or the cage pads that soak up the urine/feces is another way to estimate ongoing losses because acute weight loss is due to fluid loss.

Development of inspiratory pulmonary crackles, a gallop rhythm, or edema (especially cervical) probably indicates overhydration. A new heart murmur is not always a sign of overhydration; severely dehydrated dogs with valvular insufficiency may not have an audible murmur until they are volume replete. Central venous pressure (CVP) is excellent for detecting excessive fluid administration, but it is rarely necessary except in animals with severe cardiac or renal failure and those receiving very aggressive fluid therapy. CVP is normally less than 4 cm H_2O and generally should not exceed 10 to 12 cm H_2O even during aggressive fluid therapy. Poor technique will often produce falsely high CVP readings.

Oral rehydration therapy makes use of the facilitated intestinal absorption of sodium. Co-administration of a monosaccharide (e.g., dextrose) or amino acid with sodium speeds up sodium absorption and subsequent water uptake. This approach works if the animal can ingest oral fluids (i.e.,

is not vomiting) and the intestinal mucosa has reasonable villus function. Absorption primarily occurs in the mature epithelium near the villus tip. Various products for use in people are commercially available, and there are also recipes for making these solutions. Failure to monitor the patient or follow instructions may lead to severe hypernatremia.

The type of fluid therapy used in hypoproteinemic animals depends on the degree of hypoalbuminemia. Excessive fluids can dilute the serum albumin concentration, causing ascites, edema, diminished peripheral perfusion, or a combination of these. Careful calculation of the fluid needs and ongoing losses is therefore necessary. In animals with severe hypoalbuminemia (e.g., serum albumin of 1.5 g/dL or less), it may be desirable to increase plasma oncotic pressure. Administering plasma is not generally recommended because large volumes of plasma are needed to substantially increase serum albumin concentration, making it very expensive. Further, animals with severe protein-losing enteropathies (PLEs) and protein-losing nephropathies rapidly excrete the administered protein, making repeated transfusions necessary. Human albumin has been administered and appears efficacious; however, some animals can die acutely from anaphylaxis. Canine albumin (5-6 mL/kg) is safer but is not readily available. Hetastarch and pentastarch may be used in place of plasma or albumin. These colloids are larger than albumin and persist in the intravascular space longer than albumin, thereby helping maintain plasma oncotic pressure in animals with severe PLE. After administering these colloids, the clinician should decrease the rate of fluid administration to prevent hypertension. Sometimes, administering hetastarch causes fluids to shift to the extravascular compartment with subsequent decrease in peripheral perfusion or worsening of ascites.

DIETARY MANAGEMENT

Dietary therapy is often important in animals with gastrointestinal tract problems. Symptomatic therapy for acute problems usually involves easily digested diets (i.e., "bland"), whereas specific therapy typically involves elimination (i.e., hypoallergenic) diets, ultra–low fat diets, fiber-supplemented diets, or a combination of these.

"Bland" (i.e., easily digested) diets are low in fat and fiber (both delay gastric emptying) and high in complex carbohydrates. Extremely hyperosmolar diets (e.g., concentrated sugar solutions or honey) should be avoided because they also may delay gastric emptying. These diets are indicated in animals with acute gastritis or enteritis. Such diets are available commercially (Box 28.1). Homemade versions usually consist of boiled poultry or lean hamburger, low-fat cottage cheese, boiled rice, and/or boiled potatoes in some combination. Boiled chicken, turkey, or fish and green beans may be useful in cats. A typical mixture is one part boiled chicken or cottage cheese and two parts boiled potato. These diets also tend to be low in lactose, which helps prevent maldigestion. Frequent, small amounts of these foods are fed until diarrhea resolves, and then the diet is gradually changed back to the routine one. This diet may be continued after the event is over, but a homemade diet should be nutritionally balanced if it is used long term, especially in puppies or kittens.

Elimination diets are indicated if a dietary allergy (i.e., an immune-mediated hypersensitivity) or intolerance (i.e., a non–immune-mediated problem) is suspected. These diets contain either dietary ingredients unlikely to provoke allergy or intolerance (i.e., hydrolyzed diets that contain relatively small particles that are less antigenic) or food stuffs the patient has not been exposed to before (i.e., a novel protein diet). Excellent commercial elimination diets are available, or the clinician may suggest a homemade diet. Examples of homemade elimination diets are described in Box 28.2.

BOX 28.1

Examples of Commercial "Bland" (Highly Digestible)* Diets

Hill's Prescription Diet i/d
Iams Intestinal Plus Low-Residue
Purina CNM EN-Formula
Royal Canin Gastrointestinal High Energy
Royal Canin Canine Low Fat

This is a partial list for the purpose of showing examples; it is not an all-inclusive list of such diets.

*"Bland" refers to easily digestible diets that often contain less fat and less fiber than is found in many pet foods.

BOX 28.2

Examples of Homemade Hypoallergenic* Diets

1 part boiled white chicken or turkey meat without the skin; 2 parts boiled or baked potato (without the skin)
1 part boiled or broiled white fish without the skin; 2 parts boiled or baked potato (without the skin)
1 part boiled mutton, venison, or rabbit without the skin; 2 parts boiled or baked potato (without the skin)
1 part drained low-fat cottage cheese; 2 parts boiled or baked potato (without the skin)
A nonflavored vitamin supplement may be given three times per week.
Rice can be substituted for potato, but many dogs and cats seem to digest potato more easily than rice.

These diets are not balanced but are usually adequate for 3 to 4 months of use in sexually mature animals. If growing animals are being fed such a diet, then a nutritionist must be consulted to balance calcium and phosphorus.

**Hypoallergenic* refers to a diet specially formulated for a given animal, one that does not expose the animal to potential allergens that it has eaten in the past. Therefore the clinician must obtain a careful dietary history to determine what will or will not constitute a hypoallergenic diet for a particular animal.

When elimination diets are effective, improvement is typically evident within 3 weeks, although rare patients require 6+ weeks. It is critical that no other foods or treats (e.g., flavored pills, toys, medications) be given to the animal during this time. If signs resolve during this time, the diet should be continued for at least 4 to 6 more weeks to ensure cause and effect as opposed to a spontaneous, fortuitous fluctuation of the disease.

Partially hydrolyzed diets (Purina HA, Nestle Purina; Hill's z/d, Hill's Pet Products; Hypoallergenic Hydrolyzed Protein HP diets and Ultamino Royal Canin) have been formulated in an attempt to eliminate proteins large enough to cause immunologic reactions. Although these diets are not uniformly effective, many dogs and cats with dietary allergy or intolerance will experience clinical improvement when eating these diets exclusively. The partially hydrolyzed proteins may also make such diets easier to digest and absorb.

Ultra–low-fat diets are indicated in dogs with PLE due to intestinal lymphangiectasia. Because long-chain fatty acids enter and accumulate in lacteals, removing them from the diet helps prevent dilation and rupture of lacteals and subsequent intestinal lymphatic loss. Medium-chain triglycerides (MCTs) were once recommended as supplements to low fat, reducing diets; however, MCT oil has an unpleasant taste and is not as effective as was once thought, so it is no longer recommended.

Fiber-enriched diets may ameliorate diarrhea in many patients with large bowel disease (especially those with minimal inflammation). Although once considered important, distinguishing soluble from insoluble fiber is no longer thought critical because many fibers have characteristics of both. A commercial high-fiber diet may be used, or fiber may be added to the current diet. Psyllium hydrocolloid (e.g., Metamucil) or coarse, unprocessed wheat bran may be added to the pet's diet (i.e., 1-2 teaspoons or 1-4 tablespoons per can of food, respectively). Supplementing too much soluble fiber can produce diarrheic stools. If the patient is fiber-responsive, clinical improvement is generally seen within 4 to 5 days of beginning the diet.

Fiber-supplemented diets might also lessen constipation not due to obstruction, rectal pain, or megacolon due to colonic inertia. Such a diet should be fed for at least 2 weeks before assessing efficacy, although most animals that respond do so within the first week. Some cats will not eat these diets or fiber supplements. Canned pumpkin pie filling is effective as a fiber and usually palatable; 1 to 3 tablespoons may be given daily. It is important that the animal maintain adequate water intake, lest the increased dietary fiber produce obstipation.

SPECIAL NUTRITIONAL SUPPLEMENTATION

If the animal refuses to ingest adequate calories, special nutritional supplementation is necessary. Daily nutritional requirements should be calculated to avoid underfeeding. Approximately 60 kcal/kg/day is reasonable for the maintenance needs of mature dogs and cats that are not lactating or losing a significant amount of energy or protein.

In some cases, simply sending the animal home, warming the food, or feeding the animal a more palatable diet (e.g., chicken baby food for dogs) will result in adequate caloric intake. Force-feeding by manually placing food in the animal's mouth seldom works in hyporexic animals. Mirtazapine is usually an effective appetite stimulant for dogs and cats. It is administered once daily in dogs and once every three days in cats. Maropitant (an antiemetic) is often helpful if nausea is the cause of hyporexia. Cyproheptadine stimulates some cats to eat, but seldom induces a severely anorectic cat to ingest adequate calories. Diazepam rarely causes acute feline hepatic failure and is not recommended. Megestrol acetate is an excellent appetite stimulant but occasionally causes diabetes mellitus, reproductive problems, or tumors. Cobalamin injections have been noted to increase appetite in some patients. Appetite stimulants are usually less effective in dogs than in cats.

Feeding tubes are a reliable way to ensure adequate caloric intake. Intermittent orogastric tube feeding is useful for animals that need nutritional support for a relatively short time, although it may be used for longer periods in orphaned puppies and kittens. It is typically done two or three times daily, using manual restraint and a mouth gag. A tube is measured and marked to correspond to the length from the tip of the nose to the midthoracic region. The tube is then carefully inserted through a mouth gag to the premarked point. If the animal coughs or is dyspneic, the tube may have entered the trachea and should be repositioned. To ensure safety, the tube should be flushed with water before warmed gruel is administered. Gruel should be given over several seconds to 1 minute. Because relatively large-diameter tubes can be used, homemade gruels may be administered. The major disadvantage is the need to physically restrain the animal. Indwelling tubes circumvent this problem.

Nasoesophageal tubes are useful in animals with a functional esophagus, stomach, and intestines. They are easy to place but difficult to maintain in vomiting animals. The clinician first anesthetizes the nose by instilling a few drops of lidocaine solution in one nostril. Then a sterile polyvinyl chloride, polyurethane, or silicone tube (diameter depends on the animal's size, but 5F-12F is typical) lubricated with sterile water-soluble jelly is inserted into the ventromedial nostril. The animal's head is restrained in its normal position, and the tube is inserted until the tip is just beyond the thoracic inlet. If the clinician encounters difficulty in passing the tube, the tip should be withdrawn, redirected, and advanced again. If the clinician is unsure whether the tube is in the esophagus, thoracic radiographs should be obtained.

Tape is applied to the tube, and then the tape is glued or sutured to the skin along the dorsal aspect of the nose. If the tube touches sensory vibrissae, the animal will not tolerate it. It may be necessary to place an Elizabethan collar on some animals to prevent them from pulling out the tube. Only small-diameter tubes (e.g., 5F) can be used in small dogs and cats, which limits the rate of administration and

necessitates the use of commercial liquid diets (Table 28.2) instead of homemade gruels. The clinician should flush the tube with water after each feeding to prevent occlusion. Long-term acceptance is typical, but rhinitis occurs in some animals.

Some dogs and cats do not tolerate nasoesophageal tubes and repeatedly pull them out. However, they are usually effective for short-term therapy (e.g., 1-10 days), and some animals tolerate them for weeks.

Pharyngostomy and esophagostomy tubes are indicated in patients with functional esophagus, stomach, and intestines that require nutritional support but do not tolerate nasoesophageal or intermittent tube feeding. Vomiting may make it difficult to maintain these tubes, but they can typically be used for weeks to months.

Pharyngostomy tubes are hard to place correctly and are not recommended. Esophagostomy tubes are the primary long-term feeding tube now used. There are commercially available kits that have various nuances in how they are used. In general, the animal is placed in right lateral recumbency, the mouth is held open, and a long right-angle hemostat or other device is placed through the cricopharyngeal sphincter. The tip of the hemostat is then forced up to show where to make the incision in the left cervical region. The incision should be made midway between the cricopharyngeal sphincter and the thoracic inlet. The tip of the hemostat is forced up through the esophagus and the nick in the skin; the tip of a feeding tube is then grasped and pulled into the esophagus and out the mouth so that the flared end of the catheter (i.e., where the syringe will be attached) is left protruding from the neck. The distal end of the catheter is then redirected down the esophagus with a rigid colonoscope or long hemostat or other device. Esophagostomy tubes do not cause gagging, a problem common with pharyngostomy tubes.

Gastrostomy tubes bypass the mouth and esophagus in animals with a functional stomach and intestines. They can also be used when nasoesophageal, esophagostomy, or intermittent gastric tubing is unacceptable. Vomiting is not a contraindication. This technique requires surgery, endoscopy, or special devices for proper placement.

Endoscopy is the preferred and safest way to place gastrostomy tubes percutaneously. Use of dedicated devices for placing gastrostomy tubes has made the procedure easier and readily available for clinicians without endoscopes; however, it is easy to misplace the tube when using these "blind" techniques. It is recommended that novices use a flexible endoscope to inflate the stomach (which pushes organs out of the way) and to be sure of the tube placement. Gastrostomy tubes allow administration of thick gruels and are often tolerated for weeks to years. Either a homemade gruel or a commercial liquid diet (see Table 28.2) may be used. These tubes must be left in place for at least 7 to 10 days to allow an adhesion to form between the stomach and the abdominal wall, which prevents gastric leakage into the peritoneal cavity when the tube is removed. They are often used in cats that do not tolerate nasogastric or esophagostomy tubes. The tube should be flushed with water and air after each feeding. Although the entire caloric requirement may be administered as soon as the tube is placed, it is often safer to start with half the daily requirement and work up to complete nutritional needs over 1 to 3 days. If the tube becomes plugged, it can sometimes be unplugged by using flexible endoscopy forceps or by instilling a fresh carbonated beverage into the tube. When the tube is removed, sufficient traction is applied so that the umbrella tip collapses and passes through the stomach and skin incision. The fistula usually closes spontaneously in 1 to 2 days. The major risk of using such tubes is leakage and peritonitis, which are rare but potentially catastrophic. In dogs larger than 20 to 25 kg, gastrostomy tubes are best placed surgically or sutures are passed through the abdominal wall and into the gastric wall to ensure that the stomach and abdominal wall stay in apposition and form an adhesion that prevents leakage. Improper use of dedicated devices can result in malplacement of the tube and/or perforation of abdominal organs (e.g., spleen, omentum). Because of these potential complications, esophagostomy tubes are preferred whenever possible.

Low-profile gastrostomy tubes can be used if a stoma has been previously established by a routine gastrostomy tube. The major advantage of such tubes is that they may replace routine gastrostomy tubes that are disintegrating or have been inadvertently pulled out, and some can be placed without anesthesia or a surgical/endoscopic procedure. Typically, sedation is all that is needed. However, to use a preexisting stoma, the low-profile gastrostomy tube must usually be placed within hours of removing the old gastrostomy tube, or another tube (e.g., a red latex male urinary catheter) must be inserted into the stoma as quickly as possible to prevent the old stoma from closing.

TABLE 28.2

Selected Enteral Diets

DIET	COMMENTS
Osmolite*	Polymeric diet; contains taurine, carnitine, and MCT; gluten free; low lactose; isotonic, comes in different caloric density preparations
CliniCare†	Polymeric diet; contains taurine but no lactose
Peptamen‡	Oligomeric diet; contains taurine, carnitine, and MCT; gluten free; lactose free; low residue; isotonic
Vivonex T.E.N.‡	Elemental diet; high in carbohydrates, low in protein and fat¶; contains glutamine and arginine; gluten free; lactose free; low residue

MCT, Medium-chain triglyceride.

†Zoetis.
‡Nestle Health Science.
¶To increase protein content, reconstitute one packet of powder with 350 mL water plus 250 mL of 8.5% amino acids for injection.

Enterostomy tubes are indicated in animals with functional intestines when the stomach must be bypassed (e.g., recent gastric surgery). Laparotomy or endoscopy is typically used to place these tubes. When placing it surgically or laparoscopically, a 12-gauge needle punctures the antimesenteric border of the intestine, and a sterile 5F plastic catheter is advanced aborally through the needle until approximately 15 cm extends into the intestinal lumen. The 12-gauge needle is removed, and a purse-string suture is placed to prevent the catheter from moving freely. The needle is then used in the same manner to make a pathway for the catheter to exit through the abdominal wall. The antimesenteric border of the intestine is sutured to the abdominal wall so that the sites where the tube enters the intestine and exits the abdomen are opposed. Traction sutures are used to secure the catheter.

Another technique is to first place a percutaneous gastrostomy tube and then insert the jejunostomy tube through the gastrostomy tube (i.e., a Peg-J tube). The jejunostomy tube is then directed into the duodenum either by dragging it with a flexible endoscope, or by directing a guide wire into the duodenum and running the tube over the guidewire through the gastrostomy tube and into the duodenum. Alternatively, one may use a flexible endoscope to grasp a guide wire entering the esophagus from the nose into the jejunum, drag that wire into the jejunum, and then pass a tube over the guide wire (i.e., a nasojejunostomy tube).

The small diameter of enterostomy tubes often necessitates administration of commercial liquid diets (see Table 28.2), which are best infused at a constant rate. The rate necessary to administer daily caloric needs is calculated. Half-strength feeding solution is administered at one half the calculated rate on day 1. The next day the rate of administration is increased to the calculated rate, but half-strength solution is still used. On the third day a full-strength solution is administered at the calculated rate. If diarrhea occurs, the rate of administration can be decreased or fiber (e.g., psyllium) can be added to the liquid diet. If placed surgically or laparoscopically, the tube should be left in place for 10 to 12 days to allow adhesions to develop around the area and prevent leakage. When enteral feeding is no longer necessary, the clinician simply removes the sutures and pulls out the catheter.

DIETS FOR SPECIAL ENTERAL SUPPORT

If the feeding tube diameter is sufficiently large, a gruel made by blending one can of dog or cat food (e.g., feline p/d [Hill's Pet Products]) plus 0.35 L of water provides approximately 0.9 kcal/mL and is useful for dogs and cats. Elemental diets are rarely needed in animals with severe intestinal disease. Some elemental diets (e.g., Vivonex, Nestle Nutrition) do not have as much protein as desired for dogs and cats (see Table 28.2); therefore some of the water used in mixing the elemental diet is replaced with 8.5% amino acids for injection (e.g., 350 mL water + 250 mL 8.5% amino acids). When feeding cats, the clinician must be sure that sufficient taurine is present in the diet.

Nasoesophageal, esophagostomy, and gastrostomy tubes are typically used for bolus feeding. Animals that have been hyporexic for days to weeks should usually start by receiving small amounts (e.g., 3-5 mL/kg) every 2 to 4 hours. The amount is gradually increased and the frequency decreased until the animal is receiving its caloric needs in three or four daily feedings. The clinician should expect to ultimately administer 22 to 30 mL/kg at each feeding to most dogs and cats. Larger volumes may be given if they do not cause vomiting or distress.

Jejunostomy tubes are designed for constant-rate feeding using an enteral feeding pump. The clinician should begin by feeding the animal a half-strength diet at one half the rate that will ultimately be necessary to meet the animal's caloric needs. If diarrhea does not result after 24 to 36 hours, the clinician increases the flow rate to what will ultimately be needed. If diarrhea still does not occur, the diet may then be changed from half strength to full strength. Constant infusion of these same diets may be done through gastrostomy and esophagostomy tubes in animals that readily vomit when fed in boluses (e.g., some cats with severe hepatic lipidosis). Animals that are critically ill and vomit readily might benefit from "microalimentation," in which very small amounts of liquid diet (e.g., 1-2 mL/h in 30-40 kg dogs) are infused via nasoesophageal tubes in an effort to provide some nutrition to the intestinal mucosa and prevent bacterial translocation and sepsis.

PARENTERAL NUTRITION

Parenteral nutrition is indicated if the animal's intestines cannot reliably absorb nutrients. It is the most certain method of supplying nutrition to such animals but is expensive and can be associated with severe metabolic and infectious complications. If parenteral nutrition will be used, one should consult with a nutritionist. If parenteral nutrition is administered, the animal should also receive some oral feeding, if possible, to help prevent intestinal villous atrophy.

ANTIEMETICS

Antiemetics are indicated for symptomatic therapy in many animals with acute vomiting, those that are severely nauseated, and those in which vomiting is contributing to morbidity (e.g., discomfort or excessive fluid and electrolyte losses). Peripherally acting drugs (Table 28.3) are less effective than centrally acting ones but may suffice in animals with minimal disease. Oral administration is unreliable in nauseated animals. Parasympatholytics (e.g., atropine, aminopentamide) have some central activity, but are generally no longer recommended. Centrally acting antiemetics are more effective. Parenteral administration is often preferred to ensure blood levels in vomiting patients. Suppositories are convenient, but their absorption is erratic.

Maropitant (Cerenia) is a neurokinin-1 (NK-1) receptor antagonist that is effective in preventing vomiting in a wide range of conditions. Approved for use in dogs and cats, it has

TABLE 28.3

Selected Antiemetic Drugs

DRUG	DOSAGE*	COMMENTS
Centrally Acting Drugs		
Neurokinin-1 receptor antagonist		
Maropitant (Cerenia)	1 mg/kg SC q24h (dogs or cats) 2 mg/kg PO q24h (dogs) 1 mg/kg PO q24h (cats) 8 mg/kg PO q24h for up to 2 days for motion sickness in dogs 4 mg/cat PO q24 h for vomiting due to renal failure	Treat puppies 2-7 months old for 5 days; older animals can be treated indefinitely
Serotonin receptor antagonists		
Ondansetron (Zofran)	0.1-0.2 mg/kg IV q8-24h 0.5 mg/kg in resistant cases	Oral administration much less effective
Metoclopramide (Reglan)	0.25-0.5 mg/kg PO, IM, or IV q8-24h 0.4 mg/kg loading dose, then 0.3 mg/kg/h by CRI	Can see CNS adverse effects; poorly effective in cats Most useful when used as an "add on" to maropitant or ondansetron; protect from light when administering as CRI
Phenothiazine derivatives		
Chlorpromazine (Thorazine) Prochlorperazine (Compazine)	0.3-0.5 mg/kg IM, IV, or SC q6-8h 0.1-0.5 mg/kg IM q8-12h	Watch for hypovolemia

IM, Intramuscularly; *PO,* orally; *SC,* subcutaneously.
*Dosages are for both dogs and cats unless otherwise specified.

poor oral bioavailability (food does not affect absorption) but good absorption after SC administration. It is such an effective antiemetic that it will often prevent vomiting secondary to foreign body obstruction, so it is important to try to rule out such obstruction before administering this drug. Gastrointestinal perforations have occurred because success with maropitant delayed diagnosis and removal of foreign bodies. It has analgesic effects for visceral pain.

Ondansetron (Zofran) and dolasetron (Anzemet) are serotonin (5-hydroxytryptamine, 5-HT) receptor antagonists. They are good drugs but are typically less effective than maropitant. Mirtazapine (primarily used as an appetite stimulant) may also have some antiemetic effects due to its antagonism of 5-HT.

Metoclopramide (Reglan) is a less effective antiemetic than the NK-1 and serotonin receptor antagonists (especially in cats). It inhibits the chemoreceptor trigger zone and increases gastric tone and peristalsis. Rarely, animals show unusual behavior (e.g., excitation) after administration. The drug is excreted in the urine, and severe renal failure makes adverse effects more likely. It rarely worsens vomiting, perhaps because it causes excessive gastric contractions. The liquid form of metoclopramide given orally is often not palatable to cats. Because of its prokinetic activity, the drug is contraindicated in animals with gastric or duodenal obstruction. Metoclopramide may be more effective in animals with severe vomiting if given intravenously at a dosage of 0.3-1.0 mg/kg/hr by constant rate infusion. In particular, metoclopramide may be used as an "add on" in difficult-to-control patients not responding to NK-1 and/or serotonin receptor antagonists.

Phenothiazine derivatives (e.g., prochlorperazine [Compazine]) are often effective but are seldom used now. They inhibit the chemoreceptor trigger zone and, in higher doses, the medullary vomiting center. Antiemesis is usually achieved at doses that do not produce marked sedation. However, these drugs may cause vasodilation and can decrease peripheral perfusion in a dehydrated animal.

Many other drugs have antiemetic effects. Mu-antagonist narcotics (e.g., fentanyl, morphine, methadone) may cause vomiting initially, but vomiting is usually inhibited once the drug penetrates to the medullary vomiting center. Butorphanol has some efficacy as an antiemetic and is sometimes used in patients undergoing chemotherapy.

ANTACID DRUGS

Antacid drugs (Table 28.4) lessen gastric acidity. Although they are not antiemetics, they sometimes seemingly have an "antidyspeptic" effect due to diminishing gastric hyperacidity.

Antacids, which titrate gastric acidity, are over-the-counter preparations that are typically of limited efficacy. Compounds containing aluminum or magnesium tend to be

TABLE 28.4

Selected Antacid Drugs

DRUG	DOSAGE*
Acid Titrating Drugs	
Aluminum hydroxide (many names)	10-30 mg/kg PO q6-8h
Magnesium hydroxide (many names)	5-10 mL PO q4-6h (dogs), q8-12h (cats)
Gastric Acid Secretion Inhibitors	
H_2 receptor antagonists†	
Ranitidine (Zantac)	1-2 mg/kg, PO or IV, q8-12h (dogs) 2.5 mg/kg IV or 3.5 mg/kg PO q12h (cats)
Famotidine (Pepcid, Pepcid AC)	0.1-0.2 mg/kg, PO, SC, IM or IV, q12-24h
Proton Pump Inhibitors	
Omeprazole (Prilosec)	1-2 mg/kg PO q12
Pantoprazole (Protonix)	1 mg/kg IV q24h (dog)‡
Esomeprazole (Nexium)	1 mg/kg IV q24h (dogs)‡

IM, Intramuscularly; *IV,* intravenously; *PO,* orally; *SC,* subcutaneously.
*Dosages are for both dogs and cats unless otherwise specified.
†These drugs are competitive inhibitors of histamine. Higher doses have been tried, but have not been shown to be more effective.
‡Dosages are based upon anecdotal reports. These drugs have not been used extensively, and their safety and efficacy in dogs are not established. Twice daily administration of omeprazole PO is more effective then once daily administration of pantoprazole IV.

TABLE 28.5

Selected Gastrointestinal Protectants and Cytoprotective Agents

DRUG	DOSAGE*	COMMENT
Sucralfate (Carafate)	0.5-1 g (dogs) or 0.25 g (cats) PO q6-8h, depending on animal's size (suspension is preferred)	Potentially constipating, absorbs some other orally administered drugs, primarily used to treat existing ulcers
Misoprostol (Cytotec)	2-5 µg/kg PO q8-12h (dogs)	May cause diarrhea/abdominal cramps, primarily used to prevent ulcers, not for use in pregnant animals

PO, Orally.
*Dosages are for both dogs and cats unless otherwise specified.

more effective and do not cause the gastric acid rebound that sometimes occurs in response to calcium-containing antacids. Antacids should be administered orally every 4 to 6 hours to ensure continued control of gastric acidity; however, this may cause diarrhea, especially in animals receiving magnesium-containing compounds. Hypophosphatemia, although unlikely, is possible after extensive aluminum hydroxide administration. Hypermagnesemia, also unlikely, is possible in patients with renal failure that receive magnesium-containing compounds. These types of antacids may also interfere with the absorption of some other drugs (e.g., tetracycline, cimetidine).

Histamine-2 (H_2) receptor antagonists are competitive inhibitors of histamine. They prevent histamine from stimulating the gastric parietal cell. Cimetidine (Tagamet) must be given three or four times daily to achieve best results; it inhibits hepatic cytochrome P450 enzymes, thereby slowing the metabolism of some drugs. Famotidine (Pepcid) is more effective and has less effect on hepatic enzyme activity. The main indication for these drugs has been treatment of gastric and duodenal ulcers. However, tachyphylaxis occurs when administering famotidine for several days, making it progressively less effective over time.[1] Furthermore, these drugs are not effective when used prophylactically to prevent ulceration associated with steroids and nonsteroidal anti-inflammatory drugs (NSAIDs). Nizatidine and ranitidine have some gastric prokinetic activity. Very rarely these drugs may cause bone marrow suppression, central nervous system problems, or diarrhea. Parenteral administration, especially the rapid IV injection of ranitidine, may cause nausea, vomiting, or bradycardia.

Proton pump inhibitors (PPIs) (i.e., omeprazole [Prilosec], lansoprazole [Prevacid], pantoprazole [Protonix], esomeprazole [Nexium]) noncompetitively block the final common pathway of gastric acid secretion. This is the most effective class of drugs for decreasing gastric acid secretion. Maximum suppression of acid secretion usually requires 2 to 5 days of therapy, but the acid suppression occurring on the first day is as good as or better than that caused by H_2 receptor antagonists. Omeprazole is superior to H_2 receptor antagonists as a prophylactic drug in patients receiving ulcerogenic drugs. There is no evidence that combining PPIs and H_2 receptor antagonists is beneficial.[2] In fact, the combination might make PPIs less effective.

GASTRIC AND CYTOPROTECTIVE DRUGS

Sucralfate (Carafate) (Table 28.5) is principally indicated for animals with gastroduodenal ulceration or erosion but is also a mild analgesic for those with esophagitis. It should be administered as a suspension instead of tablets. It is a mediocre prophylactic drug. Sucralfate is a nonabsorbable sulfated sucrose complex that tightly adheres to denuded mucosa,

thus protecting it. It also inhibits peptic activity and may alter prostaglandin synthesis and the actions of endogenous sulfhydryl compounds. There is no evidence that combining sucralfate with PPIs or H_2 receptor antagonists is beneficial. Because sucralfate may adsorb other drugs, slowing their absorption, other orally administered drugs ideally should be given 1 to 2 hours before or after sucralfate administration. Sucralfate can cause constipation.

Misoprostol (Cytotec) is a prostaglandin E_1 analog designed to prevent NSAID-induced gastroduodenal ulceration, but it can be used to treat ulcers. Misoprostol does not appear to be as effective in preventing NSAID-induced ulcers in dogs as it is in people, and PPIs appear to be as effective as misoprostol. The major adverse effects of misoprostol seem to be abdominal cramping and diarrhea, which usually disappear after 2 to 3 days of therapy. It is also an abortifacient.

INTESTINAL "PROTECTANTS"

Intestinal protectants include drugs and inert adsorbents such as kaolin, pectin, and barium sulfate contrast media. Many people believe that inert adsorbents hasten clinical relief in animals with minor inflammation, possibly because they coat the mucosa or adsorb toxins. They make loose stools more normal simply by increasing fecal particulate matter. Inert adsorbents do not have proven efficacy in the treatment of gastritis or enteritis. It is inappropriate to rely on these drugs alone in very sick animals.

DIGESTIVE ENZYME SUPPLEMENTATION

Pancreatic enzyme supplementation is indicated to treat exocrine pancreatic insufficiency (EPI). Empirical use as a therapeutic trial for presumptive EPI is a poor approach. There are many products that vary greatly in potency. Although pills may work, enteric-coated pills are particularly ineffective. Powdered preparations tend to be more effective; Viokase-V (A.H. Robins Co.) and Pancreazyme (Daniels Pharmaceuticals) seem to be particularly efficacious. The powder should be mixed with food (approximately 1-2 teaspoons per meal). Incubating the mixture before feeding is not beneficial. Fat is the main nutrient that must be digested in animals with exocrine pancreatic insufficiency, and feeding a low-fat diet may ameliorate diarrhea. Antacid and/or antibiotic therapy has anecdotally helped prevent gastric acidity or small intestinal bacteria from reducing enzyme supplementation effectiveness. Occasionally, stomatitis or diarrhea develops in dogs receiving excessive enzyme supplementation.

MOTILITY MODIFIERS

Drugs that prolong intestinal transit time are used to symptomatically treat diarrhea. Infrequently needed, they are reasonable if diarrhea causes excessive fluid or electrolyte losses or owners demand control of the diarrhea at home. Opiates (Table 28.6) increase resistance to flow by augmenting segmental contraction. They are more effective than parasympatholytics, which paralyze intestinal motility and create ileus. Both classes of drugs have antisecretory effects. Because cats do not tolerate narcotics as well as dogs, opiates should be avoided in cats although loperamide may be used carefully.

Loperamide (Imodium) theoretically increases risk for bacterial proliferation in the intestinal lumen; however, this is rarely clinically important. An overdose can cause narcotic intoxication (i.e., collapse, vomiting, ataxia, hypersalivation), which requires treatment with narcotic antagonists. Dogs deficient in P-glycoprotein (i.e., those with MDR gene mutation [Collies, Australian Shepherds, etc.]) are at greater risk for adverse central nervous system signs.

Diphenoxylate (Lomotil) is similar to loperamide but somewhat less effective. It has more potential for toxicity than loperamide. It may have some antitussive properties. Rarely a dog responds to it but not to loperamide. This drug should not be used in cats.

Drugs that shorten transit time (prokinetic drugs) empty the stomach or increase intestinal peristalsis or both. Metoclopramide causes gastric prokinesis, enhancing gastric emptying of fluids. It can be administered orally or parenterally. Adverse effects are mentioned under the section on antiemetics. Cisapride is a 5-HT_4 agonist that stimulates normal motility from the lower esophageal sphincter to the anus. It is usually effective unless the tissue has been irreparably damaged (e.g., megacolon in cats). Primarily used for the treatment of constipation, it may also be used for the

TABLE 28.6

Selected Drugs Used for Symptomatic Treatment of Diarrhea

DRUG	DOSAGE*
Intestinal Motility Modifiers (Opiates)	
Diphenoxylate (Lomotil)	0.05-0.2 mg/kg PO q8-12h (dogs)
Loperamide (Imodium)	0.12 mg/kg PO q8-12h (dogs) 0.08-0.16 mg/kg PO q12h (cats)
Antiinflammatory/Antisecretory Drug	
Bismuth subsalicylate† (Pepto-Bismol, Kaopectate)	1 mL/kg/day PO divided q8-12h (dogs) for 1-2 days

PO, Orally.
*Dosages are for both dogs and cats unless otherwise specified.
†This drug contains salicylate and can be nephrotoxic if combined with other nephrotoxic drugs.

management of gastroparesis (in which it is usually more effective than metoclopramide) and small intestinal ileus. It has rarely been reported to be beneficial in dogs with megaesophagus (perhaps because the dogs had gastroesophageal reflux). Cisapride is no longer available from human pharmacies but is generally available from veterinary pharmacies. It is typically available only as an oral preparation, but can be formulated for parenteral use. It has few significant adverse effects, although intoxication with large doses may cause diarrhea, muscular tremors, ataxia, fever, aggression, and other central nervous system signs. It should not be used concurrently with drugs that are hepatic P450 inhibitors or that inhibit P-glycoprotein. Erythromycin stimulates motilin receptors and enhances gastric motility at doses less than required for antibacterial activity (i.e., 0.5-1 mg/kg). It may also increase intestinal motility. Nizatidine and ranitidine are H_2 receptor antagonists that have some gastric prokinetic effects at routinely administered doses. Bethanechol (Urecholine) is an acetylcholine analog that stimulates intestinal motility and secretion. It produces strong contractions that can cause pain or injure the animal; hence, it is infrequently used except for increasing urinary bladder contractions. Obstruction of an outflow area can be a contraindication to the use of prokinetic drugs because vigorous contractions against such a lesion may cause pain or perforation. Obstruction of the urinary outflow tract is also a contraindication to the use of bethanechol.

Pyridostigmine (Mestinon) inhibits acetylcholinesterase and is used to treat myasthenia gravis. It is preferred over physostigmine and neostigmine. It is used for the treatment of acquired megaesophagus due to localized myasthenia. It must be used cautiously because overdose may cause toxicity accompanied by signs of parasympathetic overload (e.g., vomiting, miosis, diarrhea).

ANTIINFLAMMATORY AND ANTISECRETORY DRUGS

Intestinal antiinflammatory or antisecretory drugs (or both) are indicated for lessening fluid losses due to diarrhea or for controlling intestinal inflammation that is unresponsive to dietary or antibacterial therapy.

Bismuth subsalicylate (Pepto-Bismol, Kaopectate) is effective in many dogs with acute enteritis (see Table 28.6), probably because of the antiprostaglandin activity of the salicylate moiety. Its main disadvantages are that the salicylate is absorbed (warranting cautious use in cats or dogs receiving nephrotoxic drugs), it turns stools black (mimicking melena), and it must be administered orally (many animals dislike its taste). Bismuth is bactericidal for certain organisms (e.g., *Helicobacter* spp.).

Octreotide (Sandostatin) is a synthetic analog of somatostatin that inhibits alimentary tract motility and secretion of gastrointestinal hormones and fluids. It has had limited use in dogs and cats but might be helpful in selected animals with intractable diarrhea or lymphangiectasia. The dose in the dog is unknown but suggested to be 10-40 mg/kg SC q12-24h.

Salicylazosulfapyridine (sulfasalazine [Azulfidine]) is used in dogs with colonic inflammation. This drug is generally not beneficial in animals with small intestinal problems. It is a combination of sulfapyridine and 5-aminosalicylic acid. Colonic bacteria split the molecule, and 5-aminosalicylic acid (probably the active moiety) is subsequently "deposited" on diseased colonic mucosa. Dogs generally receive 50 to 60 mg/kg divided into three doses daily, but not to exceed 3 g daily. Sulfasalazine given orally may be effective at lower-than-expected doses if used in combination with glucocorticoids. Anecdotally, 15 to 20 mg/kg/day, sometimes divided into twice-daily doses, is often tolerated by cats, but they must be closely observed for salicylate intoxication (i.e., lethargy, anorexia, vomiting, hyperthermia, tachypnea). Some cats that vomit or become hyporexic may tolerate the medication if it is given in enteric-coated tablets. Many dogs with colitis respond to therapy in 3 to 5 days. However, the drug may have to be given for 2 weeks before one decides that it is ineffective. If signs of colitis resolve, the dose should be gradually reduced. If the patient cannot be weaned off the drug entirely, the lowest effective dose should be used and the animal monitored regularly for drug-induced adverse effects (especially those resulting from the sulfa moiety). Sulfasalazine may cause transient or permanent keratoconjunctivitis sicca. Other possible complications include cutaneous vasculitis, arthritis, bone marrow suppression, diarrhea, and any other problem reported with sulfa drugs or NSAIDs.

Olsalazine and mesalamine contain or are metabolized to 5-aminosalicylic acid but do not have the sulfa, which is responsible for most of sulfasalazine's adverse effects. In people they are as effective as sulfasalazine but safer. Olsalazine and mesalamine have been used effectively in dogs. They are given in a dose generally about half that of sulfasalazine. Keratoconjunctivitis sicca has also developed in dogs receiving mesalamine.

Glucocorticoids are potentially indicated in animals with chronic alimentary tract inflammation (e.g., moderate to marked inflammatory bowel diseases) that is unresponsive to well-designed elimination diets and/or antimicrobial therapy. Prednisolone is preferred over prednisone. Relatively high doses (i.e., prednisolone, 2.2 mg/kg/day PO) are often used initially, and the dose is tapered to find the lowest effective dose. Dexamethasone is sometimes effective when prednisolone is not, but dexamethasone is much more ulcerogenic than prednisolone. If oral administration is a problem in a cat, long-lasting steroid injections (e.g., methylprednisolone acetate) may be tried. Methylprednisolone appears to be a more effective antiinflammatory than prednisolone, requiring only 80% of the dose used when administering prednisolone. Budesonide (Entocort) is a steroid that is largely eliminated from the body by first-pass metabolism in the liver, thus diminishing (but not totally eliminating) systemic steroid side effects. It is primarily indicated in patients who are known to respond to prednisolone but cannot tolerate that steroid's side effects.

Glucocorticoids are often beneficial in cats with inflammatory bowel disease (IBD), but they may worsen intestinal disease in some dogs and cats. Iatrogenic Cushing syndrome primarily occurs in dogs but can develop in cats that are grossly overdosed. It is important to have a diagnosis before using high-dose prednisolone therapy because some diseases that mimic steroid-responsive lymphocytic colitis (e.g., histoplasmosis) are absolute contraindications to glucocorticoid therapy. Although more common in the southeastern United States and the Ohio River Valley, histoplasmosis has been diagnosed in patients residing in nonendemic areas.

Retention enemas of glucocorticoids or 5-aminosalicylic acid are rarely indicated in animals with severe distal colitis unresponsive to other medications. The dose is estimated from the human dose. These enemas place large doses of an antiinflammatory agent directly on the affected area while minimizing systemic effects. Contraindications to their use are the same as those for systemic administration of the active ingredient of the enema.

Immunosuppressive therapy (e.g., cyclosporine, chlorambucil, azathioprine) is indicated in animals with severe IBD that is unresponsive to glucocorticoid, dietary, antimicrobial, and cobalamin therapy. It is also used in animals with severe disease in which it is in the animal's best interest to use aggressive immunosuppressive therapy initially. These drugs should be used only in patients with a definitive diagnosis. Immunosuppressive therapy can be more efficacious than glucocorticoid therapy alone and allows glucocorticoids to be given at lower doses and for shorter periods, thereby decreasing their adverse effects. However, the possibility of adverse effects from these drugs usually limits their use to animals with severe disease. The reader is referred to Chapter 72 for additional information on immunosuppressive therapy.

Cyclosporine (Atopica) is a potent immunosuppressive drug sometimes used in dogs with IBD, lymphangiectasia, and perianal fistulas. The dose is 3 to 6 mg/kg PO every 12 hours, but erratic bioavailability requires therapeutic drug monitoring in nonresponding patients, usually after 8 to 10 days of therapy. There is considerable variation in the bioavailability of different preparations of cyclosporine. It may be administered intravenously in vomiting patients, but then the initial dose should probably be decreased by 50%. Because of its considerable expense, it is sometimes administered with low doses of ketoconazole (3-5 mg/kg PO q12h), which inhibits metabolism of cyclosporine and in turn allows the use of lower doses at less expense to the client. Animals receiving too much cyclosporine usually first show hyporexia, which can be confusing when dealing with patients with gastrointestinal disease that are hyporexic to begin with.

Oral chlorambucil is an alkylating agent used in dogs with severe alimentary tract inflammation and sometimes lymphangiectasia, and in cats with severe IBD. It is typically administered with glucocorticoids initially. Chlorambucil has fewer adverse effects than azathioprine. In dogs, 4 to 6 mg/m^2 is administered daily for up to three weeks, and then the dose is reduced. A reasonable starting dose in cats is 1 mg twice weekly for cats weighing less than 3.2 kg and 2 mg twice weekly for cats weighing more than that. Beneficial effects may not be seen for 4 to 5 weeks. If a response is seen, the dose should then be decreased very slowly over the next 2 to 3 months. The animal should be monitored for myelosuppression.

Azathioprine (Imuran) is used only in dogs (50 mg/m^2 PO, daily or every other day), never cats. For smaller dogs a 50-mg azathioprine tablet is typically crushed and suspended in a liquid (e.g., 15 mL of a vitamin supplement) to allow more accurate dosing. The suspension must be mixed well before each dosing. Every-other-day dosing is much safer but takes much longer (i.e., 2-5 weeks) than every-day dosing to see clinical effects. Side effects in dogs may include hepatic disease, pancreatitis, and bone marrow suppression.

ANTIBACTERIAL DRUGS

In dogs and cats with gastrointestinal problems, antibiotics are primarily indicated if aspiration pneumonia, fever, a leukogram suggestive of sepsis, severe neutropenia, antibiotic-responsive enteropathy (sometimes also called "dysbiosis"), clostridial colitis, or symptomatic *Helicobacter* gastritis is being treated. Animals with an acute abdomen may reasonably be treated with antibiotics while the nature of the disease is being defined. Colitis can be a reasonable indication for amoxicillin (22 mg/kg PO q12h) or tylosin (10-20 mg/kg PO per day) if clostridial colitis is strongly suspected, but most animals with acute gastroenterocolitis of unknown cause (including those with acute hemorrhagic diarrheal syndrome—previously called *hemorrhagic gastroenteritis*) do not benefit from antibiotic therapy. Routine use of antimicrobials in animals with alimentary tract disorders is discouraged unless the patient is at high risk for infection or is being treated for a specific disorder responsive to antibiotics.

Nonabsorbable aminoglycosides (e.g., neomycin) are generally not indicated unless an infection known to be sensitive to the drug (e.g., campylobacteriosis) is strongly suspected. Metronidazole (10-15 mg/kg PO q24h) has been commonly used for a variety of gastrointestinal diseases, most of which were probably inappropriate. Metronidazole is sometimes successful for suspected ARE, and some dogs and cats diagnosed with IBD respond better to metronidazole than to glucocorticoids supporting the hypothesis that the "IBD" was probably ARE. Adverse effects are uncommon but may include salivation (because of its taste), vomiting, central nervous system abnormalities (e.g., central vestibular signs), and perhaps neutropenia. These adverse effects usually resolve after withdrawing the drug. Cats sometimes accept oral suspensions better than the 250-mg tablets, which must be cut and have an unpleasant taste. Metronidazole is potentially carcinogenic in some species, but there is no evidence of risk in dogs and cats.

Tylosin (10-20 mg/kg PO q24h or divided q12h) is commonly used to treat ARE and clostridial colitis. Tetracycline (22 mg/kg PO q12h) has also been used for ARE. The clinician should be prepared to treat the patient for 3 weeks before deciding that therapy for ARE has been unsuccessful.

Pets occasionally have enteritis caused by a specific bacterium, but this is not necessarily an indication for antibiotics. Clinical signs resulting from some bacterial enteritides (e.g., salmonellosis, enterohemorrhagic *Escherichia coli*) generally do not resolve more quickly when the animal is treated with antibiotics, even those to which the bacteria are sensitive.

Dogs and cats with viral enteritis but without obvious systemic sepsis may reasonably be treated with antibiotics if secondary sepsis is likely to occur (e.g., those with or likely to develop neutropenia). First-generation cephalosporins (e.g., cefazolin) are often effective for such use.

If systemic or abdominal sepsis is suspected to have originated from the alimentary tract (e.g., septicemia caused by parvoviral enteritis, perforated intestine), broad-spectrum antimicrobial therapy is indicated. Antibiotics with an excellent aerobic gram-positive and anaerobic spectrum of action (e.g., ampicillin plus sulbactam [Unasyn] 20 mg/kg IV q8h or clindamycin, 11 mg/kg IV q8h) combined with antibiotics with excellent activity against most aerobic bacteria (e.g., amikacin, 25 mg/kg IV q24h; or enrofloxacin, 15 mg/kg IV q24h [use 5 mg/kg in cats]) are often effective. To improve the anaerobic spectrum, especially if a cephalosporin is used instead of ampicillin, the clinician may include metronidazole (10 mg/kg IV, q8-12h). Alternatively, a second-generation cephalosporin (e.g., cefoxitin, 30 mg/kg IV q6-8h) may be used. In general, it takes at least 48 hours before the clinician can ascertain whether the therapy is being effective.

Despite the clinical imperative to control life-threatening infection as quickly as possible, it is also important to be a responsible member of the medical community, in this case specifically in regard to antibiotics effective against multi–drug-resistant infections. Some antibiotics are referred to as "drugs of last resort" because there are bacteria for which only 1 or 2 antibiotics are still effective. Vancomycin, imipenem, meropenem, doripenem, the oxazolidinone linezolid (Zyvox), the streptogramin combination of dalfopristin and quinupristin (Synercid), tigecycline (Tygacil), the lipopeptide daptomycin (Cubicin), moxifloxacin (Avelox), the glycopeptide telavancin, the oxazolidinone telithromycin (Ketek®), and the fourth- and fifth-generation cephalosporins (cefepime, cefpirome, ceftaroline, ceftobiprole) should not be used unless bacteria resistant to all other antibiotics have been cultured and there is no other therapy that is expected to be effective.

Helicobacter gastritis may be treated with various combinations of drugs. Currently, the combination of amoxicillin, metronidazole, and bismuth seems effective in dogs and cats. Antacids (i.e., omeprazole; see Table 28.4) and macrolides (i.e., erythromycin or azithromycin; see pp. 515-516) have been used in people, but they do not appear necessary in dogs or cats. Sole-agent therapy of *Helicobacter pylori* in people is typically unsuccessful, but some dogs and cats seem to respond to erythromycin or amoxicillin as a sole agent. If high doses of erythromycin (22 mg/kg PO, twice daily) cause vomiting, the dose may be lowered to 10 to 15 mg/kg twice daily. A 10- to 14-day course of treatment appears adequate for most animals, although recurrence of infection is probable.

PROBIOTICS/PREBIOTICS

Administering live bacteria or yeast in the food with the intent to produce a beneficial effect is called *probiotic therapy*. Administering a specific dietary substance to specifically increase or decrease the numbers of specific bacteria is called *prebiotic therapy*. Concurrent use of probiotics and prebiotics is called *symbiotic therapy*. Currently there are only a few reports purporting a clear benefit in dogs or cats.

Lactobacillus, Bifidobacterium, and *Enterococcus* are bacteria typically administered to dogs. These bacteria are believed to stimulate Toll-like receptors on the intestinal epithelial cells and thereby affect cytokine production. The beneficial effect seems to last only as long as the bacteria are being administered. These bacteria rarely become permanently established in the gastrointestinal microflora. Not all probiotics sold in drug or grocery stores contain what the label states, which may be at least partially responsible for why efficacy has not be demonstrated. In general, large numbers of bacteria appear to be necessary, which explains why feeding yogurt (which contains relatively modest numbers of *Lactobacilli*) is typically ineffective.

FECAL TRANSPLANTATION

Much work is being done on fecal transplantation as a means of altering the intestinal bacterial flora and avoiding the need for antibiotics in dogs and cats with chronic intestinal diseases. Currently, there is no consensus as to the best technique(s) or the appropriate indications. However, this might become an important alternative to antibiotic therapy.

ANTHELMINTIC DRUGS

Anthelmintics are frequently prescribed for dogs and cats with alimentary tract disease, even if parasitism is not the primary problem. It is often reasonable to use these drugs empirically for the treatment of suspected parasitic infections in animals with acute or chronic diarrhea. Selected anthelmintics are listed in Table 28.7.

ENEMAS, LAXATIVES, AND CATHARTICS

Enemas are classified as either cleansing or retention.

TABLE 28.7

Selected Anthelmintics/Antiprotozoals

DRUG	DOSAGE* (PO)	USE	COMMENTS
Fenbendazole (Panacur; Safe-Guard)	50 mg/kg, once daily for 3-5 days	H/R/W/G	Not approved for cats but often used for 3-5 days in cats to eliminate *Giardia*. Give with food.
Metronidazole (Flagyl)	12-15 mg/kg PO q12h for 8 days (dogs) 17 mg/kg PO q24h for 7 days (cats)	G	Rarely see neurologic signs Use of metronidazole benzoate is 62% metronidazole and requires dose of 25 mg/kg
Ronidazole	30 mg/kg PO q24h for 12 days (cats) (not approved)	G	For *Tritrichomonas* infections in cats; drug is not approved for use in animals. Rarely causes neurologic signs.
Pyrantel (Nemex)	5 mg/kg (dogs) 20 mg/kg, once only (cats)	H/R/P H/R	Give after meal, repeat in 2 weeks
Pyrantel/febantel/praziquantel (Drontal Plus)	10 mg/kg febantel PO in food q24h for 3 days (adult dogs and cats) 15 mg/kg for puppies and kittens	T/H/R/W	Can treat *Giardia*: q24h for 3 days
Imidocloprid/moxidectin (Advantage multi)	Topical—follow manufacturers' recommendations	H/R/W	
Ivermectin/Pyrantel (Heartguard plus for dogs)	Pyrantel 5 mg/kg Ivermectin 6 µg/kg	H/R	
Milbemycin (Sentinel, Trifexis)	0.5 mg/kg monthly (dog)	H/R/W	Not approved for use in cats. Not safe to use in dogs with *D. immitis* microfilaremia.
Praziquantel (Droncit)	5 mg/kg PO for dogs > 6.8 kg 7.5 mg/kg PO for dogs < 6.8 kg 7.5 mg/kg IM or SC for dogs < 2.3 kg 6.3 mg/kg IM or SC for dogs 2.7-4.5 kg 5 mg/kg IM or SC for dogs > 5 kg 11.4 mg/cat PO for cats < 1.8 kg; or IM or SC for cats 1.8-2.2 kg 22.7 mg/cat PO, SC, or IM for cats 2.3-5 kg 34.5 mg/cat PO, IM or SC for cats > 5 kg For *Heterobilharzia,* 20 mg/kg SC q8h for 1 day (dogs only)	T	10 mg/kg for juvenile *Echinococcus* spp. or *Spirometra*
Epsiprantel (Cestex)	5.5 mg/kg PO, once, for dogs 2.75 mg/kg PO, once, for cats	T	—
Sulfadimethoxine (Albon)	50 mg/kg on day 1, then 27.5 mg/kg q12h for 9 days	C	May cause dry eyes, arthritis, various cytopenias, hepatic disease
Trimethoprim-sulfadiazine (Tribrissen)	30 mg/kg for 10 days	C	May cause dry eyes, arthritis, various cytopenias, hepatic disease

C, Coccidia; *G, Giardia; H,* hookworms; *P, Physaloptera; PO,* orally; *R,* roundworms; *SC,* subcutaneously; *T,* tapeworms; *W,* whipworms.
*Dosages are for both dogs and cats unless otherwise specified.

Retention enemas are given so that the material administered stays in the colon until it exerts its desired effects (e.g., antiinflammatory retention enemas in animals with IBD, water in obstipated animals). Obstipated animals may require frequent administrations of modest volumes of water (e.g., 20-200 mL, depending on the animal's size) so that the water stays in the colon and gradually softens the feces. The clinician should avoid overdistending the colon or administering drugs that may be absorbed and produce undesirable effects. Suspected or pending colonic rupture is a contraindication to the use of enemas, but this can be difficult to predict. Animals that have undergone neurosurgery (e.g., hemilaminectomy) and are receiving glucocorticoids, especially dexamethasone, may be at increased risk for colonic perforation. Animals with colonic tumors and those that have recently undergone colonic surgery or biopsy should not receive enemas unless there is an overriding reason.

Cleansing enemas are designed to remove fecal material. They involve repeated administration of relatively large volumes of warm water. In dogs the water is administered by gravity flow from a bucket or bag held above the animal. The enema tube is gently advanced as far as it will easily go into the colon (hopefully to the flexure between the descending and transverse colon). Between 50 and 100 mL is tolerated by most small dogs, 200 to 500 mL by medium-size dogs, and 1 to 2 L by large dogs. Care should be taken to avoid overdistending or perforating the colon. Enemas are usually administered to cats with a soft canine male urinary catheter and a 50-mL syringe. Cats typically vomit if rapid fluid administration causes colonic distention. A suspected or pending colonic perforation is a contraindication to a cleansing enema.

Hypertonic enemas are potentially dangerous and should not be used unless there is a clear-cut and imperative reason to do so. They can cause massive, fatal fluid and electrolyte shifts (i.e., hyperphosphatemia, hypocalcemia, hypokalemia, hyperkalemia), especially in cats and small dogs; but any animal that cannot quickly evacuate the enema is at risk.

Cathartics and laxatives (Table 28.8) should be used only to augment defecation in animals that are not obstructed. They are not routinely indicated in small animals except as part of lower bowel cleansing before colonoscopy or colonic surgery.

Irritative laxatives (e.g., bisacodyl) stimulate defecation rather than soften feces. They are often used before colonoscopic procedures and in animals that are reluctant to defecate because of an altered environment. They are probably inappropriate for long-term use because people who use them chronically develop dependence and other colonic problems. A glycerin suppository or a lubricated matchstick is often an effective substitute for an irritative laxative. These objects are carefully placed in the rectum to stimulate defecation.

Bulk and osmotic laxatives include a variety of preparations: various fibers (especially soluble ones), magnesium sulfate, lactulose, and, in milk-intolerant animals, ice cream or milk. They promote fecal retention of water and are indicated in animals that have overly hard stools not caused by ingestion of foreign objects. Fiber is a bulking agent that is incorporated into food and can be used indefinitely. Commercial diets relatively high in fiber may be used, or existing diets may be supplemented with fiber (see p. 434). It is important to supply adequate amounts of water so that the additional fiber does not cause harder-than-normal stools. Too much fiber may cause excessive stool or inappetence resulting from decreased palatability (a danger for fat cats at risk for hepatic lipidosis). Fiber should not be given to animals with a partial or complete alimentary tract obstruction, because impaction may occur.

Lactulose (Cephulac) was designed to control signs of hepatic encephalopathy, but it is also an effective osmotic laxative. It is a disaccharide that is split by colonic bacteria

TABLE 28.8

Selected Laxatives, Cathartics, Stool-Softening Agents, and Bulking Agents

DRUG	DOSAGE (PO)	COMMENTS
Bisacodyl (Dulcolax)	5 mg (small dogs and cats) 10-15 mg (larger dogs)	Do not break tablets.
Coarse wheat bran	1-3 tbsp/454 g of food	
Canned pumpkin pie filling	1-3 tbsp/day (cats only)	Principally for cats.
Dioctyl sodium sulfosuccinate (Colace)	10-200 mg q8-12h (dogs only) 10-25 mg q12-24h (cats only)	Be sure animal is not dehydrated when treating.
Lactulose (Cephulac)	1 mL/4.5 kg q8-12h, then adjust dose as needed (dogs only) 5 mL q8-12h, then adjust dose as needed (cats only)	Can cause severe osmotic diarrhea.
Psyllium (Metamucil)	1-2 tsp/454 g of food	Be sure animal has enough water, or constipation may develop.

PO, Orally.

into unabsorbed particles. Lactulose is particularly useful for animals that refuse to eat high-fiber diets. The dose necessary to soften feces must be determined in each animal, but an initial dose of 1 ml/4.5 kg may be given two or three times daily. This initial dose is then modified to achieve the desired fecal consistency. Cats often ultimately need relatively high dosages (e.g., 5 mL two to three times daily). If gross overdosing occurs, so much water can be lost in the feces that hypernatremic dehydration ensues. There are no obvious contraindications to the use of lactulose.

CHAPTER 29

Disorders of the Oral Cavity, Pharynx, and Esophagus

MASSES, PROLIFERATIONS, AND INFLAMMATION OF THE OROPHARYNX

SIALOCELE

Etiology

Sialoceles are accumulations of saliva in subcutaneous tissues caused by salivary duct obstruction and/or rupture, and subsequent leakage of secretions into subcutaneous tissues. Most cases are probably traumatic, but some are idiopathic.

Clinical Features

A large swelling is found under the jaw or tongue or occasionally in the pharynx. Acutely the swelling may be painful, but most are nonpainful. Oral cavity sialoceles may cause dysphagia, whereas those located in the pharynx often produce gagging or dyspnea. If traumatized, sialoceles may bleed or cause anorexia due to discomfort. Classically found in 2- to 4-year-old dogs; German Shepherds and Miniature Poodles seem to be predisposed.

Diagnosis

Aspiration with a large-bore needle reveals thick fluid with some neutrophils. The fluid usually resembles mucus, strongly suggesting its salivary gland origin. Contrast sialograms and/or contrast computed tomography (CT) sometimes define which gland is involved.

Treatment

The mass is opened and drained. The salivary gland responsible for the secretions must be excised.

Prognosis

The prognosis is excellent if the correct gland is removed.

SIALOADENITIS/SIALOADENOSIS/ SALIVARY GLAND NECROSIS

Etiology

The etiology is unknown, but the condition apparently has occurred as an idiopathic event as well as secondary to chronic vomiting/regurgitation.

Clinical Features

The condition may cause a painless enlargement of one or more salivary glands (usually the submandibular). If there is substantial inflammation, animals may be dysphagic. A syndrome has been reported in which noninflammatory swelling (sialoadenosis) is associated with vomiting only responsive to phenobarbital therapy. Cause and effect are unclear, but it is clear that chronic vomiting will cause sialoadenitis and even necrosis in some dogs.

Diagnosis

Cytology or histopathology confirms that the mass is salivary tissue and determines whether inflammation or necrosis is present.

Treatment

If there is substantial inflammation and pain, surgical removal seems most efficacious. If the patient is vomiting, a search should be made for an underlying cause. If a cause is found, it should be treated and the size of the salivary glands monitored. If no other cause for vomiting can be found, phenobarbital may be administered at anticonvulsant doses (see Chapter 62).

Prognosis

The prognosis is usually excellent.

NEOPLASMS OF THE ORAL CAVITY IN DOGS

Etiology

Most soft tissue masses of the oral cavity are neoplasms, and most of these are malignant (i.e., melanoma, squamous cell carcinoma, fibrosarcoma). However, acanthomatous ameloblastomas (previously called *epulides*), fibromatous epulides (classically in Boxers), oral papillomatosis, and eosinophilic granulomas (e.g., in Siberian Huskies and Cavalier King Charles Spaniels) also occur.

Clinical Features

The most common signs of tumors of the oral cavity are halitosis, dysphagia, bleeding, salivation, or a growth

protruding from the mouth. Papillomatosis and fibromatous periodontal hyperplasia are benign growths that may cause discomfort when eating and occasionally cause bleeding, mild halitosis, or tissue protrusion from the mouth. The biologic behaviors of the different tumors are presented in Table 29.1.

Diagnosis

A thorough examination of the oral cavity (which may require that the animal be under anesthesia) usually reveals a mass involving the gingiva, although the tonsillar area, hard palate, and tongue may be affected. Diagnosis requires cytologic or histopathologic analysis, although papillomatosis and melanomas may be strongly suspected based upon their gross appearance. The preferred diagnostic approach in a dog with a mass of the oral cavity is to image the area (e.g., CT) and perform a relatively deep incisional biopsy. A deep biopsy is necessary to avoid misdiagnosis that often occurs if only the superficial, ulcerated, necrotic surface is obtained. If malignancy is possible, thoracic radiographs or CT should be obtained to evaluate for metastases (uncommon but a very poor prognostic sign if present). Fine-needle aspiration of regional lymph nodes, even if they appear normal, is indicated to detect metastases. Melanomas may be amelanotic

TABLE 29.1

Some Characteristics of Selected Oral Tumors

TUMOR	TYPICAL APPEARANCE/ LOCATION	BIOLOGIC BEHAVIOR	PREFERRED THERAPY
Squamous Cell Carcinoma			
Gingiva	Fleshy or ulcerated/on rostral gingiva	Malignant, locally invasive	Wide surgical resection on rostral gingiva ± radiation; piroxicam may help palliate.
Tonsil	Fleshy or ulcerated/on one or rarely both tonsils	Malignant, commonly spreads to regional lymph nodes	None (chemotherapy may be of some benefit); piroxicam may be helpful for palliation.
Tongue margin (dog)	Ulcerated/on margin of tongue	Malignant, locally invasive	Surgical resection of tongue/radiotherapy; piroxicam may be helpful for palliation.
Base of tongue (cat)	Ulcerated/at base of tongue	Malignant, locally invasive	None (radiotherapy of tongue may be used palliatively).
Malignant Melanoma	Gray, black, or pink; can be smooth, usually fleshy/on gum, tongue, or palate	Very malignant, early metastases to lungs	Surgery and/or radiation therapy for local control. For systemic control, carboplatin chemotherapy has been used with limited success.
Fibrosarcoma	Pink and fleshy/on palate or gums	Malignant, very invasive locally	Wide surgical resection (radiation may be of some value in selected cases after surgical excision). Biologically high-grade, histologically low-grade tumors in young Labradors, Golden Retrievers, and German Shepherd Dogs may have higher metastatic potential).
Acanthomatous Ameloblastoma (Epulis)	Pink and fleshy/on gum or rostral mandible	Benign, locally invasive into bone	Surgical resection ± radiation for gross or microscopic disease. Must remove associated tooth and dental ligament.
Fibromatous Epulis	Pink, fleshy, solitary or multiple/on gums	Benign	Surgical resection, must remove associated tooth and dental ligament
Ossifying Epulis	Pink, fleshy, solitary or multiple/on gums	Benign	Surgical resection, must remove associated tooth and dental ligament
Papillomatosis	Pink or white, cauliflower-like, multiple/seen anywhere	Benign; malignant transformation to squamous cell carcinoma may occur rarely.	Nothing, surgical resection or cryotherapy
Plasmacytoma	Fleshy or ulcerated growth on gingiva	Malignant, locally invasive, rarely metastasizes	Surgical resection and/or radiation or melphalan chemotherapy

and can cytologically resemble fibrosarcomas, carcinomas, or undifferentiated round cell tumors. Biopsy and subsequent histopathologic analysis may be required for a definitive diagnosis.

Treatment and Prognosis

The preferred therapeutic approach in dogs with confirmed malignant neoplasms of the oral cavity and lack of clinically detectable metastases is wide, aggressive surgical excision of the mass and surrounding tissues (e.g., mandibulectomy, maxillectomy) and/or radiation. Enlarged regional lymph nodes should be excised and evaluated histopathologically, even if they are cytologically negative for neoplasia. Early complete excision (especially gingival or hard palate squamous cell carcinomas and acanthomatous epulides) may be curative. Sometimes, fibrosarcomas can be cured if diagnosed early and resected completely (i.e., 3 cm margins). However, young Labrador Retrievers and Golden Retrievers in particular tend to have a histologically low-grade but biologically high-grade subtype of fibrosarcoma, which has a very high metastatic rate. Melanomas have metastatic rates of 60% to 80%, making surgical cure extremely rare. Rostral tumors tend to have a better prognosis, probably because they are diagnosed earlier than more caudal tumors. Acanthomatous ameloblastomas may respond to radiation therapy alone (complete surgical excision is preferred), and squamous cell carcinomas or fibrosarcomas with residual postoperative disease may benefit from postoperative adjunctive radiation therapy. Lingual squamous cell carcinomas affecting the base of the tongue and tonsillar carcinomas have a very poor prognosis; complete excision or irradiation usually causes severe morbidity. Melanomas metastasize early and have a very guarded prognosis. Chemotherapy is usually not beneficial in dogs with squamous cell carcinoma, acanthomatous ameloblastomas, or melanoma. Piroxicam can palliate some patients with squamous cell carcinoma. Combination chemotherapy may palliate some dogs with fibrosarcomas (see Chapter 76). Radiotherapy plus hyperthermia has been successful in some dogs with oral fibrosarcoma. In all cases, an oncologist should be consulted.

Papillomatosis usually resolves spontaneously, although it may be necessary to resect some of the masses if they interfere with eating. Rarely there may be malignant transformation to squamous cell carcinoma. Fibromatous epulides may be resected if they cause problems.

NEOPLASMS OF THE ORAL CAVITY IN CATS

Etiology

Tumors of the oral cavity are less common in cats than in dogs, but they are almost all malignant and are usually squamous cell carcinomas that are diagnosed and treated as described for dogs. Cats are different from dogs in that they also have sublingual squamous cell carcinomas and eosinophilic granulomas (which mimic carcinoma but have a much better prognosis).

Clinical Features

Dysphagia, halitosis, anorexia, and/or bleeding are common features of these tumors.

Diagnosis

A large, deep biopsy specimen is needed because it is crucial to differentiate malignant tumors from eosinophilic granulomas. The superficial aspect of many oral cavity masses is ulcerated and necrotic because of proliferation of normal oral bacterial flora, making it difficult to accurately diagnose a mass when deep tissue samples are not obtained.

Treatment

Surgical excision is desirable, but cats often do not tolerate aggressive oral surgery as well as dogs do. Long-term or permanent feeding tubes may be required. Radiation therapy and/or chemotherapy may benefit cats with incompletely excised squamous cell carcinomas not involving the tongue or tonsil.

Prognosis

In general, the prognosis for cats with oral squamous cell carcinoma is poor (see Chapter 81).

FELINE EOSINOPHILIC GRANULOMA

Etiology

The cause of feline eosinophilic granuloma is uncertain. Hypersensitivity reactions are thought to be responsible, and a genetic predisposition has been suggested.

Clinical Features

Feline eosinophilic granuloma complex includes indolent ulcer, eosinophilic plaque, and linear granuloma, but it has not been established that these diseases are related. Indolent ulcers are classically found on the lip or oral mucosa (especially the maxillary canine teeth) of middle-aged cats. Eosinophilic plaque usually occurs on the skin of the medial thighs and abdomen. Linear granuloma is typically found on the posterior aspect of the rear legs of young cats but may also occur on the tongue, palate, and oral mucosa. Severe oral involvement of an eosinophilic ulcer or plaque typically produces dysphagia, halitosis, and/or anorexia. Eosinophilic granuloma may affect the chin and paw pads in addition to the mouth.

Diagnosis

An ulcerated mass may be found at the base of the tongue or on the hard palate, the glossopalatine arches, or anywhere else in the mouth. A deep biopsy specimen of the mass is necessary for accurate diagnosis. Peripheral eosinophilia is inconsistently present.

Treatment

Systemic antibiotics directed against *Staphylococcus* spp. (e.g., amoxicillin plus clavulanic acid, trimethoprim-sulfa combinations) are often effective in treating indolent

ulcers and eosinophilic plaque. If antibiotics are ineffective, then high-dose glucocorticoid therapy (oral prednisolone, 2.2-4.4 mg/kg/day) can be used, but cyclosporine seems to be the most effective treatment for indolent ulcers and plaque not responding to antibiotics. Some cats are best treated with methylprednisolone acetate injections (20 mg every 2-3 weeks as needed) instead of oral medications. Although effective, megestrol acetate may cause diabetes mellitus, mammary tumors, and uterine problems, and should not be used except under exceptional circumstances.

Prognosis

The prognosis is good, but the lesion can recur.

GINGIVITIS/PERIODONTITIS

Etiology

Bacterial proliferation and toxin production, usually associated with tartar buildup, destroy normal gingival structures and produce inflammation. Immunosuppression caused by feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and/or feline calicivirus might predispose to this disease.

Clinical Features

Dogs and cats may be affected. Many are asymptomatic, but halitosis, oral discomfort, refusal to eat, dysphagia, drooling, and tooth loss may occur.

Diagnosis

Visual examination of the gums reveals hyperemia around the tooth margins. Gingival recession may reveal tooth roots. Accurate diagnosis can be made through probing and oral radiographs. The stage of periodontal disease is defined by radiographs.

Treatment

Supragingival and subgingival tartar should be removed, and the crowns should be polished. Antimicrobial drugs effective against anaerobic bacteria (e.g., amoxicillin, clindamycin, metronidazole; see Drugs Used in Gastrointestinal Disorders table, pp. 515-517) may be used before and after cleaning teeth. Regular brushing of the teeth and/or oral rinsing with a veterinary chlorhexidine solution formulated for that purpose helps control the problem.

Prognosis

The prognosis is good with proper therapy.

STOMATITIS

Etiology

There are many causes of canine and feline stomatitis (Box 29.1). The clinician should always consider the possibility of immunosuppression with secondary stomatitis (e.g., FeLV, FIV, diabetes mellitus, hyperadrenocorticism).

BOX 29.1

Common Causes of Stomatitis

Renal failure (primarily with severe, acute renal injury)
Trauma
- Foreign objects
- Chewing or ingesting caustic agents
- Chewing on electrical cords

Immune-mediated disease
- Pemphigus

Chronic ulcerative paradental stomatitis (especially Maltese Terriers)
Upper respiratory viruses (feline viral rhinotracheitis, feline calicivirus)
Infection secondary to immunosuppression (feline leukemia virus, feline immunodeficiency virus)
Tooth root abscesses
Severe periodontitis
Osteomyelitis
Thallium intoxication (very rare)

Clinical Features

Most dogs and cats with stomatitis have thick ropey saliva, severe halitosis, and/or anorexia caused by pain. Some animals are febrile and lose weight.

Diagnosis

A thorough oral examination usually requires anesthesia. Stomatitis is diagnosed by gross observation of the lesions, but an underlying cause should be sought. Biopsy is routinely indicated, as are routine clinical pathology data and radiographs of the mandible and maxilla, including the tooth roots. Bacterial culture is not helpful.

Treatment

Therapy is both symptomatic (to control signs) and specific (i.e., directed at the underlying cause). Thorough teeth cleaning and aggressive antibacterial therapy (i.e., systemic antibiotics effective against aerobes and anaerobes, cleansing oral rinses with antibacterial solutions such as chlorhexidine) often help. In some animals extracting teeth associated with the most severely affected areas may help. Bovine lactoferrin has been suggested to ameliorate otherwise resistant lesions in cats.

Prognosis

The prognosis depends on the underlying cause.

FELINE LYMPHOCYTIC-PLASMACYTIC GINGIVITIS AND PHARYNGITIS/ CAUDAL STOMATITIS

Etiology

An idiopathic disorder, feline lymphocytic-plasmacytic gingivitis might be caused by feline calicivirus, *Bartonella henselae,* immunodeficiency from FeLV or FIV infection, or any

stimulus-producing sustained gingival inflammation. Cats might have an excessive oral inflammatory response that can produce marked gingival proliferation.

Clinical Features

Hyporexia and/or halitosis are the most common signs. Affected cats grossly have reddened gingiva around the teeth and/or posterior pillars of the pharynx (the latter is not seen with gingivitis). The gingiva may be obviously proliferative in severe cases and bleed easily. Dental neck lesions often accompany the gingivitis. Teeth chattering is also occasionally seen.

Diagnosis

Biopsy of affected (especially proliferative) gingiva is needed for diagnosis. Histologic evaluation reveals a lymphocytic-plasmacytic infiltration. Serum globulin concentrations may be increased. Checking for FeLV and FIV infection is important, and virus isolation from biopsied tissue may be helpful.

Treatment

There is currently no reliable therapy for this disorder. Proper cleaning and polishing of teeth and antibiotic therapy effective against anaerobic bacteria may help. High-dose glucocorticoid therapy (e.g., prednisolone, 2.2 mg/kg/day, methylprednisolone 10-20 mg subcutanenous (SC), triamcinolone 0.2 mg/kg orally [PO] daily) is often useful. In some severe cases, multiple tooth extractions (especially premolars and molars) may alleviate the source of the inflammation, in which case it is important that the root and periodontal ligament also be removed. Extraction of the canine teeth should be avoided if possible. Immunosuppressive drugs such as chlorambucil or cyclosporine (initially give 2-4 mg/kg PO bid, but then adjust based upon blood levels) may also be tried in obstinate cases.

Prognosis

The prognosis is guarded; severely affected animals often do not respond well to therapy.

DYSPHAGIAS

MASTICATORY MUSCLE MYOSITIS/ATROPHIC MYOSITIS

Etiology

Masticatory muscle myositis/atrophic myositis is an idiopathic immune-mediated disorder that affects muscles of mastication in dogs. The syndrome has not been reported in cats.

Clinical Features

In the acute stages, the temporalis and masseter muscles may be swollen and painful. However, many dogs are not presented until the muscles are severely atrophied and the mouth cannot be opened.

Diagnosis

Atrophy of temporalis and masseter muscles and inability to open the dog's mouth while anesthetized allow the clinician to establish a presumptive diagnosis. Histopathology (preferably with immunohistochemistry) of the temporalis and masseter muscles confirms the diagnosis. Finding antibodies to type 2M fibers strongly supports this diagnosis. Animals may have increased serum creatine kinase (CK) activity.

Treatment

High-dose prednisolone therapy (2.2 mg/kg/day) with or without azathioprine (50 mg/m^2 q48h) typically controls acute disease but is seldom helpful in patients with chronic disease that cannot open their mouths. Once control has been achieved, the prednisolone is administered every 48 hours and then the dose of prednisolone is tapered to avoid adverse effects. However, this tapering must be done slowly to prevent recurrence (see the section on immunosuppressive drugs in Chapter 72). If the mouth cannot be opened even under anesthesia, a gastrostomy tube may be used. Although some clinicians have used force to break the adhesions in chronic cases, this approach may cause mandibular fracture and is not recommended.

Prognosis

The prognosis is usually good for acute cases, but continued medication may be needed.

CRICOPHARYNGEAL ACHALASIA/DYSFUNCTION

Etiology

The cause of cricopharyngeal achalasia/dysfunction is unknown, but it is usually congenital. There is an incoordination between the cricopharyngeus muscle and the rest of the swallowing reflex, which produces obstruction at the cricopharyngeal sphincter during swallowing (i.e., the sphincter does not open at the proper time). The problem has a genetic basis in Golden Retrievers.

Clinical Features

Primarily seen in young dogs, cricopharyngeal achalasia rarely occurs as an acquired disorder. The major sign is regurgitation immediately after or concurrent with swallowing. Some animals become hyporexic, and severe weight loss occurs. Clinically this condition may closely mimic pharyngeal dysphagia.

Diagnosis

Definitive diagnosis requires fluoroscopy or cinefluoroscopy while the animal is swallowing barium or other contrast media. A young animal regurgitating food immediately on swallowing is suggestive of the disorder, but pharyngeal dysphagia with normal cricopharyngeal sphincter function must be differentiated from cricopharyngeal disease.

Treatment

Injection of the cricopharyngeal muscle with botulism toxin benefits some patients, and it is believed that these patients stand to improve the most from cricopharyngeal myotomy, whereas those that do not respond to botulinum toxin seem to respond poorly to surgery. If surgery is performed, be careful not to cause cicatrix at the surgery site. It is critical that this disorder is distinguished from pharyngeal dysphagia and that esophageal function in the cranial esophagus is evaluated before surgery is considered (see next section on pharyngeal dysphagia). Treatment with thyroxine might rarely help some patients.

Prognosis

The prognosis is usually good if cicatrix does not occur postoperatively.

PHARYNGEAL DYSPHAGIA

Etiology

Pharyngeal dysphagia is primarily an acquired disorder with neuropathies, myopathies, and junctionopathies (e.g., localized myasthenia gravis) seeming to be the main causes. Inability to form a normal bolus of food at the base of the tongue and/or propel the bolus into the esophagus is often associated with lesions of cranial nerves IX or X. Simultaneous dysfunction of the cranial esophagus may cause food retention just caudal to the cricopharyngeal sphincter.

Clinical Features

Although pharyngeal dysphagia principally is found in adults, younger animals occasionally have transient signs. Pharyngeal dysphagia often clinically mimics cricopharyngeal achalasia; regurgitation is associated with swallowing. Pharyngeal dysphagia sometimes causes more difficulty swallowing fluids than solids. Aspiration (especially associated with liquids) is common because the proximal esophagus is often flaccid and retains food and water, predisposing to later reflux into the pharynx.

Diagnosis

Fluoroscopic examination of the patient swallowing barium is typically required for diagnosis. An experienced radiologist is needed to reliably distinguish pharyngeal dysphagia from cricopharyngeal dysphagia. With the former condition the animal does not have adequate strength to push food boluses into the esophagus, whereas in the latter the animal has adequate strength but the cricopharyngeal sphincter stays shut or opens at the wrong time during swallowing, thereby preventing normal movement of food from the pharynx to the proximal esophagus. Serum CK may be increased in some patients with myopathies. Some causes may be detected by electromyography of laryngeal, pharyngeal, and esophageal muscles and/or muscle biopsy.

Treatment

Cricopharyngeal myotomy is often curative for animals with cricopharyngeal achalasia but can be disastrous for animals with pharyngeal dysphagias because it allows food retained in the proximal esophagus to more easily reenter the pharynx and be aspirated. The clinician must either bypass the pharynx (e.g., gastrostomy tube) or resolve the underlying cause (e.g., control the myopathy, junctionopathy, or neuropathy).

Prognosis

Prognosis is guarded because it is often difficult to characterize and treat the underlying cause, and the dog or cat is prone to progressive weight loss and recurring aspiration pneumonia.

ESOPHAGEAL WEAKNESS/ MEGAESOPHAGUS

CONGENITAL ESOPHAGEAL WEAKNESS

Etiology

The cause of congenital esophageal weakness (i.e., congenital megaesophagus) is uncertain, but a defect in vagal afferent innervation of the esophagus is suspected.

Clinical Features

Affected animals (primarily dogs) are usually presented because of "vomiting" (actually regurgitation) with or without weight loss, coughing, or fever from pneumonia. Occasionally, coughing and other signs of aspiration tracheitis and/or pneumonia may be the only signs reported by the owner. In particularly severe cases, one may see the cervical esophagus balloon in and out during respiration (Video 29.1).

Diagnosis

The clinician must first determine from the history that regurgitation is likely, instead of vomiting (see p. 391). Radiographs showing generalized esophageal dilation without evidence of obstruction (see Fig. 27.3, *A*) allow presumptive diagnosis of esophageal weakness. If plain thoracic radiographs are not revealing, then static or dynamic barium contrast radiographs are appropriate because many patients with esophageal weakness do not have abnormalities on plain radiographs. Fluoroscopic examination is required to distinguish idiopathic congenital esophageal weakness from lower esophageal achalasia; however, the latter is thought to be very uncommon. The esophageal deviation normally seen in brachycephalics (Fig. 29.1) must not be confused with esophageal pathology. Diverticula in the cranial thorax caused by esophageal weakness occur occasionally and can be confused with vascular ring obstruction (Fig. 29.2). Congenital rather than acquired disease is suspected if the regurgitation and/or aspiration began when the pet was young. If clinical features have

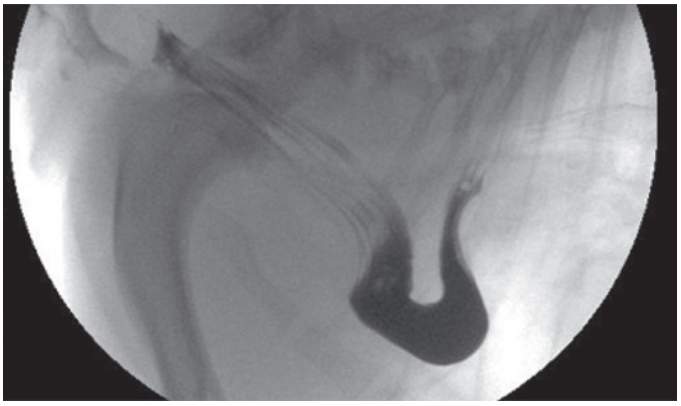

FIG 29.1
Lateral contrast radiograph of a Boston Terrier showing esophageal deviation, which is normal in brachycephalic breeds.

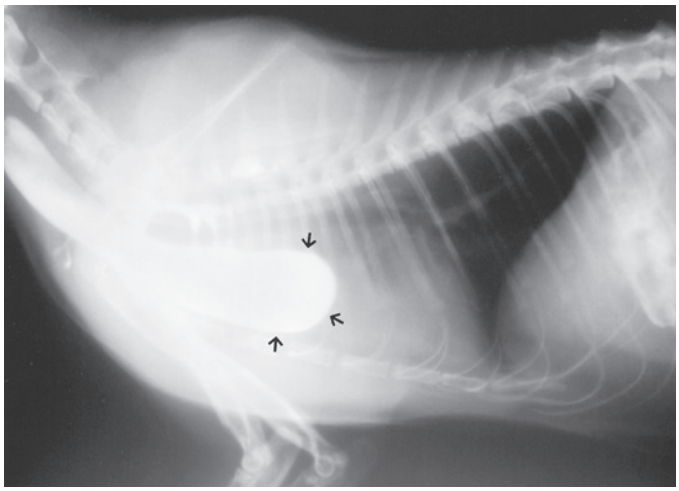

FIG 29.2
Lateral contrast thoracic radiograph of a cat. Note large diverticulum suggestive of obstruction *(arrows)*. This cat had generalized esophageal weakness without obstruction.

been relatively mild or intermittent, the diagnosis might not be made until the animal is older, but a careful history should suggest that disease has been present since the animal was young. Endoscopy is not as useful as contrast radiographs for diagnosing this disorder. In general, only very severe esophageal weakness may be diagnosed endoscopically (Video 29.1). Collies may have dermatomyositis, which also causes esophageal weakness. Some breeds (e.g., Miniature Schnauzer, Great Dane, Dalmatian, Chinese Shar-Pei, Irish Setter, Labrador Retriever) appear to be at increased risk.

Treatment

Congenital esophageal weakness currently cannot be cured or resolved by medical therapy, although cisapride (0.1-0.5 mg/kg) occasionally ameliorates signs (probably because it increases lower esophageal sphincter [LES] pressure in patients with substantial, concomitant gastroesophageal reflux). Dietary/feeding management is used to try to prevent further dilation and aspiration. The animal is fed from an elevated platform that requires the pet to stand on its rear legs making the cervical and thoracic esophagus nearly vertical so that gravity aids food passing through the esophagus and into the stomach. This position should be maintained for 5 to 10 minutes after the animal has finished eating and drinking. There are devices (e.g., "Bailey chair"; see http://petprojectblog.com/archives/dogs/megaesophagus-and-the-bailey-chair/) that aid the owner in keeping the patient vertical while feeding. Feeding several small meals a day also helps prevent esophageal retention.

Gruel is usually recommended, but some animals do better if fed dry or canned dog food. It is impossible to predict what consistency of food will be best for a given dog; therefore, trial and error are necessary. In some dogs the dilated esophagus may partially return to normal size and function. Even if the esophagus remains dilated, some dogs may be well managed by dietary/feeding modification and have a good quality of life.

In animals with severe aspiration, gastrostomy tubes can be used to bypass the esophagus, and some animals with gastrostomy tubes respond well for varying periods of time. These animals may still regurgitate saliva and also food if there is gastroesophageal reflux. Intermittent suctioning of the esophagus at home can be done in desperate situations.

Prognosis

The prognosis is hard to accurately predict. If the owners are aggressive about experimenting with different dietary consistencies and keeping the patient vertical after eating/drinking, some animals respond well. Others develop aspiration pneumonia despite all treatment efforts. Aspiration pneumonia is the major cause of death.

ACQUIRED ESOPHAGEAL WEAKNESS

Etiology

Acquired esophageal weakness in dogs is usually caused by a neuropathy, myopathy, or junctionopathy (e.g., myasthenia gravis; see Box 26.5). German Shepherds, Golden Retrievers, and Irish Setters might have increased risk. Dogs with idiopathic laryngeal paralysis often have cervical esophageal weakness, probably due to a generalized neuropathy. In cats, esophagitis may cause acquired esophageal weakness.

Clinical Features

Acquired esophageal weakness primarily occurs in dogs. Patients usually are presented because of "vomiting" (actually regurgitation), but some dogs present with respiratory signs (e.g., cough) and no history of regurgitation. Sometimes very small amounts of material are regurgitated into the pharynx where it is aspirated but never expelled. In other cases, material is expelled but re-swallowed or re-eaten by the animal (Fig. 29.3 *A,B*). Weight loss may occur if sufficient calories are lost by regurgitation.

Diagnosis

The initial diagnostic step is to document that regurgitation rather than vomiting is occurring (see p. 391). Acquired esophageal weakness is usually diagnosed by finding generalized esophageal dilation without evidence of obstruction on plain or contrast imaging (see Fig. 27.3, *A*). Severity of clinical signs does not always correlate with the magnitude of radiographic changes. It is important to note that plain thoracic radiographs may not reveal esophageal weakness; barium contrast esophagrams are indicated if esophageal regurgitation is suspected but the plain films appear normal (Fig. 29.3 *A,B*). Some symptomatic animals have segmental weakness primarily affecting the cervical esophagus, just behind the cricopharyngeus muscle (Video 29.2). Normal dogs often have minimal amounts of barium retained in this location, so it is important to distinguish insignificant from clinically important retention. Lower esophageal spasm and stricture very rarely radiographically mimic esophageal weakness. Ideally, fluoroscopy should be used to look for evidence of gastroesophageal reflux, which may benefit from prokinetic therapy (e.g., cisapride).

It is important to search for underlying causes of acquired esophageal weakness (see Box 26.5). The titer of antibodies to acetylcholine receptors (indicative of myasthenia gravis) should be measured in dogs. "Localized" myasthenia may affect only the esophagus and/or oropharyngeal muscles. Rare patients test negative initially but positive if retested months later. Resting serum cortisol measurements are indicated to screen for otherwise occult hypoadrenocorticism

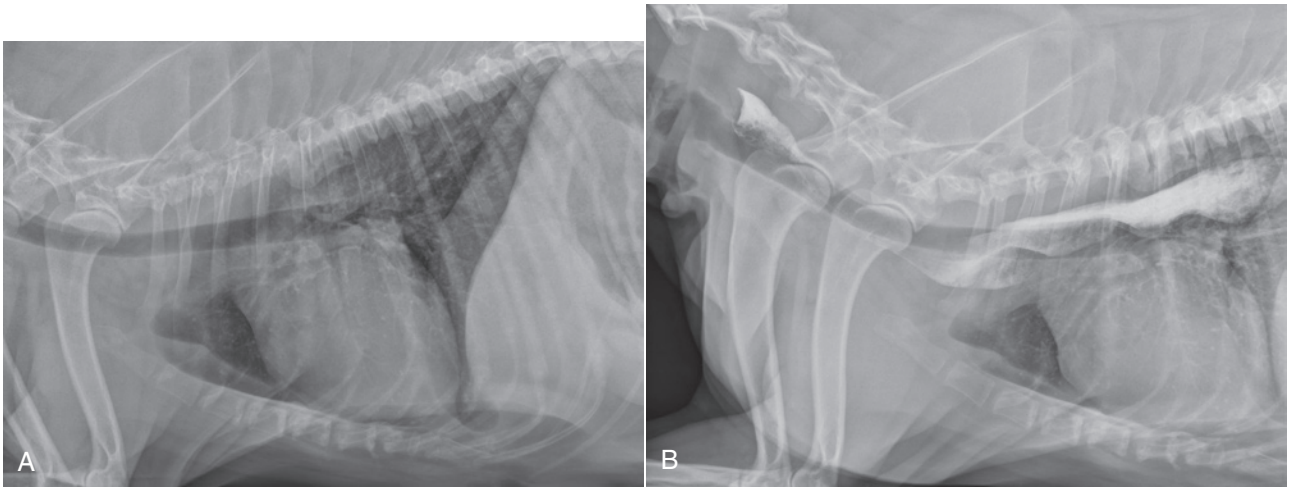

FIG 29.3
(A) Lateral radiograph of a dog with a severe cough but no history of regurgitation. There is no evidence of esophageal pathology. **(B)** A barium-contrast esophagram of the same dog showing major retention of the barium due to acquired esophageal weakness.

(even if serum electrolyte concentrations are normal; see Chapter 50). Electromyography may reveal generalized neuropathies or myopathies. Dysautonomia occurs occasionally and is suspected on the basis of clinical signs (i.e., dilated colon, dry nose, dilated pupils, keratoconjunctivitis sicca, and/or bradycardia that responds poorly to atropine). Gastric outflow obstruction in cats can cause intractable vomiting with secondary esophagitis producing megaesophagus. Other causes are rarely found (see Box 26.5). If an underlying cause cannot be found, the disease is termed *idiopathic acquired esophageal weakness* (i.e., idiopathic acquired megaesophagus).

Treatment

Dogs with acquired megaesophagus caused by hypoadrenocorticism typically respond well to glucocorticoid replacement (see Chapter 50). Localized myasthenia typically responds to pyridostigmine, which is preferred to physostigmine and neostigmine (see Chapter 66). Adjunctive immunosuppressive therapy with azathioprine may be helpful in some patients not responding well to pyridostigmine, but it is not clear that combination therapy is always superior to pyridostigmine alone. Glucocorticoid therapy is not recommended. Gastroesophageal reflux may respond to prokinetic and antacid therapy (cisapride at 0.1-0.5 mg/kg PO q8-12h and omeprazole at 1-2 mg/kg PO q12h are preferred). If the disease is idiopathic, conservative dietary therapy as described for congenital esophageal weakness is the only recourse. Some dogs with congenital esophageal weakness regain variable degrees of esophageal function, but this is less common with idiopathic acquired esophageal weakness. Severe esophagitis may cause secondary esophageal weakness, which resolves after appropriate therapy (discussed in more detail later in this chapter). In severely affected patients not responding adequately to dietary/feeding modifications, gastrostomy tubes may diminish the potential for aspiration, ensure positive nitrogen balance, and allow for administration of oral drugs. Some dogs benefit from the long-term use of a gastrostomy tube, but others continue to regurgitate and aspirate due to severe gastroesophageal reflux or accumulation of saliva in the esophagus.

Prognosis

All animals with acquired esophageal weakness are at risk for aspiration pneumonia and sudden death. If the underlying cause can be treated and the esophageal dilation and weakness can be resolved, the prognosis is often good because the risk of aspiration is eliminated. The prognosis is worse in patients with aspiration pneumonia and those with idiopathic megaesophagus that are older than 13 months of age at the time of onset of clinical signs because they are less likely to experience spontaneous remission. The prognosis is also poor for patients that fail to respond to dietary/feeding management. The size of the esophageal dilation on radiographs is not clearly associated with prognosis.

ESOPHAGITIS

Etiology

Esophagitis is principally caused by gastroesophageal reflux, persistent vomiting of gastric acid, esophageal foreign objects, and caustic agents. Medicines, especially tetracyclines, clindamycin, ciprofloxacin, and nonsteroidal antiinflammatory drugs (NSAIDs) may cause severe esophagitis if they are retained in the esophagus because they are not washed down with water or food (especially in cats).

Gastroesophageal reflux during anesthesia can produce severe esophagitis with subsequent stricture formation. It is impossible to predict which animals will reflux during anesthesia. Various factors have been suggested to place patients at increased risk for anesthesia-associated reflux, but none has consistently had a strong association that can be used clinically. An association between distal esophagitis (ostensibly caused by gastroesophageal reflux) and upper respiratory disease in brachycephalic dogs has been suggested. Eosinophilic esophagitis is rare and has uncertain causes in dogs. Pythiosis can cause severe esophagitis (see p. 484).

Clinical Features

Signs depend upon the severity of the inflammation. Regurgitation is expected, although anorexia and drooling due to refusal to swallow may predominate if swallowing is too painful. If a caustic agent (e.g., disinfectant) is ingested, the mouth and tongue are often hyperemic and/or ulcerated; hyporexia may be the primary sign.

Diagnosis

A history of vomiting followed by a change in character that sounds more like regurgitation suggests esophagitis secondary to excessive exposure to vomited gastric acid (e.g., dogs with parvoviral enteritis or foreign body obstruction). Regurgitation or hyporexia beginning shortly after an anesthetic procedure may indicate esophagitis caused by reflux. Plain and contrast radiographs may reveal hiatal hernias, gastroesophageal reflux, or esophageal foreign bodies. Contrast esophagrams do not reliably detect esophagitis (sometimes there is slight barium retention by the roughed, irregular mucosa), but contrast enhanced fluoroscopy can be definitive for gastroesophageal reflux in some cases (Video 29.3). Typically esophagoscopy is needed to diagnose esophagitis (Fig. 27.11).

Treatment

Decreasing gastric acidity, preventing reflux of gastric contents into the esophagus, and protecting the denuded esophagus are the hallmarks of treatment. Proton pump inhibitors (e.g., omeprazole) are far superior to histamine-2 (H_2) receptor antagonists for decreasing gastric acidity, a critical factor in these animals. Metoclopramide stimulates gastric emptying, resulting in less gastric volume to reflux into the esophagus; its main advantage is that it can be given intravenously. Cisapride (0.1-0.5 mg/kg) is a more effective prokinetic but must be given orally. Erythromycin and ranitidine also have

some prokinetic activity. Sucralfate (particularly suspensions) might protect denuded esophageal mucosa if there is gastroesophageal reflux (see Table 28.5), but its main value is to provide some analgesia for the discomfort of the esophagitis. For dogs in a lot of pain that will not even swallow their saliva, viscous lidocaine, which is available over the counter, may be administered orally. Antibiotics are of dubious value. In exceptional cases, a gastrostomy feeding tube protects the esophagus while the mucosa is healing and ensures a positive nitrogen balance. Glucocorticoids may be administered in an attempt to prevent cicatrix, but there is no evidence that they are effective Symptomatic hiatal hernias may have to be surgically repaired.

Proton pump inhibitors and prokinetics may be administered prophylactically to lessen anesthesia-associated reflux with subsequent esophagitis. Although such therapy lessens the frequency of acid reflux, it does not abolish it.

Prognosis

The prognosis depends on the severity of the esophagitis and whether an underlying cause can be identified and controlled. Early aggressive therapy helps prevent cicatrix formation.

HIATAL HERNIA

Etiology

Hiatal hernia is a diaphragmatic abnormality that allows part of the stomach (usually the cardia) to prolapse into the thoracic cavity. It may also allow gastroesophageal reflux.

Clinical Features

Brachycephalic breeds seem predisposed to this disorder. Regurgitation is the primary sign in symptomatic individuals, but some animals are asymptomatic.

Diagnosis

Plain radiographs or positive-contrast esophagrams may reveal gastric herniation into the thorax (Fig. 29.4); however, herniation may be intermittent and difficult to detect. Manually putting pressure on the abdomen while taking a radiograph may cause displacement of the stomach into the thorax during the study. Hiatal hernias are occasionally found endoscopically, but the endoscopic appearance can be subtle and is easily missed by novice endoscopists.

Treatment

If the hiatal hernia is symptomatic at an early age, surgery is more likely to be required to correct it. If clinical signs of hiatal hernia first appear later in life, aggressive medical management of gastroesophageal reflux (e.g., cisapride, omeprazole) is sometimes sufficient. If medical management is unsuccessful, surgery can be considered.

Prognosis

The prognosis is often good after surgical repair (congenital cases) or aggressive medical management (acquired cases).

DYSAUTONOMIA

Etiology

Dysautonomia in dogs and cats is an idiopathic condition that causes loss of autonomic nervous system function. In at least some circumstances (e.g., Key-Gaskell syndrome of cats), it might be due to a clostridial toxin.

Clinical Features

Clinical signs vary substantially. Megaesophagus and subsequent regurgitation are common but not invariable. Dysuria and a distended urinary bladder, mydriasis and lack of pupillary light response, dry mucous membranes, weight loss, constipation, vomiting, poor anal tone, and/or anorexia have all been reported.

Diagnosis

Dysautonomia is usually first suspected clinically by finding dysuria, dry mucous membranes, and abnormal pupillary light responses. Radiographs revealing distention of multiple areas of the alimentary tract (e.g., esophagus, stomach, small intestine) also are suggestive. A presumptive antemortem diagnosis is usually made by observing the effects of pilocarpine on pupil size after 1 to 2 drops of 0.05% pilocarpine are placed in one eye only. Finding that the treated eye rapidly constricts whereas the untreated eye does not is consistent with dysautonomia. Similarly, finding that a dysuric dog with a large urinary bladder can urinate after subcutaneous administration of 0.04 mg bethanechol/kg is also suggestive (although not all affected animals respond). Definitive diagnosis requires histopathology of autonomic ganglia obtained at necropsy.

Treatment

Treatment is palliative. Bethanechol can be given (2.5-15 mg once daily) to aid in urinary evacuation. The urinary bladder should be expressed as needed. Gastric prokinetics (e.g., cisapride) may help lessen vomiting. Antibiotics may be administered for aspiration pneumonia secondary to megaesophagus.

Prognosis

The prognosis is usually grim.

ESOPHAGEAL OBSTRUCTION

VASCULAR RING ANOMALIES

Etiology

Vascular ring anomalies are congenital defects. An embryonic aortic arch persists, trapping the esophagus in a ring of tissue. Persistent right fourth aortic arch (PRAA) is the most commonly recognized vascular anomaly (see Chapter 5).

Clinical Features

Vascular ring anomalies occur in dogs and cats. Regurgitation is the most common presenting complaint, although

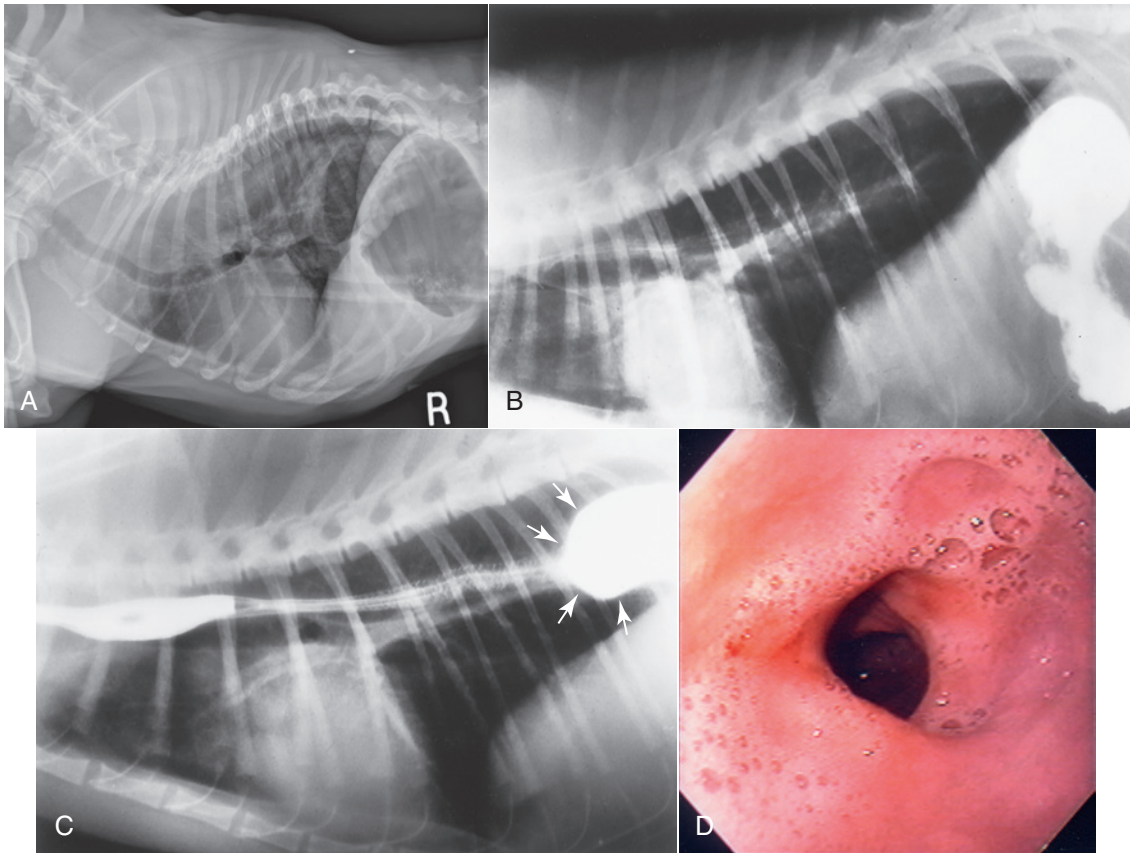

FIG 29.4

There is no evidence of hernia on this radiograph because it has apparently slid back into the abdomen. **(C)** Lateral view of contrast esophagram of the cat in **B.** The body of the stomach has now slid into the thoracic cavity *(arrows),* confirming that a hiatal hernia is present. **(D)** An endoscopic image of the lower esophageal sphincter (LES) area of a dog with a hiatal hernia. Gastric rugal folds can be seen. (**A,** Courtesy Dr. Russ Stickle, Michigan State University, East Lansing, Mich. **B** and **C,** Courtesy Dr. Royce Roberts, University of Georgia, Athens, Ga.)

aspiration (i.e., coughing or dyspnea) may occur. Clinical features often begin shortly after the animal eats solid food for the first time. However, some animals have relatively minor clinical signs and are not diagnosed until they are several years old or only if they are obstructed by an esophageal foreign body.

Diagnosis

Definitive diagnosis is usually made by contrast esophagram (see Fig. 27.3, *B*). Typically the esophagus cranial to the heart is dilated, whereas the esophagus caudal to the heart is normal. In rare cases the entire esophagus is dilated (the result of concurrent megaesophagus) except for a narrowing at the base of the heart. It has been suggested that if focal leftward deviation of the trachea is seen at the cranial border of the heart in the ventrodorsal or dorsoventral projections, this is sufficient to diagnose PRAA in young dogs that are regurgitating food. However, it is easy to misdiagnose PRAA with radiographs; therefore, advanced imaging (e.g., contrast thoracic CT) is recommended before surgery. Endoscopically, the esophagus has an extramural narrowing (Fig. 29.5; i.e., not a mucosal proliferation or scar) near the base of the heart.

Treatment

Surgical resection of the anomalous vessel is necessary. Conservative dietary management (i.e., gruel diet) by itself is inappropriate because the dilation will probably progress. In particular, the animal will be at risk for foreign body occlusion at the site of the PRAA.

Prognosis

Most patients improve dramatically after surgery, but some have minimal to no improvement, probably because of concomitant esophageal weakness. A guarded prognosis is appropriate. If a postsurgical stricture occurs, esophageal ballooning or a second surgical procedure may be considered.

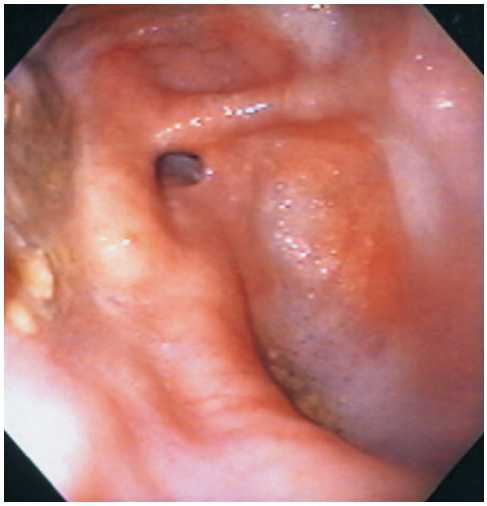

FIG 29.5
Endoscopic view of an esophageal lumen constricted by an extramural vascular ring anomaly. There is massive esophageal dilation cranial to the vascular ring, which "outlines" the trachea and the aorta. Not all vascular rings have such dilation allowing the endoscopist to see these structures so clearly.

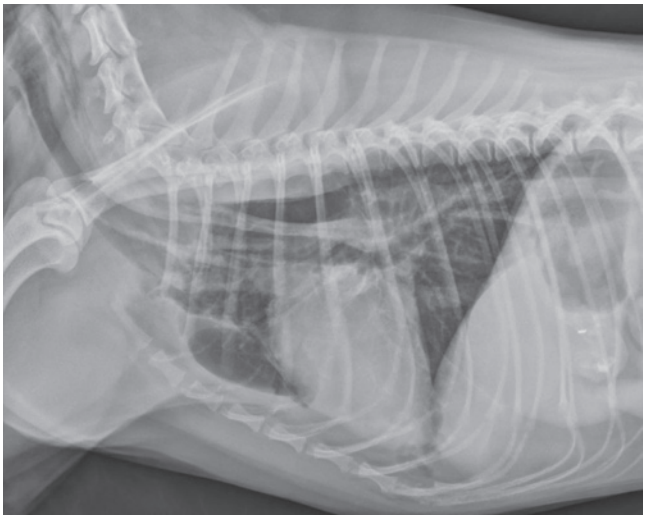

FIG 29.6
A lateral radiograph taken immediately after removing an esophageal foreign object, demonstrating pneumomediastinum and thus confirming that esophageal perforation has taken place.

ESOPHAGEAL FOREIGN OBJECTS

Etiology

Almost anything may lodge in the esophagus, but objects with sharp points (e.g., bones, fishhooks) are probably most common. Food boluses, hairballs, and chew toys can also be responsible. Most obstructions occur at the thoracic inlet, the base of the heart, or immediately in front of the diaphragm.

Clinical Features

Dogs are more commonly affected because of their less-discriminating eating habits. Regurgitation or hyporexia secondary to esophageal pain is common. Acute onset of regurgitation (as opposed to vomiting) is suggestive of esophageal foreign body. Clinical signs depend on where the obstruction occurs, whether it is complete or partial, how long the foreign body has been present, and whether esophageal perforation has occurred. Complete obstructions cause regurgitation of solids and liquids, whereas partial obstructions may allow retention of liquids. Acute dyspnea may indicate that the foreign object is impinging on airways at the base of the heart or that aspiration pneumonia has developed. Esophageal perforation usually causes fever, depression, and/or hyporexia; subsequent pleural effusion or pneumothorax/pneumomediastinum may cause dyspnea. Subcutaneous emphysema rarely occurs.

Diagnosis

Plain thoracic radiographs reveal most esophageal foreign bodies (see Fig. 27.2), although the clinician may have to search carefully to find poultry bones or other items that are relatively radiolucent. It is important to look for evidence of esophageal perforation (i.e., pneumomediastinum, pleural effusion, fluid in the mediastinum). Esophagrams are rarely necessary; esophagoscopy is diagnostic and typically therapeutic.

Treatment

Foreign objects are best removed endoscopically unless they are too firmly lodged to pull free or radiographs suggest perforation. Thoracotomy is generally indicated in these two situations. However, acute perforations due to a sharp foreign body (e.g., fish hook) may often be treated medically (see later). Objects that cannot be moved without substantial force should not be pulled vigorously because of the risk of creating or enlarging a perforation. During endoscopy, the esophagus should be insufflated carefully to avoid rupturing weakened areas, thereby causing tension pneumothorax. If the object is hard to retrieve and there are no sharp edges, the clinician may push it into the stomach where it can be retrieved via laparotomy or allowed to dissolve. Alternatively, one may pass a large Foley catheter past the foreign body, inflate the balloon so that it begins to distend the esophagus, and then pull the catheter (and the foreign body) out (Video 29.4). A lubricated Foley catheter can likewise be used to help open up the lower esophageal sphincter and make it easier to push a foreign object into the stomach.

After an object has been removed, the esophageal mucosa should be reexamined endoscopically to evaluate damage caused by the object. Thoracic radiographs should be repeated to look for indications of perforation (e.g., pneumomediastinum, pneumothorax) (Fig. 29.6). Proton pump inhibitors and prokinetic agents may be indicated post–foreign body removal. Gastrostomy tubes are very rarely used unless

there is extremely severe damage. Perforations from blunt foreign objects that caused esophageal wall necrosis usually require thoracotomy to clean out septic debris and close the esophageal defect. However, acute perforations from sharp objects (e.g., fish hooks) not associated with esophageal wall necrosis may often be treated by placing a gastrostomy tube, giving nothing per os, and allowing the perforation to spontaneously seal.

Prognosis

The prognosis for animals with esophageal foreign bodies without perforation is usually good. Perforation warrants a more guarded prognosis, depending on the size of the perforation and the presence/severity of thoracic contamination. Subsequent cicatrix and obstruction is possible if substantial mucosal damage occurs. Bone foreign bodies, small body size (i.e., < 10 kg), and chronicity appear to be risk factors for complications.

ESOPHAGEAL CICATRIX (BENIGN STRICTURE)

Etiology

Severe, deep inflammation of the esophagus from any cause (especially foreign bodies or severe gastroesophageal reflux) is usually required for cicatrix to occur.

Clinical Features

Esophageal cicatrix occurs in both dogs and cats. The main sign is regurgitation (especially of solids). Some animals are hyporexic due to pain experienced when food becomes lodged at the stricture by forceful esophageal peristalsis. Rare patients have severe respiratory stridor due to cicatrix in the nasopharynx or at the choanae (see Chapter 16).

Diagnosis

Partial obstructions due to cicatrix may be difficult to diagnose. Positive-contrast esophagrams in which barium is mixed with food are often necessary (Fig. 29.7). Esophagoscopy is definitive (Video 29.5), but a partial stricture may not be obvious in large dogs unless the endoscopist is experienced and the esophagus is carefully inspected. Likewise, it is easy to miss strictures at the lower esophageal sphincter. Strictures in the nasopharynx or at the choanae require retroflexed endoscopic examination of these areas.

Treatment

Surgical resection/anastomosis is not recommended. Treatment consists of correcting the suspected cause (e.g., esophagitis) and/or widening the stricture by ballooning or bougienage. It is important that the clinician have substantial training dilating strictures and the correct equipment. Ballooning has less chance of perforation than bougienage and may be accomplished with endoscopic or fluoroscopic guidance. Angioplasty catheters or esophageal dilation balloons are more useful than Foley catheters because the latter typically slide to one side of the obstruction during inflation.

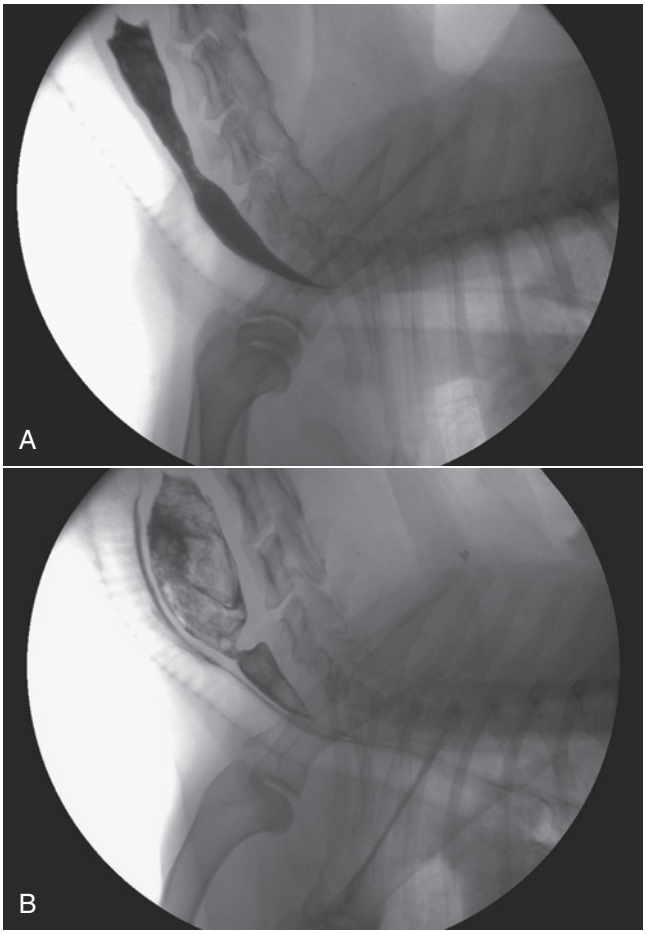

FIG 29.7
(A) Lateral contrast esophagram using liquid barium. There is some narrowing of the barium column but no obvious lesion. **(B)** Liquid barium has been mixed with canned food; a stricture in the midcervical esophagus is now very obvious. Note that the stricture is not at the thoracic inlet, which is where one might have suspected a stricture to be most likely on the first image.

Bougienage can likewise be done with endoscopic or fluoroscopic guidance. It can more easily cause a rupture but is relatively safe and equally effective if done by a trained individual. After the stricture has been dilated, significant traumatic esophagitis may be present. If it is present, it should be treated aggressively with proton pump inhibitors and gastric prokinetics. Some animals are cured after one dilatation, whereas others require multiple procedures.

In difficult patients in which the stricture recurs repeatedly after dilatation, more advanced techniques can be tried. Intralesional steroid injections, three-quadrant cuts into the stricture using endoscopic electrosurgery or laser, topical application of mitomycin C, placing a stent, and placing a balloon-esophagostomy tube have all been tried. Each has benefited some cases, but none is guaranteed to work; the author has seen each technique fail. Almost all strictures at the choanae require stenting. Nasopharyngeal strictures are very difficult to treat and should be immediately

referred to individuals with substantial experience in their treatment.

Prognosis

Early identification and appropriate treatment of high-risk animals (i.e., those with severe esophagitis or after foreign object removal) help decrease the likelihood of stricture formation. Resolving esophagitis decreases inflammation and lessens fibrous connective tissue formation. Long esophageal strictures (i.e., > 3-5 cm), continuing esophagitis at the stricture site, and very chronic strictures seem to have a more guarded prognosis. Most animals with benign esophageal strictures can be helped, but technical expertise is important. It is easy for a novice to perforate the esophagus or cause excessive trauma and make the stricture quickly recur or perhaps even come back worse than it was. Long-term gastrostomy tubes are rarely necessary.

ESOPHAGEAL NEOPLASMS

Etiology

Primary esophageal sarcomas in dogs are often due to *Spirocerca lupi*. Primary esophageal carcinomas are of unknown etiology. Leiomyomas and leiomyosarcomas are often found at the lower esophageal sphincter in older dogs. Thyroid carcinomas and pulmonary alveolar carcinomas may invade the esophagus in dogs. Squamous cell carcinomas are the most common esophageal neoplasm in cats.

Clinical Features

Dogs and cats with primary esophageal tumors may be asymptomatic until the tumor is advanced. These animals are sometimes diagnosed fortuitously when thoracic radiographs are obtained for other reasons. Regurgitation, anorexia, and/or fetid breath may occur if the tumor is large or causes esophageal dysfunction. If the esophagus is involved secondarily, clinical signs may result from esophageal dysfunction or tumor effects on other tissues.

Diagnosis

Plain thoracic radiographs may reveal a soft tissue density in the caudal lung fields. These tumors may be difficult to discern radiographically from pulmonary or mediastinal lesions and usually require contrast esophagrams (Fig. 29.8) or esophagoscopy (Fig. 29.9) to diagnose. Endoscopy typically allows differentiation of intraluminal from extraluminal masses causing esophageal stricture. Retroflexing the tip of an endoscope while it is within the stomach is the best method of identifying LES leiomyomas and leiomyosarcomas near the gastric cardia.

Treatment

Surgical resection is rarely curative (except for leiomyomas near the LES) because of the advanced nature of most esophageal neoplasms when they are diagnosed. However, resection may be palliative. Photodynamic therapy may be beneficial in dogs and cats with small superficial esophageal neoplasms. Surgery near the LES should be done only by an experienced surgeon; it is easy for an inexperienced surgeon to cause more disease than was present before.

Prognosis

The prognosis is usually poor (except for leiomyomas).

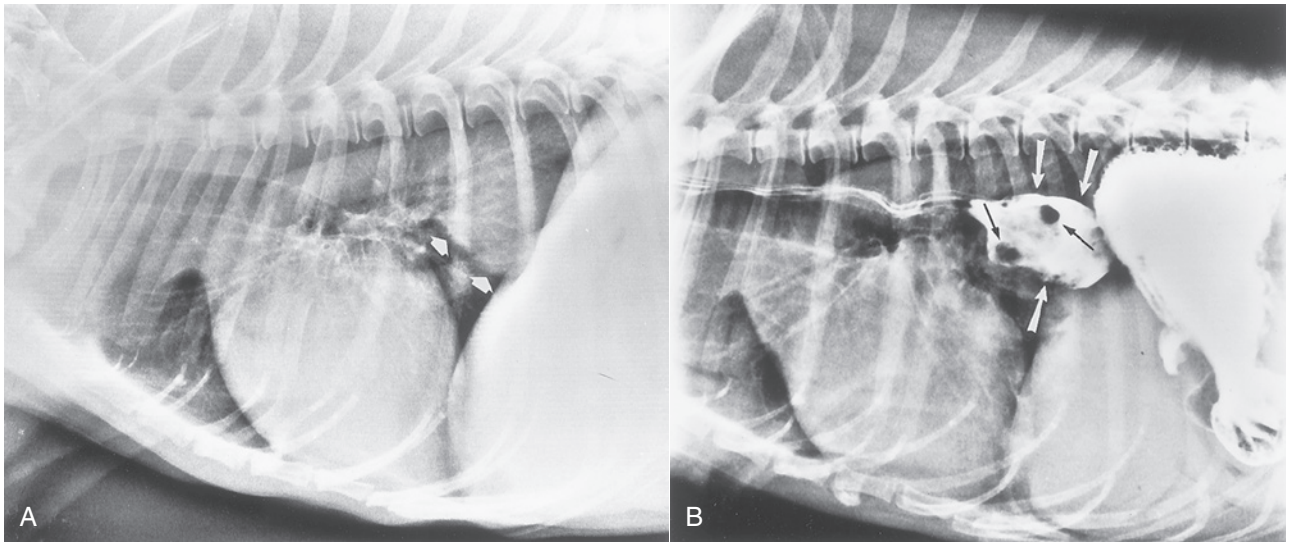

FIG 29.8
(A) Lateral thoracic radiograph of a dog with a previously unsuspected mass *(arrows)* not obviously associated with the esophagus. **(B)** Contrast esophagram in the same dog demonstrates that the esophagus is dilated *(large arrows)* and that there are intraesophageal filling defects *(small arrows)* in this dilated area. This dog had a primary esophageal carcinoma. (**A,** From Allen D, ed.: *Small animal medicine,* Philadelphia, 1991, JB Lippincott.)

CHAPTER 30

Disorders of the Stomach

GASTRITIS

ACUTE GASTRITIS

Etiology

Ingestion of spoiled or contaminated foods, foreign objects, toxic plants, chemicals, and/or irritating drugs (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) are common causes of acute gastritis. Infectious (i.e., viral and bacterial) causes occur but are poorly defined in dogs and cats.

Clinical Features

Dogs are more commonly affected than cats by acute gastritis, probably because of their less discriminating eating habits. Signs usually consist of acute onset of vomiting; food and bile are typically vomited, although small amounts of blood (usually specks or spots of blood as opposed to larger amounts) may be present. Affected animals are typically uninterested in food and may or may not feel sick. Fever and abdominal pain are uncommon.

Diagnosis

Unless the animal was seen eating some irritative substance, acute gastritis is usually a presumptive diagnosis of exclusion based on history and physical examination findings. Abdominal imaging and/or clinical pathologic data are indicated if the animal is severely ill or if other disease is suspected. In such a case, acute gastritis is a reasonable tentative diagnosis after alimentary foreign body, obstruction, parvoviral enteritis, uremia, diabetic ketoacidosis, hypoadrenocorticism, hepatic failure, hypercalcemia, and pancreatitis are ruled out. If the hyporexia/vomiting resolves after 1 to 2 days of symptomatic and supportive therapy, the tentative diagnosis is generally assumed to be correct (acute pancreatitis is still possible; see Chapter 37).

Because acute gastritis is a diagnosis of exclusion and its signs are suggestive of various other disorders (e.g., foreign bodies, intoxication), good anamnesis and physical examination are critical. The owner should monitor the pet, and if the animal's condition worsens or does not improve within 1 to 2 days, abdominal imaging (preferably ultrasound), a complete blood count (CBC), and a serum biochemistry profile are indicated.

Treatment

Withholding food and water for 24 hours often controls vomiting. If vomiting persists or is excessive, or if the animal becomes depressed because of the vomiting, central-acting antiemetics (e.g., maropitant, ondansetron) and/or fluids may be administered parenterally (see pp. 437-438). If there is minor hematemesis (i.e., a few specks of digested blood), then a proton pump inhibitor (e.g., omeprazole) might be administered but is rarely necessary. Begin oral intake by frequently offering small amounts of cool water. If the animal drinks without vomiting, then small amounts of an easily digested diet (e.g., one part cottage cheese and two parts potato; one part boiled chicken and two parts potato) are offered. Antibiotics and glucocorticoids are rarely indicated.

Prognosis

The prognosis is excellent as long as the fluid and electrolyte balance is maintained.

HEMORRHAGIC GASTROENTERITIS (ACUTE HEMORRHAGIC DIARRHEAL SYNDROME—SEE UNDER "DISORDERS OF THE INTESTINAL TRACT")

Etiology

The cause of acute hemorrhagic diarrheal syndrome (AHDS) is suspected to be *Clostridium* spp. The name has been changed to AHDS recently because histologically the damage is in the intestines, not the stomach.

Clinical Features

AHDS occurs in dogs and is a more severe disease than acute gastritis, typically causing profuse hematemesis and/or hematochezia. It classically occurs in smaller breeds that have not had access to garbage. This disorder has an acute course, which, if severe, can rapidly produce severe dehydration,

disseminated intravascular coagulation (DIC), and/or renal injury. In severe cases, the animal may be moribund by the time of presentation.

Diagnosis

These animals are typically hemoconcentrated (i.e., packed cell volume [PCV] ≥ 55%) with normal plasma total protein concentrations. Acute onset of typical clinical signs plus marked hemoconcentration allows a presumptive diagnosis. Thrombocytopenia and renal or prerenal azotemia may be seen in severely affected animals.

Treatment

Aggressive fluid therapy is initiated to treat or prevent shock, DIC secondary to hypoperfusion, and renal failure secondary to hypovolemia. Parenteral antibiotics (e.g., ampicillin) are often used because of the fear that intestinal bacteria are proliferating, but their value is doubtful and they are no longer recommended. If the patient becomes severely hypoalbuminemic, synthetic colloids or plasma may be required.

Prognosis

The prognosis is good for most animals that are presented in a timely fashion. Inadequately treated animals may die due to circulatory collapse, DIC, and/or renal failure.

CHRONIC GASTRITIS

Etiology

There are several types of chronic gastritis (e.g., lymphocytic/plasmacytic, eosinophilic, granulomatous, atrophic). Lymphocytic-plasmacytic gastritis might be an immune and/or inflammatory reaction to a variety of antigens. *Helicobacter* spp. and *Physaloptera rara* may produce such a reaction in some patients (especially cats and dogs, respectively). Eosinophilic gastritis may represent an allergic reaction, probably to food antigens. Atrophic gastritis may be the result of chronic gastric inflammatory disease and/or immune mechanisms. *Ollulanus tricuspis* may cause granulomatous gastritis in cats.

Clinical Features

Chronic gastritis appears to be more common in cats than in dogs. It is not clearly associated with chronic enteritis. Hyporexia and vomiting are the most common signs in affected dogs and cats. Frequency of vomiting varies from once weekly to many times a day. Some animals only demonstrate hyporexia, ostensibly because of low-grade nausea.

Diagnosis

Clinical pathologic findings are rarely helpful; eosinophilic gastritis inconsistently causes peripheral eosinophilia. Ultrasound sometimes documents mucosal thickening. Diagnosis requires gastric mucosal biopsy. Because gastritis may be generalized or localized, endoscopy is the best way of obtaining tissue samples. Endoscopy allows multiple biopsies over the entire mucosal surface, whereas surgical biopsy typically results in one sample that is randomly taken without knowledge of how the gastric mucosa appears. Gastric biopsy should always be performed regardless of the gross mucosal appearance. However, enteritis is far more common than gastritis, which is why duodenal biopsies are usually more important than gastric biopsies. Gastric lymphoma can be surrounded by lymphocytic inflammation, and obtaining inappropriately superficial tissue specimens can produce an incorrect diagnosis of inflammatory disease. Endoscopes with a 2.8-mm biopsy channel make it easier to avoid inappropriately superficial samples. Accurate histopathologic interpretation of alimentary tissue can be difficult; the clinician should not hesitate to request a second opinion if the histologic diagnosis does not fit the patient or the response (or lack thereof) to therapy. If *Ollulanus tricuspis* is suspected, vomitus or gastric washings should be examined for the parasites, but they might also be found in gastric biopsy specimens. *Physaloptera* can be seen endoscopically, but they can be very small if they are immature.

Treatment

Lymphocytic-plasmacytic gastritis sometimes responds to dietary therapy (e.g., low-fat, low-fiber, elimination diets) alone (see pp. 434-435). If such therapy is inadequate, glucocorticoids (e.g., prednisolone, 2.2 mg/kg/day) can be used concurrently. Even if glucocorticoids are required, appropriate dietary therapy may allow one to administer a substantially decreased dose, thus avoiding glucocorticoid adverse effects. If glucocorticoid therapy is necessary, the dose should be gradually decreased to find the lowest effective dose. However, the dose should not be tapered too quickly after obtaining a clinical response or the clinical signs may return and be more difficult to control than they were initially. In rare cases, azathioprine or similar drugs will be necessary (see Chapter 28). Proton pump inhibitors are sometimes beneficial. Ulceration should be treated as discussed on pages 470-471.

Canine eosinophilic gastritis usually responds well to a *strict* elimination diet. If dietary therapy alone fails, glucocorticoid therapy (e.g., prednisolone, 1.1-2.2 mg/kg/day) in conjunction with diet is usually effective. Feline hypereosinophilic syndrome responds poorly to most treatments.

Atrophic gastritis and granulomatous gastritis tend to be difficult to treat. Diets low in fat and fiber (e.g., one part cottage cheese and two parts potato) may help control signs. Atrophic gastritis might respond to antiinflammatory, antacid, and/or prokinetic therapy; the latter is designed to keep the stomach empty, especially at night. Idiopathic granulomatous gastritis is uncommon in dogs and cats and does not respond well to dietary or glucocorticoid therapy.

Prognosis

The prognosis for canine and feline lymphocytic-plasmacytic gastritis is often good with appropriate therapy. Lymphoma has been suggested to develop in cats with preexisting lymphocytic gastritis; however, it is impossible to know whether the original diagnosis of lymphocytic gastritis was incorrect,

if lymphoma developed independently of the gastritis, or if lymphoma developed from the gastritis.

The prognosis for canine eosinophilic gastritis is typically good. Feline eosinophilic gastritis can be a component of hypereosinophilic syndrome, which typically responds poorly to treatment. Hypereosinophilic syndrome has a guarded to poor prognosis.

HELICOBACTER-ASSOCIATED DISEASE

Etiology

Helicobacter pylori is the principal spirochete found in human gastric mucosa, whereas Non-*H. pylori* Helicobacter (NHPH) (e.g., *Helicobacter felis, Helicobacter heilmannii, Helicobacter bizzozeronii, Helicobacter salomonis*, etc.) are the principal gastric spirochetes in dogs and cats. *H. pylori* has rarely been found in cats.

Clinical Features

Most people infected with *H. pylori* are asymptomatic. Those with symptomatic *H. pylori* infections usually develop ulceration and gastritis with neutrophilic infiltrates. They can also develop low-grade mucosal-associated lymphoid tissue (MALT) lymphoma that can be cured with antibiotic therapy or gastric carcinoma. Similarly, most dogs and cats with gastric *Helicobacter* infections are asymptomatic. Some infected animals may have nausea, hyporexia, and/or vomiting associated with lymphocytic and occasionally neutrophilic infiltrates. Because so many infected animals are asymptomatic, cause and effect have not been clearly established between *Helicobacter* spp. and symptomatic gastric disease. Cats colonized with *H. pylori* seem to have more severe histologic lesions than those with *H. felis,* which in turn may be associated with more severe lesions than those with *H. heilmannii.* Currently, there is reasonable evidence that gastric *Helicobacter* infections cause clinical illness (i.e., vomiting, hyporexia) in some dogs and cats, but there is no good estimate of prevalence.

Diagnosis

Gastric biopsy is currently required to diagnose *Helicobacter* infection. The organisms are readily identified on H&E stain, but special stains (e.g., Giemsa, Warthin-Starry) as well as fluorescent *in situ* hybridization (FISH) make them stand out. The bacteria are not uniformly distributed throughout the stomach, and it is best to obtain biopsy specimens from the body, fundus, and antrum. The clinician may also diagnose this infection by cytologic evaluation of the gastric mucosa (Fig. 30.1) or by looking for gastric mucosal urease activity. Because of the uncertain pathogenicity of *Helicobacter* spp., the clinician is advised to look first for other more common explanations for the animal's clinical signs before deciding that *Helicobacter* is causing disease.

Treatment

A combination of metronidazole, amoxicillin, and bismuth (either subsalicylate or subcitrate) seems to be effective in alleviating clinical signs in veterinary patients. Contrary to people, there is no evidence that dogs or cats benefit from concurrent use of proton pump inhibitors. Azithromycin and clarithromycin have been substituted for bismuth in cats. Anecdotally, some animals seem to respond to just erythromycin or amoxicillin. Therapy should probably last for 14 days.

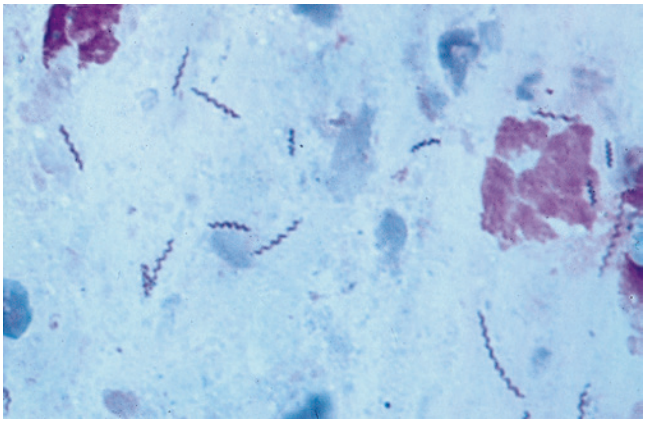

FIG 30.1
Air-dried smear of gastric mucosa obtained endoscopically and stained with Diff-Quik. Numerous spirochetes are seen. The affected dog was vomiting because of an ulcerated leiomyoma, and the spirochetes did not appear to be causing disease in this animal (×1000).

Prognosis

Animals with apparent *Helicobacter*-associated clinical illness seem to respond well to treatment and have a good prognosis. However, because cause and effect are uncertain, any animal not responding to therapy should be reexamined carefully, looking for other diseases. Recurrence of infection after treatment commonly occurs by 6 months, but it is not clear whether this represents a relapse of the original infection or reinfection from an outside source.

PHYSALOPTERA RARA

Etiology

Physaloptera rara is a nematode that has an indirect life cycle; beetles and crickets are the intermediate hosts. Frogs, snakes, mice, and birds may be paratenic hosts.

Clinical Features

In dogs, a single *P. rara* attached to the gastric mucosa can cause intractable vomiting. Cats are rarely affected, and their clinical illness associated with *P. rara* is less well characterized. The vomiting usually does not resolve with antiemetics. Vomitus may or may not contain bile, and affected animals usually appear otherwise healthy.

Diagnosis

Ova are seldom found in feces. If fecal examinations are performed, sodium dichromate or magnesium sulfate solutions are usually necessary to find the eggs. Most diagnoses are made when the parasites are found during

gastroduodenoscopy (see Fig. 27.21). There may be only one worm causing clinical signs, and it can be difficult to find if it is a juvenile worm or if it is attached within the pylorus. Alternatively, an empirical treatment trial (as described here) is reasonable.

Treatment

Pyrantel pamoate or ivermectin is usually effective. If the parasite is found during endoscopy, it can be removed with forceps.

Prognosis

Vomiting usually stops as soon as the worm(s) are removed or eliminated.

OLLULANUS TRICUSPIS

Etiology

Ollulanus tricuspis is a nematode with a direct life cycle transmitted via vomited material.

Clinical Features

Cats are the most commonly affected species, although dogs and foxes are occasionally infected. Vomiting is the principal clinical sign, but clinically normal cats may harbor the parasite. Gastric mucosal lesions may or may not be seen in infested cats.

Diagnosis

Cattery situations promote infection because the parasite is passed directly from one cat to another. However, occasionally cats with no known contact with other cats are infected. Looking for parasites in gastric washings or vomited material with a dissecting microscope is the best means of diagnosis. The parasite can be seen occasionally in gastric mucosal biopsy specimens.

Treatment and Prognosis

Therapy is uncertain, but fenbendazole might be effective. Occasionally animals have severe gastritis and become debilitated.

GASTRIC OUTFLOW OBSTRUCTION/ GASTRIC STASIS

BENIGN MUSCULAR PYLORIC HYPERTROPHY (PYLORIC STENOSIS)

Etiology

The cause of benign muscular pyloric hypertrophy is uncertain. Some research suggests that gastrin promotes development of pyloric stenosis.

Clinical Features

Benign muscular pyloric stenosis typically causes persistent vomiting in young animals (especially brachycephalic dogs and Siamese cats) but can be found in any animal. Affected animals usually vomit food shortly after eating. The vomiting is sometimes described as "projectile." Animals are otherwise clinically normal, although they may lose weight due to inadequate caloric retention. Some cats with pyloric stenosis vomit so much that secondary esophagitis, megaesophagus, and regurgitation occur, confusing the clinical picture. Hypochloremic-hypokalemic metabolic alkalosis sometimes occurs, but it is inconsistent and nonspecific for gastric outflow obstruction (excessive loss of gastric secretions for any reason and aggressive diuretic therapy are common causes).

Diagnosis

Gastric outflow obstruction is diagnosed based on plain/contrast radiographs, ultrasonography, gastroduodenoscopy (i.e., there are typically prominent folds of normal-appearing mucosa at the pylorus), and/or exploratory surgery (i.e., the surgeon can open the stomach and try to pass a finger through the pylorus to assess its patency) as well as eliminating extraalimentary tract diseases (see Box 26.6). Once diagnosed, the outflow area should be inspected endoscopically or surgically, and infiltrative pyloric disease ruled out through biopsy. At surgery the serosa appears normal, but the pylorus is usually thickened when palpated.

Treatment

Surgical correction is required. Pyloroplasty (e.g., a Y-U–plasty) is more consistently effective than pyloromyotomy. Improperly performed pyloroplasty or pyloromyotomy can cause perforation or worse obstruction. Some clinicians routinely performed one of these pyloric outflow procedures whenever an exploratory laparotomy fails to reveal the cause of vomiting; this is a very poor practice and should not be done.

Prognosis

Surgery should be curative, and the prognosis is good.

GASTRIC ANTRAL MUCOSAL HYPERTROPHY

Etiology

Antral mucosal hypertrophy is idiopathic. Gastric outflow obstruction is caused by proliferation of nonneoplastic mucosa that occludes the distal gastric antrum (Fig. 30.2). This disorder is different from benign muscular pyloric stenosis (i.e., where normal mucosa is thrown up into folds secondary to submucosal thickening).

Clinical Features

Principally found in older, small-breed dogs, antral hypertrophy clinically resembles pyloric stenosis (i.e., animals usually vomit food, especially after meals).

Diagnosis

Gastric outlet obstruction is diagnosed radiographically, ultrasonographically, or endoscopically; however, definitive diagnosis of antral mucosal hypertrophy requires mucosal

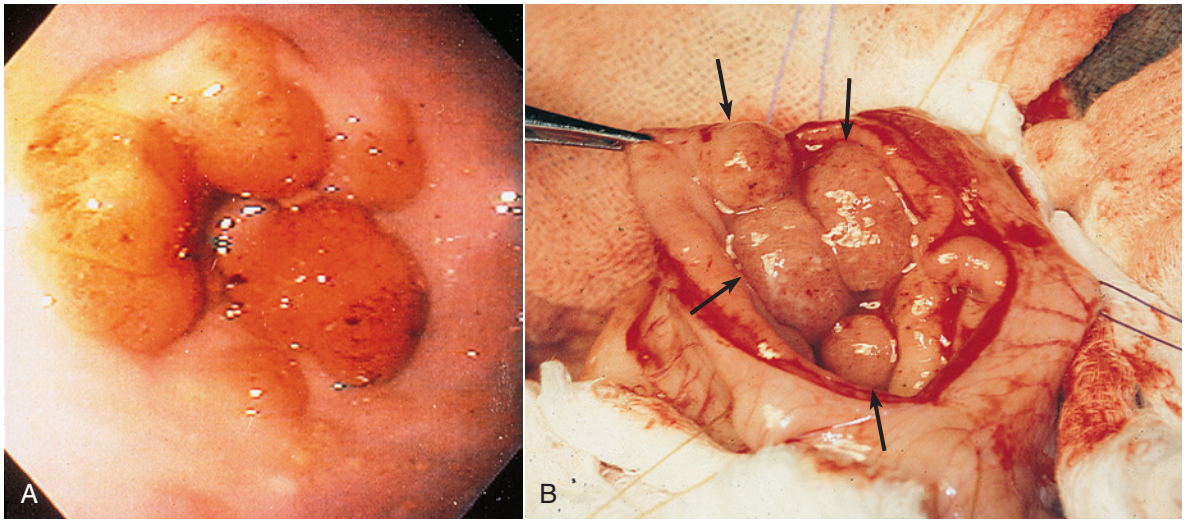

FIG 30.2
(A) Endoscopic view of the pyloric region of a dog that has gastric antral mucosal hypertrophy. If biopsy is not performed, these folds may easily be mistaken for neoplasia. **(B)** Intraoperative photograph of a dog's opened pylorus. Note the numerous folds of mucosa that are protruding *(arrows)* as a result of gastric antral mucosal hypertrophy.

biopsy. Endoscopically, the antral mucosa is redundant and may resemble a submucosal neoplasm causing convoluted mucosal folds (Video 30.1). In some cases the mucosa will be obviously reddened and inflamed. However, the mucosa in dogs with antral hypertrophy is usually not as firm or hard as expected with infiltrative carcinomas or leiomyomas. If antral mucosal hypertrophy is seen at surgery, there should be no evidence of submucosal infiltration or muscular thickening suggestive of neoplasia or benign pyloric stenosis, respectively. It is important to differentiate mucosal hypertrophy from these other diseases so that therapeutic recommendations are appropriate (e.g., gastric carcinomas typically have a terrible prognosis, and surgery is not always helpful).

Treatment

Antral mucosal hypertrophy is treated by mucosal resection, usually combined with pyloroplasty. Pyloromyotomy alone is typically insufficient to resolve clinical signs from mucosal hypertrophy.

Prognosis

The prognosis is excellent.

GASTRIC FOREIGN OBJECTS

Etiology

Objects that pass through the esophagus and then cannot leave the stomach are called gastric foreign objects. Vomiting may subsequently result from gastric outlet obstruction, gastric distention, or irritation. Linear foreign objects whose orad end lodges at the pylorus may cause intestinal perforation with subsequent peritonitis and must be dealt with expeditiously (see the section on intestinal obstruction on pp. 499-500).

Clinical Features

Dogs are affected more commonly than cats because of their less discriminating eating habits. Vomiting (*not* regurgitation) is a common sign, but some animals demonstrate only hyporexia while rare patients are asymptomatic.

Diagnosis

Acute onset of vomiting in an otherwise normal animal, especially a puppy, is potentially consistent with foreign body ingestion. Diagnosis results from palpating the object during physical examination or seeing it during imaging. Radiographs (plain and contrast), ultrasonography, and endoscopy are the most reliable means of diagnosis. However, diagnosis can be difficult if there is food in the stomach. Some diseases closely mimic gastric foreign body obstruction. Canine parvovirus in particular may initially cause an acute onset of intense vomiting, during which time viral particles might not be detected in the feces. Hypokalemic-hypochloremic metabolic alkalosis is consistent with loss of gastric fluid, but gastric outflow obstruction is only one cause of such loss. Anything causing vomiting can be responsible. Furthermore, not all animals with gastric outflow obstruction have these electrolyte changes. Excessive use of loop diuretics can produce identical electrolyte changes. Therefore these electrolyte changes are neither sensitive nor specific for gastric outflow obstruction.

Treatment

Many small foreign objects will spontaneously pass through the gastrointestinal tract; however, if there is doubt as to

whether a foreign body will or will not pass, it is best to remove it. Vomiting can be induced (e.g., apomorphine in the dog, 0.02 or 0.1 mg/kg administered intravenously or subcutaneously, respectively; xylazine in the cat, 0.4-0.5 mg/kg administered intravenously) to eliminate gastric foreign objects if the clinician believes that the object will not cause problems during forcible ejection (i.e., does not have sharp edges or points and is small enough to pass easily). If there is doubt as to the safety of this approach, the object should instead be removed endoscopically or surgically.

Before the animal is anesthetized for surgery or endoscopy, the electrolyte and acid-base status should be evaluated. Although electrolyte changes (e.g., hypokalemia) are common, they are impossible to accurately predict. Severe hypokalemia predisposes to cardiac arrhythmias and should usually be corrected before anesthesia.

Endoscopic removal of foreign objects requires a flexible endoscope and appropriate retrieval forceps. The animal should always be radiographed just before being anesthetized to confirm that the object is still in the stomach. Laceration of the esophagus and entrapment of the retrieval forceps in the object should be avoided. If endoscopic removal is unsuccessful, gastrostomy should be performed.

Prognosis

The prognosis is usually good unless the animal is debilitated or there is septic peritonitis secondary to gastric perforation.

IATROGENIC GASTRIC OUTFLOW OBSTRUCTION

Surgery of the gastric antrum and/or pylorus is technically difficult and characteristically unforgiving of mistakes. Any animal that has had surgery in this area and continues to vomit should be examined for iatrogenic outflow obstruction. Endoscopy is the best way to examine the outflow tract for iatrogenic mechanical obstruction (Video 30.2).

GASTRIC DILATION/VOLVULUS

Etiology

Gastric dilation/volvulus (GDV) is probably ultimately caused by poor gastric emptying of solids, which produces some degree of chronic gastric distention with subsequent stretching of hepatogastric and duodenogastric ligaments. Risk factors include large- and giant-breed conformation (especially those with deep, narrow chests), purebred status, age (i.e., middle aged to older animals), and having a first-degree relative with a history of GDV. Factors reported to predispose dogs to GDV include eating large volumes, eating once a day, eating rapidly, eating from an elevated platform, eating dry foods that have fats or oils listed as one of the first four ingredients, and being perceived as being a "nervous" dog. It is believed that, in many cases, the stomach is first partially twisted because of the stretched hepatogastric ligaments (i.e., typically the pylorus rotates ventrally from the right side of the abdomen below the body of the stomach to become positioned dorsal to the gastric cardia on the left side). At this point, affected dogs are clinically normal and can pass fluids and solids into the intestines. However, if subsequent aerophagia causes sufficient dilation, then gas and other gastric contents cannot be relieved through eructation or passed into the intestines. It is at this point that the patient has developed clinical GDV. The dog can continue to ingest air, but it cannot eliminate it. Splenic congestion and even torsion may occur concurrently with the spleen on the right side of the abdomen. Massive gastric distention obstructs the hepatic portal vein and posterior vena cava causing mesenteric congestion, decreased cardiac output, severe shock, DIC, and endotoxemia as well as putting pressure on the diaphragm, inhibiting respiration. The gastric blood supply (especially the short gastric vessels) may be impaired, causing gastric wall necrosis.

Clinical Features

GDV principally occurs in large- and giant-breed dogs with deep chests; it rarely occurs in small dogs or cats. Affected dogs typically retch nonproductively and may demonstrate abdominal pain (which may appear as "restlessness" to the client). Marked anterior abdominal distention may be seen later. However, abdominal distention is not always obvious in large, heavily muscled dogs. Eventually, depression and a moribund state occur.

Diagnosis

Physical examination findings (i.e., a dog of appropriate confirmation with large tympanic anterior abdomen and unproductive retching) allow presumptive diagnosis of GDV but do not permit differentiation between dilation and GDV. Plain abdominal radiographs, preferably right lateral and dorso-ventral projections, are required but should be done AFTER the patient is decompressed and shock is controlled. Volvulus is denoted by displacement of the pylorus and/or formation of a "shelf" of tissue in the gastric shadow (Fig. 30.3). It is impossible to distinguish between dilation and dilation/torsion on the basis of ability or inability to pass an orogastric tube.

Treatment

Treatment consists of initiating aggressive therapy for shock (hetastarch or hypertonic saline infusion [see pp. 432-434] may make treatment for shock quicker and easier) and decompressing the stomach. If the patient is asphyxiating, gastric decompression is initiated first. Decompression is usually performed with an orogastric tube, but it should not be excessively forced into the stomach lest too much pressure rupture the lower esophagus. After the gas is released, the stomach is lavaged with warm water to remove its contents (if blood is present in the retrieved lavage solution, gastric wall necrosis is probable). Most affected dogs can be successfully decompressed via intubation, but if the tube cannot be passed into the stomach, then the clinician may insert a large needle (e.g., 3-inch, 12- to 14-gauge) into the stomach just behind the rib cage in the left flank to decompress the stomach (which usually causes some abdominal

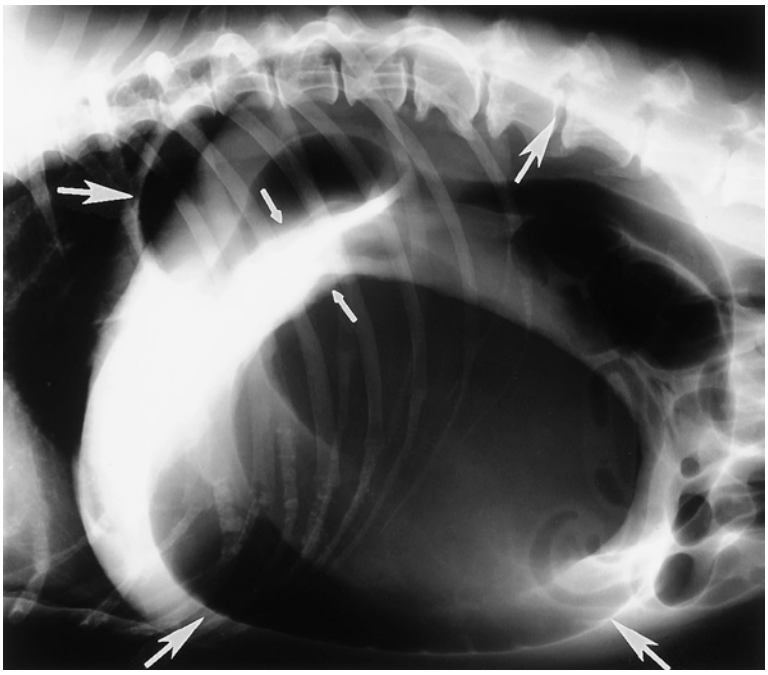

FIG 30.3
Lateral radiograph of a dog with gastric dilation/volvulus. The stomach is dilated *(large arrows),* and there is a "shelf" of tissue *(small arrows),* demonstrating that the stomach is malpositioned. Radiographs obtained from the right lateral position seem superior to those of other views in demonstrating this shelf. If the stomach were similarly distended but not malpositioned, the diagnosis would be gastric dilation.

contamination) or perform a temporary gastrostomy in the left paralumbar area (this is rarely done nowadays).

Mesenteric congestion caused by the enlarged stomach predisposes to infection and endotoxemia, making systemic antibiotic administration reasonable (e.g., cefazolin, 20 mg/kg administered intravenously). Serum electrolyte concentrations and acid-base status should be evaluated.

If the dog has GDV (see Fig. 30.3), surgery is necessary to reposition the stomach and should be performed as soon as the animal constitutes an acceptable anesthetic risk. Torsion (even when the stomach is deflated) impairs gastric wall perfusion and may cause necrosis. If there is no blood present in the gastric contents seen after gastric lavage, one can take more time to optimally resuscitate the patient; but if blood is present, then surgery needs to occur as quickly as possible. Areas of gastric wall necrosis should be resected or invaginated to prevent perforation and abdominal contamination. Gastropexy (e.g., incisional, circumcostal, belt loop, tube gastrostomy) is indicated to help prevent recurrence of GDV and seems correlated with prolongation of survival. Gastropexy is optional in dogs with gastric dilation without torsion, but it is strongly recommended to prevent future GDV. Gastropexy almost always prevents torsions but does not prevent dilation.

Postoperatively, the animal should be monitored by electrocardiogram (ECG) for 48 to 72 hours. Lidocaine or procainamide may be needed if severe cardiac arrhythmias diminish cardiac output (see Chapter 4). Hypokalemia is common in these patients and makes such arrhythmias refractory to medical control, so it should be prevented by intravenous supplementation. Serial plasma lactate measurements may indicate whether more aggressive fluid resuscitation is needed.

Although preventing exercise after meals and feeding small meals of softened food would intuitively seem useful, no data confirm this speculation. Prophylactic gastropexy (often performed at the time of neutering) can be considered in patients that appear at risk.

Prognosis

The prognosis depends on how quickly the condition is recognized and treated. Patients receiving appropriate therapy within 5 hours of onset of signs have mortality rates of approximately 15%. Factors associated with much worse prognosis include therapy being delayed more than 5 or 6 hours after onset, hypothermia, hypotension, depression, being comatose, having preoperative cardiac arrhythmias, gastric wall necrosis, peritonitis, sepsis, severe DIC, combination of partial gastrectomy and splenectomy, and postoperative acute renal failure. Increased preoperative blood lactate concentrations also seem suggestive of a poor outcome. Fewer than 10% of animals with gastropexy experience recurrence of GDV compared with over 50% of those without gastropexy. Prophylactic gastropexy may be elected for animals believed to be at increased risk for GDV. Laparoscopic-assisted gastropexy is a minimally invasive procedure.

PARTIAL OR INTERMITTENT CHRONIC GASTRIC VOLVULUS

Etiology

The causes for partial and intermittent chronic gastric volvulus are probably the same as for classic GDV.

Clinical Features

Dogs with chronic volvulus do not have the life-threatening progressive syndrome characterizing classic GDV. Although occurring in the same breeds as GDV, chronic gastric volvulus usually produces a chronic, intermittent, potentially difficult-to-diagnose problem. It may occur repeatedly and spontaneously resolve; dogs may appear normal between bouts. Some dogs have persistent nondistended volvulus and are asymptomatic.

Diagnosis

Plain radiographs are usually diagnostic (Fig. 30.4), but diagnosis may require repeated radiographs and/or contrast studies. Chronic volvulus will rarely be diagnosed endoscopically. In rare cases one may cause a temporary gastric volvulus by manipulating a gastroscope in an air-distended stomach, so the clinician must differentiate spontaneous from iatrogenic volvulus.

Treatment

If partial or intermittent chronic gastric volvulus is diagnosed, surgical repositioning and gastropexy are usually curative. Pexy will also help prevent classic GDV from occurring.

Prognosis

The prognosis is usually good once the problem is identified and surgically corrected.

IDIOPATHIC GASTRIC HYPOMOTILITY

Etiology

Idiopathic gastric hypomotility refers to an anecdotal syndrome characterized by poor gastric emptying and motility despite the lack of anatomic obstruction, inflammatory lesions, or other causes.

Clinical Features

Idiopathic gastric hypomotility has primarily been diagnosed in dogs. Affected dogs usually vomit food several hours after eating but otherwise appear well. Weight loss may or may not occur.

Diagnosis

Fluoroscopic studies document decreased gastric motility, but diagnosis requires ruling out gastric outlet obstruction, infiltrative bowel disease, inflammatory abdominal disease, and extraalimentary tract diseases (e.g., renal, adrenal, or hepatic failure; severe hypokalemia or hypercalcemia).

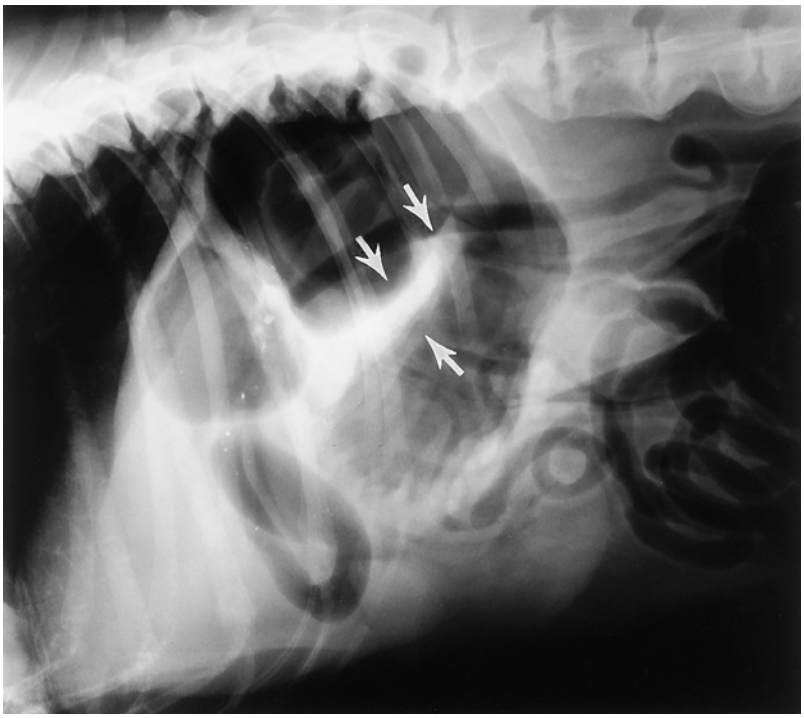

FIG 30.4
Lateral abdominal radiograph of an Irish Setter with chronic vomiting caused by gastric volvulus that did not cause dilation. A "shelf" of tissue *(arrows)* demonstrates that the stomach has twisted.

Treatment

Metoclopramide (see Table 28.3) increases gastric peristalsis in some but not all affected dogs. Cisapride, erythromycin, or ranitidine may be effective if metoclopramide fails. Diets low in fat and fiber may be helpful.

Prognosis

Dogs that respond to medical management have a good prognosis. Those that do not respond have a poor prognosis for cure, although they may still be acceptable pets.

BILIOUS VOMITING SYNDROME

Etiology

Bilious vomiting syndrome appears to be caused by gastroduodenal reflux that occurs when the dog's stomach is empty for long periods of time (e.g., during an overnight fast).

Clinical Features

Bilious vomiting syndrome usually affects otherwise normal dogs that are fed once daily in the morning. Classically, the pet vomits bile-stained fluid once a day, usually late at night or in the morning just before eating.

Diagnosis

The clinician must rule out gastrointestinal (GI) obstruction, GI inflammation, and extraalimentary tract diseases. Elimination of these disorders, in addition to the history as described, strongly suggests bilious vomiting syndrome.

Treatment

Feeding the dog an extra meal late at night to prevent the stomach from being empty for long periods of time is often curative. If vomiting continues, a gastric prokinetic may be administered late at night to prevent reflux. Rarely, a proton pump inhibitor is also required.

Prognosis

The prognosis is excellent. Most animals respond to therapy, and those that do not remain otherwise healthy.

GASTROINTESTINAL ULCERATION/EROSION

Etiology

Gastrointestinal ulceration/erosion (GUE) is more common in dogs than in cats. There are several potential causes. Drug-induced is one of the most common and most important causes. NSAIDs are a major cause of canine GUE because these drugs typically have longer half-lives in dogs than in people. Naproxen, ibuprofen, indomethacin, and flunixin are particularly dangerous to dogs. Concurrent use of more than one NSAID or use of an NSAID plus a glucocorticoid (especially dexamethasone) increases the risk of GUE. The newer COX-2–selective NSAIDs (e.g., carprofen, deracoxib, meloxicam, etodolac, firocoxib) are less likely to cause GUE; however, these drugs still have some activity against COX-1, and GUE can occur. Use of NSAIDs in animals with poor visceral perfusion (e.g., those in cardiac failure, shock) may also increase the risk of GUE.

Glucocorticoids are also common causes of GUE. Glucocorticoids such as prednisolone or prednisone, when used at doses typical for antiinflammatory effects, pose minimal risk for ulceration. However, patients receiving high doses of prednisolone, as well as those with additional risk factors for GUE (e.g., poorly perfused gastric mucosa, concurrent use of NSAIDs), are at high risk for ulceration. Some steroids such as dexamethasone are particularly ulcerogenic.

"Stress" ulceration is associated with severe hypovolemic, septic, or neurogenic shock, such as occurs after trauma, surgery, or endotoxemia. These ulcers are typically in the gastric antrum, body, and/or duodenum. Extreme exertion (e.g., in sled dogs, military working dogs) causes gastric erosions/ulcers, especially in the body and fundus, probably due to a combination of poor perfusion, high circulating levels of glucocorticoids, changes in core body temperature, and/or diet (i.e., high fat diets slowing emptying).

Gastric neoplasms and other infiltrative diseases (e.g., pythiosis) are important causes of GUE (see pp. 471-472), especially in older dogs and cats. Mast cell tumors and gastrinomas may cause ulceration as a paraneoplastic effect by increasing gastric acid secretion. Gastrinomas are principally found in the pancreas. They usually occur in older dogs and rarely in cats where they secrete gastrin, which in turn produces severe gastric hyperacidity, duodenal ulceration, esophagitis, and diarrhea.

Renal failure seldom causes GUE, but hepatic failure seems to be an important cause in dogs. Foreign objects rarely cause GUE, but they prevent healing and increase blood loss from preexisting ulcers.

Clinical Features

GUE is more common in dogs than in cats. Hyporexia may be the principal sign. If vomiting occurs, blood (i.e., fresh or digested) may or may not be present. Anemia and/or hypoproteinemia occasionally occur and may be severe enough to cause edema, pale mucous membranes, weakness, and/or dyspnea. Melena may occur if there is severe blood loss within a short period of time. Most affected dogs, even those with severe GUE, do not demonstrate pain during abdominal palpation. Perforation is associated with signs of septic peritonitis (see pp. 510-512). Some ulcers perforate and seal over before generalized peritonitis occurs. In such cases a small abscess may develop at the site, causing abdominal pain, hyporexia, and/or vomiting.

Diagnosis

A presumptive diagnosis of GUE is classically based on finding evidence of GI blood loss (e.g., hematemesis, melena, iron deficiency anemia, regenerative anemia with hypoalbuminemia) in an animal without a coagulopathy. However, lack of evidence of blood loss does not lessen the chance of GUE. History and physical examination may identify an

obvious cause (e.g., NSAID or dexamethasone administration). Perforation may cause peritonitis and signs of an acute abdomen and sepsis. Because mast cell tumors may resemble almost any cutaneous lesion (especially lipomas), *all* cutaneous masses or nodules should be evaluated cytologically. Hepatic failure is usually diagnosed based on the serum biochemistry profile. Contrast radiographs are diagnostic for foreign objects but rarely demonstrate GUE. Ultrasonography sometimes detects gastric thickening due to infiltrated lesions and/or mucosal defects (Fig. 30.5). Endoscopy (Video 30.3) is the most sensitive and specific tool for diagnosing GUE (see Figs. 27.14 to 27.17) and, in conjunction with biopsy, can be used to diagnose infiltrates (neoplastic or inflammatory) (see Fig. 27.16), foreign bodies (see Fig. 27.20), and inflammation causing GUE. Endoscopic findings may suggest gastrinoma if duodenal erosions are found. Serum gastrin concentrations should be measured if a gastrinoma is suspected or if there are no other likely causes.

Treatment

Therapy depends on the severity of GUE and whether an underlying cause is detected. Animals with suspected GUE that is not obviously life-threatening (i.e., no evidence of severe anemia, shock, sepsis, severe abdominal pain, or severe depression) may sometimes first be treated symptomatically if the clinician strongly suspects the cause is drug induced or "stress" induced.

Eliminating the underlying etiology (e.g., NSAIDs, shock) often results in resolution of the ulcer within 3 to 5 days. If the cause is unknown or cannot be removed or if it is important to resolve the ulcer quickly, then specific antiulcer medication is appropriate. Proton pump inhibitors or sucralfate are the major pharmacologic options. If appropriate medical therapy has not afforded clinical improvement after 5 or 6 days, or if the animal has life-threatening bleeding despite appropriate medical therapy, resection of the ulcer(s) must be considered. The stomach should be examined endoscopically before surgery to determine the number and location of the ulcers; it is surprisingly easy to miss ulcers during laparotomy/gastrotomy.

Prevention of GUE is desirable, and rational NSAID and glucocorticoid therapy are especially important. Sucralfate (Carafate; see Table 28.5) and histamine-2 (H_2) receptor antagonists (see Table 28.4) have been administered to prevent GUE in dogs receiving NSAIDs, but there is no good evidence that these drugs are effective prophylactic agents. Proton pump inhibitors are effective in preventing "stress"-induced ulceration as well as NSAID-induced GUE. Misoprostol (see Table 28.5) was designed to prevent NSAID-induced ulceration, and it can be used to treat ulcers. However, proton pump inhibitor therapy seems as effective and has fewer side effects. No drug has been shown to be effective in preventing steroid-induced GUE (especially dexamethasone).

Prognosis

The prognosis is favorable if the underlying cause can be controlled and if therapy prevents perforation of the ulcer.

FIG 30.5
Abdominal ultrasound of the stomach showing thickened gastric wall and an obvious defect representing an ulcer.

INFILTRATIVE GASTRIC DISEASES

NEOPLASMS

Etiology

Neoplastic infiltrations (e.g., adenocarcinoma, lymphoma, leiomyomas, leiomyosarcomas, and stromal tumors in dogs; lymphoma in cats) may produce GUE through direct mucosal disruption. Gastric lymphoma is typically a diffuse lesion but can produce masses. The cause and significance of benign gastric polyps are unknown. They seem to occur more commonly in the body and antrum.

Clinical Features

Dogs and cats with gastric tumors are usually asymptomatic until the disease is advanced. Hyporexia (not vomiting) is the most common initial sign. Vomiting caused by gastric neoplasia usually signifies advanced disease or gastric outflow obstruction. Adenocarcinomas are typically infiltrative and decrease emptying by impairing motility and/or obstructing the outflow tract. Weight loss is commonly caused by nutrient loss or cancer cachexia syndrome. Hematemesis occasionally occurs; leiomyomas seem to have the greatest potential to cause severe, acute, upper GI bleeding. Other bleeding gastric tumors are more likely to cause chronic iron deficiency anemia even if GI blood loss is not obvious. Polyps rarely cause signs unless they obstruct the pylorus.

Diagnosis

Iron deficiency anemia in a dog or cat without an obvious cause of blood loss suggests chronic GI bleeding. A regenerative anemia plus hypoalbuminemia suggests acute blood loss.

Plain and contrast imaging may reveal gastric wall thickening, decreased motility, and/or mucosal irregularities. The only sign of submucosal adenocarcinoma may be failure of one area to dilate during insufflation. Ultrasound-guided aspiration of thickened areas in the gastric wall will sometimes allow diagnosis of adenocarcinoma or lymphoma.

Most tumors will be obvious endoscopically, and it is usually easy to successfully biopsy mucosal lymphomas and nonscirrhous adenocarcinomas with flexible forceps. Leiomyomas, leiomyosarcomas, stromal tumors, and scirrhous adenocarcinomas can be very dense, to the point that sometimes diagnostic tissue samples cannot be obtained with flexible endoscopic forceps. Smooth muscle and stromal tumors also tend to be principally submucosal, making it difficult to obtain a deep enough biopsy with flexible forceps. Hence, a presumptive diagnosis of these tumors is often based upon gross appearance (i.e., thickened ulcerative lesion with hard, black center for scirrhous adenocarcinoma; submucosal mass pushing into the lumen, covered with relatively normal-appearing mucosa, often with one or more obvious ulcers for leiomyomas). Surgical biopsy may be required in such cases. Polyps are usually obvious endoscopically, but a biopsy specimen should always be obtained and evaluated to ensure that adenocarcinoma is not present.

Treatment

Most adenocarcinomas are well advanced before clinical signs are obvious, making complete surgical excision impossible. Leiomyomas, leiomyosarcomas, and stromal tumors are often resectable. Gastroduodenostomy may palliate gastric outflow obstruction caused by an unresectable tumor. Chemotherapy is rarely helpful except for dogs and cats with lymphoma.

Prognosis

The prognosis for adenocarcinomas is very poor unless they are detected early. With early diagnosis, leiomyomas and leiomyosarcomas are often cured surgically. Low-grade solitary gastric lymphoma in cats might be comparable to *Helicobacter*-induced, MALT-associated lymphoma in people; surgery and/or antibiotic therapy might be beneficial. However, most gastric lymphoma is part of a more generalized lesion of the GI tract, and chemotherapy is the only option (see Chapter 79). Resection of gastric polyps appears unnecessary unless they are causing outflow obstruction.

PYTHIOSIS

Etiology

Pythiosis is a fungal infection caused by *Pythium insidiosum*. Although principally found in the Gulf Coast area of the southeastern United States, it can be found anywhere from the east to the west coast. Any area of the alimentary tract or skin may be affected. The fungus typically causes intense submucosal infiltration of fibrous connective tissue and a purulent, eosinophilic, granulomatous inflammation causing GUE. Such infiltration prevents peristalsis, causing stasis.

Clinical Features

Pythiosis principally affects dogs, typically causing vomiting, anorexia, diarrhea, and/or weight loss. Because gastric outflow obstruction occurs frequently, vomiting is common. Colonic involvement may cause tenesmus and hematochezia. Esophageal involvement may cause severe regurgitation or hyporexia.

Diagnosis

Diagnosis requires serology or seeing the organism cytologically or histologically. Enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) tests are available to look for antibodies or antigen, respectively. Biopsy samples should include the submucosa because the organism is more likely to be there than in the mucosa. Diagnostic biopsy specimens can be procured with rigid endoscopy; however, the dense nature of the infiltrate makes it difficult to obtain diagnostic samples with flexible endoscopy. Cytologic analysis of a tissue sample obtained by scraping an excised piece of submucosa with a scalpel blade may be diagnostic; fungal hyphae that do not stain and appear as "ghosts" with typical Romanowsky-type stains are suggestive of pythiosis. The organisms may be sparse and difficult to find histologically, even in large tissue samples. Seeing an inflamed section of stomach that has a sharply demarcated border of infarcted tissue is strongly suggestive.

Treatment

Complete surgical excision provides the best chance for cure. Itraconazole, voraconazole, posaconazole, liposomal amphotericin B, and/or terbinafine may benefit some animals for varying periods of time, but cure is not expected. Immunotherapy has anecdotally been associated with remission of signs for varying periods of time.

Prognosis

Pythiosis often spreads to or involves structures that cannot be surgically removed (e.g., root of the mesentery, pancreas surrounding the bile duct), resulting in a grim prognosis.

CHAPTER 31

Disorders of the Intestinal Tract

ACUTE DIARRHEA

ACUTE ENTERITIS

Etiology

Acute enteritis is most commonly caused by infectious agents, poor diet, abrupt dietary changes, inappropriate foods, additives (e.g., chemicals), and/or parasites. Recent boarding at a kennel, being a scavenger, or having a recent diet change are risk factors for developing acute diarrhea. Except for parvovirus, parasites, and obvious dietary indiscretions, the cause is rarely diagnosed, because most affected animals spontaneously improve with or without supportive therapy.

Clinical Features

Diarrhea of unknown cause is common, especially in puppies and kittens. Signs consist of diarrhea with or without vomiting, dehydration, fever, anorexia, depression, crying, and/or abdominal pain. Very young animals may become hypothermic, hypoglycemic, and stuporous.

Diagnosis

History and physical and fecal examinations are used to identify possible causes. Fecal flotation (preferably a centrifugal flotation using zinc sulfate flotation solution) and direct fecal examinations are always indicated because parasites may worsen the problem even if they are not the main cause. The need for other diagnostic procedures depends on severity of the illness and the risk of contagion. Clinically mild enteritis is usually treated symptomatically, with few diagnostic tests being performed. If the animal is febrile, has hemorrhagic stools, is part of an outbreak of enteritis, or is particularly ill, then additional tests (e.g., complete blood count [CBC] to identify neutropenia, fecal enzyme-linked immunosorbent assay [ELISA] for canine parvovirus, serologic analysis for feline leukemia virus [FeLV] and feline immunodeficiency virus [FIV], blood glucose to identify hypoglycemia, and serum electrolytes to detect hypokalemia) are reasonable. Abdominal imaging should be evaluated if obvious abdominal pain or masses are detected or if obstruction or foreign body are suspected.

Treatment

Symptomatic therapy usually suffices. The cause is usually unknown or is a virus for which there is no specific therapy. The goal of symptomatic therapy is reestablishment of fluid, electrolyte, and acid-base homeostasis. Animals with severe dehydration (i.e., ≥8%-10% as determined by sunken eyes, fast weak pulse, and marked depression, or a history of significant fluid loss coupled with inadequate fluid intake) should receive intravenous (IV) fluids, whereas fluids administered orally or subcutaneously usually suffice for patients less severely dehydrated. Potassium supplementation is usually indicated, but bicarbonate is rarely needed. Oral rehydration sometimes allows home management of animals, especially when litters of young animals are affected. (See the discussion on fluid, electrolyte, and acid-base therapy in Chapter 28 for details.)

Antidiarrheals are seldom necessary except when excessive fecal losses make maintenance of fluid and electrolyte balance difficult. Opiates are usually the most effective antidiarrheals. Bismuth subsalicylate (see Table 28.6) is useful in stopping diarrhea in dogs with mild to moderate enteritis. However, absorption of the salicylate may cause nephrotoxicity in some animals (especially when combined with other potentially nephrotoxic drugs), and many dogs dislike the taste. Cats rarely need these medications. (See the discussion on drugs that prolong intestinal transit time in Chapter 28.) If antidiarrheals are needed for more than 2 to 5 days, the animal should be carefully reassessed. Probiotics typically shorten the duration of acute diarrhea.

Severe intestinal inflammation often causes vomiting that is difficult to control. Central-acting antiemetics (e.g., maropitant or ondansetron; see Table 28.3) are more likely to be effective than peripheral-acting drugs.

Although food is typically withheld from animals with severe enteritis to "rest" the intestinal tract, such starvation may be counterproductive. Administering even small amounts of food to the intestines helps them recover sooner

and prevents bacteria from translocating across the mucosa. Denying oral intake is occasionally necessary when eating causes severe vomiting or explosive diarrhea with substantial fluid loss. However, if feeding does not make the pet's vomiting and diarrhea *much* worse, feeding small amounts of food is probably more beneficial than withholding food. Frequent small feedings of easily digested, nonirritative foods (e.g., cottage cheese, boiled chicken, potato) is the most common approach. If food must be withheld, it should be reoffered as soon as possible. Parenteral nutrition is rarely needed in animals with severe enteritis.

If the animal is febrile or neutropenic or has systemic inflammatory response syndrome (SIRS; formerly called *septic shock*), broad-spectrum systemic antibiotic therapy (e.g., clindamycin or a β-lactam antibiotic plus either an aminoglycoside or a fluoroquinolone) are indicated (see the discussion of drugs used in gastrointestinal [GI] disorders, pp. 442-443). The clinician should observe for hypoglycemia, especially in young animals. Adding dextrose (2.5%-5%) to IV fluids or administering an IV bolus of 50% dextrose (2-5 mL/kg) may be necessary to prevent/counter hypoglycemia.

If the cause of the diarrhea is unknown, the clinician should assume it to be infectious and disinfect the premises accordingly. Bleach diluted in water (i.e., 1:32, respectively) destroys parvovirus and many other infectious agents causing diarrhea. Animals must not be injured by inappropriate contact with such disinfectants. Personnel coming in contact with the animals, cages, and litter should wear protective clothing (e.g., boots, gloves, gowns) that can be discarded or disinfected when leaving the area.

After the enteropathy appears to be clinically resolved, the animal is gradually returned to its normal diet over a 5- to 10-day period. If this change is associated with more diarrhea, then the switch is postponed for another 3 to 5 days.

Prognosis

The prognosis depends on the animal's condition and can be influenced by its age and other GI problems. Very young or emaciated animals and those with SIRS or substantial intestinal parasite burdens have a more guarded prognosis. If intussusception occurs secondary to acute enteritis, the prognosis is guarded.

ENTEROTOXEMIA

Etiology

The cause is assumed to be bacterial, although causative organisms are almost never identified.

Clinical Features

Acute onset of severe, often mucoid-bloody diarrhea with/without vomiting is typical. In severe cases, mucus casts of the intestines are expelled, making it appear that the intestinal mucosa is being lost. In contrast to animals with acute enteritis, these patients usually feel ill and may exhibit symptoms of shock early in the course of the disease. CBCs typically reveal a neutrophilic leukocytosis, often with a left shift and sometimes with white blood cell (WBC) toxicity.

Diagnosis

Exclusion of other causes by history and physical examination coupled with severe WBC changes (e.g., toxicity, left shift) on the CBC permit presumptive diagnosis. The pet should be checked for intestinal parasites that may be contributing to the problem. Fecal cultures are rarely useful.

Treatment

These patients typically need aggressive IV fluid therapy. Broad-spectrum antibiotic therapy (e.g., ampicillin plus sulbactam) is typically administered although its value is unknown. The serum albumin concentration must be monitored and colloids given if needed. Disseminated intravascular coagulation (DIC) may require plasma and/or heparin therapy.

Prognosis

The prognosis depends on how ill the patient is at presentation.

DIETARY-INDUCED ACUTE DIARRHEA

Etiology

Dietary causes of diarrhea are common, especially in young animals. Poor-quality ingredients (e.g., rancid fat), bacterial enterotoxins or mycotoxins, allergy or intolerance to ingredients (usually in older patients), or inability to digest certain foods (due to enzyme deficiencies) are common causes. Some intestinal brush border enzymes are produced in response to the presence of substrates (e.g., disaccharidases). If the diet is suddenly changed, some animals (especially puppies and kittens) are unable to digest or absorb certain nutrients until the intestinal brush border adapts to the new diet. Other animals may never be able to produce the necessary enzymes (e.g., lactase) to digest certain nutrients (e.g., lactose).

Clinical Features

Diet-induced diarrhea occurs in both dogs and cats. The diarrhea tends to reflect small intestinal dysfunction (i.e., there is usually no fecal blood or mucus) unless there is colonic involvement. The diarrhea usually starts shortly after the new diet is initiated (e.g., 1-3 days) and is mild to moderate in severity. Affected animals infrequently have other signs unless parasites or complicating factors are present.

Diagnosis

History and physical and fecal examinations are used to eliminate other common causes. If diarrhea occurs shortly after a suspected or known dietary change (e.g., after the pet is brought home), a tentative diagnosis of diet-induced disease is reasonable. However, the pet may also be showing the first clinical signs of a recently acquired infection. The animal should always be checked for intestinal parasites,

because they may contribute to the problem even when they are not the principal cause.

Treatment

An easily digested (so-called "bland") diet (e.g., boiled potato plus boiled skinless chicken) fed in multiple small feedings (see pp. 434-435) usually causes resolution of diarrhea in 1 to 3 days. Once the diarrhea resolves, the diet can be gradually changed back to the pet's regular diet.

Prognosis

The prognosis is usually excellent unless a young animal with minimal nutritional reserves becomes emaciated, dehydrated, or hypoglycemic.

INFECTIOUS DIARRHEA

CANINE PARVOVIRAL ENTERITIS

Etiology

Two types of parvoviruses infect dogs. Canine parvovirus-1 (CPV-1), also known as "minute virus of canines," is a relatively nonpathogenic virus that sometimes is associated with gastroenteritis, pneumonitis, and/or myocarditis in puppies 1 to 3 weeks old. Canine parvovirus-2 (CPV-2) is responsible for classic parvoviral enteritis, and there now are at least three strains (CPV-2 a, b, and c). CPV-2 usually causes signs 5 to 12 days after the dog is infected via the fecal-oral route by destroying rapidly dividing cells (i.e., bone marrow progenitors and intestinal crypt epithelium).

Clinical Features

The virus has mutated since it was first recognized, and the most recently recognized mutations may be more pathogenic in some dogs. CPV-2b and CPV-2c can also infect cats. Clinical signs depend on the virulence of the virus, size of the inoculum, host's defenses, age of the pup, and presence of other enteric pathogens and/or parasites. Doberman Pinschers, Rottweilers, Pit Bulls, Labrador Retrievers, and German Shepherds may be more susceptible than other breeds. Viral destruction of intestinal crypts may produce villus collapse, diarrhea, vomiting, intestinal bleeding, and subsequent bacterial invasion, but some animals have mild or even subclinical disease. Many dogs are initially presented because of depression, hyporexia, and/or vomiting (which can closely mimic foreign object ingestion) without diarrhea. Diarrhea is often absent for the first 24 to 48 hours of illness and may not be bloody if and when it does occur. Intestinal protein loss may occur secondary to inflammation, causing hypoalbuminemia. Vomiting is usually prominent and may be severe enough to mimic foreign body obstruction and/or cause esophagitis. Damage to bone marrow progenitors may produce transient or prolonged neutropenia, making the animal susceptible to serious bacterial infection, especially if a damaged intestinal tract allows bacterial translocation across the mucosa. Fever and/or SIRS are common in severely ill dogs but are often absent in less severely affected animals. Puppies infected *in utero* or before 8 weeks of age may develop myocarditis. Rarely, parvoviral infection may be associated with erythematous cutaneous lesions (erythema multiforme).

Diagnosis

Diagnosis is often tentatively made based on history and physical examination findings. Neutropenia is suggestive but neither sensitive nor specific for canine parvovirus enteritis; salmonellosis or any overwhelming infection can cause similar leukogram changes. Furthermore, the neutropenia may be very shortlived (i.e., < 12 hours). Regardless of whether diarrhea occurs, infected dogs shed large numbers of viral particles in the feces (i.e., $>10^9$ particles/g). Electron microscopic evaluation of feces detects parvovirus, but CPV-1 (usually nonpathogenic except in neonates) is morphologically indistinguishable from CPV-2. Detecting antibodies to CPV appears useful for determining if vaccination has been successful but not for diagnosis of acutely ill patients. Fecal polymerase chain reaction (PCR) testing is very sensitive and specific but must be performed at diagnostic laboratories. Fecal "point-of-care" testing is considered the standard testing for most practices. There are different point-of-care methodologies (i.e., ELISA, immunochromatography, immunomigration). All are highly specific, but the sensitivity for both CPV-2b and CPV-2c is less than desired. Vaccination with a modified live parvoviral vaccine may cause a weak positive result for 5 to 15 days after vaccination. ELISA results may be negative if the assay is performed too early in the clinical course of the disease (i.e., virus is not yet being shed in feces). Therefore, if faced with a dog that seems likely to have parvoviral enteritis but is negative on the point-of-care test, the clinician should either repeat the test in 3 to 4 days or send feces to a diagnostic laboratory for PCR testing. Shedding decreases rapidly and may be undetectable by 10 to 14 days after infection, especially if the virus is being bound by fecal antibodies and/or diluted by diarrhea. Rarely, clinically normal dogs and dogs with chronic enteropathies will test positive; this may be due to asymptomatic infection or intestinal passage of the virus.

A positive test result confirms the presumptive diagnosis of parvoviral enteritis. A negative result warrants consideration of diseases that can mimic parvovirus (e.g., salmonellosis, intussusception). If the dog dies, there are typical histologic lesions (i.e., crypt necrosis), and fluorescent antibody and fluorescent *in situ* hybridization techniques can establish a definitive diagnosis.

Treatment

Treatment of canine parvoviral enteritis is fundamentally the same as for any severe, acute, infectious enteritis and depends upon the clinical severity. Severely ill dogs need in-clinic treatment, whereas mildly affected animals can often be treated at home. Fluid and electrolyte therapy is crucial and is typically combined with antibiotics (Box 31.1). Most dogs survive if they can be supported long enough. However, very

BOX 31.1

General Guidelines for Treatment of Canine Parvoviral Enteritis*

Fluids†‡

Administer balanced electrolyte solution with 30-40 mEq potassium chloride/L.
Calculate maintenance requirements (i.e., 66 mL/kg/day, with dogs < 5 kg needing up to 80 mL/kg/day).
Estimate deficit (better to slightly overestimate rather than underestimate deficit).
Dogs with very mild cases may receive subcutaneous fluids (intravenous [IV] fluids still preferred), but watch for sudden worsening of the disease.
Dogs with moderate to severe cases should receive fluids via the IV route (can use intramedullary route if IV access cannot be established).
Add 2.5%-5% dextrose to the IV fluids if hypoglycemia or systemic inflammatory response syndrome is present or is a risk.
Administer plasma or hetastarch if dog has serum albumin ≤ 2 g/dL.
- Plasma: 6-10 mL/kg over 4 hours; repeat until the desired serum albumin concentration is attained (this approach tends to be much more expensive than using hetastarch).
- Hetastarch: 10-20 mL/kg (give in increments, not all at once) (generally do not use both plasma and hetastarch).

Antibiotics†

Administer to febrile or severely neutropenic dogs.
Prophylactic antibiotics for afebrile neutropenic patients (e.g., cefazolin).
Broad-spectrum antibiotics for febrile, neutropenic patients (e.g., β-lactam for gram-positive and anaerobic bacteria [e.g., ampicillin and sulbactam] plus broad spectrum for gram-negative bacteria [e.g., amikacin or enrofloxacin]).

Antiemetics

Given if needed for vomiting or nausea:
- Maropitant (some risk of bone marrow suppression in puppies < 11-16 weeks of age)
- Ondansetron
- Metoclopramide (best used as an add-on to maropitant or ondansetron if those drugs are inadequate—a constant rate infusion is more effective than intermittent bolusing).

Anthelmintics

Pyrantel (should be given after feeding).
Ivermectin (this drug is absorbed in the oral mucous membranes; do not give to breeds likely to have adverse effects, such as Collies, Old English Sheepdogs, etc.).

Probiotics

Controversial
Fecal transplantation
Currently being tried – of uncertain value

Dogs With Secondary Esophagitis

If regurgitation occurs in addition to vomiting, administer:
- Proton pump inhibitor (Pantoprazole injectable)

Special Nutritional Therapy

Try to feed dog small amounts as soon as feeding does not cause major exacerbation in vomiting.
"Microenteral" nutrition (slow drip of enteral diet administered via nasoesophageal tube) if dog refuses to eat and administration does not make vomiting worse.
Administer parenteral nutrition if prolonged anorexia occurs.
- Peripheral parenteral nutrition is more convenient than total parenteral nutrition.

Monitor Physical Status

Physical examination (1-3 times per day depending on severity of signs)
Body weight (1-2 times per day to assess changes in hydration status)
Potassium (every 1-2 days depending on severity of vomiting/diarrhea)
Serum protein (every 1-2 days depending on severity of signs)
Glucose (every 4-12 hours in dogs that have systemic inflammatory response syndrome or were initially hypoglycemic)
Packed cell volume (every 1-2 days)
White blood cell count: either actual count or estimated from a slide (every 1-2 days in febrile animals)

*The same guidelines generally apply to dogs with other causes of acute enteritis/gastritis.
†Usually the first considerations when an animal is presented.
‡A history of decreased intake plus increased loss such as vomiting and/or diarrhea confirms dehydration, regardless of whether dog appears to be dehydrated.

young puppies, dogs in severe SIRS, and certain breeds seem to have higher morbidity and mortality. Common therapeutic mistakes include inadequate fluid therapy, overzealous fluid administration (especially in dogs with severe hypoproteinemia), failure to administer glucose to hypoglycemic patients, failure to supplement adequate potassium, not recognizing sepsis, and not finding concurrent GI disease (e.g., parasites, intussusception).

If the serum albumin concentration is less than 2 g/dL, it is probably advantageous to administer plasma or colloids

(e.g., hetastarch). Plasma has antibodies that are presumed to be beneficial, but there is no evidence that they affect outcome. Colloids are typically preferred because they are less expensive and more effective in raising plasma oncotic pressure. Antibiotic therapy is necessary if there is evidence of infection (i.e., fever, SIRS) or increased risk of infection (i.e., severe neutropenia). If the animal is neutropenic but afebrile, administration of a first-generation cephalosporin is reasonable for prophylaxis. If the animal is in SIRS, an antibiotic combination with a broad aerobic and anaerobic spectrum is recommended (e.g., ampicillin plus either amikacin or enrofloxacin). Aminoglycosides should not be administered until the patient is rehydrated and renal perfusion is reestablished. Administering enrofloxacin to young, large-breed dogs may damage cartilage, but this is preferable to death. Severe vomiting complicates therapy and may require administration of maropitant or ondansetron (see Table 28.3). Maropitant seems to help alleviate visceral pain in addition to being an effective antiemetic. If these drugs are ineffective, then combining them with constant rate infusion of metoclopramide often enhances efficacy. If esophagitis occurs, a proton pump inhibitor may be useful (see Table 28.4). Human granulocyte colony-stimulating factor (G-CSF, 5 µg/kg SQq24h) to increase neutrophil numbers, Tamiflu (oseltamivir phosphate, 2 mg/kg orally [PO] q12-24h) to combat the virus, and equine antiendotoxin serum have been advocated, but there is no evidence that they substantively affect outcome. Flunixin meglumine has been anecdotally suggested for patients in SIRS, but there is substantial risk of iatrogenic ulceration and/or perforation. There is some evidence that recombinant feline interferon omega (rFeIFN-ω, 2.5×10^6 units/kg IV) improves outcome, but it is not readily available.

If possible, feeding small amounts of liquid diet via a nasoesophageal (NE) tube seems to help the intestines heal more rapidly. An easily digested diet may be fed once vomiting has ceased. Parenteral nutrition can benefit patients that are persistently unable to hold down oral food. Partial parenteral nutrition (also called *peripheral parenteral nutrition*) is easier and less expensive than total parenteral nutrition. The dog should be kept away from other susceptible animals for 2 to 4 weeks after discharge, and the owner should be conscientious about feces disposal. Vaccination of other dogs in the household should be considered.

When trying to prevent the spread of parvoviral enteritis, the clinician must remember that (1) parvovirus persists in the environment for long periods of time (i.e., months), making it difficult to prevent exposure; (2) asymptomatic dogs may shed virulent CPV-2; (3) maternal immunity sufficient to inactivate vaccine virus may be present in some puppies; and (4) dilute bleach (1:32) is one of the few readily available disinfectants that kills the virus, but it can take 10 minutes to be effective.

Vaccination of pups should generally commence at 6 to 8 weeks of age. The antigen density and immunogenicity of the vaccine as well as the amount of antibody transferred from the bitch determine when the pup can be successfully immunized. Inactivated vaccines generally are not as successful as attenuated vaccines, and giving a series of vaccinations is recommended. Attenuated vaccines are more successful in producing a long-lasting immunity. Typically, administering an attenuated vaccine at 6, 9, and 12 weeks of age is usually successful. If the initial vaccination is after 16 weeks of age, then two doses 2 to 4 weeks apart suffice. If vaccination is before 5 to 6 weeks of age, an inactivated vaccine is safer. After the initial series, one booster between 6 to 12 months of age is recommended. Revaccination every 3 years should be sufficient after the initial series and first booster. There is no strong evidence that parvoviral vaccination should be given separately from modified live canine distemper vaccinations. However, modified live vaccinations should not be administered to patients younger than 5 weeks of age or those suspected of incubating or being affected with distemper. Vaccination with CPV-2b virus protects against infection with CPV-2c. If necessary, serum antibody titers (which are assumed to be protective) may be measured to determine if the vaccination appeared to be effective. Regardless of the vaccine or protocol used, there is no guarantee of success. Parvoviral enteritis has occurred in supposedly well-vaccinated dogs.

If parvoviral enteritis develops in one dog in a multiple-dog household, it is reasonable to administer booster vaccinations to the other dogs, preferably using an inactivated vaccine in case they are incubating the infection at the time of immunization. If the client is bringing a puppy into a house with a dog that has recently had parvoviral enteritis, the puppy should be kept elsewhere until it has received its immunizations.

Prognosis

Dogs treated in a timely fashion with proper therapy typically live, especially if they survive the first 4 days of clinical signs. Intussusception secondary to parvoviral enteritis may cause persistent diarrhea in pups otherwise recovering. Dogs that have recovered from CPV-2 enteritis develop long-lived immunity that may be lifelong.

FELINE PARVOVIRAL ENTERITIS

Etiology

Feline parvoviral enteritis (feline distemper, feline panleukopenia) is caused by feline panleukopenia virus (FPV), which is distinct from CVP-2b. However, CPV-2a, CPV-2b, and CPV-2c can infect cats and cause disease. Kittens need to be vaccinated after 12 weeks of age to ensure protection.

Clinical Features

Many infected cats never show clinical signs of disease. Signs in affected cats are usually similar to those described for dogs with parvoviral enteritis. If a pregnant queen is infected, the result may be abortion or congenital abnormalities. If the fetus is infected later in pregnancy or immediately after birth, cerebellar hypoplasia may result.

Diagnosis

Diagnosis is similar to that described for canine parvovirus. The sensitivity and specificity of the point-of-care canine ELISA tests for fecal CPV in cats are comparable to that in dogs. However, it is important to note that the test may be positive for only 1 to 2 days after infection; by the time the cat is clinically ill, this test may not be able to detect viral shedding in the feces.

Treatment/Prevention

Cats with parvoviral infection are treated much the same way as described for dogs. Administering recombinant feline interferon omega has not been beneficial. A major difference between dogs and cats centers on immunization: parvoviral vaccine (both inactivated and attenuated live) typically is more effective in cats than in dogs. Attenuated live vaccines are preferred, but kittens younger than 4 weeks of age should receive inactivated vaccines (two doses 3-4 weeks apart). Also, the vaccine cannot be administered orally, but intranasal administration is effective. Immunity generally lasts for more than 5 to 7 years after the initial series and booster.

Prognosis

As with dogs, many affected cats live if overwhelming sepsis is prevented and they can be supported long enough. Thrombocytopenia, hypoalbuminemia, and hypokalemia are negative prognostic signs.

CANINE CORONAVIRAL ENTERITIS

Etiology

Canine coronavirus invades and destroys mature cells on the intestinal villi. Because intestinal crypts remain intact, villi regenerate more quickly in dogs with coronaviral enteritis than in dogs with parvoviral enteritis; bone marrow cells are not affected.

Clinical Features

Coronaviral enteritis is typically less severe than classic parvoviral enteritis and rarely causes hemorrhagic diarrhea, septicemia, or death. Dogs of any age may be infected. Signs usually last less than 1 to 1½ weeks, and small or very young dogs may die as a result of dehydration or electrolyte abnormalities if they are not properly treated. Dual infection with parvovirus may produce a high incidence of morbidity and mortality.

Diagnosis

Because canine coronaviral enteritis is usually much less severe than many other enteritides, it is seldom definitively diagnosed. Most dogs are treated symptomatically for acute enteritis until they improve. There is a commercial PCR available for testing feces. Electron microscopic examination of feces obtained early in the course of the disease can be diagnostic, but the virus is fragile and easily disrupted by inappropriate specimen handling. Coronavirus can be found in the feces of many clinically normal dogs; therefore, simply stating that coronavirus is present is not helpful. A history of contagion and elimination of other causes are reasons to suspect canine coronaviral enteritis.

Treatment

Fluid therapy, motility modifiers (see Chapter 28), and time should resolve most cases of coronaviral enteritis. Symptomatic therapy is usually successful except, perhaps, for very young animals. A vaccination is available but of uncertain value.

Prognosis

The prognosis for recovery is usually good.

OTHER CANINE ENTERIC VIRUSES

Canine circovirus is believed to be a cause of vomiting, diarrhea, and hemorrhagic diarrhea in dogs. It is believed that dual infection with this and CPV-2 produces more severe disease. Rotavirus has also been suggested as a cause of canine diarrhea. Diagnosis is probably important only in kennel situations where contagion is an issue.

FELINE CORONAVIRAL ENTERITIS

Cats may be infected with feline or canine enteric coronavirus. Infections in adults are often asymptomatic, whereas kittens may have mild transient diarrhea and fever. Deaths are rare, and the prognosis for recovery is excellent. This disease is important because (1) affected animals seroconvert and may become positive on feline infectious peritonitis serologic analysis and (2) mutation by the feline coronavirus may be the cause of feline infectious peritonitis. There is a commercially available PCR test on feces.

FELINE LEUKEMIA VIRUS–PANLEUKOPENIA-LIKE SYNDROME

Etiology

FeLV-associated panleukopenia is uncommon. The intestinal lesion histologically resembles that produced by feline parvovirus. The bone marrow and lymph nodes are not consistently affected as they are in cats with parvoviral enteritis. Rarely, there can be co-infection with FeLV and FPV.

Clinical Features

Chronic weight loss, vomiting, and diarrhea are common. The diarrhea often has characteristics of large bowel disease. Anemia is common.

Diagnosis

Finding FeLV infection in a cat with chronic diarrhea is suggestive. Cats are typically neutropenic. Histologic lesions resembling FPV in a cat with FeLV should be definitive.

Treatment

Symptomatic therapy (fluid/electrolyte therapy, antibiotics, antiemetics, and/or highly digestible bland diets as needed)

and elimination of other problems that compromise the intestines (e.g., parasites, poor diet) may be beneficial.

Prognosis

This disease has a poor prognosis because of other FeLV-related complications.

FELINE IMMUNODEFICIENCY VIRUS–ASSOCIATED DIARRHEA

Etiology

FIV may be associated with diarrhea. Acute infection with FIV is often associated with transient diarrhea, and terminal FIV may be associated with an "AIDS-like enteropathy," which can produce chronic diarrhea, severe weight loss, and/or purulent colitis. The pathogenesis is unclear and may involve multiple mechanisms.

Clinical Features

Severe large bowel disease is common and can occasionally cause colonic rupture. These animals generally appear ill.

Diagnosis

Detection of antibodies to FIV plus diarrhea allow presumptive diagnosis.

Treatment

Therapy is supportive (e.g., fluids/electrolytes, antiemetics, antibiotics, and/or highly digestible bland diets as needed).

Prognosis

The long-term prognosis is guarded to very poor, although some cats can be maintained for months.

SALMON POISONING/ELOKOMIN FLUKE FEVER

Etiology

Salmon poisoning is caused by *Neorickettsia helminthoeca.* Dogs are infected when they eat fish (especially salmon) infected with a fluke *(Nanophyetus salmincola)* that carries the rickettsia. The rickettsia spreads to the intestines and most lymph nodes, causing inflammation. This disease is principally found in the U.S. Pacific Northwest, because the snail intermediate host *(Oxytrema silicula)* for *N. salmincola* lives there. The Elokomin fluke fever agent may be a strain of *N. helminthoeca*.

Clinical Features

Dogs, not cats, are affected. The severity of signs varies and typically consists of an initial fever that eventually falls and becomes subnormal. Fever is followed by hyporexia and weight loss, which may also involve vomiting and/or diarrhea. The diarrhea is typically small bowel but may become bloody. Lymphadenomegaly is the most common physical examination finding.

Diagnosis

Presumptive diagnosis is usually based on the animal's habitat plus a history of recent consumption of raw fish or exposure to streams or lakes. Finding *Nanophyetus* spp. ova (operculated trematode ova) in feces is suggestive. Finding rickettsia in fine-needle aspirates or biopsies of enlarged lymph nodes is confirmatory, but aspirate cytology is not as sensitive as desired. Prior antimicrobial therapy can make it difficult to demonstrate the organisms.

Treatment

Treatment consists of symptomatic control of dehydration, vomiting, and diarrhea plus elimination of the rickettsia and fluke. Tetracycline, oxytetracycline, doxycycline, and maybe enrofloxacin (see Chapter 92) eliminate the rickettsia. The fluke is killed with praziquantel (see Table 28.7).

Prognosis

The prognosis depends on the clinical severity at the time of diagnosis. Most dogs respond favorably to tetracyclines and supportive therapy within 24 hours. The key to success is awareness of the disease. Untreated salmon poisoning has a poor prognosis.

BACTERIAL DISEASES: COMMON THEMES

The following bacterial diseases all have certain aspects in common. First, all of these bacteria may be found in feces from clinically normal dogs and cats. Simply growing the bacteria or finding bacterial toxin in the patient's feces does not confirm they are responsible for clinical disease. Diagnosis can be made only by finding clinical disease consistent with a particular organism, evidence of the organism or its toxin, eliminating other causes of the clinical signs, and seeing the expected response to appropriate therapy. If the clinician cultures feces, it is crucial to call the laboratory first, explain what is being sought, and follow instructions regarding sample collection and submission.

The problems with making a diagnosis using the previously mentioned criteria are obvious, and caution is warranted before making definitive statements regarding cause and effect. In many cases, the best chance of making a definitive diagnosis involves following the guidelines described and using molecular techniques on isolates to demonstrate toxin production.

CAMPYLOBACTERIOSIS

Etiology

There are several species of *Campylobacter*. *Campylobacter jejuni* is the species most commonly associated with GI disease, although *C. upsaliensis* is rarely implicated. *Campylobacter* spp. prefer high temperatures (i.e., 39° C-41° C); hence poultry is an important reservoir. *C. jejuni* and *C. upsaliensis* can be found in the intestinal tract of healthy dogs

and cats as or more frequently than in the feces of diarrheic animals.

Clinical Features

Symptomatic campylobacteriosis is principally diagnosed in animals younger than 6 months old living in crowded conditions (e.g., kennels, humane shelters) or as a nosocomial infection. Mucoid diarrhea (with or without blood), anorexia, and/or fever are the primary signs. Campylobacteriosis tends to be self-limiting in dogs, cats, and people but occasionally causes chronic diarrhea.

Diagnosis

Occasionally, *Campylobacter* forms may be found during cytologic examination of a fecal smear (i.e., "commas," "seagull wings"), but such cytologic findings are nonspecific and poorly sensitive. PCR analysis of feces appears sensitive and specific and can speciate *Campylobacter*.

Treatment

If campylobacteriosis is suspected, erythromycin (11-15 mg/kg PO q8h), enrofloxacin (5 mg/kg PO q24h), or neomycin (15 mg/kg PO q12h) is usually effective. β-Lactam antibiotics are often ineffective. The patient should be treated for at least 1 to 3 days beyond resolution of clinical signs, assuming that they respond within 5 days. Antibiotic therapy may not eradicate the bacteria, and reinfection is likely in kennel conditions. Chronic infections may require prolonged therapy (e.g., weeks). Therapeutic failure suggests either antibiotic resistance or a different disease is present.

Public Health Concerns

Campylobacteriosis is a potential zoonosis, and there are cases with convincing evidence of transmission from pets to people (especially *C. jejuni*). Infected dogs and cats should be isolated, and individuals working with the animal or its environment or wastes should wear protective clothing and wash with disinfectants. However, food products are the primary source of this infection in people. Currently, there is no indication to culture asymptomatic dogs and cats if the owners are diagnosed with campylobacteriosis.

Prognosis

With appropriate antibiotic therapy, the prognosis for recovery is good.

SALMONELLOSIS

Etiology

Numerous *Salmonella enterica* serovars cause disease in dogs and cats, but *Salmonella* Typhi (the cause of typhoid fever in people) is not one of them. *Salmonella* Typhimurium is the serovar of *S. enterica* most commonly associated with disease in dogs and cats. The bacteria may originate from animals shedding the organism (e.g., infected dogs and cats) or from contaminated foods (especially poultry and eggs). Dogs fed raw meat diets appear to be at increased risk of infection (not necessarily disease).

Clinical Features

Salmonellosis is an uncommon diagnosis in dogs and cats. *Salmonella* spp. may produce acute or chronic diarrhea, septicemia, and/or sudden death, especially in very young or geriatric animals. Salmonellosis in young animals can produce a syndrome that closely mimics parvoviral enteritis (including severe neutropenia), which is one reason ELISA testing for parvovirus is useful. Salmonellosis occasionally develops during or after canine parvoviral enteritis, making the situation more confusing.

Diagnosis

Culture of *Salmonella* spp. from normally sterile areas (e.g., blood) confirms that it is causing disease, but simply identifying it in feces does not allow confident diagnosis. *Salmonella* can be identified in feces by culture or PCR (faster and more sensitive than fecal culture). Tentative diagnosis of clinical salmonellosis requires finding the organism, having clinical signs consistent with salmonellosis, and eliminating other causes. The prevalence of *Salmonella* in healthy dogs is often similar to that in diarrheic dogs, and some areas (e.g., sled dogs in Alaska) have very high prevalences (i.e., 60%-70%). Consultation with an infectious disease expert may be helpful.

Treatment

Treatment depends on clinical signs. Animals that are not particularly clinically ill and have diarrhea as the sole sign may need only supportive fluid therapy. Nonsteroidal drugs (to lessen intestinal secretion) have been used in such patients. Antibiotics are of dubious value and have been suggested to promote a carrier state (which is unproven). Septicemic (i.e., febrile) animals should receive supportive therapy and parenteral antibiotics as determined by susceptibility testing, but quinolones, potentiated sulfa drugs, amoxicillin, and chloramphenicol are often good initial choices (see the discussion of drugs used in GI disorders, pp. 442-443).

Prognosis

The prognosis is usually good in diarrheic animals but guarded in septicemic patients.

Public Health Concerns

Infected animals are potentially public health risks (especially for infants, older adults, and immunosuppressed people), although most human infections come from contaminated food and exposure to reptiles. Dogs eating raw meat diets appear to be at increased risk of shedding *Salmonella* spp. Diarrheic or septicemic dogs and cats shedding *Salmonella* should be isolated from other animals until they are asymptomatic. In these patients, reculturing feces (four to six negative cultures) or performing PCR testing (three negative tests) is needed to ensure that shedding has stopped

after resolution of clinical signs. Individuals in contact with clinically ill animals, their environment, and their waste should wear protective clothing and wash with disinfectants such as phenolic compounds or diluted bleach (1:32 dilution). Although the risk of zoonotic transmission from dogs and cats to people seems small, it appears possible (but is not true typhoid fever).

CLOSTRIDIAL DISEASES, INCLUDING ACUTE HEMORRHAGIC DIARRHEAL SYNDROME

Etiology

Clostridium perfringens and *Clostridium difficile* can be found in clinically normal dogs. For *C. perfringens* to produce disease, environmental conditions must be appropriate for the bacteria to produce toxin.

Clinical Features

Infection with *C. perfringens* seemingly may produce various syndromes: an acute, bloody, self-limiting nosocomial diarrhea; acute hemorrhagic diarrheal syndrome (used to be called *hemorrhagic gastroenteritis*); or chronic large bowel diarrhea. These clostridial diseases are primarily recognized in dogs. Acute hemorrhagic diarrheal syndrome is discussed in detail separately. Disease associated with *C. difficile* is poorly characterized in small animals but might include large bowel diarrhea, especially after antibiotic therapy.

Diagnosis

Finding spore-forming bacteria on fecal smears (Fig. 31.1), culturing the bacteria from the feces, and detecting *C. perfringens* enterotoxin are neither sensitive nor specific for disease due to *C. perfringens.* Finding *C. difficile* toxin in the feces, although useful in people, is of uncertain value in dogs and cats. If toxin will be sought, then using ELISA to first check for bacterial antigen and, if positive, then ELISA to check for toxin A and B is the best approach. However, commercially available toxin assays for *C. difficile* toxin have not been validated for the dog or cat. Elimination of other causes of diarrhea plus resolution of signs when treated appropriately (see next paragraph) in addition to finding the organism and/or toxin is typically the basis for presumptive diagnosis of *C. difficile*–induced disease.

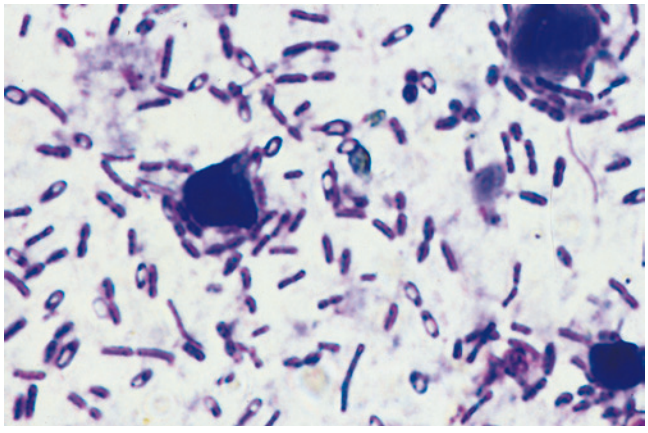

FIG 31.1
Photomicrograph of air-dried canine feces stained with Diff-Quik. Numerous spores are seen as clear vacuoles in darkly stained rods (×1000).

Treatment

If *C. perfringens* disease besides acute hemorrhagic diarrheal syndrome (AHDS) is suspected, tylosin (10-20 mg/kg PO q24h or divided q12h) or amoxicillin (22 mg/kg PO q12h) are typically effective in patients that are systemically ill or that have chronic disease. If the diagnosis is correct, response is expected within 2 to 5 days. Metronidazole is not as consistently effective as tylosin or amoxicillin. Antibiotic treatment by itself often fails to permanently cure patients with chronic diarrhea attributed to *C. perfringens*, but if a high-fiber diet is fed concurrently with administration of tylosin, the patient can often be maintained on diet alone once it is in remission. Animals that reliably respond to tylosin or amoxicillin but which relapse every time the antibacterial is withdrawn (despite remaining on a high-fiber diet) can be treated indefinitely with the drug (undesirable due to concerns with promotion of antibacterial resistance) or one can consider fecal transplantation or probiotic therapy. In contrast, if AHDS is suspected, then fluids are the most important therapy.

If disease caused by *C. difficile* is suspected, supportive fluid and electrolyte therapy may be necessary depending on the severity of signs. Metronidazole should be effective in killing this bacterium, but one must be sure to use a sufficiently high dose to achieve adequate metronidazole concentrations in the feces. Oral vancomycin is often used to treat people with this disease, but it has generally been unnecessary in dogs or cats, and this drug should be avoided in veterinary medicine as it is a "drug of last resort" in human medicine.

Prognosis

The prognosis is excellent in dogs with diarrhea caused by *C. perfringens* but uncertain for those cases caused by *C. difficile*.

Public Health Concerns

There is no obvious public health risk from dogs or cats shedding *C. perfringens* despite anecdotal evidence of transmission between people and dogs. Dogs occasionally shed strains of *C. difficile* that are found in people but do not appear to be a risk factor for human infection or disease.

ACUTE HEMORRHAGIC DIARRHEAL SYNDROME

Etiology

This disease used to be called "Hemorrhagic Gastroenteritis." Cause is uncertain but believed to involve *C. perfringens.*

Clinical Features

Patients are classically smaller breed dogs (e.g., Yorkshire Terriers, Schnauzers, Miniature Pinschers, Maltese). Many (not all) initially vomit (may be bloody or not). Hemorrhagic diarrhea quickly ensues.

Diagnosis

Diagnosis is by exclusion of other causes. Most patients have an increased PCV.

Treatment/Prognosis

Timely fluid therapy is associated with an excellent prognosis. Antimicrobial therapy has not been found beneficial.

MISCELLANEOUS BACTERIA

Etiology

Escherichia coli is of major importance as a cause of diarrhea in most mammalian species, and the subject is beyond the scope of this text. There are several different strains that produce different syndromes (e.g., enterotoxigenic *E. coli* associated with acute canine and feline diarrhea; adherent-invasive *E. coli* [AIEC] associated with histiocytic ulcerative colitis, especially in Boxers and French Bulldogs, etc.). *Yersinia enterocolitica, Aeromonas hydrophila,* and *Plesiomonas shigelloides* may cause acute or chronic enterocolitis in dogs and/or cats as well as in people. However, these bacteria (especially the latter two) are uncommonly diagnosed in the United States. *Y. enterocolitica* is primarily found in cold environments and in pigs, which may serve as a reservoir. It is also a cause of food poisoning because of its ability to grow in cold temperatures.

Clinical Features

All of these bacteria may cause small bowel diarrhea. Select *E. coli* and *Y. enterocolitica* produce chronic large bowel diarrhea.

Diagnosis

E. coli can be cultured from the feces of almost all mammals. With the exception of histiocytic ulcerative colitis, it is extremely difficult to associate an *E. coli* isolate with intestinal disease in a particular patient. If it is necessary to try to determine whether or not a particular *E. coli* is responsible for disease, then virulence factor testing is needed (but not necessarily sufficient by itself). Animals with persistent colitis, especially those that are in contact with pigs, may reasonably be cultured for *Y. enterocolitica*.

Treatment

With the exception of *E. coli*–associated histiocytic ulcerative colitis, therapy is supportive. The affected animal should be isolated from other animals. People in contact with the animal and/or its environment and wastes should wear protective clothing and clean themselves with disinfectants. Antibiotic therapy generally has not shortened duration of acute diarrhea caused by these bacteria. If chronic diarrhea is believed due to these bacteria, then appropriate antibiotics as determined by culture and sensitivity are used. The preferred length of antibiotic therapy is uncertain but should probably be continued for 1 to 3 days beyond clinical remission (except for histiocytic ulcerative colitis— see page 495).

Prognosis

The prognosis is usually good.

Public Health Concerns

Public health concerns are currently undetermined.

HISTOPLASMOSIS

Etiology

Caused by *Histoplasma capsulatum,* histoplasmosis is a mycotic infection that may affect the GI, respiratory, and/or reticuloendothelial systems, as well as the bones and eyes. Classically considered in animals from the Mississippi and Ohio River valleys, it has been diagnosed in patients that have always lived in nonendemic areas.

Clinical Features

Alimentary tract involvement is primarily found in dogs; diarrhea (with or without blood or mucus) and weight loss are common. Lungs, liver, spleen, lymph nodes, bone marrow, bones, and/or eyes may also be affected. Cats more commonly have respiratory dysfunction (e.g., dyspnea, cough), fever, and/or weight loss, but they occasionally have alimentary involvement.

In GI histoplasmosis, the colon is often the most severely affected segment. Diffuse, severe, granulomatous, ulcerative mucosal disease can produce bloody stool, intestinal protein loss, intermittent fever, and/or weight loss. Small intestinal involvement occasionally occurs. The disease may smolder for long periods of time, causing mild to moderate nonprogressive signs. Occasionally, histoplasmosis causes focal colonic granulomas or is present in grossly normal-appearing colonic mucosa.

Diagnosis

Definitive diagnosis requires finding the yeast (Fig. 31.2). There is an ELISA for antigen shed in urine that appears to have good sensitivity/specificity. Serologic tests for antibody to *H. capsulatum* are poorly sensitive/specific. Dogs from endemic areas with chronic large bowel diarrhea are especially suspect. Protein-losing enteropathy (PLE) is common in dogs with severe alimentary histoplasmosis, and PLE in a dog with large bowel disease is a strong indication to check for histoplasmosis.

Rectal examination sometimes reveals thickened rectal mucosa. Cytologic preparations from rectal mucosal scrapings sometimes reveal the yeast. Colonic biopsy is usually diagnostic, but special stains may be necessary. Mesenteric lymph node samples or repeated colonic biopsy is rarely required. Fundic examination occasionally reveals active chorioretinitis. Abdominal imaging often shows

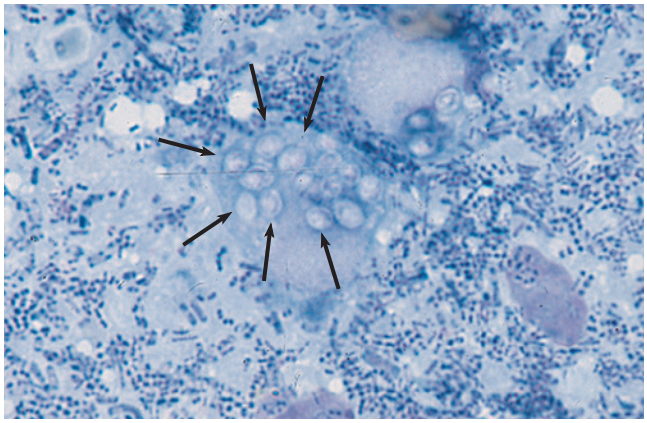

FIG 31.2
Cytologic preparation of a colonic mucosal scraping demonstrating *Histoplasma capsulatum*. Note the macrophage with numerous yeasts in the cytoplasm *(arrows)* (Wright-Giemsa stain; ×400). (From Allen D, ed.: *Small animal medicine,* Philadelphia, 1991, JB Lippincott.)

hepatosplenomegaly, and thoracic radiographs sometimes demonstrate miliary interstitial disease, sometimes with hilar lymphadenopathy. Cytologic evaluation of hepatic or splenic aspirates may be diagnostic. The CBC or a buffy coat smear rarely reveals yeasts in circulating WBCs. Thrombocytopenia may occur. Cytologic examination of bone marrow may be diagnostic. Fecal culture for the yeast is unreliable.

Treatment

It is crucial to eliminate histoplasmosis before beginning empirical glucocorticoid therapy for suspected canine inflammatory bowel disease (IBD). Glucocorticoid therapy typically allows a previously treatable case to rapidly progress and kill the animal. Itraconazole by itself or preceded by lipid emulsion amphotericin B is often effective (see Chapter 97). Treatment should usually be continued for at least 4 to 6 months to lessen chances for relapse.

Prognosis

Many dogs can be cured if treated relatively early. Multiple organ system involvement worsens the prognosis, as does central nervous system (CNS) involvement.

PYTHIOSIS

Etiology

Pythiosis is caused by *Pythium insidiosum*. Most common in the southeastern United States, it has been found in dogs as far west as California.

Clinical Features

Pythiosis may occur anywhere in the alimentary tract, but gastric, small intestinal, and large intestinal involvement are most common. Rectal lesions often cause partial obstruction. Fistulae may develop, resembling perianal fistulae, and the dog may be presented for constipation and/or hematochezia. Animals with advanced disease often lose weight. In rare cases there will be infarction of mucosa or vessels with subsequent ischemia. Cats are rarely affected.

Diagnosis

A serologic test is available (Chapter 27) and appears to have good sensitivity and specificity. If biopsy is performed, surgical biopsy or biopsy with rigid biopsy forceps are typically necessary to obtain submucosa, which is where the organisms are usually found. Eosinophils are typically prominent in affected tissues. Special stains (e.g., Warthin-Starry) are often required to find the organism.

Treatment

Complete surgical excision is preferred. No medication has consistently been effective, although itraconazole or lipid emulsion amphotericin B plus/minus terbinafine might be temporarily beneficial. Anecdotally, immunotherapy is beneficial in a few patients.

Prognosis

The prognosis is poor unless the lesion can be completely excised.

PROTOTHECOSIS

Etiology

Prototheca zopfii is an alga that invades tissue. It appears to be acquired from the environment, and some type of deficiency in the host's immune system might be necessary for the organism to produce disease.

Clinical Features

Affecting dogs and occasionally cats, protothecosis principally involves the skin, colon, and eyes but may disseminate throughout the body. Collies may be overrepresented. Colonic involvement causes bloody stools and other signs of colitis, much like histoplasmosis. Protothecosis is much less common than histoplasmosis, and the GI form primarily affects dogs.

Diagnosis

Diagnosis requires demonstrating the organism (Fig. 31.3), typically from biopsy or mucosal cytology. Some animals with disseminated disease shed the organism into the urine. The organism typically grows well if cultured.

Treatment

No drug works consistently. High doses of lipid emulsion amphotericin B seem useful in some patients. Coadministration of tetracycline might be helpful.

Prognosis

The prognosis for disseminated disease is poor because no treatment consistently works and relapse after treatment is common.

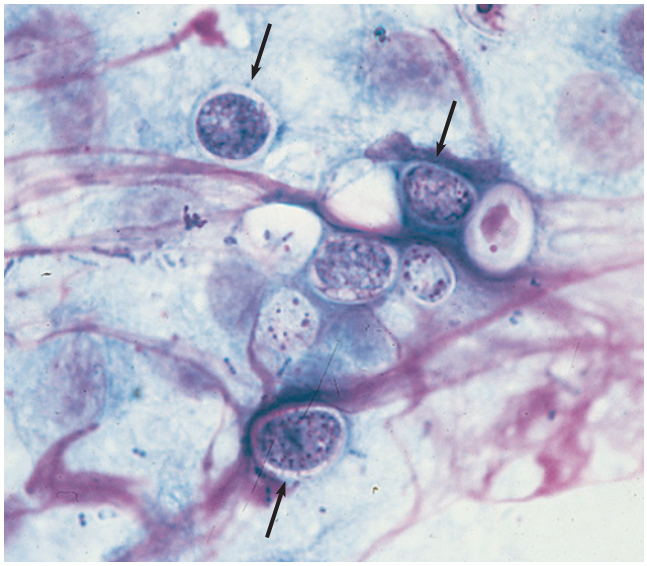

FIG 31.3
Cytologic preparation of a colonic mucosal scraping demonstrating *Prototheca* spp. Note the bean-shaped structures that have a granular internal structure and appear to have a halo *(arrows)* (Wright-Giemsa stain; ×1000). (Courtesy Dr. Alice Wolf, Texas A&M University.)

ALIMENTARY TRACT PARASITES

WHIPWORMS

Etiology

Trichuris vulpis is principally found in the eastern United States. Animals acquire the infection by ingesting ova; the adults burrow into the colonic and cecal mucosa and cause inflammation, bleeding, and/or intestinal protein loss.

Clinical Features

Dogs and rarely cats acquire whipworms, which produce a wide spectrum of mild to severe colonic disease that can include hematochezia and protein-losing enteropathy. Severe trichuriasis may cause severe hyponatremia and hyperkalemia, mimicking hypoadrenocorticism. Marked hyponatremia might be responsible for CNS signs (e.g., seizures). Whipworms generally do not affect cats as severely as dogs.

Diagnosis

T. vulpis should always be sought in dogs with large bowel diarrhea. Diagnosis is primarily made through finding ova (Fig. 31.4) in the feces. Ova are relatively dense and float only in properly prepared flotation solutions. However, they are shed intermittently and sometimes are found only if multiple fecal examinations are performed. Adults can be seen at colonoscopy (mild infestations may only affect the cecum).

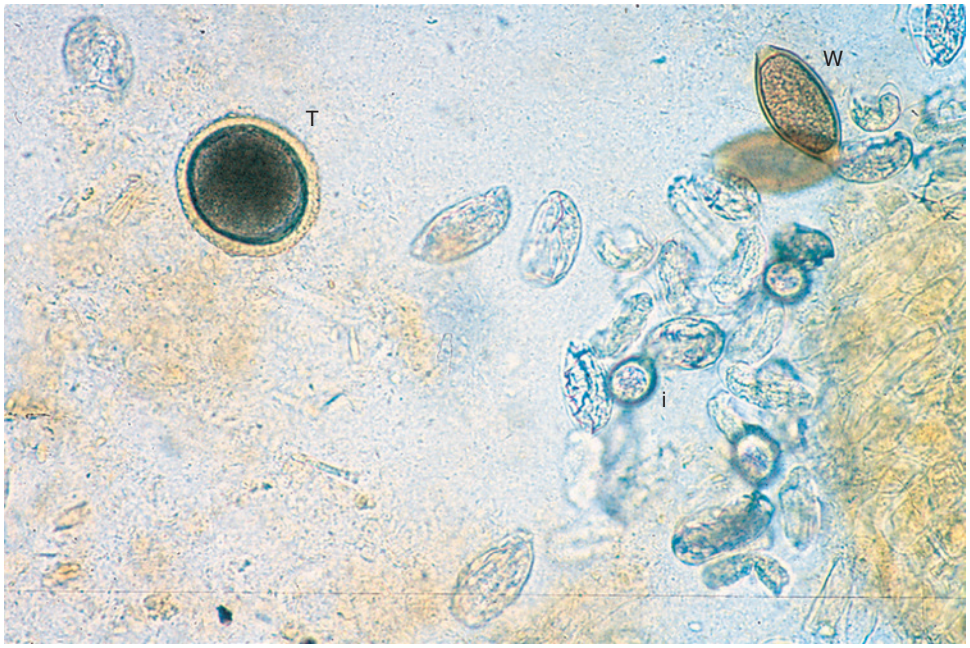

FIG 31.4
Photomicrograph of a fecal flotation analysis from a dog, demonstrating characteristic ova from whipworms *(W)*, *Toxocara canis (T)*, and *Isospora* spp. *(i)*. The remaining ova are those of an unusual tapeworm, *Spirometra* spp. (×250). (Courtesy Dr. Tom Craig, Texas A&M University.)

Treatment

Because of the potential difficulty in diagnosing *T. vulpis,* it is reasonable to empirically treat dogs with chronic large bowel disease with fenbendazole or other appropriate drugs (see Table 28.7) before proceeding to endoscopy. Ideally, patients should be treated monthly for 3 months to kill whipworms that were not in the intestinal lumen at the first treatment. Ova persist in the environment for long periods.

Prognosis

The prognosis for recovery is good.

ROUNDWORMS

Etiology

Roundworms are common in dogs *(Toxocara canis* and *Toxascaris leonina)* and cats *(Toxocara cati* and *Toxascaris leonina).* Dogs and cats can obtain roundworms from ingesting ova (either directly or via paratenic hosts). *T. canis* is often obtained transplacentally from the mother; *T. cati* may use transmammary passage, and *T. leonina* can use intermediate hosts. Tissue migration of immature forms can cause hepatic fibrosis and significant pulmonary lesions. Adult roundworms live in the small intestinal lumen and migrate against the flow of ingesta. They can cause inflammatory infiltrates (e.g., eosinophils) in the intestinal wall.

Clinical Features

Roundworms may cause or contribute to diarrhea, stunted growth, a poor haircoat, and poor weight gain, especially in young animals. Runts with "potbellies" suggest severe roundworm infection. Sometimes, roundworms gain access to the stomach, in which case they may be vomited. If parasites are numerous, they may obstruct the intestines or bile duct.

Diagnosis

Diagnosis is easy because ova are produced in large numbers and are readily found by fecal flotation (Fig. 31.5; see also Fig. 31.4). Occasionally, neonates develop clinical signs of roundworm infestation, but ova cannot be found in the feces. Transplacental migration results in large worm burdens, causing signs in these animals before the parasites mature and produce ova.

Treatment

Various anthelmintics are effective (see Table 28.7), but pyrantel is especially safe for young dogs and cats, particularly those with diarrhea. Affected animals should be retreated at 2- to 3-week intervals to kill roundworms that were initially in tissues but migrated into the intestinal lumen since the last treatment. Puppies can be treated as young as 2 weeks of age, and treatment can be repeated every 2 weeks until 3 months of age.

High-dose fenbendazole therapy (i.e., 50 mg/kg/day PO from day 40 of gestation until 2 weeks postpartum) has been suggested to reduce the somatic roundworm burden in bitches and lessen transplacental transmission to puppies. Newborn puppies can be treated with fenbendazole (100 mg/kg for 3 days), which kills more than 90% of prenatal larvae.

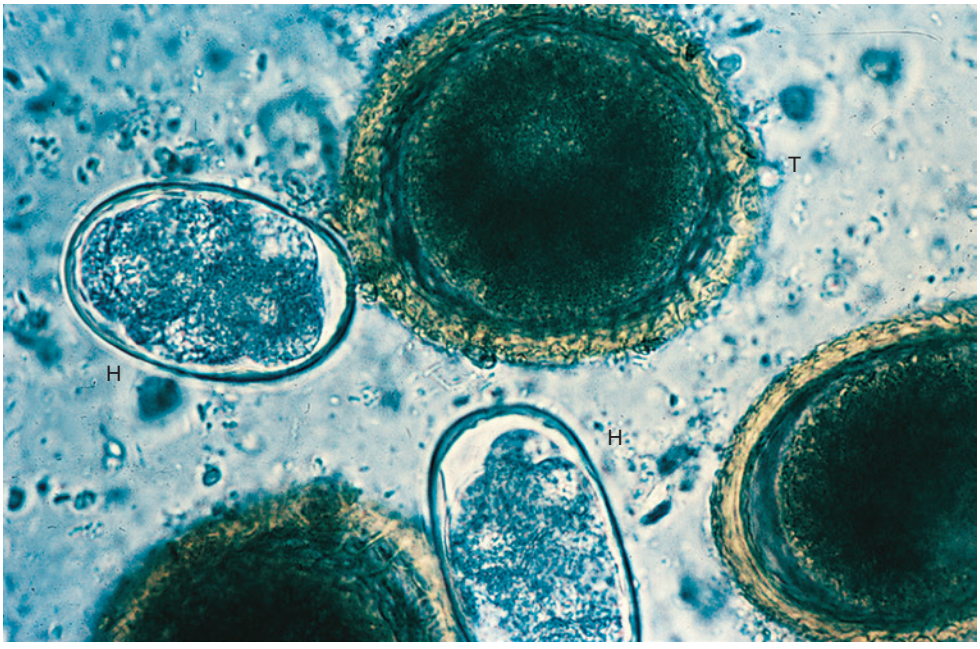

FIG 31.5
Photomicrograph of a fecal flotation analysis from a dog demonstrating characteristic ova from hookworms *(H)* and *Toxocara canis (T)* (×400). (Courtesy Dr. Tom Craig, Texas A&M University.)

This treatment can be repeated 2 to 3 weeks later. Preweaning puppies should be treated at 2, 4, 6, and 8 weeks of age to lessen contamination of the environment, because *T. canis* and *T. cati* pose a human health risk (i.e., visceral and ocular larval migrans). Preweaning kittens should be treated at 6, 8, and 10 weeks of age.

Prognosis

The prognosis for recovery is good unless the animal is already severely stunted when treated, in which case it may never attain its anticipated body size.

Public Health Concerns

Visceral larval migrans is an important zoonosis and the primary reason why veterinarians should be aggressive about treating puppies multiple times before they are 3 to 4 months old and then treating them annually.

HOOKWORMS

Etiology

Ancylostoma and *Uncinaria* spp. are more common in dogs than in cats. Infestation is usually via ingestion of ova or through transcolostral transmission; freshly hatched larvae may also penetrate the skin. Adults live in the small intestinal lumen, where they attach to the mucosa. Plugs of intestinal mucosa and/or blood are ingested, depending on the worm species. In severe infestations, hookworms may be found in the colon.

Clinical Features

Dogs are typically more severely affected than cats. Young animals may have life-threatening blood loss or iron deficiency anemia, melena, frank fecal blood, diarrhea, and/or failure to thrive. Peracute disease occurs in puppies receiving a large parasitic burden via transmammary transmission; they may die of GI blood loss before ova are found in the feces. Acute disease occurs when older puppies receive a large exposure; the primary sign is bloody diarrhea, and ova are readily found. Chronic disease occurs in dogs with enough parasites to cause chronic iron deficiency anemia but not diarrhea. Secondary disease occurs in older dogs with other GI disease in which the hookworms add on to the illness of the primary disease. Older dogs rarely have disease solely caused by hookworms unless they harbor a massive infestation.

Diagnosis

Finding ova in the feces is diagnostic (see Fig. 31.5) and easy because hookworms are prolific egg producers. However, 5- to 10-day-old puppies with peracute disease may be exsanguinated before ova appear in the feces. Such prepatent infections rarely occur in older animals that have received a sudden, massive exposure. Diagnosis is suggested by signalment and clinical signs in these animals. Iron deficiency anemia in a puppy or kitten free of fleas is highly suggestive of hookworm infestation.

Treatment

Various anthelmintics are effective (see Table 28.7). Treatment should be repeated in approximately 3 weeks to kill parasites entering the intestinal lumen from the tissues. In anemic puppies and kittens with peracute disease, blood transfusion may be life saving.

Hookworms are a potential human health hazard (i.e., cutaneous larval migrans). Use of heartworm preventives containing pyrantel or milbemycin helps minimize hookworm infestations.

Prognosis

The prognosis is good in mature dogs and cats but guarded in severely anemic puppies and kittens. If the puppies or kittens are severely stunted in their growth, they may never attain their anticipated body size.

Public Health Concerns

Cutaneous larval migrans is an important reason to control hookworms.

TAPEWORMS

Etiology

Several tapeworms infect dogs and cats, the most common being *Dipylidium caninum*. Tapeworms usually have an indirect life cycle; the dog or cat is infected when it eats an infected intermediate host. Fleas and lice are intermediate hosts for *D. caninum,* whereas wild animals (e.g., rabbits) are intermediate hosts for some *Taenia* spp. People and sheep are intermediate hosts for *Echinococcus granulosus,* and rodents are intermediate hosts for *E. multilocularis*.

Clinical Features

Aesthetically offensive, tapeworms are rarely pathogenic in small animals. *Mesocestoides* spp. can reproduce in the host and cause disease (e.g., abdominal effusion), and *Echinococcus* spp. rarely causes hydatid cysts in dogs. The most common sign in dogs and cats infested with tapeworms is anal irritation associated with shed segments "crawling" on the area. Typically the owner sees motile tapeworm segments on the feces and requests treatment. Occasionally a segment enters an anal sac and causes inflammation. Very rarely, large numbers of tapeworms cause intestinal obstruction.

Diagnosis

Taenia spp. and especially *D. caninum* eggs are typically confined in segments not detected by routine fecal flotations. *Echinococcus* spp. and some *Taenia* spp. ova may be found in the feces. Tapeworms are usually diagnosed when the owner reports tapeworm segments (e.g., "rice grains") on feces or the perineal area.

Treatment

Praziquantel and episprantel are effective against all species of tapeworms (see Table 28.7). Prevention of tapeworms

involves controlling the intermediate hosts (i.e., fleas and lice for *D. caninum*).

Public Health Concerns

Echinococcus spp. are a major human health hazard and an important reason to use anticestode drugs in dogs. *Diphyllobothrium* spp. and *Spirometra* spp. can also cause significant human disease.

STRONGYLOIDIASIS

Etiology

Strongyloides stercoralis principally affects puppies, especially those in crowded conditions. These parasites produce motile larvae that penetrate unbroken skin or mucosa; thus the animal may be infested from its own feces even before the larvae are evacuated from the colon. In this manner, animals can quickly acquire large parasitic burdens. Most animals are infested after being exposed to fresh feces containing motile larvae. Humane shelters and pet stores are likely sources for infestation.

Clinical Features

Infested animals may be asymptomatic, or they can have mucoid or hemorrhagic diarrhea and be systemically ill (e.g., lethargy). Respiratory signs (i.e., verminous pneumonia) occur if parasites penetrate the lungs.

Diagnosis

S. stercoralis is diagnosed by finding larvae in fresh feces, either by direct fecal examination or by Baermann sedimentation. *Strongyloides* larvae must be differentiated from *Oslerus* spp. larvae. The feces must be fresh because old feces may contain hatched hookworm larvae, which resemble those of *Strongyloides* spp.

Treatment

Fenbendazole (used for 5 days instead of 3; see Table 28.7), thiabendazole, and ivermectin are effective anthelmintics. This disease is a potential human health hazard because larvae penetrate unbroken skin. Immunosuppressed people are at risk for severe disease after being infected.

Prognosis

The prognosis is guarded in young animals with severe diarrhea and/or pneumonia.

Public Health Concerns

Strongyloides stercoralis is zoonotic, but dogs are rarely documented to be the cause of human infection.

COCCIDIOSIS

Etiology

Cystoisospora spp. are the coccidia infecting cats and dogs. The pet is usually infested by ingesting infective oocysts from the environment. The coccidia invade and destroy villous epithelial cells.

Clinical Features

Infections with *Cystoisospora* are very common in puppies and kittens and may be asymptomatic or may cause copious, watery diarrhea with or without blood. Rarely, a kitten or puppy may lose enough blood to require a blood transfusion.

Diagnosis

Coccidiosis is diagnosed by finding oocysts on fecal flotation examination (see Fig. 31.4). Repeated fecal examinations may be necessary, and small numbers of oocysts do not ensure that the infestation is insignificant. Diagnosis can be confusing because *Cystoisospora* oocysts must be distinguished from *Eimeria* oocysts (these are "passing through" after the dog was copraphagic) and giardial cysts. If a necropsy is performed, multiple areas of the intestine should be sampled because the infection may be localized to one area.

Treatment

If coccidia are believed to be causing a problem, sulfadimethoxine or trimethoprim-sulfa should be administered for 10 to 20 days (see Table 28.7). The sulfa drug does not eradicate the coccidia but inhibits it so that body defense mechanisms can reestablish control. Amprolium, toltrazuril, and ponazuril have been reported to be effective, but these are off label uses in the United States.

Prognosis

The prognosis for recovery is usually good unless there are underlying problems that allowed the coccidia to become pathogenic in the first place.

CRYPTOSPORIDIA

Etiology

Cryptosporidium spp. may infect animals that ingest sporulated oocysts. These oocysts originate from infested animals but may be carried in water. Thin-walled oocysts are produced, which can rupture in the intestine and produce autoinfection. The organism infests the brush border of small intestinal epithelial cells and causes diarrhea.

Clinical Features

Cryptosporidiosis is a potential cause of diarrhea in dogs and cats, but determining cause and effect is often difficult because it can be found in clinically normal patients. Dogs with diarrhea due to cryptosporidiosis are usually younger than 6 months of age, but a similar age predilection has not been recognized for cats.

Diagnosis

Diagnosis requires finding the oocysts by fecal flotation examination, immunofluorescence assay (IFA), ELISA, or PCR. *C. parvum* is the smallest of the coccidians and is easy to miss on fecal examination. It is best to submit the feces to

a laboratory experienced in diagnosing cryptosporidiosis. The laboratory must be warned that the feces may contain *C. parvum,* a potential zoonosis.

Treatment and Prognosis

Nitazoxanide and paromomycin (both potentially toxic in the cat) are used to treat cryptosporidiosis in people. Tylosin has been suggested to be effective, but this is dubious. Azithromycin (7-10 mg/kg PO q12h) might be safe and effective. Immunocompetent persons and cattle often spontaneously eliminate the infestation, but whether small animals do so is unknown. Any time cryptosporidiosis is diagnosed one should look for causes of immunosuppression in the host. Most young dogs with diarrhea associated with cryptosporidiosis die or are euthanized. Many cats have asymptomatic infestations, and those with diarrhea have an uncertain prognosis.

GIARDIASIS

Etiology

Animals are infected with the protozoan *Giardia* when they ingest cysts shed from infected animals, often via water. Organisms are principally found in the small intestine, where they interfere with digestion through uncertain mechanisms. In people *Giardia* organisms may occasionally ascend into the bile duct and cause hepatic problems.

Clinical Features

Patients may be asymptomatic or have mild to severe diarrhea, which may be persistent, intermittent, or self-limiting. Diarrhea can begin 5 days after exposure, before cysts appear in the feces. Typically the diarrhea is "cow patty"–like without blood or mucus, but there is substantial variation. Some animals experience weight loss; others do not. Diarrhea caused by *Giardia* can mimic large bowel diarrhea in some patients. In cats there may be an association between shedding giardial oocysts and shedding either cryptosporidial or coccidian oocysts.

Diagnosis

Giardiasis is diagnosed by finding motile trophozoites (Fig. 31.6) in fresh feces or duodenal washes, finding cysts with fecal flotation techniques or IFA, or finding giardial antigens in feces using ELISA or PCR methodology. Zinc sulfate solutions are the best for demonstrating cysts (especially when centrifugal flotation is performed); other flotation solutions may distort them. At least three fecal examinations should be performed over the course of 7 to 10 days before discounting giardiasis. However, there can be false-positive results due to particles in the feces (e.g., pollen) that resemble giardial cysts. Fecal ELISA techniques (e.g., SNAP Giardia Test, Idexx Laboratories) have high sensitivity and are easier than centrifugal fecal flotation examinations, but none offers 100% sensitivity. The ELISA is better at ruling out giardiasis than ruling it in. Some asymptomatic patients are repeatedly ELISA positive even though oocysts cannot be demonstrated on fecal examination. ELISA is not useful in determining efficacy of therapy because the antigen often persists for 4+ weeks after successful therapy. PCR of feces is very specific but is too insensitive to be reliable. Therefore IFA testing of feces is believed to be more specific than ELISA, but it requires sending feces to a diagnostic laboratory. Testing asymptomatic patients that are not in close contact with a known infected patient is of dubious value.

Treatment

Treatment of giardiasis consists of (1) decontaminating the environment, (2) bathing the patient to remove cysts from the hair, and (3) administering drugs to eliminate the intestinal infection. Because of the difficulty in finding *Giardia* organisms, therapeutic trials are often used (see Table 28.7).

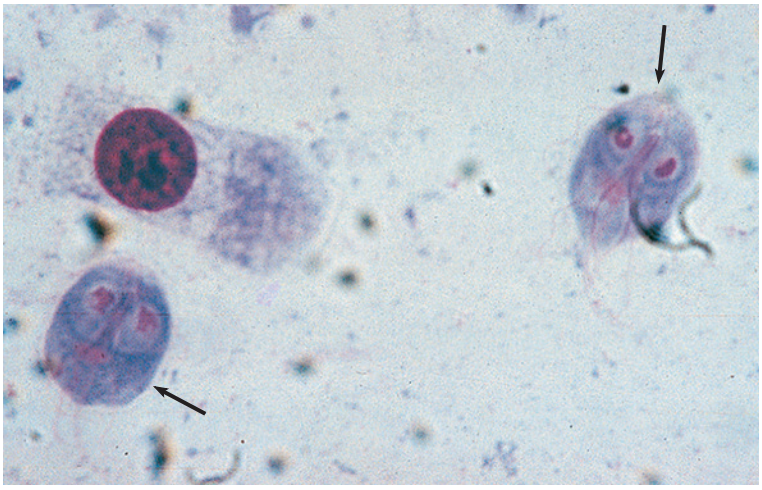

FIG 31.6
Giardia trophozoites *(arrows)* in a canine fecal smear that has been stained to enhance internal structures (×1000). (Courtesy Dr. Tom Craig, Texas A&M University.)

This approach has limitations because no drug is 100% effective (i.e., therapeutic failure does not rule out giardiasis). Seven days of metronidazole, 5 days of fenbendazole, or 5 days of febantel plus pyrantel plus praziquantel appear to be the preferred treatments. Metronidazole has few adverse effects if properly dosed and seems reasonably effective. Tinidazole and ronidazole appear to be effective. Quinacrine, furazolidone, and albendazole are either not available or not recommended.

It can be difficult to eliminate *Giardia* spp. because reinfection is easy; giardial cysts are resistant to environmental influences and relatively few are required to reinfect a patient. This is why bathing the patient and cleansing the environment are important. Quaternary ammonium compounds and pine tars are effective disinfectants. Concurrent host intestinal disease (or immunodeficiency) makes it particularly difficult to eliminate the organism. Rarely, *Giardia* becomes resistant to some drugs. Other protozoal agents (e.g., *Tritrichomonas*) are often mistaken for *Giardia*, which can cause confusion when the patient does not respond to therapy. Vaccination is generally unsuccessful as a treatment for patients not responding to the aforementioned drugs. It is reasonable to treat asymptomatic housemates of an affected pet. One-time treatment of asymptomatic patients not associated with clinically ill patients that are fortuitously diagnosed is reasonable, but repeated treatment of such patients is not recommended.

Prognosis

The prognosis for recovery is usually good, although in some cases the organisms are difficult to eradicate.

Public Health Concerns

There are seven genetic assemblages (A-G); two of them (A and B) may occur in people *and* animals, whereas the other five only occur in animals. The risk of zoonotic transmission from dogs and cats to people in the face of routine sanitary practices appears minor. The risk to young children (who do not routinely practice good sanitation) is unknown.

TRICHOMONIASIS

Etiology

Trichomoniasis in cats is caused by *Tritrichomonas blagburnii*. Animals are probably infected by the fecal-oral route. Dogs are rarely affected, and it is not clear whether they contract *T. blagburnii* or *T. foetus*.

Clinical Features

Trichomoniasis typically is associated with large bowel diarrhea, which rarely contains blood or mucus. Exotic cat breeds (e.g., Somalis, Ocicats, Bengals) are seemingly at increased risk for clinical disease. Affected cats are typically otherwise normal, although there may be anal irritation and defecation in inappropriate places. Diarrhea typically resolves spontaneously, although it can be months to years before it does so. *T. blagburni* has been detected in the feces of asymptomatic cats, too.

Diagnosis

Diagnosis requires identifying the motile trophozoite, but live *Tritrichomonas* trophozoites can be mistaken for *Giardia* trophozoites (Fig. 31.7, *A*) as well as nonpathogenic *Pentatrichomonas hominis*. Prompt examination of fresh feces diluted with warm saline solution is the easiest technique, but it is insensitive (approximately 14%). Fecal culture using a pouch technique is available but seldom used. PCR of feces is the most sensitive test available. The organism can sometimes be found in colonic mucosal biopsies.

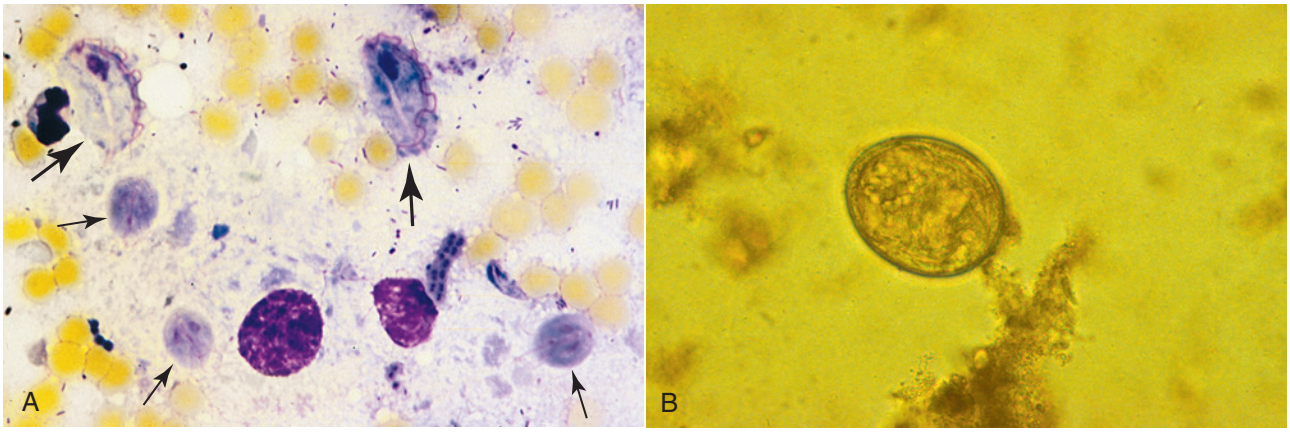

FIG 31.7
(A) Comparison of *Giardia* trophozoites *(small arrows)* and *Tritrichomonas* trophozoites *(large arrows)* in a smear that has been stained to enhance internal structures. Note that the *Tritrichomonas* trophozoites are larger and have one large undulating membrane (×1000). **(B)** Ova of *Heterobilharzia americana* in a fecal sedimentation. (Both images courtesy Dr. Tom Craig, Texas A&M University.)

Treatment and Prognosis

Because *T. blagburnii* does not have a cyst stage, it is much more fragile in the environment than is *Giardia*. Therefore, unlike *Giardia*-infected patients, *Tritrichomonas*-infected patients only need routine sanitation. Ronidazole (30 mg/kg PO q24h for 10-14 days) is the only drug currently known to safely and reliably eliminate *Tritrichomonas,* but neurologic signs have been reported. If trichomoniasis is diagnosed, it is important to look for other causes of diarrhea (e.g., *C. perfringens,* diet, *Cryptosporidium* spp.); treatment for one of these other causes may resolve the diarrhea. Clinical signs of trichomoniasis in most affected cats will eventually subside, although diarrhea may recur if the patient undergoes stressful events (e.g., elective surgery). There appears to be minimal risk of zoonotic transmission.

HETEROBILHARZIA

Etiology

Heterobilharzia americana infects dogs and establishes itself in the liver. Ova laid in the veins end up in the intestinal wall and in the liver, where they elicit a granulomatous inflammation. The organism is primarily found in Gulf Coast states and southern Atlantic coast states.

Clinical Features

Large bowel and/or hepatic disease are the primary presentations. Diarrhea, hematochezia, and weight loss are typical findings. PLE may occur, and the granulomatous reaction is associated with hypercalcemia in some dogs. Hepatic disease ranges from mild to severe.

Diagnosis

Finding the ova in feces or in mucosal biopsy specimens is diagnostic. There is a commercially available PCR test for feces.

Treatment and Prognosis

Fenbendazole plus praziquantel is successful in killing the parasite and the ova. However, the prognosis is seemingly dependent on the severity of the granulomatous reaction in the bowel and liver.

MALDIGESTIVE DISEASE

EXOCRINE PANCREATIC INSUFFICIENCY

Etiology

Canine exocrine pancreatic insufficiency (EPI) is caused by pancreatic acinar cell atrophy or destruction due to pancreatitis.

Clinical Features

EPI occurs in dogs and cats. Chronic small intestinal diarrhea, a ravenous appetite, and weight loss are classic findings in dogs. Cats may also have hyporexia and lethargy. Steatorrhea (i.e., slate-gray stools) is sometimes seen, and animals occasionally have weight loss without diarrhea. The diarrhea is classified as a small bowel problem (because of weight loss). Physical examination and routine clinical pathologic findings are not diagnostic. The most sensitive and specific test for EPI is measurement of serum trypsin-like immunoreactivity (TLI), which must be species specific. Finding undetectable levels of canine pancreatic lipase immunoreactivity (cPLI) might be suggestive of EPI but is not specific. Treatment involves administering good quality pancreatic enzymes with food and manipulation of dietary fat content. Cats often clinically benefit from cobalamin supplementation. The reader is referred to Chapter 37 for more information on EPI.

NON–PROTEIN-LOSING MALABSORPTIVE DISEASES

DIETARY-RESPONSIVE SMALL INTESTINAL DIARRHEA

Etiology

Dietary-responsive diarrhea is an all-inclusive term that includes dietary allergy (a hyperimmune response to a dietary antigen) and dietary intolerance (a non–immune-mediated response to a dietary substance). From a clinical standpoint, there is minimal value in distinguishing between the two. This is a very common cause of chronic GI signs in both dogs and cats.

Clinical Features

Affected patients may have vomiting and/or diarrhea (large and/or small bowel) plus/minus allergic skin disease.

Diagnosis

Diagnosis consists of showing response to feeding an elimination diet that is appropriate for the patient (see discussion of dietary management in Chapter 28). There is typically minimal value in distinguishing between allergy and intolerance. Tests for IgE antibodies in the patient's blood to specific antigens are not as sensitive or specific as seeing response to an elimination diet. The diet must be carefully chosen. It should consist of either relatively nonallergenic substances (e.g., hydrolyzed diets) or foods that have proteins to which the patient has not previously been exposed (e.g., novel protein diets). Hydrolyzed diets (especially ultra-hydrolyzed) are generally excellent choices for food trials when looking for dietary-responsive diarrhea, but they are not the gold standard for response to elimination diets. Some dogs respond better to novel protein diets. It would be best to try one and, if unsuccessful, then try the other. High-fat diets are generally avoided in such patients (because fat is difficult to digest), but there is no evidence that elimination diets have to be low in fat to be effective in cats. Most dogs and cats that respond to an appropriate diet do so within 3 weeks, although rare individuals require longer.

Treatment

Most patients that respond can simply be fed the diet they responded to in the dietary trial (assuming it is balanced) for the rest of their lives. Rare patients develop allergies to the elimination diet and require different elimination diets to be fed on rotating 2- to 3-week cycles.

Prognosis

The prognosis is usually good.

ANTIBIOTIC-RESPONSIVE SMALL INTESTINAL ENTEROPATHY

Etiology

Antibiotic-responsive enteropathy (ARE; also called *antibiotic-responsive diarrhea* or *dysbiosis*) is a syndrome in which there are many *E. coli* or similar enterics coupled with an intestinal host defense that is not capable of maintaining tolerance and subsequently has an abnormal response to these bacteria. Presumably, enterocytes are damaged by deconjugation of bile acids, fatty acid hydroxylation, generation of alcohols, increased permeability, generation of inflammatory cytokines, and/or other mechanisms.

Clinical Features

ARE can be found in any dog. Clinical signs are principally diarrhea or weight loss (or both), although vomiting and/or hyporexia may also occur.

Diagnosis

Currently available diagnostic tests for ARE have poor sensitivity and specificity. Quantitative duodenal fluid cultures are difficult to obtain and interpret. Serum cobalamin and folate concentrations have poor sensitivity and specificity for this disorder. Duodenal mucosal cytology and histopathology are routinely nondiagnostic for ARE. Most affected dogs have nonspecific mild to moderate lymphoplasmacytic infiltrates in the intestinal mucosa.

Treatment

Because of the difficulty in diagnosing ARE with laboratory tests, a therapeutic trial is reasonable when this disorder is suspected. Therapy consists of removal of potential causes (e.g., blind or stagnant loops of intestine [very rare]) and administering antibacterial drugs. Because mixed bacterial populations are expected, broad-spectrum oral antibiotics effective against aerobic and anaerobic bacteria are recommended. Tylosin (10-20 mg/kg q24h or divided q12h) is often effective. Metronidazole by itself (15 mg/kg q24h) sometimes is sufficient. A combination of metronidazole (15 mg/kg q24h) and enrofloxacin (7 mg/kg q24h) is effective in some patients not responding to the previous treatments, but this combination should only be used when ARE is strongly suspected and prior therapy has failed (it is important to avoid long-term quinolone therapy to lessen problems with bacterial resistance to antibiotics).

The clinician should treat 3 weeks before deciding that the therapy was ineffective. If therapy appears successful, it is often wise to continue to treat for an additional 1 to 2 weeks to establish cause and effect. Some animals can then have the antibiotic therapy stopped while the dietary therapy is maintained, but others will need repeated or indefinite antibiotic therapy. The clinician should warn the owner that the goal is typically control, not cure. Patients that have nearly constant diarrhea when not being treated with antibiotics may need constant antimicrobial therapy (undesirable) or alternative therapies (e.g., fecal transplantation, probiotics). Patients who have episodes every 3 to 4 months might best be treated when they relapse as opposed to having them on antibiotics constantly.

As of this writing, fecal transplantation is being tried in many dogs with chronic diarrheas, and it might eventually replace antibiotic therapy as the first line therapy for ARE or chronic enteropathy (CE). It is too early to know whether this will take place.

Prognosis

The prognosis is usually good for control of ARE, but the clinician must be concerned with possible underlying causes.

RELATION OF SMALL INTESTINAL DIETARY-RESPONSIVE DIARRHEA AND ANTIBIOTIC-RESPONSIVE ENTEROPATHY

Currently, approximately 70% of dogs with chronic diarrhea are suggested to have dietary-responsive diarrhea, whereas approximately 15% are suggested to have antibiotic-responsive enteropathy. However, it may be more complex than that. Although there are some dogs that only respond to dietary therapy and some that only respond to antibiotic therapy, there appears to be a substantial number that respond to either therapy (i.e., it just depends upon which is done first). Even patients that respond to antibiotic therapy by itself seem to often respond better when concurrently treated with an elimination diet. Further complicating the issue is a smaller subset that appears to require simultaneous dietary and antibiotic therapy. Therefore recommendations for therapeutic trials for CE patients should involve a definite sequence. Parasites should be eliminated first. After that, dietary trials are appropriate (often starting with a hydrolyzed diet for 3 weeks and then going to a novel protein diet for 3 weeks if that fails). Cobalamin may be supplemented during this time, even if blood levels have not been measured. By itself, cobalamin benefits relatively few CE dogs, but it is safe and easy and does help some. If this trial is not successful, then antibiotics (e.g., tylosin) may be added to the elimination diet (preferably another hydrolyzed diet if both diets had previously failed) for another 3 weeks. The hope is that even if antibiotics were necessary for resolution of clinical signs, one will be able to stop the antibacterial drugs and maintain clinical remission by feeding the elimination diet (i.e., it is often easier to maintain remission than

attain remission). If these therapeutic trials fail, the next step may be further therapeutic trials (e.g., fecal transplantation, probiotics), or perhaps biopsy (which should be done before administering antiinflammatory or immunosuppressive drugs).

SMALL INTESTINAL "INFLAMMATORY BOWEL DISEASE" (CHRONIC ENTEROPATHY)

Clinical Features

Contrary to human medicine, there is not a uniformly accepted definition of the term *inflammatory bowel disease* (IBD) in veterinary medicine. Some have suggested the term *chronic enteropathy* (CE) as an alternative. In this text, IBD is defined as an *idiopathic* inflammation affecting any portion of the canine or feline small or large intestine. The cause is believed to involve an inappropriate response by the intestinal immune system to bacterial and/or dietary antigens that evolves into a self-perpetuating state of inflammation. Lymphocytic-plasmacytic enteritis (LPE) is the most commonly diagnosed form of canine and feline IBD. Chronic small intestinal diarrhea is common, but patients can have weight loss despite normal stools. If the duodenum is severely affected, vomiting may be the major sign. PLE can occur with the more severe forms. The clinical and histologic features of IBD can closely resemble those of alimentary lymphoma (see pp. 502-503), especially well-differentiated, small cell alimentary lymphoma in cats.

Eosinophilic gastroenterocolitis (EGE) is usually an allergic reaction to dietary substances (e.g., beef, milk). Clinical signs usually but not always respond to dietary change, and glucocorticoids may be necessary. It is less common than LPE. Some cats have eosinophilic enteritis as part of a hypereosinophilic syndrome (HES). The cause of feline HES is unknown, but immune-mediated and neoplastic mechanisms may be responsible. Less severely affected cats without HES seem to have a condition similar to canine EGE.

Diagnosis

If IBD is defined as idiopathic inflammation, it is a diagnosis of exclusion and not just a histologic diagnosis. No physical examination, history, clinical pathology, imaging, or histologic findings are diagnostic of IBD. Diagnosis requires elimination of known causes of diarrhea (e.g., dietary-responsive, antibiotic-responsive, parasitic, neoplastic, fungal, etc.) plus histology showing mucosal inflammatory infiltrates, architectural changes (e.g., villus atrophy, crypt changes), and/or epithelial changes. Mucosal cytologic evaluation is unreliable for diagnosing lymphocytic inflammation because lymphocytes and plasma cells are normally present in intestinal mucosa. Unfortunately, histologic diagnosis of mucosal inflammation is subjective, and biopsy samples are frequently overinterpreted with substantial inconsistency among pathologists. It can be extremely difficult to histologically distinguish well-differentiated small cell lymphocytic lymphoma from severe LPE, even with full-thickness tissue samples. Animals with intense dietary reactions rarely have biopsy findings that resemble lymphoma. If the tissue specimens are of poor quality (i.e., small size, excessive artifact), it is easy to mistakenly diagnose lymphoma as LPE. Biopsy of more than one intestinal site (e.g., duodenum and ileum, as opposed to just duodenum) is sometimes critical in finding inflammatory and neoplastic changes. Diagnosis of feline LPE is similar to that of canine LPE. Many cats with IBD have mild to moderate mesenteric lymphadenopathy, which ultrasonographically mimics lymphoma. Cats symptomatic with severe IBD should be evaluated for the presence of "triaditis" (i.e., simultaneous inflammation of the intestines, pancreas, and liver).

Diagnosis of EGE is similar to diagnosis of LPE. Dogs with EGE may have eosinophilia and/or concurrent eosinophilic respiratory or cutaneous dietary allergies with pruritus. German Shepherds seem overrepresented. Diagnosis of feline EGE centers on finding intestinal eosinophilic infiltrates, but splenic, hepatic, lymph node, and bone marrow infiltrates and peripheral eosinophilia are common.

Treatment

"Mild" LPE is typically dietary-responsive or ARE that was not diagnosed before biopsy. Severe LPE is usually dietary- and/or antibiotic-responsive enteropathy that has become self-perpetuating such that antiinflammatory therapy is necessary. It is often important to co-administer dietary and antimicrobial therapy along with antiinflammatory/immunosuppressive therapy. Prednisolone (2.2 mg/kg/day PO) is typically first-line therapy in these patients. If a patient responds to prednisolone but cannot tolerate the steroid side effects, then budesonide may be considered. Disease not responding to prednisolone, especially if associated with hypoalbuminemia, sometimes requires immunosuppressives (e.g., cyclosporine, chlorambucil, azathioprine). Cyclosporine seems to be reasonably effective and works faster than azathioprine. However, relatively few dogs with non–protein-losing chronic enteropathies require these immunosuppressive drugs. Failure of a dog to respond to the various therapeutic trials followed by aggressive antiinflammatory or immunosuppressive therapy usually means that the diagnosis is incorrect. Typically such patients are ultimately found to be dietary-responsive or antibiotic-responsive animals.

Feline LPE is approached a bit differently. First, some cats with chronic diarrhea will have complete resolution of clinical signs after parenteral cobalamin supplementation. Dietary-responsive diarrhea is common, but finding an elimination diet that the cat will eat can be challenging; hence, the clinician may have to settle for a mediocre elimination diet that the patient will eat as opposed to a more strict elimination diet that the patient refuses. Antimicrobials (e.g., tylosin or metronidazole) are often helpful, but administering the drug can be difficult or impossible for some clients. Because some cats make it extremely difficult to perform good dietary and/or antimicrobial trials,

glucocorticoid therapy is common in cats with chronic enteropathies. Fortunately, cats are more resistant to iatrogenic hyperadrenocorticism and have alimentary histoplasmosis less often than dogs. Prednisolone is preferred to prednisone, and methylprednisolone is typically more effective than prednisolone. If oral administration is not possible, reposital injections of methylprednisolone (Depo-Medrol) may become necessary. Budesonide is primarily indicated when the cat responds to prednisolone but cannot tolerate the systemic side effects of glucocorticoids (e.g., those with diabetes mellitus). Chlorambucil is used instead of azathioprine in cats with biopsy-proven severe LPE that does not respond to other therapy (see Chapter 28) or for cats with well-differentiated small cell lymphoma. If the cat responds to pharmacologic therapy, hopefully the clinician will be able to eventually stop the drugs and maintain the patient in clinical remission with dietary therapy alone.

Canine EGE treatment should focus on dietary management such as an ultrahydrolyzed diet. If signs do not resolve with dietary therapy, then addition of glucocorticoid therapy to the dietary therapy is usually effective. Many affected dogs only respond to glucocorticoids if they are also eating an elimination diet. Sometimes an animal initially responds to dietary management but relapses while still eating this diet because the animal becomes allergic to one of the ingredients; therefore, it is sometimes necessary to find a second acceptable elimination diet. Some animals are very prone to developing dietary intolerances, necessitating switching back and forth from one elimination diet to another at 2-week intervals to prevent relapse. (See Chapter 28 for more information on these therapies.)

Feline EGE associated with HES usually requires high-dose prednisolone (4.4-6.6 mg/kg/day PO), and response is often poor. Cats with eosinophilic enteritis not caused by HES often respond favorably to elimination diets plus glucocorticoid therapy.

If the dog or cat responds to any of these therapies, it is usually a good idea to continue this therapy without change for another 2 to 3 weeks to ensure that clinical improvement is the result of the therapy and not an unrelated transient improvement. Once the clinician is convinced that the prescribed therapy and improvement are cause-and-effect, the patient should be slowly weaned from the drugs, starting with those that have the greatest potential for adverse effects. If it is not possible to completely withdraw drug therapy, then the lowest effective dose should be determined. Dietary therapy is typically the last to be altered.

Prognosis

The prognosis for dogs and cats with non–protein-losing chronic enteropathies is often good if therapy is begun before the patient becomes emaciated. These diseases are typically controlled but not cured; hence, many patients will require a special diet for the rest of their lives. LPE has been suggested to be a prelymphomatous lesion. This is uncertain in the dog (see p. 497 for immunoproliferative enteropathy in Basenjis), and the relationship between small cell lymphoma (SCL) and LPE is confusing in the cat (see pp. 502-503). If a dog or cat with a prior diagnosis of LPE is later diagnosed as having lymphoma, it may be just as likely that either the initial diagnosis of IBD was wrong (i.e., the patient had lymphoma) or that the lymphoma developed independently of the IBD.

DIETARY-RESPONSIVE LARGE INTESTINAL DIARRHEA

The use of elimination diets for large bowel disease in dogs and cats is essentially the same as for small bowel disease.

FIBER-RESPONSIVE LARGE BOWEL DIARRHEA

Clinical Features

A common problem in both dogs and cats, diarrhea is typically a mild large bowel problem, blood and mucus being infrequent. This is probably the same disease that was once called *irritable bowel syndrome* in the dog. Irritable bowel syndrome in people is a very different disease, and this terminology is no longer commonly used in veterinary medicine.

Diagnosis/Treatment

A therapeutic trial with a fiber-supplemented diet often produces marked clinical improvement within 3 to 5 days.

Prognosis

Most patients respond well.

CLOSTRIDIAL COLITIS

Clinical Features

This is a common problem in dogs and cats. It is not certain that the disease is caused by *Clostridium perfringens*, and "tylosin-responsive" or "amoxicillin-responsive" disease may be more accurate terminology.

Diagnosis/Treatment/Prognosis

This is discussed in detail under Clostridial Diseases (page 482).

LARGE INTESTINAL INFLAMMATORY BOWEL DISEASE

Clinical Features

In dogs, *Clostridium* colitis, parasites, dietary intolerance, and fiber-responsive diarrhea are responsible for most patients referred for "intractable" large bowel "IBD." Canine lymphocytic-plasmacytic colitis (LPC) is rarely diagnosed. Cats are more commonly diagnosed with LPC, but whether that is because it is harder to perform therapeutic trials in cats than dogs or because LPC is more common in cats is uncertain. In both species, LPC causes large bowel diarrhea (i.e., soft stools with or without blood or mucus; no

appreciable weight loss). In cats hematochezia is the most common clinical sign, and diarrhea is the second most common sign. Feline LPC may occur by itself or concurrently with small bowel IBD, whereas canine large bowel IBD seems to be infrequently associated with small bowel IBD.

Diagnosis

Diagnosis requires excluding other causes (e.g., parasites, dietary-responsive diarrhea, fiber-responsive diarrhea, Clostridial colitis, and fungal/algal colitis) plus demonstrating colonic mucosal inflammation. In particular, *Tritrichomonas* must be eliminated in cats.

Treatment

Antiinflammatory glucocorticoid (i.e., prednisolone) therapy is usually effective. Dogs sometimes benefit from sulfasalazine, mesalamine, or olsalazine therapy. Feeding a fiber-supplemented diet may enhance therapeutic effectiveness.

Prognosis

The prognosis for patients with colonic IBD tends to be better than for small bowel IBD.

GRANULOMATOUS/HISTIOCYTIC ULCERATIVE COLITIS

Etiology

This disease principally affects Boxers and French Bulldogs, but other breeds can be affected. It is caused by adherent-invasive *E. coli* and may reflect immune system idiosyncrasies in the commonly affected breeds.

Clinical Features

Affected animals initially often appear just like any other dog with chronic colitis (i.e., healthy except for the diarrhea ± hematochezia). However, this disease tends to be progressive; chronic cases can develop weight loss and hypoalbuminemia and eventually die.

Diagnosis

Although colonoscopy is often delayed to see how patients with chronic colitis will respond to anthelmintic, dietary, and antimicrobial therapeutic trials, early endoscopy should be considered for Boxers and French Bulldogs with chronic large bowel signs. Histopathology is required for diagnosis. Finding PAS-positive macrophages in the mucosa (usually the deeper mucosa) is diagnostic.

Treatment

This is an antibiotic-responsive disease, but increased bacterial resistance to commonly used antibiotics is making it difficult to treat. Therefore colonic mucosal biopsy for culture is strongly recommended. It is critical to treat for at least 8 weeks (even if the patient seems normal by week 2). Stopping antibiotics before 8 weeks has been associated with recurrence of infection and resistance to previously used antibiotics.

Prognosis

Prognosis is good if the patient is diagnosed before it is cachexic and antibiotics are administered long enough. Presumptive treatment for "IBD" with glucocorticoids is associated with mortality.

PROTEIN-LOSING ENTEROPATHY

CAUSES OF PROTEIN-LOSING ENTEROPATHY

Any intestinal disease producing sufficient inflammation, infiltration, congestion, or bleeding can produce a PLE (or gastropathy if it affects the stomach) (see Box 26.10). In dogs, lymphangiectasia and alimentary tract lymphoma seem to be the most common causes in adult dogs, whereas hookworms and chronic intussusception appear to be more common in very young dogs. If IBD is responsible, it is usually a very severe form. ARE has also been noted to cause PLE, which is reasonable since IBD may originate from ARE. Immunoproliferative enteritis of Basenjis, GI ulceration/erosion, and bleeding tumors may also produce PLE. Cats have PLE less frequently than dogs, and the major cause is lymphoma although severe IBD can occasionally cause it.

INTESTINAL LYMPHANGIECTASIA

Etiology

Intestinal lymphangiectasia (IL) primarily affects dogs. Lymphatic obstruction causes dilation and rupture of intestinal lacteals with subsequent leakage of protein, lymphocytes, and chylomicrons into the intestinal submucosa, lamina propria, and lumen. Because these proteins may be digested and resorbed, there must be sufficient loss so that the intestine's ability to resorb the protein is exceeded. Rupture of lymphatics in the intestinal wall or at the mesenteric border can produce lipogranulomas, which exacerbate lymphatic obstruction. A common misconception is that most of the intestine must be affected, but many severely symptomatic patients only have segmental disease (e.g., just jejunum or just ileum affected). Most cases of canine IL are idiopathic.

Clinical Features

Yorkshire Terriers, Soft-Coated Wheaten Terriers, and Lundehunds appear to be at higher risk than other breeds. Soft-Coated Wheaten Terriers may have concomitant protein-losing nephropathy. Diarrhea is inconsistent and may not occur; low protein transudative ascites is the only sign in a substantial number of dogs. These dogs can be hypercoagulable; pulmonary thromboembolism occasionally occurs.

Diagnosis

Clinical pathologic evaluation is not diagnostic. Severe hypoalbuminemia (serum albumin < 2.0 g/dL) and hypocholesterolemia are expected, but panhypoproteinemia is inconsistent. Lymphopenia is inconsistent. Finding

hyperechoic intestinal mucosal striations at ultrasound is very suggestive of lymphangiectasia (Fig. 31.8), but the sensitivity of this finding for lymphangiectasia is uncertain. Diagnosis generally requires intestinal histopathology, but gross endoscopic appearance can sometimes be diagnostic. It is important to perform ileoscopy as well as duodenoscopy. Feeding fat the night before endoscopy or ultrasonography seems to make diagnosis easier. If numerous dilated lacteals (Fig. 31.9) are seen endoscopically in a patient that is hypoalbuminemic due to PLE, one may diagnose lymphangiectasia.

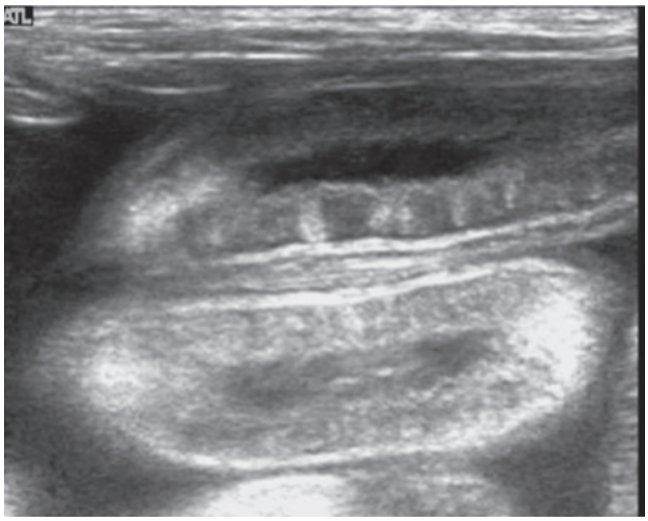

FIG 31.8
An ultrasonographic image of the small intestines of a dog with lymphangiectasia. Note the hyperechoic streaks resembling the spokes on a wagon wheel. These are fat-filled lymphatics. (Courtesy of Dr. Marie-Aude Genain, University of Cambridge, Department of Veterinary Medicine, Queen's Veterinary School Hospital.)

FIG 31.9
Endoscopic image of the duodenum of a dog with lymphangiectasia. The large white "dots" are dilated lacteals in the tips of the villi.

However, a few dilated lacteals may be found in any normal dog. Not seeing mucosal striations at ultrasonography or dilated lacteals at endoscopy does not lessen the chance of lymphangiectasia because the disease may be confined to a section of bowel not examined by ultrasound or endoscopy. When biopsying, high-quality tissue samples are critical. Submitting distorted, poorly oriented mucosal fragments or shredded villi makes it difficult to diagnose lymphangiectasia. Surgical biopsies are sometimes required. Finding lipogranulomas (Fig. 31.10) or obviously dilated, tortuous lymphatics on the intestines during surgery is extremely suggestive of IL.

Treatment

The underlying cause of IL is rarely determined, necessitating reliance on symptomatic therapy. An ultra–low-fat diet essentially devoid of long-chain fatty acids helps prevent further intestinal lacteal engorgement and subsequent protein loss. In many cases diagnosed early, this dietary therapy alone will cause the serum albumin to undergo a major increase within 7 to 12 days. More advanced cases will require concurrent prednisolone (1.1-2.2 mg/kg/day PO) or cyclosporine (3-5 mg/kg PO q12h) therapy. Cases that respond to diet alone may ultimately benefit from a 2- to 3-month course of prednisolone or cyclosporine to help prevent enlargement of lipogranulomas with subsequent relapse. If cyclosporine is used and the patient is not responding, therapeutic drug monitoring is indicated. Cases diagnosed late in the clinical course may not respond to therapy.

Monitoring serum albumin concentration (be sure to use the same laboratory each time) is critical to assessing response to therapy. If the animal improves, it should be fed the ultra–low-fat diet indefinitely.

FIG 31.10
Small intestines from a dog with intestinal lymphangiectasia. The white spots are lipogranulomas caused by rupture of lymphatics within the submucosa and/or muscularis of the intestine.

Prognosis

Some dogs respond well to ultra–low-fat diets, although some require antiinflammatory/immunosuppressive therapy in addition to the diet. A few dogs die despite all therapy. Early diagnosis and therapy may be associated with a better prognosis.

PROTEIN-LOSING ENTEROPATHY IN SOFT-COATED WHEATEN TERRIERS

Etiology

Soft-Coated Wheaten Terriers have a predisposition to PLE and protein-losing nephropathy. The cause is uncertain, although food hypersensitivity has been reported to be present in some affected dogs.

Clinical Features

Individual dogs may have PLE or protein-losing nephropathy (or both). Typical clinical signs may include vomiting, diarrhea, weight loss, and ascites. Affected dogs are often middle aged when diagnosed.

Diagnosis

Hypoalbuminemia and hypocholesterolemia are common, as with any PLE. Histopathology of intestinal mucosa may reveal lymphangiectasia, lymphangitis, and/or lymphocytic inflammation.

Treatment and Prognosis

Treatment is typically as for lymphangiectasia and/or IBD. The prognosis appears guarded to poor for clinically ill animals, with most dying within a year of diagnosis.

IMMUNOPROLIFERATIVE ENTEROPATHY OF BASENJIS

Etiology

Immunoproliferative enteropathy in Basenjis is an intense lymphocytic-plasmacytic small intestinal infiltrate often associated with villous clubbing, mild lacteal dilation, gastric rugal hypertrophy, lymphocytic gastritis, and/or gastric mucosal atrophy. It probably has a genetic basis or predisposition, and intestinal bacteria may play an important role.

Clinical Features

The disease tends to be a severe form of LPE that waxes and wanes, particularly when the animal is stressed (e.g., traveling). Weight loss, small intestinal diarrhea, vomiting, and/or hyporexia are commonly seen. Most affected Basenjis start showing clinical signs by 3 to 4 years of age.

Diagnosis

Marked hypoalbuminemia and hyperglobulinemia are common, especially in advanced cases. The early stages of the disease resemble many other intestinal disorders. In advanced cases the clinical signs are so suggestive that a presumptive diagnosis is often made without biopsy. However, because other diseases (e.g., lymphoma, histoplasmosis) may mimic immunoproliferative enteropathy, alimentary tract biopsy is necessary before aggressive immunosuppressive therapy is begun.

Treatment

Therapy includes diet modification (i.e., highly digestible elimination diet) and antimicrobials (see pp. 442-443), usually plus immunosuppressive therapy (i.e., glucocorticoids and/or cyclosporine). Response to therapy is variable, and affected dogs that respond are at risk for relapse, especially if stressed.

Although a genetic basis is suspected, not enough is known to be able to confidently recommend a breeding program. Intestinal biopsy of asymptomatic dogs is questionable.

Prognosis

Many affected animals die 2 to 3 years after diagnosis. The prognosis is poor for recovery, but some dogs can be maintained for prolonged periods of time with careful monitoring and care. In a few dogs, GI lymphoma eventually develops.

ENTEROPATHY IN CHINESE SHAR-PEIS

Etiology

Chinese Shar-Peis are prone to a severe enteropathy as well as other immune system abnormalities (i.e., Shar-Pei fever syndrome, renal amyloidosis) that probably reflect the immunologic abnormality that predisposes them to exaggerated inflammatory reactions in the GI tract. Shar-Peis are also recognized as often having extremely low serum cobalamin levels.

Clinical Features

Diarrhea and/or weight loss (i.e., small intestinal dysfunction) are the main clinical signs.

Diagnosis

Small intestinal biopsy is necessary for diagnosis. Eosinophilic and lymphocytic-plasmacytic intestinal infiltrates are typically found.

Treatment

Elimination diets, antimicrobial drugs, and antiinflammatory/immunosuppressive drugs are typically used. Shar-Peis are recognized as being prone to exceptionally low blood cobalamin levels, so supplementation is reasonable.

Prognosis

Affected Chinese Shar-Peis have a guarded prognosis.

ENTEROPATHY IN SHIBA DOGS

Etiology

Enteropathy in Shiba dogs has only recently been reported; the cause is unknown.

Clinical Features

Diarrhea and weight loss (i.e., small intestinal dysfunction) are the most common signs. Hyporexia is also a frequent problem.

Diagnosis

Leukocytosis, hypoalbuminemia, and hypocholesterolemia may occur. Typical histopathologic findings are moderate to severe lymphocytic/plasmacytic infiltrates in the duodenum and ileum. Architectural changes are also expected (i.e., crypt distention, blunt villi, lymphangiectasia).

Treatment

Optimal therapy is uncertain. Therapy for IBD (i.e., elimination diets, antimicrobial drugs, and antiinflammatory/immunosuppressive drugs) is currently recommended.

Prognosis

Most affected dogs die within 3 months of diagnosis.

IDIOPATHIC GRANULOMATOUS ENTERITIS AND/OR COLITIS

Canine granulomatous enteritis or colitis is diagnosed histologically and is usually caused by fungi or algae, and sometimes by bacteria. Idiopathic granulomatous infiltrates are uncommon. The clinician should request special stains, culture, and perhaps PCR testing before diagnosing idiopathic granulomatous disease. Regardless of cause, clinical signs are typically more severe than most cases of large bowel disease and may often cause a protein-losing enteropathy. If it is idiopathic and the disease is localized, surgical resection should be considered. If it is diffuse, glucocorticoids and cyclosporine may be considered. Too few cases of idiopathic granulomatous enteritis or colitis have been described and treated to allow generalizations. The prognosis is poor.

INTESTINAL OBSTRUCTION

SIMPLE INTESTINAL OBSTRUCTION

Etiology

Simple intestinal obstruction (i.e., lumenal obstruction without peritoneal leakage, severe venous occlusion, or bowel devitalization) is usually caused by foreign objects. Infiltrative disease and intussusception may also be responsible.

Clinical Features

Simple intestinal obstructions usually cause vomiting with or without hyporexia, depression, or diarrhea. Abdominal pain is uncommon. The more orad the obstruction, the more frequent and severe vomiting tends to be. If the intestine becomes devitalized and septic peritonitis results, the animal may be presented in a moribund state or in SIRS.

Diagnosis

Vomiting of gastric contents (which can occur with gastric outflow obstruction or intestinal obstruction) classically produces a hypokalemic-hypochloremic metabolic alkalosis and paradoxical aciduria, whereas vomiting of intestinal contents classically causes varying degrees of hypokalemia often with some degree of lactic acidosis from poor perfusion. However, these changes are not reliable for diagnosis. Hence, serum electrolyte and acid-base determinations are important when planning therapy.

Abdominal palpation, plain abdominal radiographs, or ultrasonographic imaging can be diagnostic if they reveal a foreign object, mass, or obvious obstructive ileus (see Fig. 27.5, *A*). Abdominal ultrasonography performed by a competent clinician tends to be the most sensitive technique (unless intestines are filled with gas) because it can reveal dilated or thickened intestinal loops not obvious on radiographs. Furthermore, ultrasound may allow aspirate cytology of masses and diagnosis of some diseases (e.g., lymphoma) without surgery. If it is difficult to distinguish obstruction from physiologic ileus, abdominal contrast radiographs may be considered, but they are rarely needed if good ultrasound support is available. Finding a foreign object is usually sufficient to establish a diagnosis, but not all foreign objects cause obstruction.

Treatment

If an abdominal mass, foreign object, or obstructive ileus is found, a presumptive diagnosis of obstruction is typically made, and endoscopy or exploratory surgery is planned. Routine preanesthetic laboratory tests with subsequent stabilization of the patient are indicated before proceeding to endoscopy or surgery.

Prognosis

If septic peritonitis is absent and massive intestinal resection is not necessary, the prognosis is usually good.

INCARCERATED INTESTINAL OBSTRUCTION

Etiology

Incarcerated intestinal obstruction involves a loop of intestine trapped or "strangulated" as it passes through a hernia (e.g., abdominal wall, mesenteric) or similar rent. The entrapped intestinal loop quickly dilates, accumulating fluid in which bacteria flourish and release endotoxins. SIRS occurs rapidly. This is a true surgical emergency, and animals deteriorate quickly if the entrapped loop is not removed.

Clinical Features

Dogs and cats with incarcerated intestinal obstruction typically have acute vomiting, abdominal pain, and progressive depression. Palpation of the entrapped loop often causes severe pain and occasionally vomiting. On physical examination, "muddy" mucous membranes and tachycardia may be noted, suggesting SIRS.

Diagnosis

A presumptive diagnosis is made by finding a distended, painful intestinal loop, especially if the loop is contained within a hernia. Radiographically, a markedly dilated segment of intestine is detected (Fig. 31.11) that is sometimes obviously outside the peritoneal cavity. Otherwise, an obviously strangulated loop of intestine will be found at exploratory surgery.

Treatment

Immediate surgery and aggressive therapy for SIRS are indicated. Devitalized bowel should be resected, with care taken to avoid spillage of septic contents into the abdomen.

Prognosis

The prognosis is guarded. Rapid recognition and prompt surgery are necessary to prevent mortality.

MESENTERIC TORSION/VOLVULUS

Etiology

The intestines twist about the root of the mesentery, causing severe vascular compromise. Much of the intestine is typically devitalized by the time surgery is performed.

Clinical Features

This uncommon cause of intestinal obstruction principally occurs in large dogs (especially German Shepherds). Mesenteric torsion typically causes an acute onset of severe nausea, retching, vomiting, abdominal pain, and depression. Bloody diarrhea may or may not occur. Abdominal distention is not as severe as expected in animals with gastric dilation/volvulus (GDV).

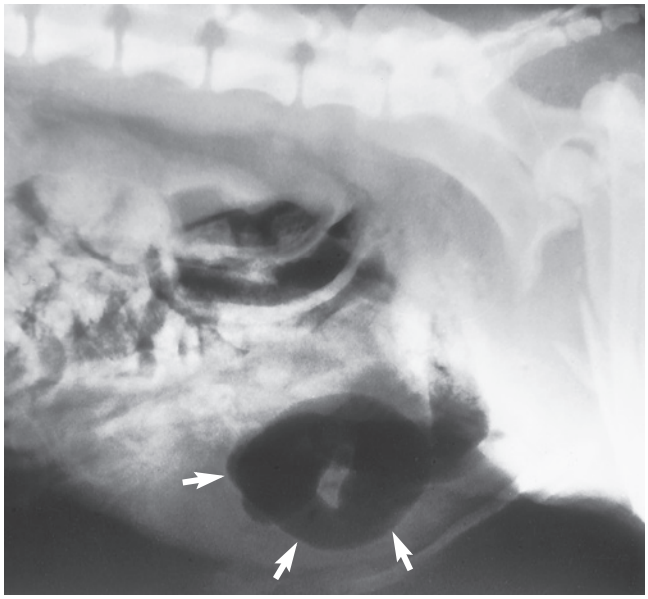

FIG 31.11
Lateral abdominal radiograph of a dog with a ruptured prepubic tendon and incarcerated intestinal obstruction. Note the dilated section of intestine in the area of the hernia *(arrows)*. (From Allen D, editor: *Small animal medicine,* Philadelphia, 1991, JB Lippincott.)

Diagnosis

Abdominal radiographs are often diagnostic and typically show widespread uniform ileus (see Fig. 27.6).

Treatment

Immediate surgery is necessary. The intestines must be properly repositioned and devitalized bowel resected.

Prognosis

The prognosis is extremely poor; most animals die despite heroic efforts. Animals that live may develop short bowel syndrome if massive intestinal resection is necessary.

LINEAR FOREIGN OBJECTS

Etiology

Numerous objects can assume a linear configuration in the alimentary tract (e.g., string, thread, nylon stockings, cloth). The foreign object lodges or fixes at one point (e.g., base of the tongue, pylorus) while the rest trails off into the intestines. The small intestine seeks to propel the object aborally via peristaltic waves and in this manner gathers around it and becomes pleated. As the intestines continue trying to propel it aborally, the linear object cuts or "saws" into the intestines, often perforating them at multiple sites on the antimesenteric border. Fatal peritonitis can result.

Clinical Features

Linear foreign objects appear to be more frequent in cats than in dogs. Vomiting food, bile, and/or phlegm is common, but some animals show only hyporexia or depression. Rare patients (especially dogs with chronic linear foreign bodies) can be relatively asymptomatic for days to weeks while the foreign body continues to embed itself in the intestines.

Diagnosis

The history may be suggestive of a linear foreign body (e.g., the cat was playing with cloth or string). Bunched, painful intestines are occasionally detected by abdominal palpation. The object is sometimes seen lodged at the base of the tongue, but failure to find a foreign object at the base of the tongue does not eliminate linear foreign body. Even when such objects lodge under the tongue, they can be very difficult to find despite a careful oral examination; some become embedded in the frenulum. If necessary, chemical restraint (e.g., IV ketamine, 2 mg/kg) should be used to allow adequate oral examination. Rarely, the end of the linear foreign object protrudes from the anus.

Foreign objects lodged at the pylorus and trailing off into the duodenum must be diagnosed by abdominal palpation, imaging, or gastroduodenoscopy. The objects themselves are infrequently seen radiographically and only rarely produce dilated intestinal loops suggesting anatomic ileus; proximity to the stomach and pleating of the intestines around the

object usually prevent the intestines from dilating. Plain radiographs may reveal small gas bubbles in the intestines, especially in the region of the duodenum, and obvious intestinal pleating may occasionally be seen (Fig. 31.12). If contrast radiographs are performed (use an isotonic iodine contrast agent), they typically reveal a pleated or bunched intestinal pattern, which is diagnostic of linear foreign body. These objects are sometimes seen endoscopically, lodged at the pylorus.

Treatment

Abdominal surgery is typically required to remove linear foreign objects. If the animal is otherwise healthy, if the linear foreign object has been present for only 1 or 2 days, and if it is fixed under the tongue, the object may be cut loose from its attachment at the base of the tongue to see if it will now pass through the intestines without further problem. Surgery is indicated if the animal does not appear better 12 to 24 hours after the object is cut free from its point of fixation.

If there is doubt as to the length of time the object has been present or if it is fixed at the pylorus, surgery is usually a safer therapeutic approach. Endoscopic removal occasionally succeeds, but the clinician must be careful because it is easy to rupture devitalized intestine and cause peritonitis. If the clinician can pass the tip of the endoscope to near the aborad end of the object and pull it out by grabbing the aborad end, surgery is sometimes unnecessary.

Prognosis

The prognosis is usually good if severe septic peritonitis is absent and massive intestinal resection is unnecessary. If a

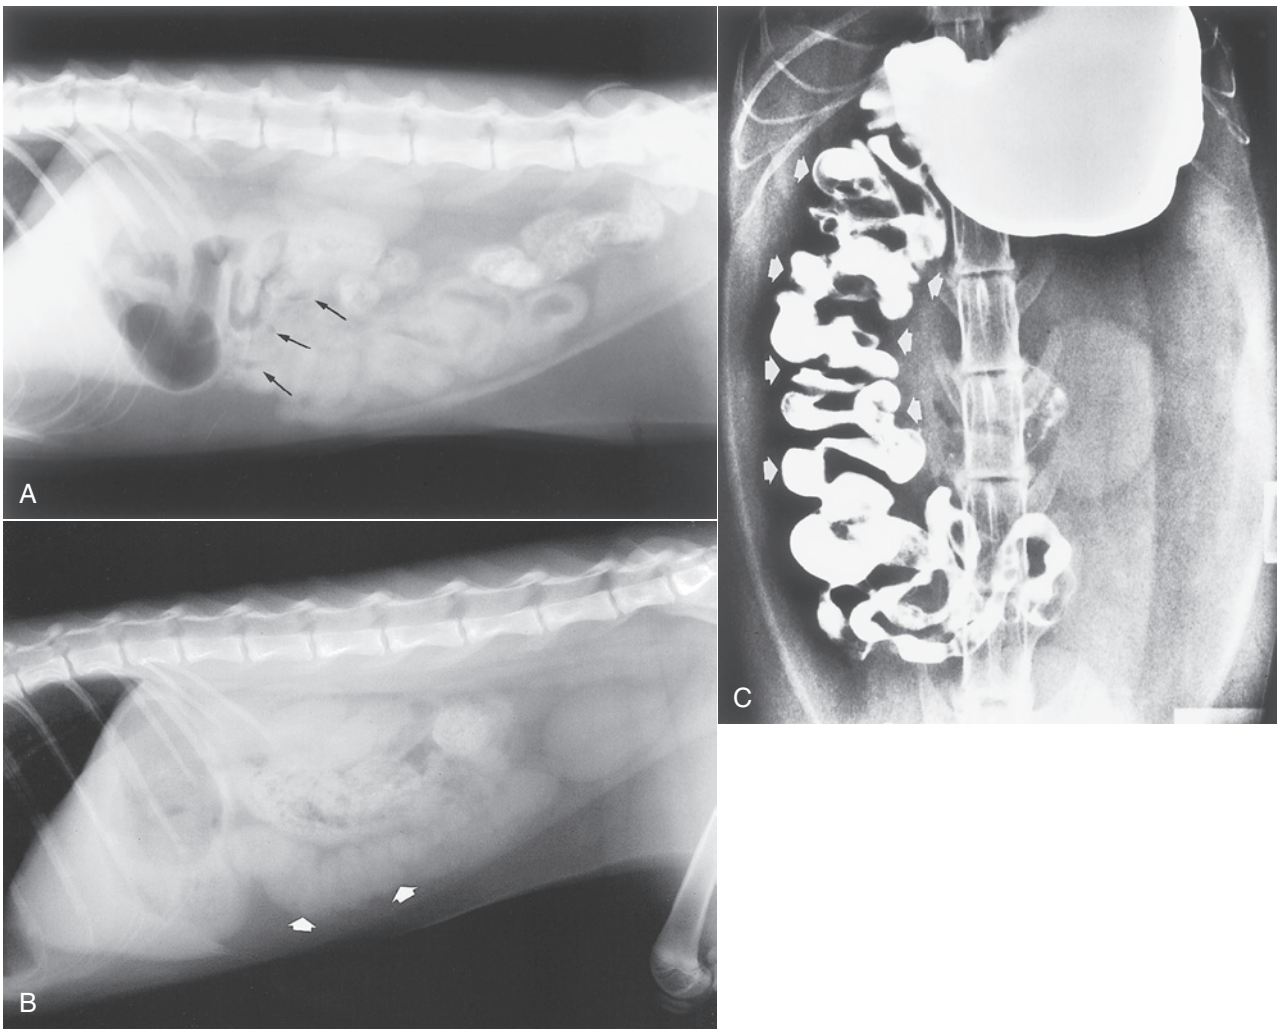

FIG 31.12
(A) Plain abdominal radiograph of a cat with a linear foreign body lodged at the pylorus. Note the small gas bubbles in the mass of intestines *(arrows)*. **(B)** Plain abdominal radiograph of a cat with a linear foreign body. Note the obviously pleated small bowel *(arrows)*. **(C)** Contrast radiograph of a cat with a linear foreign body. Note the pleated, bunched pattern of intestines *(arrows)*. (**A** from Allen D, editor: *Small animal medicine,* Philadelphia, 1991, JB Lippincott.)

linear foreign object has been present a long time, it may embed itself in the intestinal mucosa, making intestinal resection necessary. When massive intestinal resection is necessary, short bowel syndrome might result.

INTUSSUSCEPTION

Etiology

Intussusception is a telescoping of one intestinal segment (the intussusceptum) into an adjacent segment (the intussuscipiens). It may occur anywhere in the alimentary tract, but ileocolic intussusceptions (i.e., ileum entering colon) seem most common. Ileocolic intussusceptions seem to be associated with active enteritis (especially in young animals), which ostensibly disrupts normal motility and promotes the smaller ileum to intussuscept into the larger-diameter colon. However, ileocolic intussusception may occur in animals with acute renal failure, leptospirosis, prior intestinal surgery, and other problems. Main Coon Cats may have a much higher incidence of intussusception than the general population.

Clinical Features

Acute ileocolic intussusception causes obstruction of the intestinal lumen and congestion of the intussusceptum's mucosa. Scant bloody diarrhea, vomiting, abdominal pain, and a palpable abdominal mass are classic. Chronic ileocolic intussusceptions typically produce less vomiting, abdominal pain, and hematochezia. These animals often have intractable diarrhea and hypoalbuminemia because of protein loss from the congested mucosa. PLE in a young dog without hookworms or a puppy that seems to be having an unexpectedly long recovery from parvoviral enteritis should prompt suspicion of chronic intussusception. Acute jejunojejunal intussusceptions usually do not cause hematochezia. Mucosal congestion can be more severe than that in ileocolic intussusception; intestinal devitalization eventually occurs, and bacteria and their toxins may gain access to the peritoneal cavity.

Diagnosis

Palpation of an elongated, obviously thickened intestinal loop establishes a presumptive diagnosis; however, some infiltrative diseases produce similar findings. Ileocolic intussusceptions that are short and do not extend far into the descending colon may be especially difficult to palpate because they are just under the vertebral column and within the rib cage. Occasional intussusceptions "slide" in and out of the colon and can be missed during abdominal palpation. If the intussusception protrudes as far as the rectum, it may resemble a rectal prolapse. Therefore if tissue is protruding from the rectum, the clinician should perform a careful rectal palpation to determine whether a fornix exists (i.e., it is a rectal prolapse) as opposed to an intussusception (in which a fornix is absent).

Plain abdominal radiographs infrequently allow diagnosis of ileocolic intussusceptions because they usually cause minimal intestinal gas accumulation. Abdominal ultrasonography is quick and reasonably sensitive and specific for detecting intussusceptions (see Fig. 27.8, *B*). Colonoscopy can be definitive if the intussuscepted intestine is seen extending into the colon (Fig. 31.13). Jejunojejunal intussusceptions may be easier to palpate because of their location.

A reason for the intussusception (e.g., parasites, mass, enteritis) should always be sought. Fecal examination for parasites and evaluation of full-thickness intestinal biopsy specimens obtained at the time of surgical correction of the intussusception should be performed. In particular, the tip of the intussuscepted bowel (i.e., the intussusceptum) should be examined for a mass lesion (e.g., tumor) that could have served as a focus and helped the intussusception occur. Additional diagnostic tests may be warranted depending on the history, physical examination findings, and results of clinical pathologic evaluation.

Treatment

Intussusceptions are treated surgically. Acute ones may be reduced or resected, whereas chronic ones usually must be resected. Recurrence (in the same or a different site) is reasonably common. Surgical plication might prevent recurrence.

Prognosis

The prognosis is often good if septic peritonitis has not occurred and the intestines do not reintussuscept.

CECOCOLIC INTUSSUSCEPTION

Etiology

Cecocolic intussusception, in which the cecum intussuscepts into the colon, is rare. The cause is unknown, although some suggest that whipworm-induced typhlitis may be responsible.

Clinical Features

Primarily occurring in dogs, intussuscepted cecums can bleed sufficiently to cause anemia. Hematochezia is the major sign. It does not lead to intestinal obstruction and infrequently causes diarrhea.

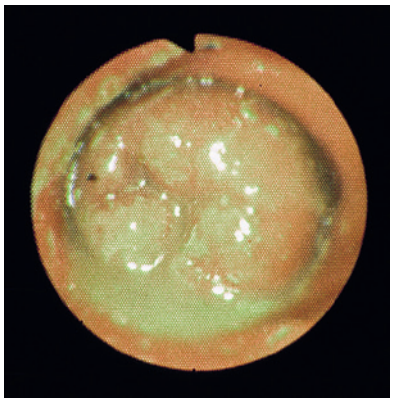

FIG 31.13
Endoscopic view of the ascending colon of a dog with an ileocolic intussusception. Note the large "hot dog"–like mass in the colonic lumen, which is the intussusception.

Diagnosis

Flexible colonoscopy and ultrasonography are the primary ways it is diagnosed.

Treatment

Typhlectomy is curative, and the prognosis is good.

MISCELLANEOUS INTESTINAL DISEASES

SHORT BOWEL SYNDROME

Etiology

Short bowel syndrome occurs when massive resection of small intestines results in the need for special nutritional therapy until the intestines are able to adapt. This is caused by resection of more than 75% to 90% of the small intestine so that the remaining intestine is unable to adequately digest and absorb nutrients. Large numbers of bacteria may reach the upper small intestines, especially if the ileocolic valve is removed. Not all animals with substantial small intestinal resections develop this syndrome. Dogs and cats tolerate loss of large amounts of small intestine better than people do.

Clinical Features

Affected animals usually have severe weight loss and intractable diarrhea (typically without mucus or blood), which often occurs shortly after eating.

Diagnosis

A history of substantial resection in conjunction with the clinical signs is sufficient for diagnosis.

Treatment

The best treatment is prevention. Avoid massive resections if at all possible, even if it means doing a "second-look" surgery 24 to 48 hours later. If massive resection occurs and the animal cannot maintain its body weight with oral feedings alone, total parenteral nutrition is necessary until intestinal adaptation has occurred and treatments have become effective in controlling clinical signs. It is important to continue oral feedings to stimulate intestinal mucosal hypertrophy. The diet should be highly digestible (e.g., low-fat cottage cheese, potato) and should be fed in small amounts at least three to four times a day. Opiate antidiarrheals (e.g., loperamide) and proton pump inhibitors may help lessen diarrhea. Antibiotics might be required to control the large bacterial populations that occur in the small intestine (see pp. 442-443).

Prognosis

If intestinal adaptation occurs, the animal may eventually be fed a near-normal diet. However, some animals will never be able to resume regular diets, and others die despite all efforts. Animals that are initially malnourished seem to have a worse prognosis than those that are initially well nourished.

NEOPLASMS OF THE SMALL INTESTINE

ALIMENTARY LYMPHOMA

Etiology

Lymphoma is a neoplastic proliferation of lymphocytes (see Chapter 79). Alimentary lymphoma must often be considered in patients with severe malabsorptive disease or protein-losing enteropathies. The cause is uncertain; FeLV might be involved in cats (even those that are ELISA negative). LPE has been suggested to be prelymphomatous (especially in cats), but this is uncertain. Lymphoma often affects the intestines, although extraintestinal forms (e.g., lymph nodes, liver, spleen) are more common in dogs. Alimentary lymphoma appears to be more common in cats than in dogs. There are different forms of alimentary lymphoma. Lymphoblastic lymphoma (LL) is found in dogs and cats; well-differentiated SCL is primarily found in cats. Large granular lymphocyte lymphoma is a rare, very severe form found in cats.

Clinical Features

Alimentary LL tends to produce dramatic signs (i.e., chronic progressive weight loss, hyporexia, small intestinal diarrhea, vomiting). Nodules, masses, diffuse intestinal thickening resulting from infiltrative disease, dilated sections of intestine that are not obstructed, and/or focal constrictions are possible, although it may also be present in grossly normal-appearing intestine. PLE may occur. Mesenteric lymphadenopathy (i.e., enlargement) is typical but not invariable. Remember that feline IBD can cause mild to moderate mesenteric lymphadenopathy. Extraintestinal abnormalities (e.g., peripheral lymphadenopathy) are inconsistently found in dogs and cats with alimentary LL.

Alimentary SCL in cats often has a much less aggressive course with relatively mild signs of weight loss, vomiting, and/or diarrhea.

Diagnosis

Diagnosis of LL requires demonstration of neoplastic lymphocytes, which may be obtained by fine-needle aspiration, imprint, or squash cytologic preparations. Paraneoplastic hypercalcemia is neither sensitive nor specific for alimentary lymphoma. Histopathology of intestinal tissue is the most reliable diagnostic method. Some have suggested that full-thickness tissue samples obtained surgically or laparoscopically are preferred over endoscopy. Although such samples are sometimes necessary, the majority of dogs and many cats can be successfully diagnosed endoscopically if the endoscopist obtains good-quality tissue samples and biopsies duodenum and ileum. Occasionally, neoplastic lymphocytes are found only in the serosal layer and full-thickness surgical biopsy specimens are necessary.

Diagnosis of LL tends to be relatively easy in the dog and cat (finding a few obviously malignant lymphocytes confirms it), but diagnosis of feline SCL remains difficult. Poor-quality endoscopic biopsy samples (i.e., too superficial,

having excessive artifact) are notorious for resulting in an erroneous diagnosis of LPE instead of SCL. Finding lymphocytes in the submucosa is not specific for lymphoma. In some cases, finding lymphocytes in organs where they should not be found (e.g., liver) allows diagnosis of SCL.

SCL of the feline intestines tends to be T-cell lymphoma and sometimes has obvious epitheliotrophism. Routine hematoxylin and eosin (H&E) staining does not allow reliable differentiation of SCL from LPE. Immunohistochemistry (i.e., staining for CD3 and CD79a) has been used to help distinguish SCL from LPE. Clonality testing with PCR appears necessary to accurately diagnose SCL in some cases. Clonality testing requires submitting samples to specialized laboratories and takes time and resources.

Treatment

Chemotherapy may palliate some patients with LL, but many become quite ill if given aggressive chemotherapy. In distinction, cats with SCL treated with prednisolone and chlorambucil usually respond well, comparable to cats with IBD that receive the same therapy. Treatment protocols are outlined in Chapter 79.

Prognosis

The long-term prognosis is very poor with LL. Many cats with SCL will have a high quality of life for years with therapy.

INTESTINAL ADENOCARCINOMA

Intestinal adenocarcinoma is more common in dogs than in cats. It typically causes diffuse intestinal thickening or focal circumferential mass lesions. Primary clinical signs are weight loss and vomiting caused by intestinal obstruction. Diagnosis requires demonstrating neoplastic epithelial cells. Endoscopy, surgery, and ultrasound-guided fine-needle aspiration may be diagnostic. Scirrhous carcinomas have very dense fibrous connective tissue that often cannot be adequately biopsied with fine-needle aspiration or a flexible endoscope, so surgery is sometimes required to obtain diagnostic biopsies. The prognosis is good if complete surgical excision is possible, but metastases to regional lymph nodes are common by the time of diagnosis. Postoperative adjuvant chemotherapy does not appear to substantially affect survival time.

INTESTINAL LEIOMYOMA/ LEIOMYOSARCOMA/STROMAL TUMOR

Intestinal leiomyomas and leiomyosarcomas, and stromal tumors are connective tissue tumors that usually form a distinct mass and are primarily found in the small intestine and stomach of older dogs. Primary clinical signs are intestinal hemorrhage, iron deficiency anemia, and obstruction. They can also cause hypoglycemia as a paraneoplastic effect. Diagnosis requires demonstration of neoplastic cells. Evaluation of ultrasound-guided fine-needle aspirates may be diagnostic, but these tumors do not exfoliate as readily as many carcinomas or lymphomas, and incisional or excisional biopsy is often necessary. Surgical excision may be curative if there are no metastases. Metastases make the prognosis poor, although some animals are palliated by chemotherapy.

NEOPLASMS OF THE LARGE INTESTINE

ADENOCARCINOMA

Etiology

Very few canine colonic adenocarcinomas arise from polyps. These tumors can extend into the lumen or be infiltrative and produce a circumferential narrowing.

Clinical Features

Principally found in dogs, colonic and rectal adenocarcinomas are more common in older animals. Hematochezia is common. Infiltrative tumors are likely to cause tenesmus and/or constipation secondary to obstruction.

Diagnosis

Finding carcinoma cells is necessary for a diagnosis. Histopathologic evaluation is often preferable to cytologic analysis because epithelial dysplasia may be present in benign lesions, causing a false-positive cytologic diagnosis of carcinoma. Relatively deep biopsies obtained with rigid biopsy forceps are best for distinguishing carcinomas from benign polyps because invasion of the submucosa is an important feature of rectal adenocarcinomas. Because most colonic neoplasms arise in or near the rectum, digital examination is the best screening test. Colonoscopy is required for masses farther orad. Imaging is used to detect sublumbar lymph node or pulmonary metastases.

Treatment

Complete surgical excision is curative. Transanal pull-through rectal amputation is beneficial in selected cases. There are transabdominal approaches to the distal colon, but long-term outcome is uncertain. However, many patients with rectal adenocarcinoma do not respond as well owing to late diagnosis and extensive local invasion plus distant metastasis to regional lymph nodes.

Prognosis

Timely diagnosis and surgery may give survival times up to 4 years for some patients. The prognosis for unresectable adenocarcinoma is poor. Preoperative and intraoperative radiotherapy may be palliative for some dogs with nonresectable colorectal adenocarcinomas.

RECTAL POLYPS

Etiology

The cause of rectal polyps is unknown.

Clinical Features

Principally found in dogs, hematochezia (which may be considerable) and tenesmus are the primary clinical signs. Obstruction is rare.

Diagnosis

Usually detected during rectal examination, many adenomatous polyps resemble sessile adenocarcinomas because they are so large. Histopathologic analysis is required for diagnosis and to distinguish polyps from malignancies.

Treatment

Complete excision via surgery (everting the rectal mucosa) or endoscopy (using a polypectomy snare) is curative. Although a thorough endoscopic or imaging evaluation of the colon should be done before surgery to ensure that additional polyps are not present, it is rare that there are more. If they are incompletely excised, polyps return and must be excised again (which is common with endoscopically removed polyps).

Prognosis

Most canine rectal and colonic polyps do not result in carcinoma *in situ*, possibly because they are diagnosed relatively sooner than colonic polyps in people. The prognosis is good.

DISEASES OF THE PERINEAL AREA AND ANUS

ACUTE PROCTITIS

Etiology

Acute colitis has many causes (e.g., bacteria, diet, parasites). The underlying cause is seldom diagnosed because this problem tends to be self-limiting. Acute proctitis probably has similar causes but may also be secondary to passage of a rough foreign object that traumatizes the rectal mucosa.

Clinical Features

Animals with acute colitis often feel good despite large bowel diarrhea (i.e., hematochezia, fecal mucus, tenesmus). Vomiting occurs infrequently. The major clinical signs of acute proctitis are constipation, tenesmus, hematochezia, dyschezia, and/or depression.

Diagnosis

Rectal examination is important; animals with acute colitis may have rectal discomfort and/or hematochezia. Eliminating obvious causes (e.g., diet, parasites) and resolving the problem with symptomatic therapy allow presumptive diagnosis. Rectal examination of animals with acute proctitis may reveal roughened, thick, and/or obviously ulcerated mucosa, or it may appear normal. Endoscopy/biopsy are definitive but seldom necessary unless the clinical signs are unduly severe or prolonged.

Treatment

Symptomatic therapy is typically sufficient because acute proctitis and colitis are usually idiopathic. Withholding food for 24 to 36 hours lessens severity of clinical signs. The animal should then be fed small amounts of an easily digested diet (e.g., cottage cheese and rice) with or without fiber. After resolution of clinical signs, the animal may be gradually returned to its original diet. Areas of anal excoriation should be cleansed, and an antibiotic-corticosteroid ointment should be applied. Most animals recover within 1 to 3 days. For proctitis, stool softeners are often helpful. Broad-spectrum antimicrobial therapy is not indicated.

Prognosis

The prognosis for idiopathic disease is good.

RECTAL PROLAPSE

Etiology

Rectal prolapse usually occurs secondary to enteritis or colitis in young animals. They begin to strain because of rectal irritation, and eventually some or all of the rectal mucosa prolapses. Mucosal exposure increases irritation and perpetuates straining, which promotes prolapse. Hence a positive feedback cycle is initiated. Manx cats appear to be predisposed to rectal prolapse.

Clinical Features

Dogs and cats (especially juveniles) are affected. The presence of colonic or rectal mucosa extending from the anus is obvious during the physical examination.

Diagnosis

The diagnosis is based on physical examination. Rectal examination is necessary to differentiate rectal prolapse from an intussusception protruding from the rectum (see p. 501).

Treatment

Treatment consists of resolving the original cause of straining if possible, repositioning the rectal mucosa, and preventing additional straining/prolapse. A well-lubricated finger is used to reposition the mucosa. If it readily prolapses after being replaced, a purse-string suture in the anus is used for 1 to 3 days to hold it in position. The subsequent rectal opening must be large enough so that the animal can defecate. Occasionally, an epidural anesthetic is required to prevent repeated prolapse. If the everted mucosa is so irritated that straining continues, retention enemas with kaolin or barium may provide relief. If a massive prolapse is present or the rectal mucosa is irreversibly damaged, resection may be necessary.

Prognosis

The prognosis is usually good, but some cases tend to recur.

PERINEAL HERNIA

Etiology

Perineal hernia occurs when the pelvic diaphragm (i.e., coccygeus and levator ani muscles) weakens and the rectal canal deviates laterally.

Clinical Features

This condition is principally found in older, small-breed, intact male dogs (especially Boston Terriers, Cardigan Welsh Corgis, Pekingeses, and Boxers); cats are rarely affected. Most animals have dyschezia, constipation, or perineal swelling, but urinary bladder herniation into this defect may cause a potentially fatal postrenal uremia with depression and vomiting.

Diagnosis

Digital rectal examination should be diagnostic (i.e., rectal deviation, lack of muscular support, rectal diverticulum). The clinician should check for retroflexion of the urinary bladder into the hernia. If such herniation is suspected, it can be confirmed by ultrasonography, radiographs, catheterizing the bladder, or aspirating the swelling (after imaging) to see if urine is present.

Treatment

Animals with postrenal uremia constitute an emergency; the bladder should be emptied and repositioned, and IV fluids should be administered. Preferred treatment is surgical reconstruction of the muscular support, but surgery may fail, and clients should be prepared for repeated reconstructive procedures.

Prognosis

The prognosis is fair to guarded.

PERIANAL FISTULAE

Etiology

Impacted anal crypts and/or anal sacs have been hypothesized to become infected and rupture into deep tissues. An immune-mediated mechanism is likely.

Clinical Features

Perianal fistulae occur in dogs and are more common in breeds with a sloping conformation and/or a broad base to the tail head (e.g., German Shepherds). There are typically one or more painful draining tracts around the anus, and constipation (caused by the pain), odor, rectal pain, and/or rectal discharge are typically present.

Diagnosis

Diagnosis is made by physical and rectal examination. Care should be taken when examining the patient, because the rectal area can be very painful. Draining tracts are sometimes absent, but granulomas and abscesses can be palpated via the rectum. Rectal pythiosis rarely mimics perianal fistulae.

Treatment

Most affected dogs are cured with immunosuppressive therapy (e.g., cyclosporine, 3-6 mg/kg PO q12h or topical 0.1% tacrolimus q24h to q12h) with or without antibacterial drugs (e.g., metronidazole, erythromycin). Administering oral ketoconazole (5 mg/kg PO q12h) may allow a lower dose of cyclosporine to be effective, thus decreasing the client's cost. If cyclosporine is used, therapeutic blood monitoring of cyclosporine levels may be needed if the patient is not responding or has signs consistent with toxicity (e.g., hyporexia). Hypoallergenic diets may also be beneficial. Rarely, animals not responding to medical therapy will require surgery. Surgery may cause fecal incontinence. Postoperative care is important and consists of keeping the area clean. Fecal softeners are sometimes useful.

Prognosis

Many patients are treated successfully, but the prognosis is guarded, and repeated medical care or surgeries may be required.

ANAL SACCULITIS

Etiology

In anal sacculitis the anal sac becomes infected, resulting in an abscess or cellulitis.

Clinical Features

Anal sacculitis is relatively common in dogs and occasionally occurs in cats. Small dogs (e.g., Poodles, Chihuahuas) probably have a higher incidence of this disorder than other breeds. Mild cases cause irritation (i.e., scooting, licking, or biting the area). Anal sacs occasionally bleed onto the feces. Severe cases may be associated with obvious pain, swelling, and/or draining tracts. Dyschezia or constipation may develop because the animal refuses to defecate. Fever may occur in dogs and cats with severe anal sacculitis.

Diagnosis

Physical and rectal examinations are usually diagnostic. The anal sacs are often painful, and sac contents may appear purulent, bloody, or normal but increased in volume. In severe cases it may be impossible to express the affected sac. If the sac ruptures, the fistulous tract is usually in a 4 o'clock or 7 o'clock position relative to the anus. Occasionally there is an obvious abscess.

Treatment

Mild cases require only that the anal sac be expressed and an antibiotic-corticosteroid preparation be infused. Infusion with saline solution may aid in expressing impacted sacs. If clients express the anal sacs at home, they can often prevent impaction and reduce the likelihood of severe complications.

Abscesses should be lanced, drained, flushed, and treated with a hot pack; systemic antibiotics should also be administered. Hot packs also help soft spots form in early abscesses. If the problem recurs, is severe, or is nonresponsive to medical therapy, affected sacs can be resected.

Prognosis

The prognosis is usually good.

PERIANAL NEOPLASMS

ANAL SAC (APOCRINE GLAND) ADENOCARCINOMA

Etiology

Anal sac adenocarcinomas are derived from the apocrine glands and are usually found in older female dogs.

Clinical Features

An anal sac or pararectal mass can often be palpated, but some are not obvious. Paraneoplastic hypercalcemia causing hyporexia, weight loss, vomiting, and polyuria-polydipsia is common. Occasionally, constipation due to hypercalcemia or perineal mass occurs. Metastasis to sublumbar lymph nodes occurs early, but metastases to other organs are rare.

Diagnosis

Cytologic and/or histopathologic evaluation is necessary to establish a diagnosis. Hypercalcemia in an older female dog should lead to careful examination of both anal sacs and pararectal structures. Abdominal ultrasonography may reveal sublumbar lymphadenopathy.

Treatment

Hypercalcemia, if present, must be treated (see Chapter 53). The tumor should be removed, but these tumors have often metastasized to regional lymph nodes by the time of diagnosis. Palliative chemotherapy (see Chapter 76) may be transiently beneficial in some dogs.

Prognosis

The prognosis is guarded.

PERIANAL GLAND TUMORS

Etiology

Perianal gland tumors arise from modified sebaceous glands. Perianal gland adenomas have testosterone receptors.

Clinical Features

Perianal gland adenomas are often sharply demarcated, raised, and red, and they may be pruritic. Commonly found around the anus and base of the tail, they may be solitary or multiple and can occur over the back half of the dog. Male hormones appear to stimulate their growth, and they are often found in older intact male dogs (especially Cocker Spaniels, Beagles, and German Shepherds). Pruritus may lead to licking and ulceration of the tumor. Perianal gland adenocarcinomas are rare; they are usually large, infiltrative, ulcerated masses with a high metastatic potential.

Diagnosis

Cytologic and/or histopathologic evaluation is required for diagnosis, but neither reliably distinguishes malignant from benign masses. Finding metastases (e.g., regional lymph nodes, lungs) is the most definitive method of determining malignancy.

Treatment

Surgical excision is preferred for benign or solitary tumors that have not metastasized. Neutering is recommended for dogs with adenomas. Radiation is recommended for multicentric and some malignant tumors. Chemotherapy is helpful in some dogs with adenocarcinomas (see Chapter 76).

Prognosis

The prognosis is good for benign lesions but guarded for malignant lesions.

CONSTIPATION

Constipation may be caused by any perineal or perianal disease already discussed that causes pain (e.g., perianal fistulae, perineal hernia, anal sacculitis) or obstruction as well as anything causing colonic weakness. It may also be caused by other disorders (see Box 26.15).

PELVIC CANAL OBSTRUCTION CAUSED BY MALALIGNED HEALING OF OLD PELVIC FRACTURES

Etiology

Prior trauma (e.g., automobile-associated injuries) is a common cause of pelvic canal obstruction in cats because they frequently sustain pelvic trauma that heals if they are allowed to rest. Cats appear clinically normal once the fractures heal, but diminution of the pelvic canal can produce megacolon and/or dystocia.

Diagnosis

Digital rectal examination should be diagnostic. Radiographs will further define the extent of the problem.

Treatment

Constipation caused by minimal pelvic narrowing may be controlled with stool softeners, but orthopedic surgery may be necessary. The prognosis depends in part on how severely the colon has been distended. Unless the colon is massively stretched out of shape, it can often resume function if it is kept empty and allowed to regain its normal diameter. Prokinetic drugs such as cisapride (0.25 mg/kg PO q8-12h) may stimulate peristalsis but must *not* be used if there is residual obstruction.

Prognosis

The prognosis depends on the severity and chronicity of colonic distention and surgical success in widening the pelvic canal.

BENIGN RECTAL STRICTURE

Etiology

The cause is uncertain but may be congenital.

Clinical Features

Constipation and tenesmus are the principal clinical signs.

Diagnosis

Digital rectal examination should detect the stricture, although it can be missed if a large dog is palpated carelessly or if the stricture is beyond reach. Proctoscopy and evaluation of a deep biopsy specimen (i.e., including submucosa) of the stricture are required to confirm that the lesion is benign and fibrous as opposed to neoplastic or fungal.

Treatment

Simple dilation via balloon or retractor will sometimes tear the stricture and allow normal defecation; other patients require surgery. Owners should be warned that strictures may re-form during healing, and surgery can cause incontinence in rare cases. Prednisolone (1.1 mg/kg/day PO) administered after dilatation might impede stricture reformation.

Prognosis

The prognosis is guarded to good.

DIETARY INDISCRETION LEADING TO CONSTIPATION

Etiology

Dogs often eat inappropriate foods or other materials (e.g., paper, popcorn, hair, bones). Excessive dietary fiber supplements can cause constipation if the animal becomes dehydrated.

Diagnosis

Dietary causes are common in dogs that eat trash. Dietary indiscretion is best diagnosed by examining fecal matter retrieved from the colon.

Treatment

Controlling the pet's eating habits, adding appropriate amounts of fiber to the diet, and feeding a moist diet (especially in cats) help prevent constipation. Repeated retention and cleansing (*not* hypertonic) enemas may be needed to remove retained feces. Manual disruption of hard feces should be avoided, but can be done. The animal should be anesthetized to help prevent colonic trauma during the procedure. Sponge forceps or curved hemostats can be used to mechanically break apart the feces. It often helps to insert a rigid colonoscope up to the fecal mass and then insert a tube with a vigorous stream of running water at body temperature issuing from the tip. This will soften the fecal mass and wash away debris that break off.

Prognosis

The prognosis is usually good. The colon should function normally after cleansing unless the distention has been prolonged and severe.

IDIOPATHIC MEGACOLON

Etiology

The cause is unknown but may involve behavior (i.e., refusal to defecate) or altered colonic neurotransmitters.

Clinical Features

Idiopathic megacolon is principally a feline disease, although dogs are occasionally afflicted. Affected patients may be depressed and hyporectic and are often presented because of infrequent defecation.

Diagnosis

Diagnosis is based upon palpating a massively dilated colon (not one just filled to normal capacity) plus elimination of dietary, behavioral, metabolic, and anatomic causes. Abdominal radiographs should be performed to look for potential causes (e.g., masses pressing on the colon).

Treatment

Impacted feces must be removed. Multiple warm water retention and cleansing enemas over 2 to 4 days usually work. Future fecal impaction is prevented by adding fiber to a moist diet (e.g., Metamucil, pumpkin pie filling) although some cats do better with a low-residue diet. Making sure clean litter is always available, using osmotic laxatives (e.g., lactulose) and/or prokinetic drugs (e.g., cisapride) are sometimes necessary. Lubricants are not as helpful because they do not change fecal consistency. If this conservative therapy fails or is refused by the client, subtotal colectomy helps some cats (dogs seldom tolerate this procedure well). Cats typically have soft stools for a few weeks postoperatively before regaining normal consistency, but some have soft stools for the rest of their lives.

Prognosis

The prognosis is fair to guarded. Many cats respond well to conservative therapy if treated early.

CHAPTER 32

Disorders of the Peritoneum

INFLAMMATORY DISEASES

SEPTIC PERITONITIS

Etiology

Septic peritonitis is usually *secondary peritonitis*, caused by leakage from the gastrointestinal (GI) or biliary tract or pyometras. In the dog, GI tract perforation or devitalization is usually caused by neoplasia, ulceration (especially nonsteroidal antiinflammatory drug or steroid induced), intussusception, foreign objects, or dehiscence of suture lines. In cats, GI perforation due to lymphosarcoma is an important cause. Biliary tract leakage is typically from a ruptured gallbladder secondary to necrotizing cholecystitis (i.e., mucocele or chronic bacterial infection). Septic peritonitis can also develop after surgery or hematogenous spread from elsewhere. Trauma (i.e., gunshot, car accident, bite wounds) is a more common cause in cats than in dogs. Barium sulfate can leak from a GI perforation after a radiographic contrast procedure and produces particularly severe peritonitis.

Occasionally dogs and cats develop primary (also called *spontaneous*) bacterial peritonitis (PBP) in which there is no identifiable source of the infection. Oral bacteria are suspected to be the source in cats with PBP, but translocation from the intestines might be responsible. Gram-positive organisms tend to be more common in PBP.

Clinical Features

Septic peritonitis secondary to intestinal suture line dehiscence classically manifests 3 to 6 days postoperatively. Dogs with two or more of the following have been reported to be at increased risk for dehiscence of intestinal suture lines: serum albumin < 2.5 g/dL, intestinal foreign body, and preoperative peritonitis. Dogs with secondary septic peritonitis due to leakage from the GI tract, biliary tract, or a pyometra are usually severely depressed, febrile (or hypothermic), nauseated, and may have abdominal pain (if they are not too depressed to respond). Abdominal effusion is usually mild to modest in amount. Signs usually progress rapidly until systemic inflammatory response syndrome (SIRS; formerly known as *septic shock*) occurs. However, some animals with septic peritonitis may have mild vomiting, slight fever, and copious volumes of abdominal fluid and feel relatively well for days or longer. Cats with SIRS due to septic peritonitis tend to present differently than dogs; sometimes they only show bradycardia, hypothermia, and hypotension.

Dogs with PBP tend to have larger abdominal fluid accumulations than dogs with secondary septic peritonitis. Clinical signs in dogs (especially those with PBP associated with severe hepatic disease) can sometimes be much less severe than is usually seen in secondary peritonitis. Cats with PBP do not necessarily present differently than those with sepsis due to GI tract leakage.

Diagnosis

Most animals with septic peritonitis due to GI or biliary tract perforation have small amounts of abdominal fluid that are difficult to detect by physical examination but which decrease serosal detail on plain abdominal radiographs. Ultrasonography is more sensitive than radiography for detecting small amounts of abdominal fluid. Free peritoneal gas not related to recent abdominal surgery strongly suggests GI tract leakage (Fig. 32.1) or peritoneal infection with gas-forming bacteria. Ultrasonography may detect masses (e.g., tumors), biliary mucocele, cholecystitis, or pyometra. Neutrophilia is common but nonspecific in dogs and cats with septic peritonitis. Neutropenia and/or hypoglycemia may occur with severe septicemia.

Abdominocentesis is indicated if free abdominal fluid is detected. Ultrasound guidance should allow clinicians to sample effusions even when only modest amounts are present. Retrieved fluid is examined cytologically and cultured. Abdominal fluid is expected to be an exudate (i.e., high protein, large numbers of nucleated cells with toxic or degenerating neutrophils predominating); however, this finding does not diagnose septic peritonitis. Bacteria (especially if phagocytized by white blood cells) or fecal contents in abdominal fluid are necessary to definitively diagnose septic peritonitis (Fig. 32.2). Unfortunately, fecal contents and bacteria are sometimes difficult to find. Prior antibiotic use in particular may suppress bacterial numbers and the percentage of neutrophils demonstrating degenerative

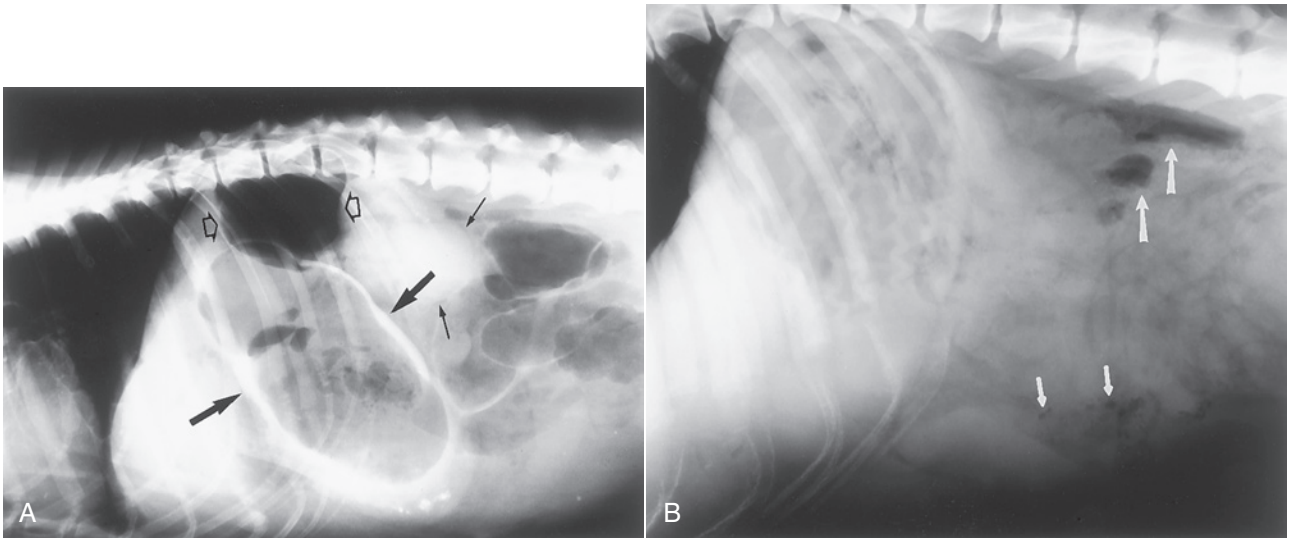

FIG 32.1
(A) Plain lateral abdominal radiograph of a dog. Visceral margins of kidney *(small solid arrows)* and stomach *(large solid arrows)* are outlined by negative contrast (i.e., air). In addition, there are pockets of free air in the abdomen *(open arrows)*. This dog had a gastric ulcer that spontaneously perforated. **(B)** Plain lateral radiograph of a dog with a splenic abscess. There are air bubbles in the region of the spleen *(short arrows)* and free gas in the dorsal peritoneal cavity *(long arrows)*.

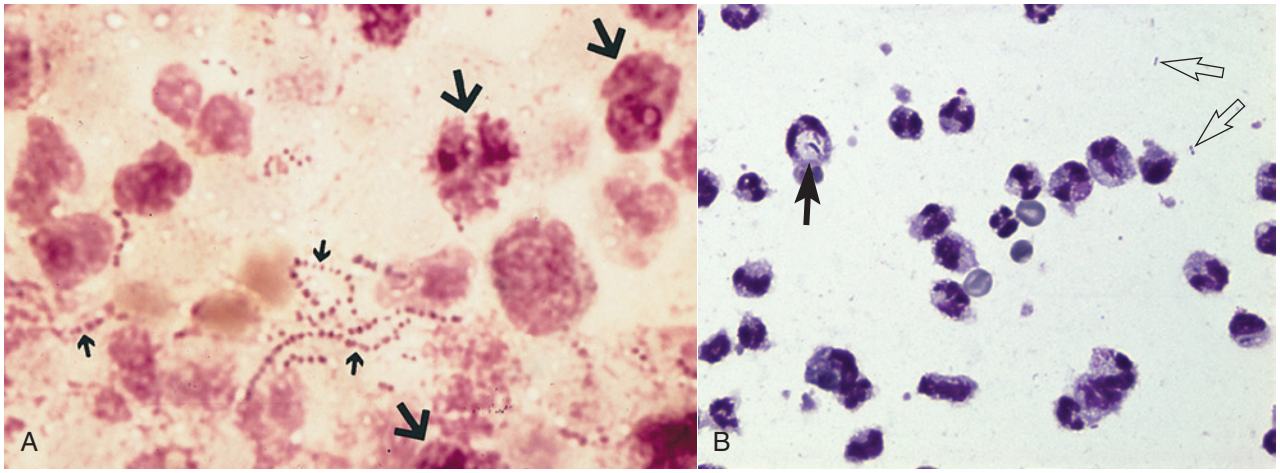

FIG 32.2
(A) Photomicrograph of peritoneal exudate from a dog with septic peritonitis. Note bacteria *(small arrows)* and neutrophils that have degenerated so much that it is difficult to identify them as neutrophils *(large arrows)* (Wright's stain; ×1000). **(B)** Photomicrograph of septic peritoneal fluid. There is one intracellular bacterium *(large arrow)* and two things *(clear arrows)* that may or may not be bacteria. The neutrophils are not nearly as degenerated as in **A.** (**A** courtesy Dr. Claudia Barton, Texas A&M University.)

changes. Furthermore, mildly degenerative neutrophils are common in effusions after recent abdominal surgery.

If bacteria or plant material cannot be found in the abdominal effusion, it can be difficult to quickly distinguish septic peritonitis from sterile abdominal diseases that mimic septic peritonitis (e.g., severe acute pancreatitis). Both can cause SIRS, and ultrasound is not as sensitive in detecting pancreatitis as desired. Degenerative neutrophils in the abdominal fluid are suggestive of septic peritonitis, but severe sterile pancreatitis can produce degenerative changes identical to those seen with infection. Comparing lactate levels in blood and effusion is not always accurate in distinguishing septic from nonseptic effusions. Finding a plasma (not whole blood) glucose concentration that is > 38 mg/dL more than the peritoneal fluid or the peritoneal fluid supernatant glucose concentration strongly suggests septic

peritonitis, but the test is not perfect.[1] In patients in which septic peritonitis is strongly suspected but unproven, the clinician may need to proceed with exploratory laparotomy before abdominal fluid culture results are available.

Canine pancreatic lipase immunoreactivity (cPLI) is very sensitive for acute pancreatitis, but specificity for clinically important pancreatic disease is uncertain. High values have been found in patients that do not clearly have pancreatitis as an important clinical problem, and dogs with septic peritonitis may have inflammation of the pancreas secondary to generalized abdominal sepsis. The clients need to understand that in some cases there is no quick, simple, reliable way to distinguish septic from nonseptic peritonitis before surgery.

A potentially important distinction is PBP versus secondary septic peritonitis. Dogs with PBP may be more difficult to diagnose based upon abdominal fluid analysis because they may have exudates, modified transudates, or pure transudates. They can have relatively few bacteria in the effusion, and concentration techniques (e.g., cytospin) may be required to demonstrate bacteria in the effusion. Some dogs with PBP are clinically less ill than expected for patients with secondary peritonitis.

Treatment

Animals with septic peritonitis usually have leakage from the alimentary tract or biliary tract, or a pyometra; they should be surgically explored as soon as they are acceptable anesthetic risks. In contrast, dogs with PBP do not usually benefit from surgery. If there is a good reason to strongly suspect PBP (e.g., low-grade peritonitis with gram-positive cocci in a modestly ill dog with hepatic cirrhosis and no evidence or reason to suspect GI or biliary perforation), conservative medical management plus close observation might be a reasonable initial plan.

If secondary peritonitis (which is much more common than PBP) is suspected, then surgery is almost always indicated. Preanesthetic complete blood count (CBC), serum biochemistry profile, and urinalysis are desirable, but surgery usually should not be inappropriately delayed while waiting for laboratory results. During surgery a careful search should be made for GI tract defects. Tissue surrounding a perforation should be submitted for histopathology to search for underlying disease (especially neoplasia). Serosal patch grafting has not been shown to be advantageous when closing such defects. After the defect is corrected, the abdomen should be repeatedly lavaged with large volumes of warm crystalloid solutions to dilute and remove debris and bacteria. The abdomen cannot be adequately lavaged via a drain tube or even a peritoneal dialysis catheter except in the mildest cases. Adhesions re-form quickly; they should not be broken down unless necessary to examine the intestines. If barium sulfate is present, as much as possible should be mechanically removed, even if it requires omentectomy. Intestines should be resected only if they are truly devitalized; excessive resection may produce short bowel syndrome (see p. 502).

Many consider substantial abdominal contamination an indication for postoperative abdominal drainage. Closed suction drains have been used postoperatively with success and are much preferred to Penrose drains. Open abdominal drainage is very time and labor intensive and seldom necessary. At this time, there is no good evidence that abdominal drainage significantly impacts outcome.

Systemic antimicrobial therapy should initially consist of broad-spectrum parenteral antibiotics. For very ill patients (e.g., SIRS), a combination of a β-lactam drug (e.g., ampicillin plus sulbactam), metronidazole, and an aminoglycoside (e.g., amikacin) or a fluoronated quinolone is usually an excellent choice (see the discussion of antibacterial drugs used in GI disorders, pp. 442-443). Remember that when enrofloxacin is given parenterally, it must be administered over 30 to 40 minutes in a diluted form. Aminoglycosides and quinolones are dose-dependent drugs; administration of the entire daily dose in one injection is safer and as or more effective than administering smaller doses two to three times daily. For patients less severely ill, the clinician may elect to use less-aggressive antibiotic therapy (e.g., Cefoxitin [30 mg/kg IV q6-8h]). Dogs with PBP can often be treated with oral antibiotics (e.g., Clavamox or enrofloxacin).

Fluid and electrolyte support helps prevent aminoglycoside-induced nephrotoxicity. Hypoalbuminemia is common. Administration of colloids (e.g., hetastarch, pentastarch) can increase plasma oncotic pressure and improve peripheral perfusion, but close observation is indicated because sometimes the colloid leaks into the extravascular space, worsening perfusion. The clinician may administer human or canine albumin to improve plasma oncotic pressure, but human albumin sometimes causes anaphylactoid reactions in dogs. Fresh-frozen plasma (with or without heparin) seems indicated if disseminated intravascular coagulation (DIC) is present, but (1) this is a very inefficient way to increase serum albumin concentrations, and (2) one should monitor AT III concentrations and coagulation times. Early nutritional support seems to shorten hospitalization time.[2]

Prognosis

The prognosis depends on the cause. Prognosis in patients with GI leakage depends on the cause of the leakage (e.g., perforations may be caused by malignancies) and the animal's condition when it is diagnosed. Hypotension, long surgery time, glucocorticoid administration, and postoperative hypoalbuminemia worsen the prognosis after small intestinal surgery. Glucocorticoid administration after colonic surgery is a major risk factor for death. High blood lactate levels on admission and failure to lower blood lactate levels within 6 hours of admission are bad prognostic signs.[3]

Patients with leakage of infected bile into the abdomen can decompensate and die very quickly and precipitously. Dogs with SBP usually have a relatively good prognosis.

HEMOABDOMEN

Most red effusions are blood-tinged transudates, not hemoabdomen. Hemoabdomen is usually indicated by an abdominal fluid with a hematocrit of > 10% to 15%. Blood in the abdominal cavity can be iatrogenic (i.e., caused by abdominocentesis), traumatic (e.g., automobile-associated trauma, splenic torsion, splenic hematoma), due to coagulopathy (e.g., ingestion of vitamin K antagonist), or caused by malignancy (e.g., hemangiosarcoma). Clots or platelets in the fluid sample mean the bleeding is iatrogenic or currently occurring near the site of abdominocentesis. History, physical examination, coagulation studies, and/or abdominal ultrasonography usually establish the diagnosis. Spontaneous hemoabdomen in older dogs is often caused by a bleeding hemangiosarcoma or hepatocellular carcinoma, and these tumors are typically easy to find ultrasonographically. Thrombocytopenia can be confusing; it may be the cause of abdominal bleeding or may be caused by vigorous abdominal bleeding. Even when a coagulopathy is secondary to the original cause of the hemoabdomen (e.g., tumor), it may become severe enough to promote bleeding by itself. In cats, the causes of hemoabdomen are more evenly divided between neoplastic (i.e., hemangiosarcoma and hepatocellular carcinoma) and nonneoplastic (e.g., coagulopathy, hepatic disease, ruptured urinary bladder) diseases. The prognosis depends upon the cause.

ABDOMINAL HEMANGIOSARCOMA

Etiology

Abdominal hemangiosarcoma often originates in the spleen or liver (see Chapter 81). It can spread throughout the abdomen by implantation, causing widespread peritoneal seepage of blood, or it can metastasize to distant sites (e.g., liver, lungs, heart).

Clinical Features

Abdominal hemangiosarcoma is principally found in older dogs, especially German Shepherd Dogs, Labrador Retrievers, and Golden Retrievers. Anemia, abdominal effusion, and periodic weakness or collapse from poor peripheral perfusion are common presenting complaints. Some animals have bicavity hemorrhagic effusion.

Diagnosis

Ultrasonography is the most sensitive test for splenic and hepatic masses, especially when there is copious abdominal effusion. Radiographs may reveal a mass if there is minimal free peritoneal fluid. Splenic hematoma, hemangioma, and widespread accessory splenic tissue masquerade as hemangiosarcoma but have a much better prognosis; therefore a definitive diagnosis is important. Definitive diagnosis requires cytology or histopathology because fluid analysis rarely reveals neoplastic cells. Fine-needle biopsy (especially fine-needle core biopsy) is sometimes diagnostic, but there is a risk of life-threatening hemorrhage; the patient must be watched closely for hypovolemia after the procedure. Two or more large tissue samples from the resected mass should be submitted, and the clinician should be prepared to request recuts; hemangiosarcoma may be difficult to find histologically because there is often hematoma surrounding the tumor.

Treatment

Solitary masses should be excised. Chemotherapy may be palliative for some animals with multiple masses; chemotherapy may also be used as an adjuvant postoperative treatment modality (see Chapter 81).

Prognosis

The prognosis is poor because the tumor metastasizes early.

MISCELLANEOUS PERITONEAL DISORDERS

ABDOMINAL CARCINOMATOSIS

Etiology

Abdominal carcinomatosis involves widespread miliary peritoneal carcinomas that can originate from various sites. Intestinal and pancreatic adenocarcinomas are common causes of carcinomatosis.

Clinical Features

Weight loss may be the predominant complaint, although some animals are presented because of obvious abdominal effusion.

Diagnosis

Physical examination and radiography are inadequate for diagnosis. Ultrasonography may reveal larger masses or infiltrates, but small miliary lesions are typically missed by ultrasound. Fluid analysis reveals a nonseptic exudate or a modified transudate; epithelial neoplastic cells are occasionally found (see Chapter 34) but must be differentiated from reactive mesothelial cells. Laparoscopy or abdominal exploratory surgery with histologic examination of tissue specimens is usually needed for diagnosis.

Treatment

Intracavitary chemotherapy has been palliative for some animals, although generally there is no effective treatment for this disorder. An oncologist should be consulted.

Prognosis

The prognosis is grim.

MESOTHELIOMA

Etiology

The cause of mesothelioma in dogs and cats is unknown.

Clinical Features

Mesothelioma often causes bicavity effusion. The tumor may appear as fragile clots adhering to the peritoneal surface of various organs.

Diagnosis

Imaging reveals only fluid accumulations. Fluid cytology rarely is diagnostic because reactive mesothelial cells are notorious for mimicking malignancy. Laparoscopy or laparotomy is typically required for a definitive diagnosis.

Treatment

Intracavity chemotherapy may be attempted. An oncologist should be consulted.

Prognosis

The prognosis is grim, but chemotherapy sometimes prolongs survival.

FELINE INFECTIOUS PERITONITIS

Feline infectious peritonitis (FIP) is a viral disease of cats and is discussed in detail in Chapter 96. Only the abdominal effusion of FIP is discussed here. Although a major cause of feline abdominal effusion, FIP is not generally a common disease (unless one is involved with catteries), and it is not the only cause of feline abdominal effusions. Furthermore, not all cats with FIP have effusions. FIP effusions are classically pyogranulomatous (i.e., macrophages and nondegenerate neutrophils) with a relatively low nucleated cell count (i.e., ≤10,000/μL). However, some cats with FIP have effusions that primarily contain neutrophils. A nonseptic exudate in a nonazotemic cat suggests FIP until proven otherwise.

PART FOUR ▪ Hepatobiliary and Exocrine Pancreatic Disorders

Penny J. Watson

CHAPTER 33

Clinical Manifestations of Hepatobiliary and Pancreatic Disease

GENERAL CONSIDERATIONS

Clinical signs of hepatobiliary and pancreatic diseases in dogs and cats are very variable with considerable overlap in signs. Dogs or cats with disease of either the liver or pancreas can present with nonspecific signs such as anorexia, lethargy, and vomiting, or more specific signs such as jaundice (which can be hepatic in origin in liver disease or posthepatic in pancreatic disease due to extrahepatic biliary obstruction) or cranial abdominal pain, which is more common in pancreatitis and biliary tract disease than in hepatic parenchymal disease. Clinical signs of pancreatitis in dogs and cats show a spectrum from mild abdominal pain and anorexia to "acute abdomen" and potential multiorgan failure and diffuse intravascular coagulation (DIC). Clinical presentation is even more challenging in cats because pancreatic and liver disease often occur concurrently in this species, but cats also tend to hide their pain. Clinical signs of hepatobiliary and pancreatic disease are listed in Box 33.1. It is important to remember that none of these signs are pathognomonic of hepatobiliary or pancreatic disease, and they must be distinguished from identical signs caused by disease of other organ systems. Cause of death in severe, acute pancreatitis and acute hepatitis is usually multiorgan failure and DIC. In lower-grade chronic liver disease, death may eventually occur as a result of loss of function, whereas prolonged survival is possible with chronic pancreatitis in spite of functional loss, provided this is recognized and treated with enzyme supplementation and/or insulin. Dogs and cats with acute pancreatitis, more severe clinical signs, and compromise of more organ systems at presentation are more likely to die. In chronic liver disease, the severity of clinical signs does not necessarily correlate with the prognosis or with degree of liver injury, although several of these signs are often seen together, particularly in dogs with end-stage hepatic disease (e.g., ascites, metabolic encephalopathy from hepatocellular dysfunction, acquired portosystemic venous shunting with gastrointestinal [GI] bleeding). Both ascites and jaundice have been shown to be significant negative prognostic indicators in dogs with chronic hepatitis. The presence of cirrhosis is also a negative prognostic indicator in dogs, and these cases are more likely to present with ascites, acquired portosystemic shunts (PSS), and hepatic encephalopathy (HE). It is important to appreciate that any prognostic data is on a population basis, and that individual dogs with chronic hepatitis and ascites can have a good prognosis. At the opposite end of the spectrum of hepatobiliary and pancreatic disease, because of the tremendous reserve capacity of both the liver and the pancreas, there may be no clues for the presence of a hepatic disorder or low-grade chronic pancreatitis except for abnormal screening blood test results obtained before an elective anesthetic procedure. However, it is important to investigate persistent elevation of liver enzymes even if there are no clinical signs, because treatment is likely to be much more effective if instituted early.

GASTROINTESTINAL SIGNS

Vomiting, diarrhea, and anorexia are common clinical signs associated with both pancreas and liver disease. Vomiting in dogs and cats with liver disease can be as a result of local inflammation, portal hypertension, or HE. Animals with portal hypertension may have hematemesis and melena as a result of upper GI ulceration.

Vomiting is a prominent sign in acute and chronic pancreatitis in dogs and cats, and is due to focal or more generalized peritonitis, and also delayed gastric emptying and duodenal hypomotility due to the proximity of pancreatic inflammation. Dogs with severe acute pancreatitis usually present with acute onset of vomiting, anorexia, marked abdominal pain, and varying degrees of dehydration, collapse, and shock. Differential diagnoses in these cases include other causes of acute abdomen. Signs in cats overlap the signs of cholangitis and inflammatory bowel disease (IBD), which often occur concurrently in cats, with anorexia and

BOX 33.1

Clinical Signs and Physical Examination Findings in Cats and Dogs With Hepatobiliary and Pancreatic Disease*

General, Nonspecific, Both Hepatobiliary and Pancreatic Disease

Anorexia
Depression
Lethargy
Weight loss
Poor or unkempt haircoat
Nausea, vomiting
Diarrhea
Dehydration
Polydipsia, polyuria

More Specific but Not Pathognomonic
Hepatobiliary disease

Abdominal enlargement (organomegaly, effusion, or muscular hypotonia)
Jaundice, bilirubinuria, acholic feces
Metabolic encephalopathy
Coagulopathies

Pancreatic disease

Severe intractable vomiting
Cranial abdominal pain
Steathorrea

*Individual animals will show some but not all of these signs, and many animals with hepatobiliary disease will show no clinical signs at all.

lethargy being most common. Vomiting and abdominal pain occur in fewer than half reported cases of pancreatitis in cats.

Dogs and cats with milder acute or chronic pancreatitis present with mild GI signs—typically anorexia and sometimes some mild vomiting, followed by the passage of some colitis-like feces (e.g., tenesmus, hematochezia, frequent bowel movements), accompanied by some fresh blood resulting from local peritonitis in the area of the transverse colon.

ABDOMINAL PAIN

Abdominal pain is a prominent clinical sign of acute and chronic pancreatitis in dogs. It undoubtedly also occurs in cats with acute pancreatitis but is much more challenging to recognize in this species because of their propensity to hide their pain in the consulting room, even in the face of severe peritonitis. Subtle signs of pain in cats should be taken seriously, as should reports by the owner that their cat is in pain. Some forms of liver disease also cause abdominal pain; the liver parenchyma is poorly supplied with pain fibers, but the liver capsule and biliary tract are well innervated. Biliary tract disease is particularly painful in dogs and cats; gallstones in cats, gallbladder mucoceles in dogs, and extrahepatic biliary obstruction in both species are particularly painful. Dogs and cats with hepatomegaly of any cause often show pain on cranial abdominal palpation, presumably due to stretching of the liver capsule.

POLYURIA AND POLYDIPSIA

Increased thirst and volume of urination can be clinical signs of serious hepatocellular dysfunction and also of PSS both congenital and acquired. The underlying mechanisms are poorly understood, but several factors are suspected to contribute to polydipsia (PD) and polyuria (PU), which are seen primarily in dogs and rarely in cats. Altered sense of thirst may be a manifestation of HE. Early studies suggested that dogs with congenital and acquired PSS have hypercortisolemia associated with a reduced metabolism of cortisol in the liver and decreased cortisol-binding protein concentration in the plasma. However, more recent studies have failed to support this. Changes in the function of portal vein osmoreceptors that stimulate renal water loss early after drinking, before a change in systemic osmolality, may also be partly responsible for PU in patients with liver disease, although studies have been published only for rodents and humans. Loss of the renal medullary-concentrating gradient for urea because of the inability to produce urea from ammonia may also be involved and would first cause PU and then compensatory PD.

PD/PU is an unusual finding in pancreatitis but is sometimes reported in chronic pancreatitis in dogs, perhaps in response to nausea or abdominal pain. It is important to rule out diabetes mellitus (DM) in any dog or cat with chronic pancreatitis that shows PD/PU, because DM can develop due to endocrine tissue destruction in end-stage chronic pancreatitis.

ABDOMINAL EFFUSION

Abdominal effusion occurs in both liver and pancreas disease in both dogs and cats. It is much more common in dogs than in cats with liver disease. With the exception of liver disease associated with feline infectious peritonitis (FIP) or congenital ductal plate abnormalities, cats with liver disease rarely have ascites, whereas ascites are seen in about a third of dogs with chronic hepatitis. A small amount of effusion is suspected when abdominal palpation yields a slippery sensation during physical examination. Moderate- to large-volume effusion is frequently conspicuous but may distend the abdomen so much that details of abdominal organs are obscured during palpation. With acute pancreatitis in either species, abdominal effusion is common although it is usually a much smaller volume than the ascites of liver disease and may only be visible on ultrasound.

PATHOGENESIS OF TRANSUDATES

Whether there is small- or large-volume effusion, the general pathogeneses of third-space fluid accumulation (excessive formation by increased venous hydrostatic pressure,

decreased intravascular oncotic pressure, or altered vascular permeability and insufficient resorption), singly or in combination, apply to cats and dogs with hepatobiliary diseases. In parenchymal liver disease, the commonest cause of ascites formation is portal hypertension, which is a sustained increase in pressure in the portal system, with or without a contribution from reduced serum albumin concentration (Fig. 33.1). The fluid is typically a relatively high protein-modified transudate. A low protein transudate is occasionally seen in animals with liver disease and concurrent hypoalbuminemia. It is very rare to have an albumin concentration low enough to cause ascites alone. Portal hypertension is common in dogs with end-stage liver disease but rare in cats. It is also recognized in some cases of acute liver disease. Typically, it results in the triad of ascites, HE, and GI congestion, and propensity to ulceration. It is caused by the increased resistance to blood flow through the sinusoids of the liver or, less commonly, by more direct obstructions to the portal vein or caudal vena cava, such as those caused by thromboemboli. The presence of a large arteriovenous fistula in the liver can also result in portal hypertension. Early in chronic liver disease, portal hypertension can be the result of multiplication and phenotypic transformation of hepatic Ito (stellate) cells, which become contractile myofibroblasts that surround the sinusoids and cause constriction. In the longer term, fibrous tissue laid down by these transformed

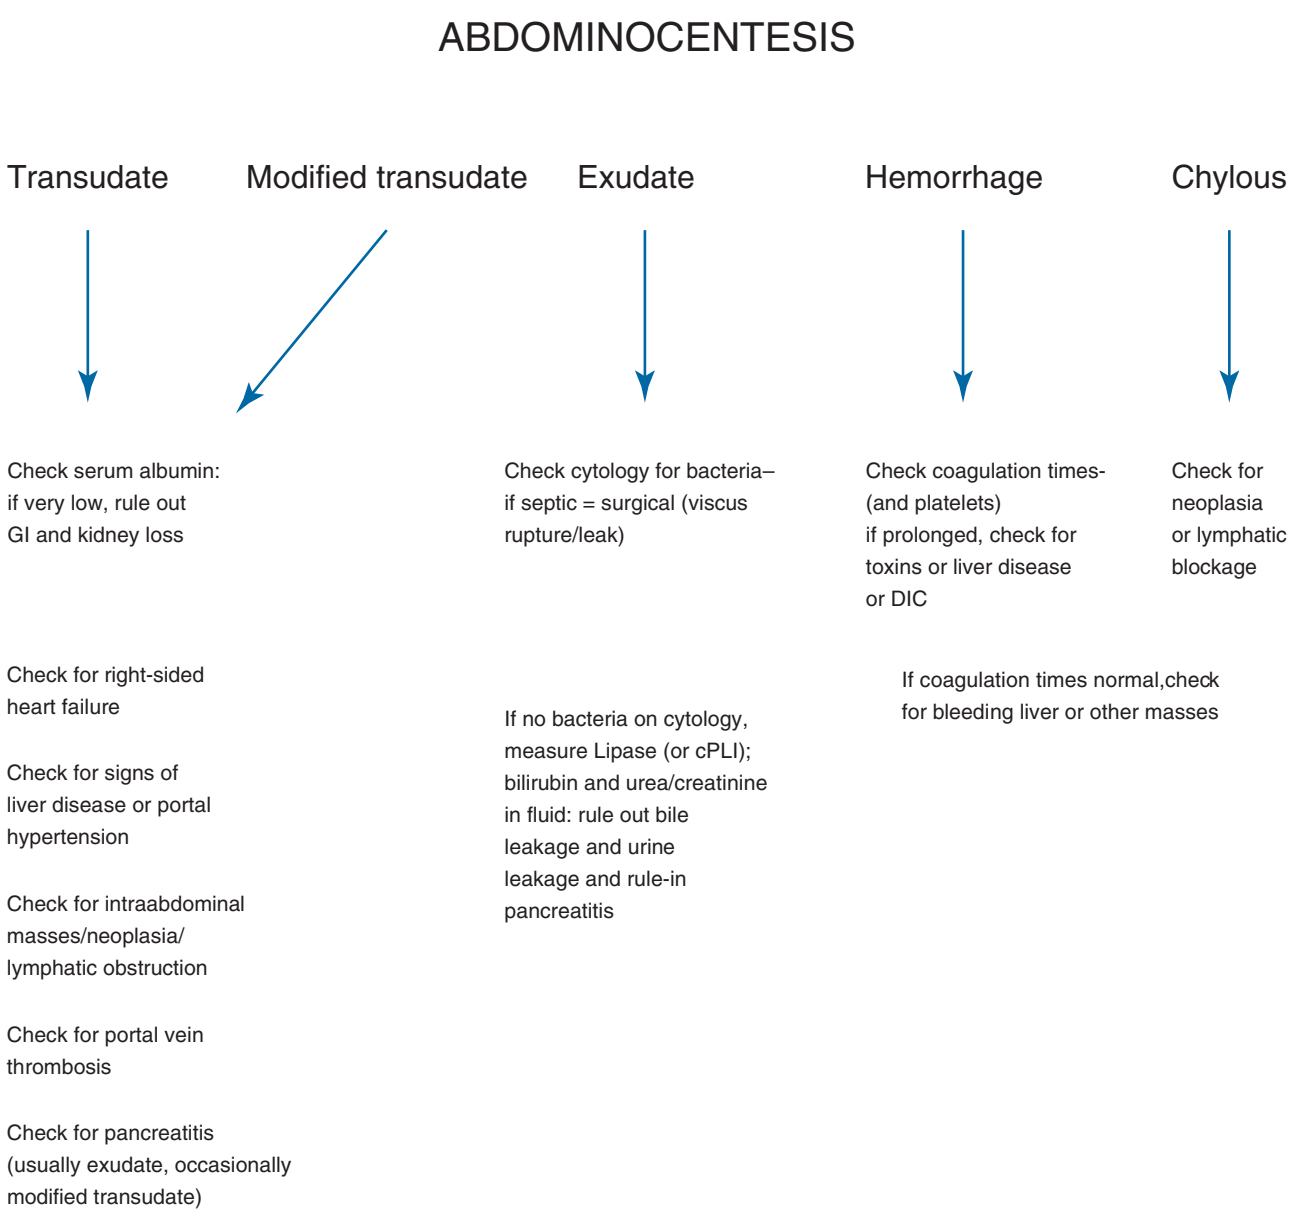

FIG 33.1
Algorithm for initial evaluation of a dog with abdominal effusion and suspected liver or pancreas disease.

stellate cells results in more irreversible sinusoidal obstruction. Thus the most common cause of portal hypertension is chronic hepatitis progressing to cirrhosis in dogs (Fig. 33.2). It can also occur in association with hepatic neoplasia or in acute liver disease as a result of diffuse hepatic swelling. In one study of acute liver disease, 41% of dogs had ascites.

The pathogenesis of the development of ascites in portal hypertension is complex and has really been studied only in humans; it is assumed that the mechanisms of ascites are similar in dogs. One way in which dogs differ from humans is that dogs do not develop the "spontaneous" infection of ascites of liver origin by extension of gut bacteria into the fluid that results in peritonitis, which is commonly reported in people. The presence of ascites is a poor prognostic indicator in humans with chronic hepatitis, and the same appears to be true in dogs. Sodium retention by the kidneys is an important mechanism in the development of ascites in liver disease. As demonstrated in Fig. 33.2, portal hypertension results in congestion of splanchnic vessels with pooling of blood in the splanchnic circulation. This results in a drop in systemic circulating blood volume and thus blood pressure that leads to increased renal sodium retention, partly as a result of reduced glomerular filtration rate and decreased sodium delivery to the tubules and partly as a result of increased release of renin-angiotensin-aldosterone (RAAS) that results in increased sodium retention in the distal tubules. This leads to an increase in circulating fluid volume, which precipitates the formation of ascites, which in turn reduces venous return because of increased pressure on the caudal vena cava and initiates a vicious cycle of renal sodium retention and ascites. This is the "over-fill" theory of ascites formation in liver disease. Therefore aldosterone antagonists (e.g., spironolactone) are usually most effective in dogs with ascites secondary to portal hypertension, whereas loop diuretics, such as furosemide used alone, can be ineffective or even, in some cases, actually increase the volume of effusion by causing a further decrease in systemic blood pressure as a result of hemoconcentration and secondary increases in RAAS activation.

Ascites will also occur as a result of venous congestion from disease of the major hepatic veins and/or distally (i.e., thoracic caudal vena cava, heart; posthepatic venous congestion). This is not as a result of portal hypertension, but rather this increases the formation of hepatic lymph, which exudes from superficial hepatic lymphatics. Because the endothelial cell-lined sinusoids are highly permeable, hepatic lymph is of high protein content.

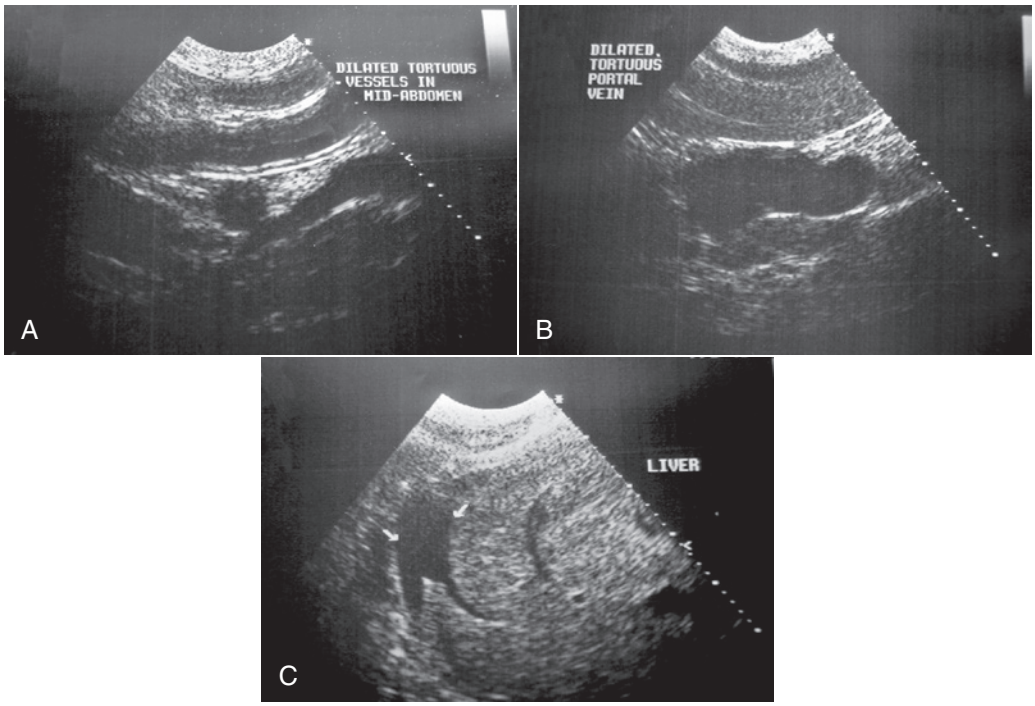

FIG 33.2
Ultrasonographic images demonstrating the progressive development of ascites with portal hypertension in a dog with cirrhosis. **(A)** Ultrasonography on the first visit showed no evidence of free abdominal fluid but revealed dilated vessels in the midabdomen (including splenic congestion) and also a dilated portal vein **(B). (C)** When the dog returned for a liver biopsy 2 weeks later, ultrasonography now revealed the development of mild early ascites. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

PATHOGENESIS OF EXUDATES

In pancreatitis, the cause of abdominal fluid accumulation is usually increased vascular permeability due to peritonitis, which in most cases results in serosanguinous sterile exudates with high protein and cell contents, although modified transudates and chylous effusions are occasionally reported. Pancreatitis can also occasionally result in a more generalized vasculitis and bicavitary effusions. Demonstrating a sterile exudate on cytology should trigger investigations to differentiate bile peritonitis, pancreatitis, or urinary tract leakage as the causes, as detailed in Fig. 33.1. Urea, creatinine, bilirubin, lipase, or cPLI concentrations can be measured in the fluid and be very helpful diagnostically. Extravasation of bile from a ruptured biliary tract elicits a strong inflammatory response and stimulates the transudation of lymph by serosal surfaces. In experimental animal models, the damaging component of bile has been identified as bile acids. Unlike with most other causes of abdominal effusion associated with hepatobiliary disease, there may be evidence of cranial abdominal or diffuse abdominal pain identified during physical examination in cats and dogs with bile peritonitis. The fluid appears characteristically dark orange, yellow, or green and has a high bilirubin content on analysis, which is higher than the serum bilirubin concentration, and the predominant cell type is the healthy neutrophil, except when the biliary tract is infected. Because normal bile is sterile, the initial phase of bile peritonitis is nonseptic, but unless treatment is initiated rapidly, secondary infection, usually with anaerobes of gut origin, may become life-threatening.

Perivenular pyogranulomatous infiltrates in the visceral and parietal peritoneum of cats with the effusive form of FIP increase vascular permeability and promote the exudation of straw-colored, protein-rich fluid into the peritoneal space. Typically, the fluid is of low to moderate cellularity, with a mixed cell population of neutrophils and macrophages, and with a moderate to high protein concentration. It is usually classified as an exudate but occasionally is a modified transudate.

Hepatobiliary or pancreatic malignancies or other intra-abdominal carcinomas that have disseminated to the peritoneum can elicit an inflammatory reaction, with subsequent exudation of lymph and fibrin. The fluid may be serosanguineous, hemorrhagic, or chylous in appearance. Regardless of the gross appearance of the fluid, the protein content is variable, and the fluid may contain exfoliated malignant cells if the primary neoplasm is a carcinoma, mesothelioma, or lymphoma, although often it does not, in which case further investigation is required to diagnose the neoplasm.

HEPATIC ENCEPHALOPATHY

PATHOGENESIS

HE describes neurologic dysfunction in patients with liver disease as a result of exposure of the cerebral cortex to toxins. It is most commonly reported in dogs and cats with congenital portosystemic shunts (CPSS) but is also recognized in dogs with cirrhosis and acquired PSS secondary to portal hypertension, in dogs and cats with acute liver failure, and in cats with hepatic lipidosis (which is in effect a reversible acute liver failure). In a study of dogs with acute liver failure, 57% showed signs of HE, and reports of chronic hepatitis in dogs suggest HE in about 7% of cases.

The most important toxin implicated is ammonia (NH_3), which crosses the blood-brain barrier. The brain is very sensitive to the toxic effects of NH_3 but does not possess a urea cycle, so the NH_3 is detoxified by conversion to glutamine by astrocytes. Excessive NH_3 and thus glutamine buildup results in osmotic stress of astrocytes with cell swelling and cerebral edema. Recent studies in dogs with congenital PSS have confirmed increases in arterial, venous, and CSF NH_3 when compared with normal dogs. Sophisticated imaging techniques (single photon emission tomography) have also demonstrated reduced perfusion in the temporal lobes and increased perfusion in the subcortical regions of dogs with congenital PSS and HE, which are similar to the findings in humans with acquired PSS and HE. Other toxins implicated in HE historically such as mercaptans and aromatic amino acids have little evidence in humans or animals, although both manganese and neurosteroids have been implicated in both species recently. Serum manganese concentrations are high in dogs with congenital PSS, although the clinical relevance of this finding is unclear because ligation of congenital PSS in dogs resolves HE while hypermagnesemia persists.

Buildup of NH_3 in the systemic circulation occurs as a result of diversion of portal flow from the liver by the development of PSS or as a result of a marked reduction in functional hepatic mass. In most cases of acquired portosystemic shunting, there is a combination of vascular and functional mechanisms leading to HE (Fig. 33.3). Rarely, if congenital

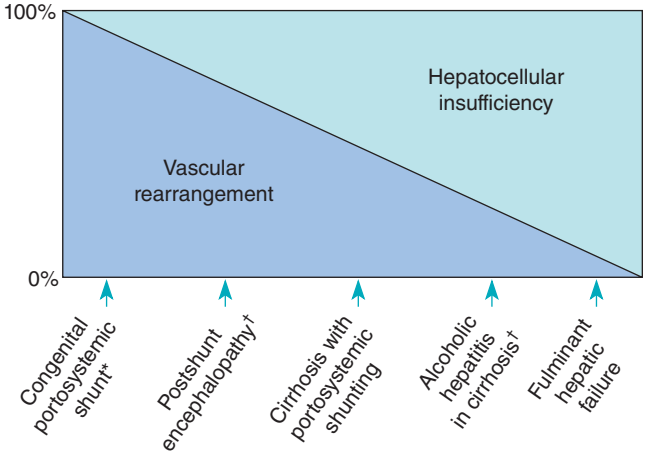

FIG 33.3
Spectrum of hepatic encephalopathy in cats and dogs ranging from pure vascular to pure hepatocellular causes. *, Clinically relevant only in dogs and cats; †, clinically relevant only in human patients. (Modified from Schafer DF et al: Hepatic encephalopathy. In Zakim D, Boyer TD, editors: *Hepatology: a textbook of liver disease,* Philadelphia, 1990, WB Saunders.)

portovascular anomalies and severe primary hepatobiliary disease with acquired shunting have been ruled out, congenital urea enzyme cycle deficiencies and organic acidemias, in which NH_3 cannot be degraded to urea, are considered. HE has also been reported in congenital cobalamin deficiency in dogs. Animals with systemic diseases having hepatic manifestations do not undergo sufficient loss of hepatic mass or change in hepatic blood flow to develop signs of HE.

The sources of increased blood ammonia levels in animals with liver disease are outlined in Fig. 33.4 and include the following:

- Small intestinal enterocyte catabolism of glutamine as their main energy source
- Endogenous hepatic protein metabolism from excess dietary protein, GI bleeding, or breakdown of lean body mass
- Bacterial breakdown of undigested amino acids and purines that reach the colon
- Bacterial and intestinal urease action on urea, which freely diffuses into the colon from the blood

It is very important to realize that the traditional view that the toxins causing HE are predominantly of dietary origin is misleading; although the gut is an important source of NH_3 in animals on high-protein diets, in many animals, particularly those with protein-calorie malnutrition, endogenous sources of NH_3 may be more important, and further dietary protein restriction just worsens the hyperammonemia in these cases. Certain conditions are known to accentuate or precipitate HE and should be avoided or treated aggressively when detected (Box 33.2). In fact, in many cases it is the precipitating factors (rather than the diet) that are most important in triggering HE. It is particularly important to identify and treat any concurrent inflammatory disease that can trigger HE episodes in susceptible individuals. Recent work in humans, experimental animals, and dogs with spontaneous disease has highlighted the importance of inflammation and inflammatory cytokines in triggering HE. It is known that clinically relevant episodes of HE in dogs and cats with congenital or acquired PSS are often precipitated not just by feeding but also by stress and infections, emphasizing the role of hypermetabolism, inflammation, and breakdown of body protein in the development of HE. A

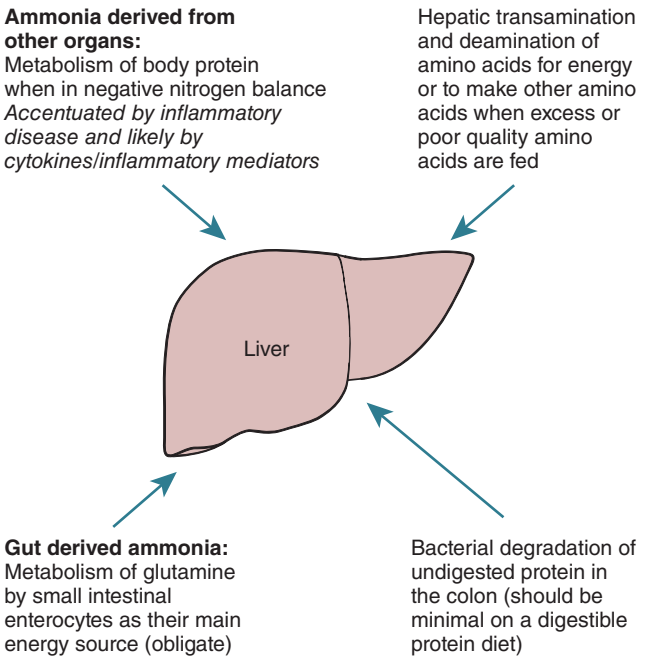

FIG 33.4
Sources of ammonia that can contribute to hepatic encephalopathy. Note that it is now believed that bacterial degradation of undigested protein in the colon is not the most important factor in dogs fed a normal diet.

BOX 33.2

Precipitating Factors for Hepatic Encephalopathy in Susceptible Individual

Increased Generation of Ammonia in the Intestine

- High-protein meal (e.g., puppy or kitten food)
- Very poorly digestible protein reaching the colon and allowing bacterial metabolism to ammonia
- Increased glutamine metabolism in small intestine as energy source from large meal or increased energy requirements for digestion
- GI bleeding (e.g., bleeding ulcer in acquired shunts with portal hypertension) or ingestion of blood
- Constipation (increases contact time between colonic bacteria and feces and therefore increases ammonia production)
- Azotemia (urea freely diffuses across colonic membrane and is split by bacteria to ammonia)

Increased Generation of Ammonia Systemically

- Transfusion of stored blood
- Catabolism, hypermetabolism, protein-calorie malnutrition (increases breakdown of lean body mass with release of NH_3)
- Feeding a poor-quality protein (excessive deamination as protein is used for energy)

Effects on Uptake, Metabolism, and Action of Ammonia in the Brain

- Metabolic alkalosis (increases amount of nonionized NH_3 in circulation, which increases passage across blood-brain barrier)
- Hypokalemia (results in alkalosis with consequences previously outlined)
- Sedatives or anesthetics (direct interaction with various neurotransmitters)
- Estrus (may be caused by production of neurosteroids with neurologic effects)
- Inflammation (inflammatory cytokines have been implicated in having a direct central effect)

recent study in dogs confirmed that animals with congenital PSS and symptomatic HE had higher serum C-reactive protein concentrations than dogs with congenital PSS and no HE. C-reactive protein, an acute-phase protein, is a sensitive nonspecific marker of inflammation in dogs, so this study adds support to the theory that inflammation may trigger symptomatic HE in dogs with PSS. Furthermore, successful ligation of congenital PSS resulted in the reduction of inflammatory indicators in the blood as well as resolution of HE. In the author's experience, it is often initially undetected infections in the urinary tract, particularly pyelonephritis or cystitis, which trigger HE in susceptible dogs. These may be acting in two ways: partly through production of inflammatory cytokines but also partly through absorption of ammonia produced by urease-producing bacteria in the urinary tract.

CLINICAL SIGNS

HE in humans is described as overt HE when there are obvious clinical signs and covert HE when signs are only picked up on neuropyschometric testing. Such testing is not undertaken in dogs and cats, so only the more severe, overt HE is recognized. Subtle, nonspecific signs of HE in cats and dogs that could be noted at any time and that represent chronic or subclinical HE include anorexia, depression, weight loss, lethargy, nausea, fever, hypersalivation (particularly in cats), intermittent vomiting, and diarrhea. Almost any central nervous system (CNS) sign may be observed in cats and dogs with HE, although typical signs tend to be nonlocalizing, suggesting generalized brain involvement—trembling, ataxia, hysteria, dementia, marked personality change (usually toward aggressiveness), circling, head pressing, cortical blindness, or seizures (Box 33.3; Fig. 33.5). Occasionally, animals with hyperammonemia have asymmetric, localizing neurologic signs that regress with appropriate treatment for HE. Acute HE is a true medical emergency. Fortunately, it is much less common than chronic, waxing and waning HE. Animals may present in status epilepticus or comatose, and although HE initially causes no permanent brain damage, prolonged seizures, status epilepticus, or coma will; prolonged severe HE by itself may lead to serious cerebral edema as a result of accumulation of the osmolyte glutamine (from ammonia detoxification) in astrocytes. In addition, the systemic effects of acute HE, particularly hypoglycemia, can be fatal if not recognized and treated.

Typical Clinical Signs of Hepatic Encephalopathy in Dogs and Cats

Lethargy
Depression
Behavioral changes
Head pressing
Circling
Pacing
Central blindness
Seizures (uncommon)
Coma (uncommon)
Hypersalivation (especially cats)

CHANGE IN LIVER SIZE

In normal cats and dogs, the liver is palpable just caudal to the costal arch along the ventral body wall, but it may not be palpable at all. Inability to palpate the liver, especially in dogs, does not automatically mean that the liver is small. In lean cats, it is usually possible to palpate the diaphragmatic surface of the liver. In cats or dogs with pleural effusion or other diseases that expand thoracic volume, the liver may be displaced caudally and give the false appearance of being enlarged.

Liver enlargement (hepatomegaly) is much more common in cats than in dogs with liver disease. Dogs more often have a reduced liver size because of chronic hepatitis with fibrosis but can show hepatomegaly particularly in association with tumors. The pattern of liver enlargement may be generalized or focal, depending on the cause. Infiltrative and congestive disease processes, or those that stimulate hepatocellular hypertrophy or mononuclear-phagocytic system (MPS)

FIG 33.5
Head-pressing is one manifestation of hepatic encephalopathy (Courtesy Georgina Harris).

hyperplasia, tend to result in smooth or slightly irregular, firm, diffuse hepatomegaly. Focal or asymmetrical hepatic enlargement is often seen with proliferative or expansive diseases that form solid or cystic mass lesions. Examples of diseases that cause a change in liver size are listed in Table 33.1.

Smooth generalized hepatosplenomegaly may be associated with nonhepatic causes, such as increased intravascular hydrostatic pressure (passive congestion) secondary to right-sided congestive heart failure or pericardial disease. In rare cases, hepatic vein occlusion (Budd-Chiari syndrome) results in similar findings. Hepatosplenomegaly in icteric dogs or cats may be attributable to benign MPS hyperplasia and extramedullary hematopoiesis secondary to immune-mediated hemolytic anemia. Hepatosplenomegaly may also occur due to infiltrative processes such as lymphoma, systemic mast cell disease, malignant histiocytosis, or leukemias.

Another cause of hepatosplenomegaly is primary hepatic parenchymal disease with sustained intrahepatic portal hypertension. In dogs and cats with this syndrome, the liver is usually firm and irregular on palpation, and often the liver itself is reduced in size as a result of fibrosis. However, the spleen can be enlarged and congested as a result of portal hypertension. For conditions that involve primarily the spleen, see Chapter 88.

JAUNDICE, BILIRUBINURIA, AND CHANGE IN FECAL COLOR

By definition, jaundice in cats and dogs is the yellow staining of serum or tissues by an excessive amount of bile pigment or bilirubin (Fig. 33.6); the terms *jaundice* and *icterus* are used interchangeably. Jaundice may be prehepatic, due to very marked red cell breakdown; hepatic, due to primary liver disease; or posthepatic, due to biliary tract obstruction or rupture. Because the normal liver has the ability to take up and excrete a large amount of bilirubin, there must be either a large, persistent increase in the production of bile pigment (hyperbilirubinemia) or a major impairment in bile excretion (cholestasis with hyperbilirubinemia) before jaundice is detectable as yellow-stained tissues (serum bilirubin concentration ≥2 mg/dL) or serum (serum bilirubin concentration ≥1.5 mg/dL).

In normal animals, bilirubin is a waste product of heme protein degradation. The primary source of heme proteins is senescent erythrocytes, with a small contribution by myoglobin and heme-containing enzyme systems in the liver. After phagocytosis by cells of the MPS, primarily in the bone marrow and spleen, heme oxygenase opens the protoporphyrin ring of the hemoglobin molecule, forming biliverdin. Biliverdin reductase then converts biliverdin to fat-soluble bilirubin IXa, which is released into the circulation, where it is bound to albumin for transport to hepatic sinusoidal membranes. After uptake, transhepatocellular movement, and conjugation to various carbohydrates, conjugated bilirubin, now water-soluble, is excreted into the bile

TABLE 33.1

Differential Diagnoses for Changes in Hepatic Size

DIAGNOSIS	SPECIES
Hepatomegaly	
Generalized	
Infiltration	
Primary or metastatic neoplasia	C, D
Cholangitis	C
Extramedullary hematopoiesis*	C, D
Mononuclear-phagocytic cell hyperplasia*	C, D
Amyloidosis (rare)	C, D
Passive congestion	
Right-sided heart failure	C, D
Pericardial disease	D
Caudal vena cava obstruction	D
Caval syndrome	D
Budd-Chiari syndrome (rare)	C, D
Hepatocyte swelling	
Lipidosis	C (moderate to marked), D (mild)
Hypercortisolism (steroid hepatopathy)	D
Anticonvulsant drug therapy	D
Acute extrahepatic bile duct obstruction	C, D
Acute hepatotoxicity	C, D
Focal or asymmetric	
Primary or metastatic neoplasia	C, D
Nodular hyperplasia	D
Chronic hepatic disease with fibrosis and nodular regeneration	D
Abscess(es) (rare)	C, D
Cysts (rare)	C, D
Microhepatia (Generalized Only)	
Reduced hepatic mass	
Chronic hepatic disease with progressive loss of hepatocytes and fibrosis	D
Decreased portal blood flow with hepatocellular atrophy	
Congenital portosystemic shunt	C, D
Intrahepatic portal vein hypoplasia	D
Chronic portal vein thrombosis	D
Hypovolemia	
Shock?	?
Addison's disease	D

canaliculi. Conjugated bilirubin is then incorporated into micelles and stored with other bile constituents in the gallbladder until it is discharged into the duodenum. However, in dogs, only 29% to 53% of bile produced is stored in the gallbladder; the rest is secreted directly into the duodenum. After arrival in the intestine, conjugated bilirubin undergoes bacterial deconjugation and then reduction to urobilinogen, with most urobilinogen being resorbed into the enterohepatic circulation. A small fraction of urobilinogen is then excreted in the urine, and a small portion remains in the intestinal tract to be converted to stercobilin, which imparts normal fecal color.

Inherited abnormalities of bilirubin metabolism have not been identified in cats and dogs, so in the absence of massive increases in bile pigment production by hemolysis, jaundice is attributable to impaired excretion of bilirubin, and usually other constituents of bile, by diffuse intrahepatic hepatocellular or biliary disease or by interrupted delivery of bile to the duodenum. The inability to take up, process intracellularly, or excrete bilirubin into the bile canaliculi (the rate-limiting step) is the mechanism of cholestasis believed to be operational in many primary hepatocellular diseases. Jaundice is more likely to be a clinical feature if the liver disorder primarily involves the periportal (zone 1) hepatocytes (Fig. 33.7) than if the lesion involves centrilobular (zone 3) hepatocytes. Inflammation and swelling of larger intrahepatic biliary structures could similarly delay bile excretion.

Extrahepatic biliary duct obstruction (EBDO) occurs as a result of intraluminal or extraluminal obstruction of the bile duct at any point along its length. This may be obstruction of the cystic duct by a gallbladder mucocele in dogs or obstruction of the common bile duct in dogs and cats by choleliths, neoplasia of occasionally foreign bodies. Jaundice can develop in both cats and dogs as a result of acute flare-up of a chronic pancreatitis causing transient extrahepatic biliary obstruction. Indeed, an acute flare-up of chronic pancreatitis is the commonest cause of EBDO in dogs.

Obstruction of the bile duct near the duodenum results in increased intraluminal biliary tract pressure, interhepatocellular regurgitation of bile constituents into the circulation, and jaundice. If only one of the hepatic bile ducts exiting the liver is blocked, or if only the cystic duct exiting the gallbladder is obstructed for some reason, there may be biochemical clues for localized cholestasis, such as high serum alkaline phosphatase activity; however, the liver's overall ability to excrete is preserved, and jaundice may not ensue.

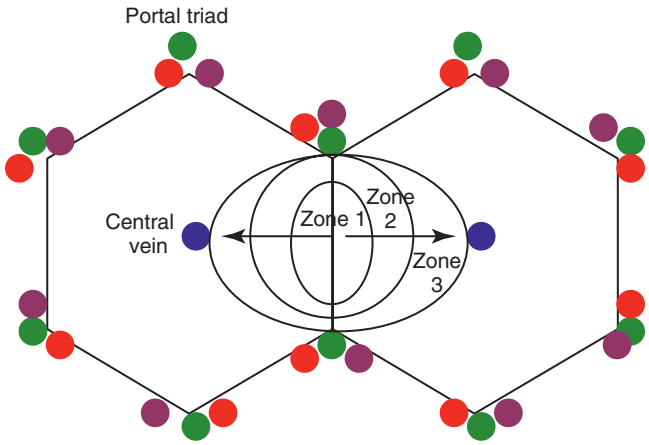

FIG 33.7
Rappaport scheme of the hepatic functional lobule (acinus), organized according to biochemical considerations (1958). This is centered on a line connecting two portal triads and describes functional zones radiating from the triad to the central vein. For example, zone 1 cells are responsible for protein synthesis, urea and cholesterol production, gluconeogenesis, bile formation, and β oxidation of fatty acids; zone 2 cells also produce albumin and are actively involved in glycolysis and pigment formation; and zone 3 cells are the major site of liponeogenesis, ketogenesis, and drug metabolism. Zone 3 hepatocytes, being farther from the hepatic artery and hepatic portal veins, also have the lowest oxygen supply and are therefore most susceptible to hypoxic damage. *Arrows* show direction of blood flow. The portal triad comprises one or more branches of bile duct *(green),* hepatic artery *(red),* and hepatic portal vein *(violet).*

Traumatic or pathologic biliary tract rupture allows leakage of bile into the peritoneal space and some absorption of bile components. Depending on the underlying cause and the time elapsed between biliary rupture and diagnosis, the degree of jaundice may be mild to moderate. If biliary rupture has occurred, the total bilirubin content of the abdominal effusion is higher than that of serum.

Reference ranges for serum total bilirubin concentrations in dogs and cats may vary among laboratories, but most published resources agree that concentrations over 0.3 mg/dL in cats and 0.6 mg/dL in dogs are abnormal. When results of laboratory tests are assessed, species differences in the formation and renal processing of bilirubin between cats and dogs must be taken into account. Canine renal tubules have a low resorptive threshold for bilirubin. Dogs (males to a greater extent than females) have the necessary renal enzyme systems to process bilirubin to a limited extent; therefore bilirubinuria (up to 2+ to 3+ reaction by dipstick analysis) may be a normal finding in canine urine specimens with a specific gravity greater than 1.025. Cats do not have this ability, and they have a ninefold higher tubular absorptive capacity for bilirubin than dogs. Bilirubinuria in cats is associated with hyperbilirubinemia and is always pathologic (Fig. 33.8). Because unconjugated and most conjugated bilirubin is albumin-bound in the circulation, only a small amount of non–protein-bound conjugated bilirubin is expected to appear in the urine in physiologic and pathologic states. In dogs with hepatobiliary disease, increasing bilirubinuria often precedes the development of hyperbilirubinemia, and clinical jaundice and may be the first sign of illness detected by owners.

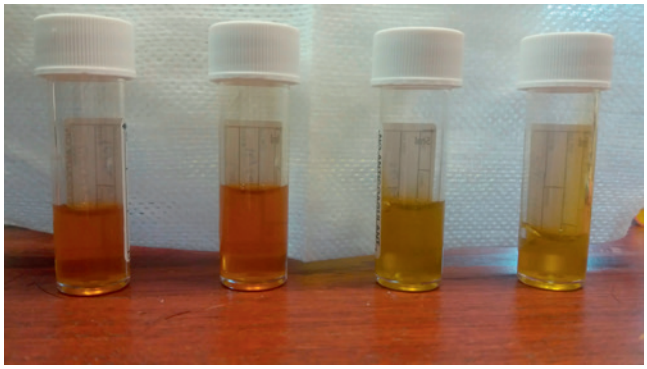

FIG 33.8
Samples of urine (two pots on the left) and gallbladder bile (two pots on the right) from a cat with chronic biliary tract obstruction due to a stricture of the common bile duct. Note the grossly abnormal pale appearance of the bile due to reduced excretion of bilirubin into bile. This is not unusual in cats with chronic biliary obstruction. The serum and urine contained a large amount of bilirubin, so it is assumed that the bilirubin transporters in this case had moved from the luminal surface of the bile ducts to the hepatic side. (Reproduced with permission from Watson P. Liver and biliary tract: hepatocellular disorders. In: Hall EJ, Williams DA, Kathrani A, eds. BSAVA Manual of Canine and Feline Gastroenterology 3rd edition. Gloucester: British Small Animal Veterinary Association, 2019. © BSAVA.)

Several nonhepatobiliary disorders impede bilirubin excretion by poorly understood means. Jaundice with evidence of hepatocellular dysfunction but minimal histopathologic changes in the liver has been described in septic human, feline, and canine patients. Certain products released by bacteria, such as endotoxin, are known to interfere with bile flow reversibly. As yet unexplained mild hyperbilirubinemia (≤2.5 mg/dL) may also be detected in approximately 20% of hyperthyroid cats. Experimental investigations of thyrotoxicosis in laboratory animals have demonstrated increased production of bilirubin, which has been proposed to be associated with increased degradation of hepatic heme proteins. There is no histologic evidence of cholestasis at the light microscopic level in affected cats, and the hyperbilirubinemia resolves with return to euthyroidism. Guidelines for initial evaluation of the icteric cat or dog are given in Fig. 33.9. Finally, lipemia is a common cause of pseudohyperbilirubinemia in dogs as a result of lipid interference with the colorimetric laboratory methods.

Acholic feces result from the total absence of bile pigment in the intestine (Fig. 33.10). Only a small amount of bile pigment is needed to be changed to stercobilin and yield a normal fecal color; therefore bile flow into the intestine must be completely discontinued to result in acholic feces, and this is very rare in dogs and cats. In addition to appearing pale from lack of stercobilin and other pigments, acholic feces are pale because of steatorrhea resulting from the lack of bile acids to facilitate fat absorption. Mechanical diseases of the extrahepatic biliary tract (e.g., unremitting complete EBDO, traumatic bile duct avulsion from the duodenum) are the most common causes of acholic feces in cats and dogs.

Feces also become pale as a result of exocrine pancreatic insufficiency in dogs and cats, either as a result of pancreatic acinar atrophy of end-stage chronic pancreatitis and marked loss of pancreatic tissue mass. Fat maldigestion caused by a lack of pancreatic lipase result in pale yellow, voluminous, and smelly feces. Pancreatic enzyme lack can also be transient for example in an acute flare-up of chronic pancreatitis, which may also cause biliary obstruction resulting in two mechanisms for pale feces (see Fig. 33.10).

COAGULOPATHIES

Coagulopathies can be recognized in dogs and cats with liver disease and with acute pancreatitis. In acute pancreatitis in dogs and cats, coagulopathies most commonly occur in association with severe disease as a result of DIC. However, particularly in cats, they can also occur in more low grade and chronic disease as a result of acquired vitamin K deficiency due to fat maldigestion, particularly in cats with concurrent IBD and biliary tract disease.

Because of the integral role of the liver in hemostasis, hemorrhagic tendencies can be a presenting sign in cats and dogs with severe hepatobiliary disease: either end-stage chronic disease, particularly in dogs, or severe acute disease in both species. Despite the fact that most coagulation proteins and

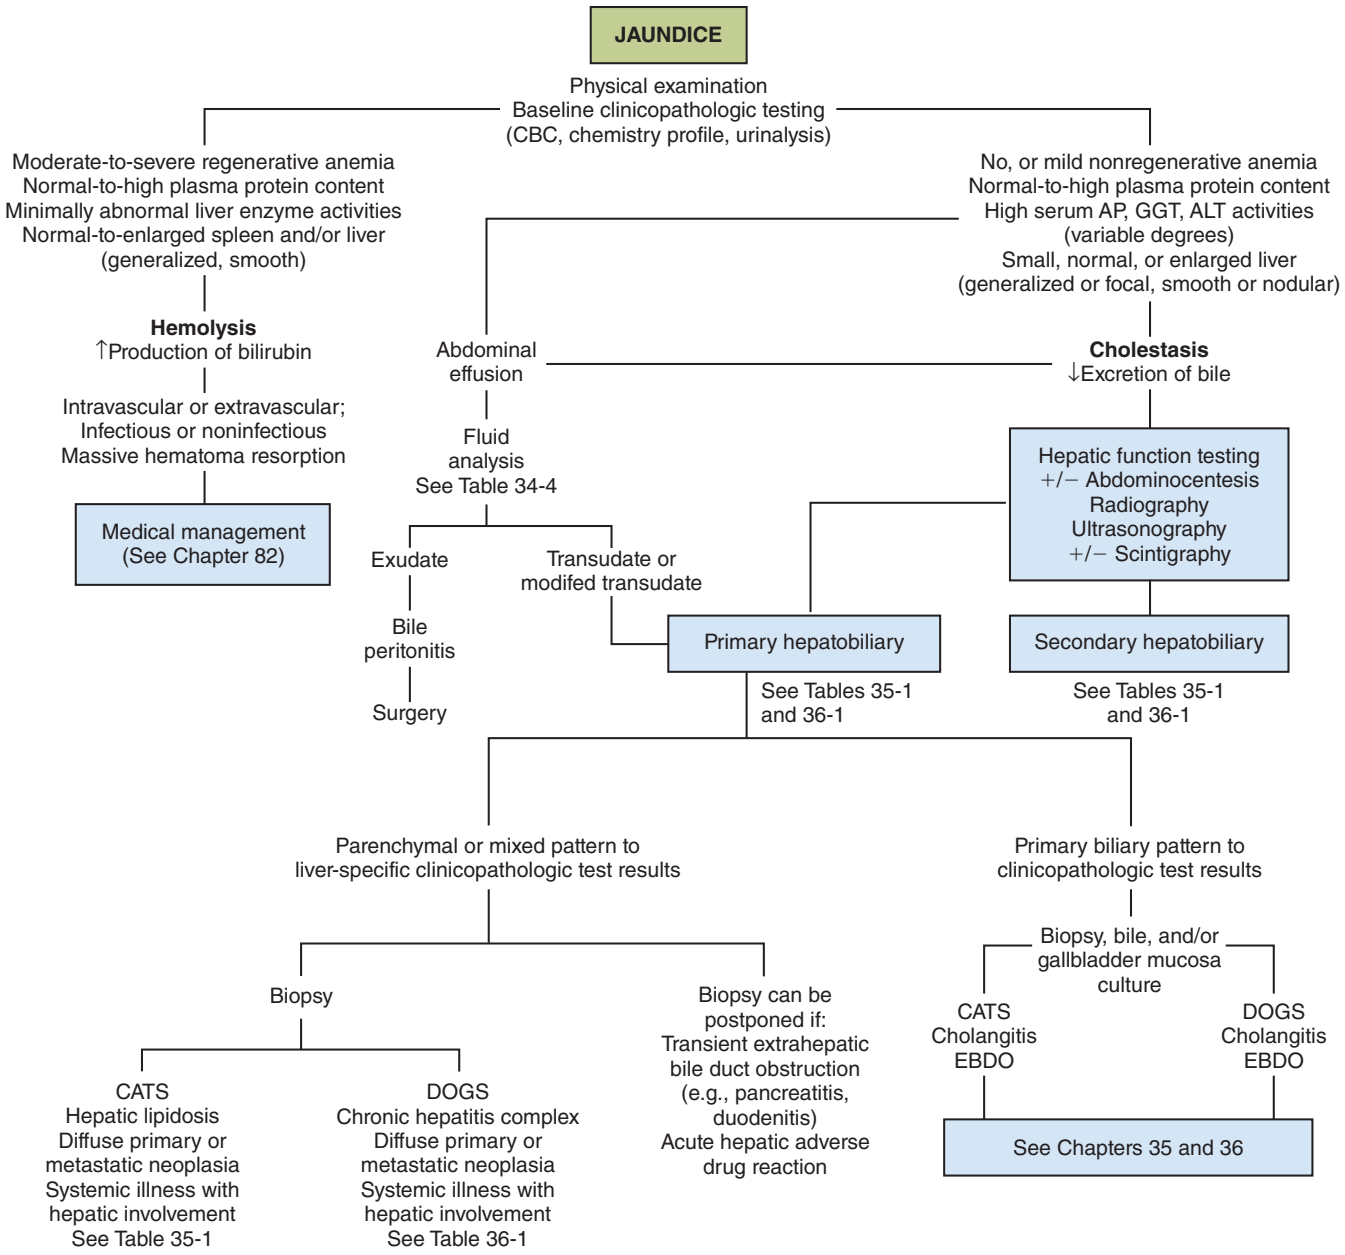

FIG 33.9

inhibitors, except for von Willebrand factor (vWF) and possibly factor VIII, are synthesized in the liver (Box 33.4), the overall frequency of clinical sequelae of disturbances in hemostasis is low. A recent study using thromboelastography in dogs with chronic hepatitis showed some dogs were hypocoagulable, some were hypercoagulable, and some had normal TEG results. Dogs with portal hypertension and more end-stage liver disease were more likely to be hypocoagulable. Similar results were reported in dogs with acute liver disease, with a more common occurrence of a hypocoagulable state in dogs with more severe disease. The inability to synthesize vitamin K–dependent factors (II, VII, IX, and X) because of the absence of bile acid–dependent fat absorption secondary to complete EBDO or a transected bile duct from abdominal trauma can cause clinically apparent bleeding. This is likely more important in cats than dogs because of the high prevalence of biliary tract disease in cats, and because concurrent pancreatic and/or intestinal disease in cats further compromises the absorption of fat-soluble vitamins. Subclinical and clinical coagulopathies are also noted in animals with severe diseases of the hepatic parenchyma. In early studies of the mechanism of impaired coagulation after partial hepatectomy in dogs, after surgical removal of 70% of the hepatic mass, dogs developed significant alterations

in plasma clotting factor concentrations without spontaneous hemorrhage. Having severe hepatic parenchymal disease predisposes a dog or cat not only to changes in coagulation factor activity from hepatocellular dysfunction but also to DIC, particularly in those with acute disease. In dogs with acute hepatic necrosis, some clinicians have observed thrombocytopenia, thought to be associated with increased platelet use or sequestration. Splenic sequestration of platelets is common in humans with chronic liver disease and portal hypertension but has not been not reported in dogs and cats.

Other than noticeable imbalances in coagulation factor activity, the only other mechanism whereby bleeding might occur in a cat or dog with severe hepatic disease is portal hypertension–induced vascular congestion and fragility. In such cases, which are expected considerably more often in dogs than in cats because of the types of hepatobiliary diseases that they acquire, the common site affected is the upper GI tract (stomach, duodenum); therefore hematemesis and melena are common bleeding presentations and a common cause of death in dogs with chronic liver disease. In contrast to human patients, in whom fragile esophageal varices develop and can burst, causing severe and often fatal hemorrhage, the mechanism of GI hemorrhage in companion animals is unknown but is suspected to be related to poor mucosal perfusion and reduced epithelial cell turnover associated with portal hypertension and splanchnic pooling of blood.

FIG 33.11
English Cocker Spaniel with chronic pancreatitis showing loss of body weight and poor coat as a result of developing exocrine deficiency. Weight loss is slow and insidious, and often not recognized initially by owner or vet.

PROTEIN-CALORIE MALNUTRITION

Pathogenesis

Protein-calorie malnutrition is very common in dogs with chronic hepatitis and dogs and cats with chronic pancreatitis as a result of reduced intake caused by anorexia, vomiting, and diarrhea, and increased loss/wastage of calories caused by hypermetabolism and poor liver function or (in the case of chronic pancreatitis) lack of digestive enzymes. In chronic pancreatitis, the development of exocrine pancreatic insufficiency is progressive and insidious, and it may not be initially recognized (Fig. 33.11). In human medicine, anyone with confirmed chronic pancreatitis is assumed already to have some degree of exocrine insufficiency and is given enzyme supplementation. A more proactive approach to supplementation would also be wise in dogs and cats because protein-calorie malnutrition in both liver and pancreatic

disease is likely to have a serious effect on both longevity and quality of life. There are no studies specifically addressing the effect of malnutrition on survival and infections of dogs with liver disease, but in other canine diseases it is known to increase the risk of septic complications. This is true in humans with portal hypertension and also likely in dogs. In humans with portal hypertension, malnutrition also predisposes to gut ulceration. In addition, negative nitrogen balance and reduced muscle mass predispose to HE. Breakdown of body protein results in more ammonia production, and also in a normal individual up to 50% of arterial ammonia is metabolized in skeletal muscle by conversion of glutamate to glutamine, so loss of muscle mass will reduce the ability to detoxify ammonia. What gives the most cause for concern regarding protein-calorie malnutrition in the small animal patient is that it is often partly caused by well-meaning but unhelpful manipulations by the clinician or even by a lack of recognition and attention. For this reason, it is very important that clinicians treating dogs with chronic liver disease or cats and dogs with chronic pancreatic disease remain alert to the possibility of protein-calorie malnutrition.

Malnutrition can also be seen in dogs and cats with congenital PSS, either as a result of reduced liver synthetic capability or as a result of inappropriately severe protein restriction by the attending clinician. Cats with chronic liver disease may have negative energy balance, often as a result of the effects of concurrent intestinal and pancreatic disease reducing digestion and absorption of food. In addition, cats in negative nitrogen balance are at a particular risk of developing acute hepatic lipidosis (see Chapter 35), so protein-calorie malnutrition in this species requires particularly aggressive management.

Clinical Signs and Diagnosis

When suffering from severe malnutrition, dogs and cats appear cachectic, with reduced muscle mass (see Fig. 33.11). However, loss of muscle mass occurs relatively late in the process, and in the earlier stages of protein-calorie malnutrition the animal's body condition score may be normal and yet many potentially deleterious effects on the immune system and gut wall will already be underway. There is no simple blood test that allows diagnosis of malnutrition. The most effective means to do this is by taking a careful history as well as performing a clinical examination. Any animal with chronic liver or pancreatic disease should be considered as being at risk of protein-calorie malnutrition, and in this context an older animal that was previously overweight and has recently lost weight should be considered seriously for nutritional and (if appropriate) pancreatic enzyme support. A history of partial or complete anorexia for more than 3 days or recent weight loss of >10% not associated with fluid shifts should trigger rapid and aggressive nutritional management.

CHAPTER 34

Diagnostic Tests for the Hepatobiliary and Pancreatic System

DIAGNOSTIC APPROACH

The diagnosis of either liver or pancreatic disease is challenging and relies on a combination of clinicopathologic tests, diagnostic imaging, and often also some form of biopsy, particularly for the liver. Hepatic involvement is common in cats and dogs with pancreatitis, either because of concurrent disease in both organs (particularly in cats) or because of reactive hepatopathy or extrahepatic biliary obstruction in some cases of pancreatitis (particularly in dogs), further complicating interpretation of diagnostic test results. Many of these tests point to liver or pancreatic involvement but do not give an indication of the type of disease present or of organ function or prognosis. Only a limited number of tests give functional information. It is important to remember that both the liver and pancreas have large structural and functional reserves, particularly in chronic disease. In dogs with chronic hepatitis, signs of functional impairment may not be evident until 75% of the hepatic mass has been lost, and in chronic pancreatitis in dogs and cats, endocrine and exocrine insufficiency will not be apparent until about 90% of islet or acinar tissue have been lost, respectively.

DIAGNOSTIC APPROACH TO LIVER DISEASE

Because the liver is physiologically and anatomically diverse and because of the high prevalence of secondary (reactive) liver disease, no single test adequately identifies liver disease or its underlying cause. For this reason, a battery of tests must be used to assess the hepatobiliary system. A reasonable package of screening tests recommended for an animal suspected of having hepatobiliary disease includes a complete blood count (CBC), serum biochemical profile, urinalysis, fecal analysis, and survey abdominal radiography or ultrasonography (US). Results of these tests may suggest evidence of hepatobiliary disease that can be confirmed by other, more specific tests, which would usually be some form of tissue sample. It is important at this stage to rule out secondary hepatopathy as much as possible because, with hepatopathies secondary to other diseases, time and resources should be devoted as soon as possible to identify and treat the underlying cause rather than investigate the liver.

Box 34.1 lists common diagnostic tests for liver disease and indicates which can give functional or prognostic information. It is important to remember that some hepatobiliary diseases are characterized by subtle changes in enzyme activity in association with severe functional disturbance, and some have high enzyme activities and normal functional indices. In addition, secondary hepatopathies can result in very high hepatic enzyme activities but no functional impairment, so the degree of enzyme activity elevation is in no way prognostic. Diseases that cause acute hepatocyte loss result in evidence of functional impairment more quickly than diseases with chronic hepatocyte loss, in which the remaining hepatocytes have time to compensate.

By using a combination of history, physical examination findings, and results of screening and hepatobiliary-specific laboratory tests, the clinician may be able to do the following: describe the disorder as primary or secondary (reactive) hepatopathy, active or quiescent; characterize the pattern of hepatobiliary disease as primarily hepatocellular, primarily biliary, or mixed hepatobiliary; and estimate the degree of hepatobiliary dysfunction. However, without the results of a liver biopsy, the clinician should be aware that this pattern recognition may be misleading. For example, a dog with apparently predominantly biliary disease on clinical pathology may have severe hepatocellular disease on biopsy, and a dog suspected of having secondary (reactive) hepatopathy may have primary hepatic disease. Without histologic confirmation, conclusions drawn from other diagnostic tests remain speculative. However, once a definitive diagnosis of hepatic disease has been made, it is also possible to deduce from the results of hepatic function tests whether the dog or cat has hepatic failure, in which there is a state of multiple function loss. Some primary hepatic diseases may progress to failure; most secondary hepatic diseases do not (see Tables 35.1 and 36.1). Often, use of the term *failure* inappropriately connotes a poor prognosis; if the underlying cause can be removed, full recovery is possible.

BOX 34.1

Summary of Biochemical Tests for the Hepatobiliary System and Their Relevance to Assess Function

Tests for liver involvement (primary or secondary)	Tests for liver function
Liver enzymes: predominantly hepatocellular (but overlap with hepatobiliary—see text) • Alanine aminotransferase • Aspartate aminotransferase	Nonspecific: • Total protein and albumin/globulin ratio* • Coagulation tests* • Urea • Glucose • Cholesterol†
Liver enzymes: predominantly hepatobiliary (but overlap with hepatocellular—see text) • Alkaline phosphatase • Gamma-glutamyltransferase	More specific tests of function and/or portosystemic shunting • Bile acids pre- and poststimulation† • Ammonia
Bilirubin	Relatively specific tests of function only and not portosystemic shunting • Bilirubin*,†

*Also prognostic indicators when interpreted correctly—see text.
†Only useful tests of function in an animal with no evidence of cholestasis.

Most importantly, before an accurate prognosis can be given, a complete evaluation must be conducted, including, for most primary hepatobiliary diseases in dogs and cats, a liver biopsy.

DIAGNOSTIC APPROACH TO PANCREATIC DISEASE

The use of appropriate clinicopathologic tests in a dog or cat with typical clinical signs can help in the diagnosis of pancreatitis, but some form of diagnostic imaging is advisable to confirm this. Secondary causes of enzyme elevation are less common in the pancreas than in the liver. Nonetheless, pancreatitis may not be the most clinically significant disease in an individual sick animal, and diagnostic imaging is important to rule out other causes of acute abdomen with secondary pancreatic involvement such as gastrointestinal (GI) obstruction or gallbladder rupture. More general clinicopathologic tests also allow assessment of the degree of concurrent systemic inflammatory response and evidence of multiorgan failure in severe acute pancreatitis (Box 34.2). In more chronic pancreatitis, exocrine and/or endocrine functional impairment can occur and are assessed as indicated in Box 34.2 in addition to clinical signs. Exocrine function is also impaired in pancreatic acinar atrophy (PAA). A fecal sample is an important addition to the diagnostic panel in dogs with diarrhea associated with pancreatic disease to rule out infectious causes of the clinical signs, particularly as dogs with PAA tend to be younger animals also more predisposed to GI parasites.

BOX 34.2

Summary of Biochemical Tests for the Pancreatitis and to Assess the Associated Systemic Inflammatory Response or Pancreatic Function

Tests for pancreatitis	Tests for pancreatic function
Relatively specific • Pancreatic lipase immunoreactivity (species specific tests) • Lipase and DGGR lipase* • Trypsin-like immunoreactivity (elevated) (species specific—Poorly sensitive; more specific for pancreatitis in dog than cat) • Serum elastase— rarely used • Amylase—poor sensitivity and specificity	Tests for exocrine function: • Trypsin-like immunoreactivity (reduced)—species specific • Fecal elastase (rarely used) • Cobalamin (reduced due to lack of pancreatic intrinsic factor)
Nonspecific tests which assess systemic inflammatory response and associated organ failure (see text) • Complete blood count—particularly neutrophil and platelet counts • Urea and creatinine with concurrent urine SG • Electrolytes: particularly potassium; sodium; calcium • Liver enzymes • Bilirubin	Tests for endocrine function • Blood glucose • Urine glucose and ketones • Fructosamine

*DGGR lipase more specific than traditional lipase—see text

DIAGNOSTIC TESTS PREDOMINANTLY TO ASSESS THE STATUS OF THE HEPATOBILIARY SYSTEM

A summary of laboratory tests for cats and dogs with hepatobiliary disease and interpretation of the results are given in Table 34.1.

Serum Liver Enzyme Activities

Liver-specific serum enzyme activities are included routinely in screening serum biochemistry panels and are regarded as markers of hepatocellular and biliary injury and reactivity. However, this can be due to primary liver disease or secondary to other disease particularly in the splanchnic bed. Hepatocellular enzymes are increased in more than 60% of dogs and cats with acute pancreatitis, and cholestatic markers are increased in more than 60% of dogs and cats with acute pancreatitis.

Because marked hepatic disease can be present in patients with normal serum enzyme activity, finding normal values should not preclude further investigation, especially if there are clinical signs or other laboratory test results that suggest

TABLE 34.1

First- and Second-Line Clinicopathologic Tests Useful in the Diagnosis of Hepatobiliary Disease

SCREENING TEST	PARAMETER EXAMINED	COMMENTS
Serum ALT, AST activities	Integrity of liver cell membranes, escape from cells	Degree of increase roughly correlates with number of hepatocytes involved but not severity of disease
Serum AP, GGT activities	Reactivity of biliary epithelium to various stimuli, increased synthesis and release	Increase associated with intrahepatic or extrahepatic cholestasis or drug effect (dogs only)—corticosteroids, anticonvulsants (AP only, not GGT)
Serum albumin concentration	Protein synthesis	Rule out other causes of low concentration (glomerular or intestinal loss); low value indicates ≥80% overall hepatic function loss or negative acute phase response
Serum urea concentration	Protein degradation and detoxification	With low values, rule out prolonged anorexia, dietary protein restriction, severe PU-PD, urea cycle enzyme deficiency (rare), congenital PSS, severe acquired chronic hepatobiliary disease
Serum bilirubin concentration	Uptake and excretion of bilirubin	Rule out marked hemolysis first; if PCV is normal, intrahepatic or extrahepatic cholestasis is present
Serum cholesterol concentration	Biliary excretion, intestinal absorption, integrity of the enterohepatic circulation	High values compatible with severe cholestasis of any type; low values suggest congenital PSS, anticonvulsant drug–induced change, severe acquired chronic hepatobiliary disease, or severe intestinal malassimilation
Serum glucose concentration	Hepatocellular gluconeogenic or glycolytic ability, insulin and other hormone metabolism	Low values indicate severe hepatocellular dysfunction, PSS, presence of primary liver tumor
Plasma ammonia concentration	Integrity of the enterohepatic circulation, hepatic function and mass	High fasting or postprandial values suggest congenital or acquired PSS or acute hepatocellular inability to detoxify ammonia to urea (massive necrosis)
Serum bile acid concentrations	Integrity of the enterohepatic circulation, hepatic function and mass	High fasting or postprandial values compatible with hepatocellular dysfunction, congenital PSS, or loss of hepatic mass; elevated in cholestasis independent of hepatocellular dysfunction or shunting, so rule out first
Coagulation profile	Hepatocellular function, adequacy of vitamin K absorption and stores	Abnormal values may indicate marked hepatocellular dysfunction, acute or chronic DIC, complete EBDO

ALT, Alanine aminotransferase; *AP,* alkaline phosphatase; *AST,* aspartate aminotransferase; *DIC,* disseminated intravascular coagulation; *EBDO,* extrahepatic bile duct obstruction; *GGT,* γ-glutamyltransferase; *PCV,* packed cell volume; *PSS,* portosystemic shunt; *PU-PD,* polyuria-polydipsia.

hepatobiliary disease. In these cases, a function test such as a bile acid stimulation test should be performed. If this is also normal, it is very unlikely that the animal has hepatic disease. Increased serum activity of enzymes normally located in hepatocyte cytosol in high concentration reflects structural or functional cell membrane injury that would allow these enzymes to escape or leak into the blood. Two hepatocellular enzymes found to be of most diagnostic use in cats and dogs are alanine transaminase (ALT; also, glutamic pyruvic transaminase [GPT]) and aspartate transaminase (AST; also, glutamic oxaloacetic transaminase [GOT]). Because ALT is found principally in hepatocytes and AST (also located within hepatocyte mitochondria) has a wider tissue distribution (e.g., in muscle), ALT is the enzyme selected to reflect hepatocellular injury most accurately. Less is known about the behavior of AST in various hepatobiliary diseases in companion animals, although some studies have indicated that AST is a more reliable indicator of liver injury in cats. The AST level is also elevated in muscle injury, so it should always be interpreted along with serum concentrations of the muscle-specific enzyme creatine kinase. In dogs with skeletal muscle necrosis, several studies have also demonstrated mild to moderately high serum ALT activity, without histologic or biochemical evidence of liver injury, in addition to expected high serum activities of muscle-specific creatine kinase and AST.

In general, the magnitude of serum ALT and AST activity elevation approximates the extent, but not the reversibility, of hepatocellular injury. Severe acute hepatocellular necrosis will elevate levels more markedly than chronic hepatic

disease. However, generalized hypoxia, regeneration, and metabolic activity will also cause moderate to marked elevations, which may be higher than those with primary chronic liver disease. The author has seen very marked hepatocellular liver enzyme level elevations in a dog with a liver lobe trapped in a diaphragmatic hernia, with no underlying primary liver disease. The degree of elevation of liver enzyme activities cannot therefore be used as a prognostic indicator. ALT, and to a lesser extent AST, activities are also often increased by glucocorticoids in dogs, although to a lesser extent than alkaline phosphatase.

The activities of serum enzymes that reflect new synthesis and release of enzymes from the biliary tract in response to certain stimuli include the enzymes alkaline phosphatase (AP) and γ-glutamyltransferase (GGT). Bile retention (i.e., cholestasis) is one of the strongest stimuli for accelerated production of these enzymes. Unlike ALT and AST, AP and GGT are in low concentration in the cytoplasm of hepatocytes and biliary epithelium, and are membrane-associated, so the fact that they simply leak out of damaged cells does not account for increased serum activity. Measurable AP activity is also detectable in nonhepatobiliary tissues of cats and dogs, including osteoblasts, intestinal mucosa, renal cortex, and placenta, but serum activity in healthy adult cats and dogs arises only from the liver, with some contribution by the bone isoenzyme in young, rapidly growing dogs and in kittens younger than 15 weeks. The renal form is generally measurable in the urine; the gut form has a very short half-life and is not usually measurable, although the steroid-induced isoenzyme of AP in dogs is believed to be an altered gut isoenzyme with a prolonged half-life. Cats do not have a steroid-induced isoenzyme of AP. The half-life of feline AP is shorter than that of canine AP, so serum activity is relatively lower in cats than in dogs with a similar degree of cholestasis and, conversely, even mild elevations of AP levels in cats are clinically significant. Markedly high serum AP activity of bone origin (mean total serum AP values > fivefold higher than those in nonaffected individuals, with only the bone isoenzyme detected) was identified in certain healthy juvenile members (7 months old) of a family of Siberian Huskies. This change is believed to be benign and familial, and should be considered when results of serum AP activity are interpreted in this breed. A young growing dog of any breed can have a mild increase in serum AP. Increased serum AP activity has also been described in adult Scottish Terriers. This is believed to be associated with a vacuolar hepatopathy and adrenal dysfunction. More details are given in Chapter 36.

Certain drugs, the most common of which are anticonvulsants (specifically phenytoin, phenobarbital, and primidone) and corticosteroids, can elicit striking increases (up to 100-fold) in serum AP activity (and to a lesser extent GGT and ALT activity) in dogs but not in cats. There usually is no other clinicopathologic or microscopic evidence of cholestasis in these cases (i.e., hyperbilirubinemia). Anticonvulsant drugs stimulate the production of AP identical to the normal liver isoenzyme; GGT activity does not change. Pharmacologic levels of corticosteroids administered orally, by injection, or topically reliably provoke a unique AP isoenzyme that is separable from the others by electrophoretic and immunoassay techniques. However, measurement of AP isoenzymes has been shown to be of limited usefulness in dogs treated with phenobarbital or in dogs with hyperadrenocorticism. In the latter, it has a high sensitivity but very low specificity, so finding a low steroid-induced isoenzyme rules out hypercortisolism, but a high concentration of steroid-induced isoenzyme may be found in many diseases other than hypercortisolism. Serum GGT activity rises similarly in response to corticosteroid influence but less spectacularly. Serum AP and GGT activities tend to rise in parallel in cholestatic hepatopathies of cats and dogs, although they are much less dramatic in cats. Simultaneous measurement of serum AP and GGT levels may aid in differentiating seemingly benign drug-induced effects from nonicteric cholestatic hepatic disease in dogs. Assessing serum AP and GGT activities together may also offer clues to the type of hepatic disorder in cats. Both enzymes are in low concentration in feline liver tissue compared with that in the canine liver and have short half-lives, so relatively smaller increases in serum activity, especially of GGT, are important signs of the presence of hepatic disease in cats. In cats, a pattern of high serum AP activity with less strikingly abnormal GGT activity is most consistent with hepatic lipidosis (see Chapter 35), although extrahepatic bile duct obstruction (EBDO) must also be considered.

DIAGNOSTIC TESTS TO ASSESS HEPATOBILIARY SYSTEM FUNCTION

Serum Bilirubin Concentration

Because of the large reserve capacity of the mononuclear-phagocytic system and liver to process bilirubin (e.g., 70% hepatectomy will not cause jaundice), hyperbilirubinemia usually occurs only from greatly increased production or decreased excretion of bile pigment. However, in severe chronic liver disease in dogs, hepatocyte senescence may also play a role because senescent cells are no longer able to process bilirubin (Kortum et al., 2018). Specific inborn errors of bilirubin uptake, conjugation, and excretion have not been documented in cats or dogs. The increased production of bilirubin from red blood cell destruction arises from intravascular or extravascular hemolysis and rarely from resorption of a large hematoma; hyperbilirubinemia also occurs in association with rhabdomyolysis or after diffuse subcutaneus bleeding in Greyhounds and other dog breeds. Under these circumstances, in dogs, serum bilirubin concentrations are usually lower than 10 mg/dL; values rarely exceed 10 mg/dL unless there is a concurrent flaw in bilirubin excretion. This has been observed clinically in studies of dogs with immune-mediated hemolytic anemia in which high liver enzyme activities are observed, even before treatment with corticosteroids, and moderately delayed bilirubin excretion has been documented. It has been proposed that cholestasis results from liver injury associated with

hypoxia and, in some cases, because of early disseminated intravascular coagulation (DIC). Because increased production and decreased excretion of bilirubin occur in dogs with severe hemolysis, serum bilirubin concentrations can therefore be as high as 35 mg/dL. Icterus in cats with pure hemolytic disease is an inconsistent finding and, if present, is mild.

Because almost all diseases associated with hyperbilirubinemia in cats and dogs are characterized by a mixture of conjugated and unconjugated bilirubinemia, quantifying the two fractions by the use of the van den Bergh test achieves little in regard to distinguishing primary hepatic or biliary disease from nonhepatobiliary disease in a clinical setting. This lack of benefit in using the van den Bergh test may relate to the time between onset of illness and examination, which is usually at least several days. Under conditions of acute massive hemolysis, the total serum bilirubin concentration may initially consist primarily of the unconjugated form. As hemolysis continues, the liver is able to take up and conjugate bilirubin, accounting for a combination of unconjugated and conjugated bilirubin.

Hyperbilirubinemia is attributed primarily to hemolysis when there is moderate to marked anemia with strong evidence of regeneration (except in the first 1-3 days, when the response is less regenerative) and minimal changes in serum markers of cholestasis. Most dogs and cats with liver disease are not severely anemic.

Serum Bile Acid Concentration

The validation of rapid, technically simple methods for serum bile acid (SBA) analysis in cats and dogs has provided a sensitive, variably specific test of hepatocellular function and the integrity of the enterohepatic portal circulation. Primary bile acids (e.g., cholic, chenodeoxycholic) are synthesized only in the liver, where they are conjugated with various amino acids (primarily taurine) before secretion into the bile. Bile is stored in the gallbladder, where it is concentrated until it is released into the duodenum under the influence of cholecystokinin. After facilitating fat absorption in the small intestine, the primary bile acids are efficiently absorbed into the portal vein and returned to the liver for reuptake and resecretion into the bile. The stored bile acid pool typically circulates twice in this way after a meal. A small percentage of primary bile acids that escapes resorption is converted by intestinal bacteria to secondary bile acids (e.g., deoxycholic, lithocholic), some of which are also resorbed into the portal circulation. Absorption of bile acids by the intestine is extremely efficient, but hepatic extraction from portal venous blood is not. This accounts for the low concentrations of cholic, chenodeoxycholic, and deoxycholic acids that are released into the peripheral blood of healthy cats and dogs in the fasting state—total, <5 µmol/L by the enzymatic method and 5-10 µmol/L by radioimmunoassay (RIA). During a meal, a large load of bile acids is delivered to the intestine and portal circulation for recycling; postprandial values in normal dogs and cats may increase up to threefold to fourfold over fasting values (15 µmol/L with the enzymatic method for cats and dogs; 25 µmol/L with the RIA method for dogs). Normal values for juvenile animals are similar to adult reference ranges. Abnormally high fasting and/or postprandial SBA concentrations reflect a disturbance in hepatic secretion into the bile or at any point along the path of portal venous return to the liver and hepatocellular uptake.

The standard way to assess SBA concentration is outlined in Box 34.3. Collective experience indicates that the likelihood of precipitating an episode of HE during this part of the test is extremely low, even in predisposed animals. After the serum is harvested, the samples may be refrigerated for several days or frozen almost indefinitely before assay. The stability of the blood sample is one of the major advantages over the much more labile serum ammonia test.

Studies of SBAs have confirmed their value in detecting clinically relevant hepatobiliary disease requiring definitive diagnostic testing in cats and dogs, especially in anicteric animals with equivocal clinical signs and unexplained high liver enzyme activity. There continues to be controversy about whether a fasting or postprandial value alone is sufficient or whether fasting and postprandial measurements are required. If only one sample can be obtained, and the animal will eat or can tolerate being force-fed a small meal, the postprandial value is most useful to determine the presence or absence, but not the type, of clinically relevant hepatobiliary disease in most cats and dogs. Current recommendations state that for animals suspected of having acquired hepatobiliary disease, biopsy is needed when the postprandial SBA concentration using the enzymatic method in animals without icterus exceeds 20 µmol/L in cats and 25 µmol/L in dogs. However, other researchers, particularly in the United Kingdom, have suggested that an SBA concentration of between 20 and 40 µmol/L in dogs represents a gray area (Hall et al., 2005). Elevations in this range have been seen

BOX 34.3

Summary of Techniques for Bile Acid Stimulation Test and Postprandial Ammonia Challenge Test

Bile Acid Stimulation Test

Collect a 3-mL blood sample in a serum tube after the animal was fasted for 12 hours.

Feed a small amount of food that is normal in fat content (≈20% fat [dry matter basis] in dogs).

Collect another 3-mL blood sample in a serum tube 2 hours after the meal.

Postprandial Ammonia Challenge Test

Collect a 3-mL blood sample after the animal was fasted for 12 hours.

Feed an amount of food corresponding to 25% of the dog's daily metabolic energy requirement.

Collect another 3-mL blood sample in a serum tube 6 hours after the meal.

with secondary hepatopathies, particularly hyperadrenocorticism, and with small intestinal bacterial overgrowth because of reduced hepatic clearance of deconjugated bile acids. Therefore the author would recommend a liver biopsy with a higher cut-off value of 40 μmol/L for postprandial bile acids. In patients with PSS, the magnitude of elevation does not correlate with the degree of shunting or severity of clinical signs. The change between the fasting and postprandial values likely corresponds to portosystemic shunting, either microscopic (intrahepatic) or macroscopic. There is so much overlap in fasting and postprandial SBA patterns among primary hepatobiliary diseases that no definitive statement can be made regarding the specific causative hepatobiliary disease. Occasionally, fasting SBA levels are higher than postprandial levels, which signify nothing more than occasional, normal, spontaneous gallbladder contraction in fasting. In general, secondary hepatic diseases cause more modest hepatobiliary dysfunction (SBA level < 100 μmol/L). It is very important to remember that elevation of the SBA level has no functional significance in a dog or cat with jaundice of hepatic or posthepatic origin. In these cases, elevations will purely reflect cholestasis, and measuring the SBA level does not provide any further information.

For the diagnosis of congenital PSS, fasting and postprandial SBA level determinations are recommended to enhance detection ability; this is because it is relatively common for fasting values to be well within normal limits and for postprandial values to be as high as 10- to 20-fold higher than normal postprandial values.

Because the measurement of fasting and postprandial SBA concentrations assesses the same functions as the ammonium chloride (NH_4Cl) tolerance test, but without potentially dangerous consequences, it is the preferred method. As with any specially requested test, the laboratory chosen should use methods verified for clinical use in the target species and be able to provide reference ranges.

Several factors may affect SBA levels and therefore their interpretation. One aspect of the SBA challenge test that has not been standardized is the feeding step. The ideal quantity and composition of the test meal have not been determined. Size of the test meal and therefore consumption of the entire meal or only part of the meal may affect gastric emptying. Delayed gastric emptying could cause the peak SBA concentration to occur more than 2 hours later. Hastened or delayed intestinal transit time or the presence of intestinal disease, especially of the ileum, may also impede and blunt peak absorption of the test meal. It is likely that fat content of the test meal is important because fat is the primary stimulus for the small intestinal mucosa to secrete cholecystokinin, which causes gallbladder contraction. Expulsion of bile during periodic physiologic gallbladder contraction between meals may complicate interpretation of the fasted sample result. Lipemia of the sample can seriously affect the validity of the test, particularly on heparinized blood. For this reason, it is far preferable to use serum, both for the external samples and for the SNAP test. It is possible to use erythromycin at a small fraction of the therapeutic antibiotic dose (1-2.5 mg/kg orally) with a meal to increase the stimulation of gallbladder emptying. The effect of this treatment on gallbladder emptying has been studied but not its effect on the bile acid stimulation test.

Several questions remain to be answered regarding the clinical use of SBA level measurement in cats and dogs. Investigation of individual SBA profiles in cats and dogs with various hepatobiliary diseases has provided interesting information but no clear and specific profile for any one disease. Can sequential SBA levels be used to monitor a cat's or dog's progress more precisely? Until this and other questions are answered, the use of SBA analysis is limited to measuring total serum values, in the absence of cholestasis and jaundice, as a sensitive and relatively specific screening test for the presence or absence of clinically significant hepatobiliary disease and/or congenital or acquired portosystemic shunting. Additional diagnostic testing must always follow to identify the specific cause.

Urinary Bile Acid Concentration

Determination of bile acids accumulating in urine over time can be used to assess hepatobiliary function. Urine bile acids are believed to reflect average SBA concentrations during the interval of urine formation. Expressing urine bile acid concentrations as a ratio with the urine creatinine concentration eliminates the influence of urine concentration and flow. Random urine sampling for bile acid determination does not require attending to the timing of an enterohepatic challenge or obtaining a sample after withholding food. Studies of urinary bile acid concentrations have shown that they were increased in dogs and cats with hepatobiliary disease and portosystemic vascular anomalies compared with dogs and cats with nonhepatic disorders, except for hepatic neoplasia in dogs. The urine nonsulfated bile acid–to–creatinine ratio and the urine sulfated plus nonsulfated bile acid–to–creatinine ratio positively correlated with SBA test results and had similar overall diagnostic performance and substantially higher (dogs) or similar (cats) specificity compared with the SBA test. Therefore these are recommended. The urine sulfated bile acid–to–creatinine ratio had lower sensitivity in dogs and cats compared with the SBA test.

Plasma Ammonia Concentration

One test that is not included in a standard screening battery of tests but is available through reference laboratories is plasma ammonia concentration. Fasting plasma ammonia can be measured in any cat or dog with historic or physical examination findings suggestive of HE. Signs of HE, whether they have a congenital or acquired basis, appear the same (see Box 33.3). Quantifying the plasma ammonia concentration not only can confirm HE, although normal fasting values in animals with hepatobiliary disease are relatively common, but can also provide baseline data and help in evaluating response to treatment. SBA values, particularly postprandial levels, provide similar information in dogs with congenital PSS. A high plasma ammonia concentration usually indicates reduced hepatic mass available to process

ammonia and/or the presence of portosystemic shunting, which disrupts presentation of ammonia to the liver for detoxification. However, ammonia is very labile in the blood sample and can be falsely elevated—for example, if the blood sample is taken in an environment contaminated with urine. Sample handling has to be undertaken with caution, and some benchtop analyzers are inaccurate, particularly in the moderately elevated range. For these reasons, determination of SBA levels is often a preferred test. The exception to this would be an animal with suspected HE and concurrent cholestasis. As outlined in the preceding paragraphs, bile acid concentrations will be high in cholestasis because they are excreted in the bile, independent of any reduction in liver function or shunting. Measuring blood ammonia in these cases will provide useful additional information about potential shunting and HE.

In one study, the 12-hour fasting plasma ammonia concentration had higher sensitivity and specificity than the 12-hour fasting bile acid concentration for detecting portosystemic shunting in a general population of dogs and in dogs with liver disease. However, a bile acid stimulation test (fasting and 2-hour postprandial bile acid) has a much higher sensitivity for detecting a PSS than a single fasting bile acid, and a single postprandial bile acid concentration is likely as sensitive as a fasting ammonia concentration, although the author did not test this.

Although reference ranges vary among laboratories, fasting plasma ammonia values for normal dogs are typically 100 mg/dL or less and 90 mg/dL or less for normal cats. At least 6 hours of fasting should precede sample collection. Samples must be collected into iced ammonia-free heparinized tubes and spun immediately in a refrigerated centrifuge. Plasma must be removed within 30 minutes so that values will not be spuriously elevated by hemolysis because red blood cells contain two to three times the ammonia concentration of plasma. To obtain accurate values, feline plasma can be frozen at –20° C and assayed within 48 hours; canine plasma must be assayed within 30 minutes.

If signs are compatible with HE at the time of sample collection, a single fasting sample will suffice. If there are no signs of HE and results of other tests are equivocal, a postprandial challenge test may be performed (see Box 34.3). The older ammonium chloride challenge tests (oral or rectal) are contraindicated because of the significant potential for either test to trigger a severe encephalopathic crisis in the patient. The postprandial ammonia test is safer, with a 91% sensitivity for portosystemic shunting but only a 31% sensitivity for diffuse hepatocellular disease.

Plasma Protein C Activity

Plasma protein C activity has been evaluated as a marker of hepatobiliary disease in dogs. Protein C is an anticoagulant protein that is synthesized in the liver and circulates as a plasma zymogen. Low protein C activity has been associated with thrombotic disorders in humans and animals. Low protein C activity has also been documented in dogs with acquired and congenital hepatobiliary disorders, and dogs with a PSS appear to have the lowest protein C activity. In a study by Toulza et al. (2006), protein C activity was significantly lower in dogs with a congenital or acquired PSS, compared with dogs without a PSS. Plasma protein C activity improved or normalized after surgery for the shunt. These findings suggest that plasma protein C activity reflects the adequacy of hepatoportal perfusion in dogs and that protein C activity may prove useful as a means to monitor improvement of hepatic-portal perfusion after the ligation of portosystemic vascular anomalies. Plasma protein C activity may also help differentiate dogs with intrahepatic portal vein hypoplasia from those with portal systemic vascular anomaly—plasma protein C activity, ≥70% versus <70%, respectively.

NONSPECIFIC TESTS OF LIVER FUNCTION

Serum Albumin Concentration

The liver is almost the only source of albumin production in the body, so hypoalbuminemia can be a manifestation of hepatic inability to synthesize this protein. Causes other than lack of hepatic synthesis (i.e., marked glomerular or GI loss, or bleeding) must be considered before ascribing hypoalbuminemia to hepatic insufficiency. Renal protein loss can be detected presumptively by routine urinalysis. Consistent identification of positive protein dipstick reactions, especially in dilute urine with inactive sediment, justifies further evaluation by at least the measurement of the random urine protein-to-creatinine ratio (normal ratio, <0.2 in cats and dogs). If proteinuria is ruled out, diseases that cause GI protein loss should be considered; however, these GI diseases usually result in an equivalent loss of globulins and thus panhypoproteinemia. This is not invariably the case in inflammatory GI disease, in which a concurrent increase in gamma globulin levels masks the gut loss. Conversely, although panhypoproteinemia is reportedly not typical of hypoproteinemia of hepatic origin, globulin concentrations can be low in liver disease, particularly portosystemic shunts (PSS), because all plasma globulins except gamma globulins are made in the liver. Globulin concentrations frequently are normal to increased in dogs and cats with chronic inflammatory hepatic disease because they reflect the inflammatory response. The plasma half-life of albumin in cats and dogs is long (8-10 days), and there must be a loss of approximately 80% of functioning hepatocytes before hypoalbuminemia occurs, so the finding of hypoalbuminemia usually indicates severe chronic hepatic insufficiency.

The exception to this is the hypoalbuminemia associated with a negative acute phase response in acute or acute-on-chronic inflammatory liver disease. The serum albumin concentration can decrease when there is an increase in hepatic production of acute phase proteins in animals without hepatic insufficiency. Serum protein electrophoresis can help differentiate this condition from a true lack of hepatic function. Sevelius and Andersson (1995) have shown that a low albumin concentration associated with a low concentration

of acute-phase proteins in electrophoresis indicates severe hepatic dysfunction with a poor prognosis, whereas hypoalbuminemia combined with normal or elevated acute-phase protein levels indicates a good prognosis. Hypoalbuminemia of any cause is unusual in cats, except in those with nephrotic syndrome. When interpreting serum protein concentrations, the clinician should remember that total protein values for young cats and dogs are lower than those for adults, and puppy serum albumin concentration is similar to that in adults, whereas kitten serum albumin concentration is lower than that in adult cats.

Serum Urea Nitrogen Concentration

The formation of urea as a means of detoxifying ammonia derived from intestinal sources takes place only in the liver. Despite this apparent advantage as a specific measure of hepatic function, serum urea concentration is commonly affected by several nonhepatic factors; the capability of the liver to detoxify urea is so great that it is not noticeably reduced until severe, extensive end-stage liver disease has developed. Prolonged, restricted protein intake because of complete anorexia or intentional reduction in protein intake for therapeutic purposes (e.g., chronic kidney disease; urate, cystine, or struvite urolithiasis) is the most common cause of low blood urea nitrogen (BUN) concentration. Prior fluid therapy and/or marked polydipsia or polyuria of nonrenal causes will also result in a decrease in the BUN level. As always, reference ranges should be considered for each species when interpreting BUN values. For example, a BUN concentration of 12 mg/dL is well within normal limits for dogs but is subnormal for cats. If low BUN levels are noted in a cat or dog with normal water intake and a good appetite for a diet with the appropriate protein content for the species (on a dry matter basis, 22% for dogs and 35%-40% for cats), the possibility of hepatic inability to convert ammonia to urea or portosystemic shunting of ammonia away from the liver should be investigated.

Serum Cholesterol Concentration

Total cholesterol concentration is included in serum chemistry profiles by many commercial laboratories but affords useful information for only a limited number of hepatobiliary diseases. High total cholesterol values are observed in cats and dogs with severe intrahepatic cholestasis involving bile ducts or EBDO because of impaired excretion of free cholesterol into the bile and subsequent regurgitation into the blood. Hypocholesterolemia has been documented in dogs with chronic severe hepatocellular disease and frequently in cats and dogs with congenital PSS. It has been speculated that hypocholesterolemia is a sign of markedly altered intestinal absorption of (and increased use of) cholesterol for bile acid synthesis when the enterohepatic recirculation of bile acids is disturbed, as occurs with PSS. In other hepatobiliary diseases of cats and dogs, the total cholesterol values vary considerably. Normal values in 4-week-old kittens are higher than those for adults; 8-week-old puppy reference ranges are the same as those for adults.

Serum Glucose Concentration

Hypoglycemia is an unusual event associated with hepatobiliary disease in dogs and especially in cats. There is a lost ability to maintain normal serum glucose concentrations in animals with acquired chronic progressive hepatobiliary disease when 20% of the functional hepatic mass or less remains. This inability to maintain a normal serum glucose concentration is presumably caused by the loss of hepatocytes with functioning gluconeogenic and glycolytic enzyme systems and impaired hepatic degradation of insulin. Hepatocyte senescence may also play a role. Hypoglycemia is often a near-terminal event in dogs with chronic progressive hepatobiliary disease. In striking contrast is the frequent observation of hypoglycemia in dogs with congenital PSS, particularly small-breed dogs. Hypoglycemia in patients with PSS has been suggested to be the result of an increase in circulating insulin concentration caused by reduced first-pass metabolism in the liver, as observed in humans, but a more recent study showed normal to low insulin concentration in dogs with PSS and hypoglycemia, which did not support this hypothesis, so the cause remains unknown. Hypoglycemia is also common as a paraneoplastic syndrome in dogs with large hepatocellular carcinomas and can be associated with the production of insulin-like growth factor by the tumor. In either case, if hypoglycemia is identified and confirmed by repeating the test using sodium fluoride, if necessary, and if nonhepatic causes (e.g., functional hypoglycemia, sepsis, insulinoma or other neoplasm producing an insulin-like substance, or Addison disease; see Chapter 50) are excluded, a primary hepatic tumor (e.g., hepatocellular carcinoma), PSS, or severe generalized hepatopathy is suspected.

DIAGNOSTIC TESTS TO ASSESS PANCREATIC INFLAMMATION AND FUNCTION

Specific Tests of Pancreatic Inflammation

The most specific tests for the pancreas are the catalytic assays for amylase and lipase and the immunoassays for trypsin-like immunoreactivity (TLI) and pancreatic lipase immunoreactivity (PLI). Catalytic assays rely on the ability of the molecule to catalyze a reaction in vivo and thus rely on the presence of active enzyme; however, they are not species-specific. The sensitivity and specificity of the traditional catalytic assays in dogs are relatively poor, particularly for amylase, and in cats, traditional amylase and lipase are of questionable diagnostic value. However, recently a new lipase assay has been developed, which appears to be more sensitive and specific than the traditional lipase and also shows very good agreement with PLI. This is the 1,2-o-dilauryl-rac-glycero glutaric acid-(6′-methylresorufin) ester (DGGR) lipase assay. The enzyme and substrate interactions in this assay are more selective than with the traditional multistep colorimetric lipase assay that uses 1,2-diglyceride (1,2-DiG) as the substrate. It is proposed that, with the new assay, hydrolysis with other lipases and

esterases is less likely to occur. Recent studies in dogs suggested good agreement between the DGGR lipase assay and PLI (Kook et al., 2014; Goodband et al. (2018)) and two other studies suggests that it may also be useful in cats, unlike the older lipase assay (Oppliger et al., 2013 and 2014).

Immunoassays, however, use an antibody against a part of the enzyme molecule distant from the active site and thus will also measure inactive precursors (e.g., trypsinogen); these tend to be organ- and species-specific. The advantages and disadvantages of the different assays are outlined in Table 34.2. Overall, PLI has the highest sensitivity and likely the highest specificity in both species. Recent studies of PLI for the diagnosis of acute pancreatitis in dogs suggest a sensitivity of between 86.5% and 94.1% and a specificity of 80% to 90% or 66.3% to 77.5%, depending on the cut-off and methodology used in the studies, respectively (Mansfield et al., 2012; McCord et al., 2012). The positive predictive value is high in animals with a high likelihood of acute

TABLE 34.2

Catalytic Enzyme Tests and Immunoassays in the Diagnosis of Acute and Chronic Pancreatitis in Dogs and Cats

ASSAY	ADVANTAGES	DISADVANTAGES
Catalytic Assays		
Dogs only; of no use in cats except for DGGR lipase (see following and text for more details)		May be normal in severe ± chronic pancreatitis caused by enzyme depletion ± loss of tissue; degree of elevation of no prognostic value, except where stated; both renally excreted and elevated two or three times in azotemia
Amylase	Widely available on in-house analyzers; steroids do not elevate it, so can help diagnose pancreatitis in dog with hyperadrenocorticism	Low sensitivity and specificity because of high background level from other sources, including small intestine
Lipase	Widely available on practice analyzers; more sensitive than amylase; degree of elevation may have prognostic significance New DGGR lipase has higher sensitivity and specificity than older assays and correlates well with PLI in both dogs and cats (see details in text)	Extrapancreatic sources so high background level Steroids elevate up to five times
Immunoassays		
Canine TLI	Elevations—high specificity for pancreatitis	Low sensitivity for diagnosis of pancreatitis (but high sensitivity for EPI); said to rise and fall more quickly than lipase or amylase; renally excreted: elevated two or three times in azotemia May be inappropriately low in severe ± chronic cases caused by pancreatic depletion ± loss of tissue mass; no clear prognostic significance
Feline TLI	No advantages for diagnosis of pancreatitis— reserve for diagnosis of EPI	Lower sensitivity and specificity than canine TLI, better used for diagnosis of EPI; renally excreted so elevated in azotemia
Canine PLI	Most sensitive and specific test for canine pancreatitis together with DGGR lipase (see text for figures); organ-specific, so no interference from extrapancreatic sources Available as in-house test (see URL in text)	Increased in renal disease but may not be significantly increased (?) (unclear yet if affected by steroids)
Feline PLI	Most sensitive and specific test available for feline pancreatitis, together with DGGR lipase (see text for figures); available as in-house test (see URL in text)	Very little published data yet available on its use

PLI, Pancreatic lipase immunoreactivity; *TLI*, trypsin-like immunoreactivity.

pancreatitis, but the negative predictive value in this population is unclear, as negative predictive value has only been shown to be high in a population with low prevalence of disease (McCord et al., 2012). In the author's experience, a negative PLI is uncommon in dogs with severe acute pancreatitis but does occur, so pancreatitis should not be completely ruled out by a negative result. A single study in cats showed the test to have 100% sensitivity in moderate to severe acute pancreatitis but only 54% for mild pancreatitis, with a specificity of 91% (Forman et al., 2004). However, the sensitivity is lower in chronic pancreatitis in dogs and cats. SNAP tests for canine and feline PLI are commercially available (see details at https://www.idexx.com/small-animal-health/products-and-services/snap-cpl-test.html for dogs and https://www.idexx.com/small-animal-health/products-and-services/snap-fpl-test.html for cats), which should aid in rapid diagnosis in both species.

Tests of Pancreatic Exocrine Function

Exocrine pancreatic insufficiency (EPI) can develop in dogs and cats as a result of chronic pancreatitis and in dogs with PAA (see Chapter 37 for more details). The diagnosis of EPI in dogs and cats relies on showing consistent clinical signs (weight loss and steatorrhea) combined with demonstrating reduced pancreatic enzyme output. The most sensitive and specific way of doing this is by measuring reduction in circulating enzyme activity. This is achieved by use of the immunoassay TLI, which measures both trypsin and trypsinogen. Measurement of decreased TLI in the blood has a high sensitivity and specificity for the diagnosis of EPI in dogs and cats, and is currently the single test of choice for diagnosis in small animals. It is important to measure it on a fasting sample because the release of pancreatic enzymes associated with feeding can raise the activity in the serum. It is not necessary to stop exogenous pancreatic enzyme supplementation before measuring TLI because exogenous enzymes should not be absorbed from the gut into the circulation; even if they are, the test is an immunoassay that does not cross-react with the trypsin or trypsinogen of other species in the supplement. However, there are some problems in interpreting the results, as shown in Box 37.3. In particular, in a dog with ongoing chronic pancreatitis and EPI, the TLI will be unpredictable because bouts of pancreatic inflammation can raise it in to the normal range.

Unlike in humans, amylase and lipase levels are not consistently low in dogs and cats with EPI because of the high background levels of enzymes from other organs. A low cPLI also has a good sensitivity and specificity for the diagnosis of EPI in dogs (Steiner et al., 2001). However, this test is not superior to TLI. PLI is also likely to be low in cats with EPI.

Fecal tests for EPI are rarely used because of their low sensitivity and specificity compared with serum tests. Measuring fecal trypsin levels has a very low sensitivity and specificity for EPI, as do assessment of fecal proteolytic activity or microscopic examination of feces for undigested fat, starch, and muscle fibers. All these tests have been superseded by the measurement of serum TLI and cPLI. Measurement of fecal elastase may have some usefulness in dogs with EPI as a result of chronic pancreatitis or duct blockage, in which TLI results may be misleading. Elastase testing appears to have higher sensitivity and specificity than the other fecal tests for the diagnosis of EPI in dogs. Elastase is a pancreatic enzyme, and a species-specific ELISA for canine elastase is available for commercial use in dogs (ScheBo Biotech USA Inc, PMB 168, 445 E Cheyenne Mountain Blvd., Suite C, Colorado Springs, CO 80906, USA; Spillmann et al., 2000, 2001). There is also a bed-side elastase ELISA test available now: ScheBo Elastase 1 Quick–Canine rapid (available to vets in the United States through http://catacheminc.com/veterinary-diagnostics/schebo-pancreas-elastase). This test is also being marketed online for owner use.

As with canine TLI, because there is no cross-reaction with elastase from other species, dogs can remain on enzyme supplementation while the test is performed. There is marked variation in elastase levels in normal canine feces compared with humans. The sensitivity and specificity of the test are improved by taking three separate fecal samples on 3 days or using a cut-off value for the diagnosis of EPI, which is below this variation in most dogs.

It is also advisable to measure the serum cobalamin concentration in animals with EPI because it is often decreased due to a deficiency of pancreatic intrinsic factor. Dogs produce most intrinsic factor in the pancreas but a small amount in the stomach, whereas cats produce all their intrinsic factor in the pancreas. Cobalamin bound to intrinsic factor is absorbed in the ileum so concurrent inflammatory bowel disease affecting the ileum will also predispose to deficiency. Cats with EPI as an end stage of chronic pancreatitis should therefore always be cobalamin deficient, particularly if they have concurrent inflammatory bowel disease. However, normal concentrations are often found in affected cats, presumably because of persistence of liver stores.

Tests of Pancreatic Endocrine Function

End-stage chronic pancreatitis in dogs and cats can result in a loss of endocrine function and diabetes mellitus. For details of tests of pancreatic endocrine function, see the chapter on diabetes mellitus (Chapter 49).

NONSPECIFIC TESTS IMPORTANT FOR PROGNOSIS AND SUPPORTIVE CARE IN BOTH LIVER AND PANCREAS DISEASE

Nonspecific changes in serum biochemistry, particularly electrolytes and urea and creatinine, are important for supportive care of dogs and cats with pancreas and liver disease, particularly acute hepatitis and acute pancreatitis, where multiorgan failure is a possible sequela. Likewise, assessment of a CBC, particularly PCV and platelet count, and coagulation status are important to check for significant intestinal bleeding and/or coagulopathy in acute or chronic pancreatitis or hepatitis.

Serum Biochemistry

Alterations in urea, glucose, cholesterol, and albumin as nonspecific indicators of liver function have been considered in the previous section. Azotemia may also occur in acute liver disease as a result of multiorgan failure, although when azotemia occurs in the context of acute liver disease in dogs, leptospirosis is important to rule out (see Chapter 36), particularly if there is concurrent glycosuria and thrombocytopenia.

In acute pancreatitis, azotemia is very common and is usually prerenal due to dehydration or shock, although intrinsic renal damage may also occur. This and other common changes in serum biochemistry in acute pancreatitis in dogs and cats are detailed in Table 34.3. It is particularly important to monitor electrolyte concentrations in animals with acute pancreatitis because hypokalemia is common and potentially life-threatening. Hypokalemia is also relatively common in hepatobiliary disease where it is attributed to a

TABLE 34.3

Typical Clinicopathologic Findings in Dogs and Cats With Acute Pancreatitis

PARAMETER	CHANGES IN DOGS	CHANGES IN CATS	CAUSE AND SIGNIFICANCE
Urea ± creatinine	Increased in 50%-65% of cases	Urea increased in 57% of cases and creatinine in 33%	Usually prerenal because of dehydration and hypotension (urea > creatinine), indicates need for aggressive fluid therapy Often also some intrinsic renal failure (sepsis and immune complexes)
Potassium	Decreased in 20% of cases	Decreased in 56% of cases	Increased loss in vomiting and renal loss with fluid therapy + reduced intake and aldosterone release caused by hypovolemia Requires treatment because it contributes to gastrointestinal atony
Sodium	Can be increased (12%), decreased (33%), or normal	Usually normal or decreased (23%) Increased only in 4% of cases	Increase caused by dehydration; decrease caused by loss in gastrointestinal secretions with vomiting
Chloride	Very commonly decreased (81%)	Unknown	Loss in gastrointestinal secretions with vomiting
Calcium	Increased in ≈9% of cases and decreased in ≈3% of cases	Total calcium reduced in 40% to 45% of cases; ionized calcium reduced in 60% of cases; total calcium increased in 5%	Reduction poor prognostic indicator in cats but of no prognostic significance in dogs; caused by saponification in peripancreatic fat (unproven) and glucagon release, stimulating calcitonin in some Increased calcium likely cause rather than effect of disease in cats, but unproven in dogs
Phosphate	Often increased (55%)	Increased in 27%, decreased in 14%	Increase usually caused by reduced renal excretion secondary to renal compromise; decrease (in cats) caused by treatment for diabetes mellitus
Glucose	Increased in 30%-88%, decreased in up to 40%	Increased in 64%, very rarely decreased	Increased because of decreased insulin and increased glucagon, cortisol, and catecholamines; about 50% return to normal; decreases caused by sepsis and anorexia
Albumin	Increased in 39%-50%, reduced in 17%	Increased in 8%-30%, reduced in 24%	Increase caused by dehydration; decrease caused by gut loss, malnutrition, concurrent liver disease, or renal loss
Hepatocellular enzymes (ALT and AST)	Increased in 61%	Increased in 68%	Hepatic necrosis and vacuolation caused by sepsis, local effects of pancreatic enzymes ± concurrent hepatic disease in cats
Cholestatic enzymes (ALP and GGT)	Increased in 79%	Increased in 50%	Biliary obstruction caused by acute-on-chronic pancreatitis ± concurrent cholangitis ± lipidosis in cats; steroid-induced ALP in dogs

Continued

TABLE 34.3

Typical Clinicopathologic Findings in Dogs and Cats With Acute Pancreatitis—cont'd

PARAMETER	CHANGES IN DOGS	CHANGES IN CATS	CAUSE AND SIGNIFICANCE
Bilirubin	Increased in 53%	Increased in 64%	Same as GGT
Cholesterol	Increased in 48%-80%	Increased in 64%	Can be caused by cholestasis; unclear in others if cause or effect; often caused by concurrent or predisposing disease
Triglycerides	Commonly increased	Rarely measured	Unclear if cause or effect; often caused by concurrent or predisposing disease
Neutrophils	Increased in 55%-60%	Increased in about 30%, decreased in 15%	Increase caused by inflammatory response; decrease in some cats caused by consumption; may be poor prognostic indicator
Hematocrit	Increased in ≈20% and decreased in ≈20%	As dogs	Increase caused by dehydration; decrease caused by anemia of chronic disease; gastrointestinal ulceration
Platelets	Commonly decreased in severe cases (59%)	Usually normal	Decrease caused by circulating proteases ± disseminated intravascular coagulation

ALP, Alkaline phosphatase; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *GGT,* γ-glutamyltranspeptidase.
Data from Schaer M: A clinicopathological survey of acute pancreatitis in 30 dogs and 5 cats, *J Am Anim Hosp Assoc* 15:681, 1979; Hill RC et al: Acute necrotizing pancreatitis and acute suppurative pancreatitis in the cat: a retrospective study of 40 cases (1976-1989), *J Vet Intern Med* 7:25, 1993; Hess RS et al: Clinicopathological, radiographic and ultrasonographic abnormalities in dogs with fatal acute pancreatitis: 70 cases (1986-1995), *J Am Vet Med Assoc* 213:665, 1998; Mansfield CS et al: Review of feline pancreatitis. combination of excessive renal and GI losses, reduced intake, and secondary hyperaldosteronism in dogs and cats with severe chronic hepatobiliary disease. Metabolic alkalosis, presumptive evidence of which might be an abnormally high serum total carbon dioxide content confirmed by blood gas analysis, is usually caused by overzealous diuretic therapy in dogs with chronic hepatic failure and ascites. Hypokalemia and metabolic alkalosis potentiate each other and may also worsen signs of hepatic encephalopathy (HE) by promoting the persistence of readily membrane-diffusible ammonia (NH_3).

COMPLETE BLOOD COUNT

There are few changes in blood cells that suggest hepatobiliary disease. Most are changes in erythrocytes associated with fragmentation or changes in cell size or membrane composition. Microcytosis (mean corpuscular volume [MCV] < 60 fL in canine breeds other than the Japanese Akita or Shiba Inu), with normochromasia or slight hypochromasia (mean cell hemoglobin concentration, 32-34 g/dL), is a common finding in dogs with congenital PSS (≥60%); it is less common in cats with congenital PSS (≤30%). Most affected animals are not anemic. The cause of microcytosis, which has also been observed with less frequency in dogs with chronic hepatic failure and acquired PSS, is chelation of iron in the liver rather than absolute iron deficiency; therefore iron supplementation does not help. However, the change in the size of red blood cells is reversible upon restoration of portal blood flow. If anemia is also present, microcytosis must be distinguished from anemia of inflammatory disease, which can occasionally cause small red blood cells and relative iron deficiency, or from iron deficiency anemia associated with chronic GI blood loss, which might particularly be seen in a dog with chronic hepatitis and portal hypertension (see Chapter 36). The anemia sometimes seen in association with the microcytosis of PSS is usually mild. A marked microcytic anemia greatly increases the index of suspicion for chronic GI blood loss.

Strongly regenerative anemia, with macrocytosis, high reticulocyte count, and normal to slightly increased serum protein concentration in a jaundiced dog, especially if spherocytes are also identified, indicates hemolytic anemia and increased bilirubin formation as the cause of jaundice. Cats and dogs with hemolytic anemia typically also have high serum liver enzyme and bile acid concentrations, which indicate hepatic consequences developing secondary to the effects of marked hemolysis, such as hypoxia and thromboembolism.

Certain red blood cell morphologic changes are consistent with serious hepatobiliary disease and are related to alterations in lipoprotein metabolism and irregularities in red blood cell membrane structure. Poikilocytes (abnormally shaped red blood cells), such as acanthocytes (spiked red blood cells), leptocytes (elongated, pale staining red blood

cells), and codocytes (target cells) are good examples. Poikilocytosis of unknown pathogenesis is a consistent finding in cats with congenital PSS and occasionally with other hepatobiliary diseases; cats with chronic hepatobiliary disease frequently have Heinz bodies in their red blood cells. Fragmented red blood cells or schistocytes constitute an expected finding in animals with DIC; hemangiosarcoma is considered when an inappropriate number of nucleated red blood cells is also detected. Mild to moderate nonregenerative anemia is common in cats with many different illnesses, including those of the hepatobiliary tract.

Few changes in the leukon are expected in cats or dogs with hepatobiliary disease, except when an infectious agent is present as the initiating event (histoplasmosis, bacterial cholangitis, or leptospirosis in dogs), where there is concurrent pancreatitis, which is particularly common in cats, or when infection has complicated a primary hepatobiliary disorder (e.g., gram-negative sepsis in a dog with cirrhosis, septic bile peritonitis). Neutrophilic leukocytosis is likely in such cases, whereas pancytopenia is typical of disseminated histoplasmosis and severe toxoplasmosis in cats and of early infectious canine hepatitis.

In contrast, neutrophilic leukocytosis is very common in dogs with pancreatitis, reported in 55% to 60% of cases but only 30% of cases in cats (see Table 34.3).

COAGULATION TESTS

Clinically relevant coagulopathies are unusual in cats and dogs with hepatobiliary disease except for those with acute hepatic failure (including acute hepatic lipidosis in cats or hepatic lymphoma in both species), complete EBDO, or active DIC. It is more common to have subtle prolongation of activated partial thromboplastin time (APTT; 1.5 times normal), abnormal fibrin degradation products (10-40 µg/mL or more), and variable fibrinogen concentration (<100-200 mg/dL) in cats and dogs with severe parenchymal hepatic disease. Elevated D-dimers are common in patients with liver disease and do not always indicate DIC in these cases. It has been proposed that nonspecific elevation can occur in liver disease as a result of reduced clearance by the liver. Platelet numbers may be normal or low; mild thrombocytopenia (130,000-150,000 cells/µL) is usually associated with splenic sequestration or chronic DIC. More severe thrombocytopenia (≤100,000 cells/µL) is expected in acute DIC or decompensated chronic DIC.

Primary or metastatic cancer of the liver could also cause coagulopathy unrelated to a loss of hepatocellular ability to make or degrade coagulation proteins. A recent study evaluating thromboelastography (TEG) in dogs with partial or complete extrahepatic biliary obstruction found that all 10 affected dogs were hypercoagulable compared with 19 normal dogs, which was perhaps the opposite of the expected result (Mayhew et al., 2013). In contrast, TEG results in dogs with chronic hepatitis were found to be very variable, with some dogs being hypercoagulable, some normocogulable, and some hypocoagulable, and dogs with negative prognostic indicators tended to be hypocoagulable (Fry et al., 2017). Dogs with acute liver disease also had a variety of TEG results although with a predominance of hypocoagulable and hyperfibrinolytic results, particularly as functional impairment occurred (Kelley et al., 2015).

Abnormal coagulation function and thrombocytopenia are common in dogs with severe acute pancreatitis and suggest the development of DIC, although recent systematic studies of coagulation in dogs and cats with acute pancreatitis are lacking. In one study, pancreatitis was a common diagnosis in dogs with low blood antithrombin activity suggesting an increased risk of hypercoagulability and thrombosis, although there was no significant difference in antithrombin activity between survivors and nonsurvivors with pancreatitis (Kuzi et al., 2010).

ABDOMINOCENTESIS—FLUID ANALYSIS—IN LIVER AND PANCREAS DISEASE

If abdominal fluid is detected during physical examination, abdominal radiography, or US, a sample must always be obtained for analysis. For moderate- to large-volume effusion, simple needle paracentesis is sufficient to obtain 5 to 10 mL of fluid for gross inspection, determination of protein content, cytologic evaluation, and, in selected cases, special biochemical analysis. Pancreatitis is usually associated with small volume effusions whereas liver disease can be associated with large volumes.

Removal of a significant volume of abdominal fluid for clinical reasons should be avoided unless it is absolutely necessary because this often causes a precipitous decrease in serum protein concentrations in animals with liver disease because of the inability of the liver to replace proteins removed in the fluid. It is preferable in cases other than peritonitis to remove fluid gradually, using diuretics. In cases in which large-volume fluid removal is necessary (e.g., in peritonitis), concurrent administration of fresh-frozen plasma or a colloid solution is essential to replace protein lost. In dogs with chronic hepatic failure and sustained intrahepatic portal hypertension, abdominal fluid is usually a modified transudate with a moderate nucleated cell count and protein content (Table 34.4). A pure transudate with a low cell count (<2500 cells/µL) and protein concentration (<2.5 g/dL), and a clear, minimally colored appearance, are noted when the dog is hypoproteinemic. Abdominal fluid in dogs with intrahepatic postsinusoidal venous obstruction (e.g., venoocclusive disease) or posthepatic venous obstruction (e.g., any cause of right-sided heart failure) can be any color but is typically red- or yellow-tinged and is classified as a modified transudate. Feline infectious peritonitis fluid and neoplastic effusions are also commonly classified as modified transudates or nonseptic exudates. Bile peritonitis also results in an exudate, which is initially sterile but can become septic with time. Measuring bilirubin concentration in the fluid helps with diagnosis. With neoplasia, effusions can occasionally be chylous or even hemorrhagic, and the latter can also be seen in amyloidosis as a result of rupture of the liver capsule. Reactive mesothelial cells can be

TABLE 34.4

Characteristics of Abdominal Effusion in Hepatobiliary Disease

TYPE OF EFFUSION	APPEARANCE	NUCLEATED CELL COUNT	PROTEIN CONTENT	SPECIFIC GRAVITY	EXAMPLE(S)
Transudate					
Pure	Clear, colorless	<1500/µL	<2.5 g/dL	<1.016	Chronic hepatic failure with marked hypoalbuminemia
Modified	Serosanguineous, amber	<7000/µL	≥2.5 g/dL	1.010-1.031	Chronic hepatic failure, right-sided heart failure, pericardial disease, caval syndrome, Budd-Chiari–like syndrome, intrahepatic portal vein hypoplasia, chronic portal vein thrombosis, feline infectious peritonitis (some cases), neoplasia (some cases), pancreatitis (some cases)
Exudate					
Septic	Cloudy; red, dark yellow, green	>7000/µL	≥2.5 g/dL	1.020-1.031	Perforated duodenal ulcer, bile peritonitis (fluid bilirubin concentration > serum bilirubin concentration)
Nonseptic	Clear; red, dark yellow, green	>7000/µL	≥2.5 g/dL	1.017-1.031	Feline infectious peritonitis, neoplasia with serosal involvement, ruptured hemangiosarcoma, early bile peritonitis, pancreatitis with EBDO
Effusion					
Chylous	Opaque, white to pink ("strawberry milkshake")	Variable; usually 1000-10,000/µL	Variable; 2.5-6.5 g/dL	1.030-1.032	Neoplasia (some cases), diseases obstructing lymphatic drainage
Hemorrhagic	Red	Variable; usually 1500 to 1000/µL	Usually >3.0 g/dL	<1.013	Neoplasia (some cases), amyloidosis with hepatic capsule rupture, ruptured hemangiosarcoma

EBDO, Extrahepatic bile duct obstruction.

mistaken for neoplastic cells, emphasizing the need for experience in evaluating cytologic specimens. Exudates have a high cell count (>20,000 cells/µL) and protein content (>2.5 g/dL) and, on the basis of whether the inflammatory cells look toxic or contain ingested bacteria, are further classified as septic or nonseptic. Fluid analysis provides additional clues to the origin of the hepatobiliary disease and must not be overlooked. A guide to interpreting fluid analysis results is given in Table 34.4.

Abdominal effusions are common in dogs and cats with pancreatitis but are usually of small volume. Effusions form as a result of peritonitis but also vasculitis, which may explain why some animals with pancreatitis have pleural as well as peritoneal fluid. The effusions are usually serosanguineous exudates, although modified transudates and chylous effusions have been reported, particularly in cats. Lipase, amylase, and PLI concentrations may be elevated in the fluid and may be much higher than the serum, helping the diagnosis of pancreatitis. Importantly, measuring pancreatic enzymes in the fluid helps differentiate the cause of a sterile exudate from the other possibilities of bile peritonitis or urinary tract leakage.

URINALYSIS

In pancreatitis, urinalysis is important to differentiate prerenal from intrinsic renal disease, so ideally a urine sample should be taken before fluid therapy. A high urine specific gravity (SG) with azotaemia suggests acute prerenal failure due to dehydration and shock. However, dogs with severe

pancreatitis often have poorly concentrated or even isosthenuric urine, suggesting concurrent intrinsic renal damage. Proteinuria is reported in up to 78% of dogs with acute pancreatitis (Hess et al., 1998), probably due to a combination of systemic inflammation and tubular damage. In English Cocker Spaniels with chronic and acute-on-chronic pancreatitis, glomerulonephritis is often also recognized as part of a polysystemic immune-mediated disease targeting ducts, and affected dogs should be screened for proteinuria. Finding glucose in the urine in a dog or cat with pancreatitis will raise the suspicion of diabetes mellitus. Glucosuria can be transient during a bout of pancreatitis, presumably due to insulin resistance and stress. This is rare in dogs but anecdotally more common in cats. Diabetes mellitus can be differentiated from stress by concurrent measurement of serum fructosamine, assessment of the urine for ketones and careful monitoring of blood and urine glucose during recovery. The presence of ketones, in addition to glucosuria, in the urine in both dogs and cats with pancreatitis usually indicates diabetic ketoacidosis, which requires immediate and urgent treatment. Ketonuria is occasionally seen in dogs and cats with negative calorie balance that have depleted their hepatic glycogen reserves, but concurrent glucosuria would be very unusual in these circumstances as these animals are usually hypoglycemic.

Common findings in urinalysis consistent with hepatobiliary disease include excessive bilirubinuria in a nonanemic dog (≥2+ in urine of SG ≤1.025), presence of bilirubin in the urine of cats, and ammonium biurate crystalluria in properly processed urine specimens (Fig. 34.1). In dogs, excessive bilirubinuria may precede the onset of hyperbilirubinemia and jaundice. Small numbers of bilirubin crystals may be found in concentrated urine specimens from normal dogs, and ammonium biurate crystals are also occasionally found in normal animals and in Dalmatian dogs with a defect in urate metabolism (see Chapter 43). Therefore these are not pathognomonic for PSS. Hyperammonemia combined with excess uric acidemia from diminished hepatic conversion to allantoin exceeds the renal threshold and favors the precipitation of crystals, especially in alkaline urine. Their presence in the urine may fluctuate, but alkalinizing the urine specimen with a few drops of sodium or potassium hydroxide may increase the likelihood of identifying ammonium biurate crystals during sediment examination.

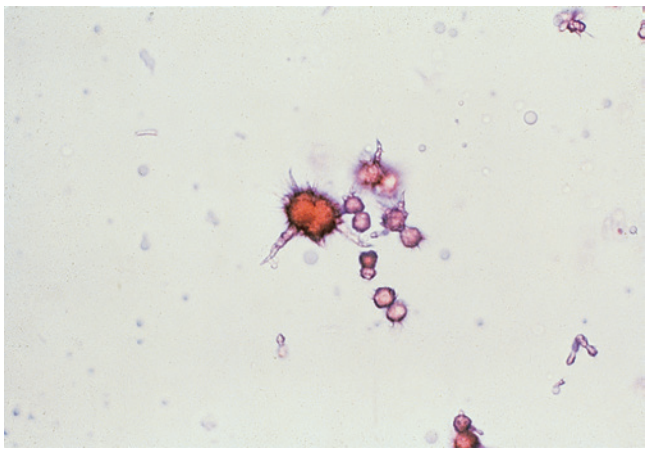

FIG 34.1
Ammonium biurate crystals in the urine of a dog with a congenital portosystemic shunt.

Measurement of urinary urobilinogen by dipstick analysis has traditionally been used to assess the patency of the extrahepatic biliary system. However, the test is now considered to be of minimal value in diagnosing EBDO because so many factors influence the detection of urobilinogen in the urine (e.g., intestinal flora and transit time, renal function, urine pH and specific gravity, exposure of the urine specimen to light). If urine samples are obtained serially and processed properly, repeated absence of urobilinogen suggests but is not diagnostic of complete EBDO.

Consistently dilute urine (SG as low as 1.005) may be a feature of congenital and acquired PSS and severe hepatocellular diseases because of the associated polydipsia and polyuria (see Chapter 33). Urine SG must also be interpreted in light of concurrent drug therapy, such as administration of diuretics, corticosteroids, or anticonvulsants.

Glucosuria in the absence of a significantly increased blood glucose concentration might increase the index of suspicion of hepatic leptospirosis, particularly if there is concurrent azotemia.

FECAL EVALUATION

Fecal specimen analysis rarely provides useful information in the evaluation of a dog or cat with suspected hepatobiliary disease, except for a change in appearance associated with two specific conditions. Absence of fecal pigment (acholic feces; see Fig. 33.10) and steatorrhea are consequences of chronic, complete EBDO, and dark, orange-colored feces reflect increased bilirubin production and excretion after marked hemolysis or rhabdomyolysis. It should also be noted that GI ulceration is a serious and important complication of portal hypertension, particularly in dogs (see Chapter 33), so the clinician should always be alert to the development of melena in a dog with chronic liver disease.

In pancreatitis, it is not uncommon to see some diarrhea and often with signs of colitis with some mucus and fresh blood because the inflamed left limb of the pancreas is adjacent to the transverse colon. Fat malabsorption as a result of exocrine insufficiency produces steatorrhea with yellow, smelly, voluminous feces.

DIAGNOSTIC IMAGING

SURVEY RADIOGRAPHY

In hepatobiliary disease, radiographic evaluation of the abdomen is used to complement physical examination findings and to confirm suspicions regarding the character and location of the hepatobiliary disease suggested by the clinicopathologic examination findings. Survey radiographs provide subjective information regarding the size and shape

of the liver (see Table 33.1). Optimally, the animal should have an empty GI tract when the radiographs are obtained. In the normal dog and cat in right lateral recumbency, the gastric axis is parallel to the ribs at the 10th intercostal space, and the caudoventral border of the liver (the left lateral liver lobe) appears sharp. The image is made possible by the contrasting fat-filled falciform ligament (Fig. 34.2). In dog breeds with narrow, deep chests, the entire liver shadow may be contained within the caudal rib cage. In dogs with a wide, shallow thoracic conformation, the liver may extend slightly beyond the costal arch. In the ventrodorsal view, the borders of the liver are defined by the cranial duodenum and the gastric fundus; in this view, the gastric shadow is perpendicular to the spine. This view is less useful for assessing liver size unless it is markedly and asymmetrically enlarged. The gallbladder and extrahepatic biliary tree are not separately visible radiographically in healthy animals.

Survey radiography is of minimal to no benefit if there is moderate to marked abdominal effusion because the similar radiographic opacities of the liver and fluid preclude distinction of liver size and shape, except by indirect assessment (e.g., malposition of a gas-filled stomach and duodenum; Fig. 34.3). However, because abdominal fluid increases ultrasonographic contrast, this is the imaging modality of choice in animals with ascites. Poor abdominal detail in emaciated or very young animals lacking abdominal fat stores also makes the detection of subtle hepatic changes difficult.

In cats and dogs with generalized hepatomegaly, the liver extends beyond the costal arch; it causes displacement of the gastric axis and pylorus caudally and dorsally in the lateral projection, and shifting of the gastric shadow caudally and to the left in the ventrodorsal view (see Fig. 34.2). In addition, the edges of the liver in the lateral view may appear rounded (see Fig. 34.2). Occasionally, the spleen and liver cannot be differentiated when they are in direct contact, as seen in the right lateral view. A ventrodorsal view would help determine the size, shape, and position of each organ. Increased intrathoracic volume associated with deep inspiration, severe pleural effusion, or overinflation of the lungs

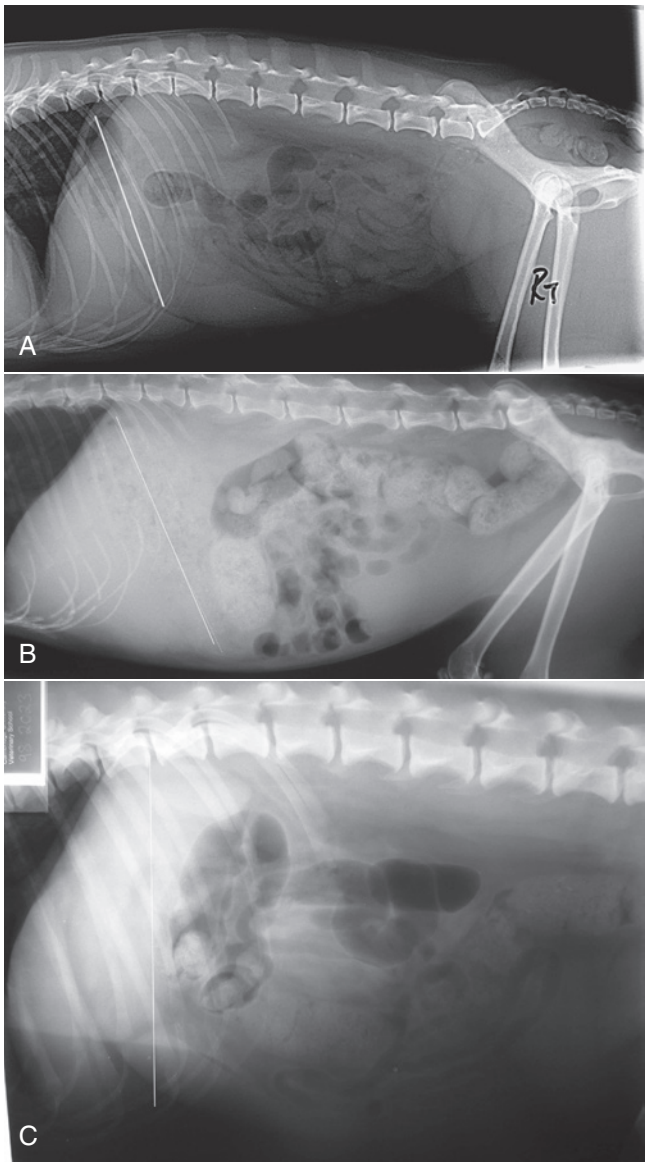

FIG 34.2

may result in caudal displacement of the liver, giving the erroneous impression of hepatomegaly using other radiographic criteria.

Because the liver may be contained entirely within the rib cage in normal cats and dogs, microhepatia is more difficult to recognize than hepatomegaly. Changes in the angle of the gastric fundus in the right lateral projection (see Fig. 34.2) could indicate a small hepatic shadow if the angle is more upright or perpendicular to the spine, especially if the stomach seems rather close to the diaphragm. The liver may also seem small in animals with traumatic diaphragmatic hernia and herniation of liver lobes into the thorax or in those with congenital peritoneopericardial hernia.

Focal hepatic enlargement is indicated by the displacement of organs adjacent to the affected lobe. The most common radiographically detectable focal hepatic enlargement is that of the right lateral lobe (Fig. 34.4). In this case, the body and pyloric regions of the stomach are shifted dorsally (lateral view) and to the patient's left (ventrodorsal view); the gastric fundus remains in normal position. Shifting of the stomach to the left is normal in cats and should not be mistaken for right hepatomegaly. If the left lateral lobe or lobes are enlarged, the gastric fundus moves to the left and caudally; the lesser curvature of the stomach may appear indented. Primary or metastatic neoplasia, hyperplastic or regenerative nodules, and cysts usually account for focal hepatic enlargement or for irregular liver margins without enlargement. If the gallbladder is massively enlarged because of EBDO, it may mimic a right cranial abdominal mass or an enlarged, rounded liver lobe. Changes in hepatic radiographic opacity are rare and are usually associated with hepatic or biliary tract infection caused by gas-forming bacteria (patchy and/or linear areas of decreased opacity) or mineralization (focal or diffuse spots of mineralization or mineralized bile ducts or biliary calculi; Fig. 34.5).

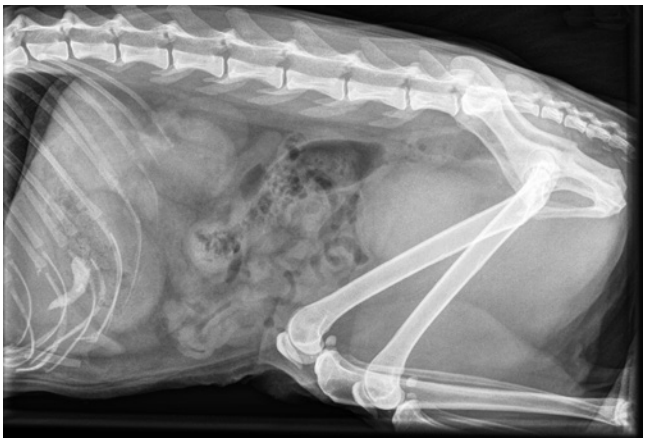

FIG 34.5

Note the radiodensity overlying the liver shadow, which was identified at surgery as a gallstone in the common bile duct. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

With the advent of US and computed tomography (CT), contrast radiographic procedures are seldom needed to confirm the presence of hepatic masses, cholelithiasis, EBDO, congenital PSS, and other structural diseases. The contrast study that can localize congenital PSS and is achievable in private practice is portal venography, although CT

angiography is the preferred method to diagnose PSS when available. Acceptable approaches for portal venography are splenoportography, operative mesenteric portography, and operative splenoportography. The two operative procedures require general anesthesia and a small abdominal incision; however, little sophisticated equipment is needed, and these procedures are associated with few complications.

A 22-gauge catheter is placed in the splenic vein or a mesenteric vein (Fig. 34.6), and the resting portal venous pressure is measured with a water manometer (normal = 6-13 cm H_2O). Portal pressure is measured as soon as possible in the procedure because prolonged anesthesia may complicate its interpretation. An injection of iodine-based contrast medium, 0.5 to 1 mL/kg, is then quickly made. Lateral and possibly ventrodorsal and oblique radiographs are made at the end of the injection. Contrast medium given to a normal cat or dog should flow into the portal vein, enter the liver, and branch multiple times, opacifying the extrahepatic and intrahepatic portal vasculature. Diversion of the contrast medium into the systemic circulation indicates PSS (Fig. 34.7). Measurement of portal pressure and a liver biopsy can be performed during the operative techniques; they are required to distinguish acquired PSS from congenital PSS, which is essential to rendering an accurate prognosis and developing the correct treatment plan. As a general rule, cases of congenital PSS are usually single, whereas acquired PSS are multiple, so the mesenteric portography may suggest a diagnosis. It may be necessary to repeat the contrast study after congenital PSS ligation if there is concern about the adequacy of the intrahepatic portal vasculature. In addition, it has been shown that the degree of intrahepatic portal vessel opacification on postligation portography is predictive for outcome (Lee et al., 2006).

Abdominal radiographs in patients with pancreatitis usually show mild or no changes, even in those with severe disease (Fig. 34.8). However, in patients with acute disease, abdominal radiography plays an important role in ruling out acute intestinal obstruction, which would result in obvious changes, primarily dilated, gas-filled, stacking loops of intestine and the presence of radiopaque foreign bodies. Typical radiographic changes in dogs and cats with acute pancreatitis include a focal decrease in contrast in the cranial abdomen associated with local peritonitis; a dilated, fixed (C-shaped),

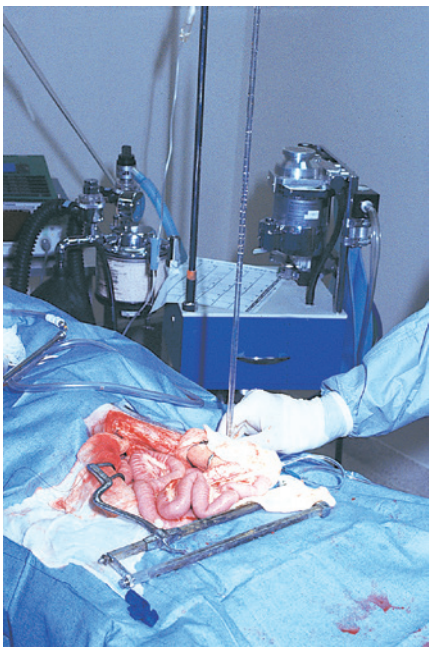

FIG 34.6

and laterally displaced proximal duodenum on ventrodorsal views; and caudal displacement of the transverse colon. Occasionally, a mass effect may be seen in the region of the pancreas, usually the result of fat necrosis. Pancreatic tumors by contrast are usually small, but it is impossible to differentiate fat necrosis from neoplasia using imaging alone. Abdominal radiographs appear normal in many dogs and cats with acute or chronic pancreatitis. Barium studies should be avoided, if possible, because they do not contribute to diagnosis.

ULTRASONOGRAPHY

Abdominal US is the preferred diagnostic modality for evaluating the hepatobiliary system in dogs and cats. However, it is important to realize that it has limited sensitivity and specificity for liver disease. Operating on the principle that a pulse of sound (echo) can be reflected when it passes through the interface between two different materials, US can detect differences between homogeneous liquids of low echogenicity, such as blood and bile, and more heterogeneous echogenic structures made up of several soft tissues. Whereas abdominal effusion obscures abdominal detail on survey radiography, it enhances the ability of US to detect abnormalities (Fig. 34.9). However, bone and gas-filled organs reflect the sound beam completely (acoustic shadowing), so that structures beneath cannot be imaged by US. The procedure does not require anesthesia but the patient must be still, and good contact between the transducer and abdominal skin must be ensured by clipping the haircoat and applying acoustic coupling gel. Animals are usually positioned in dorsal or lateral recumbency. The hepatic parenchyma, gallbladder, large hepatic and portal veins, and adjacent caudal vena cava are all visible in the liver of the normal cat and dog. Unlike plain radiography, which requires two views to complete the study, US makes many slices through several planes to create a three-dimensional reconstruction of the target structures.

Performing US and interpreting the recorded images are a blend of technical skill and experience. It is important to note that the sensitivity of US in hepatic disease is not 100%. In a recent study, the liver appeared ultrasonographically abnormal in only 48% of dogs with histologically confirmed chronic hepatitis and in only 68% of dogs with hepatic lymphoma. Therefore a normal ultrasonographic appearance certainly does not rule out hepatic disease or neoplasia (Warren-Smith et al., 2012). It is also important to remember that US does not diagnose what the lesions are (i.e., it cannot yield a histologic diagnosis). With a few exceptions, which predominantly involve lesions of the biliary tract and vessels, the ultrasonographic appearance of a variety of benign and malignant hepatic lesions can appear similar and histology of a liver biopsy is usually required for diagnosis. An animal should never be euthanized on the basis of an ultrasonographically identified tumor without histologic confirmation because benign nodular hyperplasia or focal inflammatory lesions can look the same. Table 34.5 outlines the typical appearances of different hepatic lesions on US.

Neoplasia may appear as hyperechoic or hypoechoic and focal, diffuse, or normal liver. Hepatic lymphoma often appears diffusely hypoechoic but can also appear hyperechoic or normal. Some tumors, such as metastatic hemangiosarcomas, have a classically nodular hypoechoic appearance (Fig. 34.10) and may appear as target lesions, which are relatively

TABLE 34.5

Ultrasonographic Findings in Dogs and Cats With Hepatobiliary Disease

FINDING	POSSIBLE INTERPRETATIONS
Parenchyma	
Anechogenicity	
Focal	Cyst(s)—may be singular or multiple with septae; thin-walled Abscess(es)—may be poorly demarcated and have a heterogeneous echo pattern Hematoma(s)—appearance depends on maturity Lymphoma—may look like cyst if solitary
Hypoechogenicity	
Focal	Focal or multifocal neoplasia Regenerative nodule formation Extramedullary hematopoiesis Normal liver surrounded by hyperechoic liver Hematoma(s)
Diffuse	Abscess(es) or granuloma(s) Neoplastic or inflammatory cell infiltrates (hepatitis) Passive congestion Hepatocellular necrosis Amyloid Extramedullary hematopoiesis
Hyperechogenicity	
Focal	Focal or multifocal neoplasia Nodular hyperplasia Mineralization (creates shadowing artifact) Fibrosis Gas (creates reverberation artifact) Hematoma or abscess
Diffuse	Fatty infiltration (attenuates the sound beam) Lymphoma Fibrosis Neoplastic or inflammatory cell infiltrates (hepatitis) Hepatocellular necrosis Steroid hepatopathy (dogs only)
Tubular Structures—Biliary Tract	
Dilated intrahepatic and extrahepatic bile ducts	Extrahepatic bile duct obstruction; persistent or recently relieved Some cases cholangitis syndrome (cats) Choledochal cyst (rare)
Distended gallbladder	Normal (prolonged fasting)
Distended gallbladder and cystic duct	Cystic duct obstruction
Distended gallbladder and common bile duct	Extrahepatic bile duct obstruction; persistent or recently relieved
Focal areas of gravity-dependent hyperechogenicity within biliary tract or gallbladder that cause acoustic shadowing	Cholelithiasis
Focal areas of hyperechogenicity within gallbladder that settle to dependent portion of gallbladder when animal's position changes	"Sludged" or inspissated bile from severe cholestasis, prolonged anorexia, and dehydration
Stellate or "kiwi fruit" appearance to gallbladder	Gallbladder mucocele
Intraluminal echoic masses in gallbladder	Neoplasia (polyp, malignant neoplasm) Adherent inspissated bile

TABLE 34.5

Ultrasonographic Findings in Dogs and Cats With Hepatobiliary Disease—cont'd

FINDING	POSSIBLE INTERPRETATIONS
Apparent thickened gallbladder wall	Cystic hyperplasia (focal) Cholecystitis, cholangitis Infectious canine hepatitis Hypoalbuminemia with edema formation Abdominal effusion Neoplasia
Tubular Structures—Blood Vessels	
Dilated hepatic veins and portal veins	Right-sided congestive heart failure Pericardial disease Intrathoracic caudal vena cava occlusion Hepatic vein occlusion (Budd-Chiari syndrome)
Prominent hepatic arteries	Reduced portal blood flow
Distended portal vein with reduced velocity and flow with or without hepatofugal flow	Portal hypertension of any cause (by Doppler)
Inapparent hepatic vessels	Cirrhosis Severe fatty infiltration
Inapparent portal veins	Congenital portosystemic shunt Portal vein thrombus Intrahepatic portal vein hypoplasia
Aberrant vessel that communicates with systemic circulation	Intrahepatic or extrahepatic congenital portosystemic shunt
Connection between a portal vein and an artery within one or more liver lobes	Arterioportal venous fistula
Many tortuous veins clustered around left kidney and along colon	Acquired portosystemic shunts associated with portal hypertension

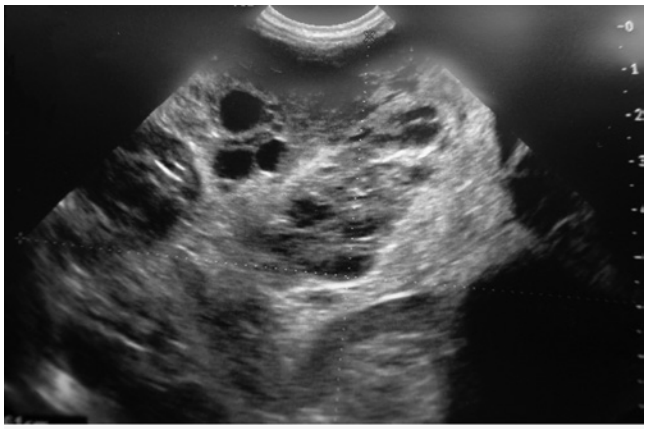

FIG 34.10

specific for neoplasia, but even hemangiosarcomas may be missed on US in 15% of cases. Contrast-enhanced US has been used to improve visualization of small hepatic metastases in dogs. Marolf (2017) has reviewed this and other advanced imaging modalities in liver disease. Typically, hepatic lipidosis in cats causes an increase in echogenicity and so do steroid hepatopathy, diffuse hepatic steatosis, and diffuse fibrosis (e.g., cirrhosis) in dogs. However, a cirrhotic liver may also appear normal ultrasonographically.

Dilated anechoic (black) vascular channels and echoic bile ducts can be identified; biliary tract imaging is particularly useful in cats with suspected biliary tract disease (Fig. 34.11) or dogs and cats with suspected EBDO. The bile duct can be followed ultrasonographically along its course toward the small intestine, and lesions in the pancreas or duodenum obstructing it can be identified. A dilated gallbladder may indicate prolonged anorexia, unless dilated bile ducts, particularly the common bile duct, are also seen, which supports EBDO or chronic cholangitis/cholangiohepatitis in cats (see Fig. 34.11). The bile ducts and gallbladder can also appear normal in cats with acute or chronic cholangitis.

Intrahepatic or extrahepatic anomalous vessels may also be identified in animals with clinicopathologic evidence of

congenital or acquired PSS (Fig. 34.12). Congenital PSS are typically single vessels, whereas acquired PSS are usually multiple. Use of Doppler color flow imaging confirms the location of the suspicious vessel(s) and the direction of blood flow within it. Doppler imaging can also provide supportive evidence of intrahepatic portal hypertension by allowing the assessment of the speed and direction of portal flow, although the accuracy of transhepatic ultrasonographic measurement of portal pressure is low compared with direct measurement with a manometer in the portal vein. Portal blood flow toward the liver (hepatopetal) is normal; away from the liver (hepatofugal) is abnormal and indicates portal hypertension. It is also possible to investigate liver shunting with US using a microbubble technique to demonstrate the passage of bubbles in agitated saline injected in the spleen beyond the sinusoids of the liver in dogs with PSS (Gómez-Ochoa et al., 2011).

Whether the lesion is determined to be focal or diffuse, US can also be used as a guide to obtain diagnostic specimens for cytologic or histopathologic evaluation. However, with the exception of gallbladder aspiration for the diagnosis of suppurative cholangitis in cats and dogs, US-guided fine-needle and Tru-Cut biopsies have potentially serious limitations (see later section, "Liver Biopsy").

In humans, an adapted US machine (Fibroscan) is used to assess the degree of hepatic fibrosis in chronic liver disease by a technique called transient elastography. It works on the principle that the echo reflected from the plane of liver through which the US beam passes will vary, depending on the amount of fibrosis present. The manufacturer's machine settings are critical for accurate readings and are optimized for human patients. However, the results of a pilot study in dogs were promising (Rivero-Juárez et al., 2012), and this technology may become more widely available for veterinarians in the future.

US is a relatively specific method of diagnosing pancreatitis in dogs. Locating the pancreas can be a challenge and ultrasound is only sensitive in the hands of an experienced operator. Pancreatitis is ultrasonographically visible because of the associated edema, pancreatic swelling, and peripancreatic fat necrosis and peritonitis (Fig. 37.5). It therefore

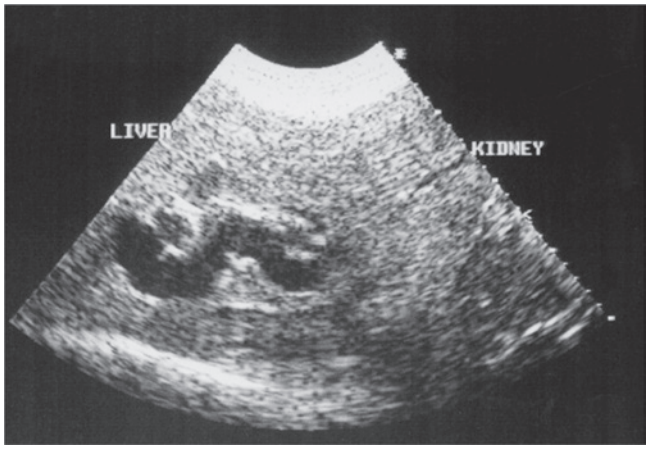

FIG 34.11
Ultrasonographic appearance of dilated biliary tract in a cat with chronic cholangitis. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

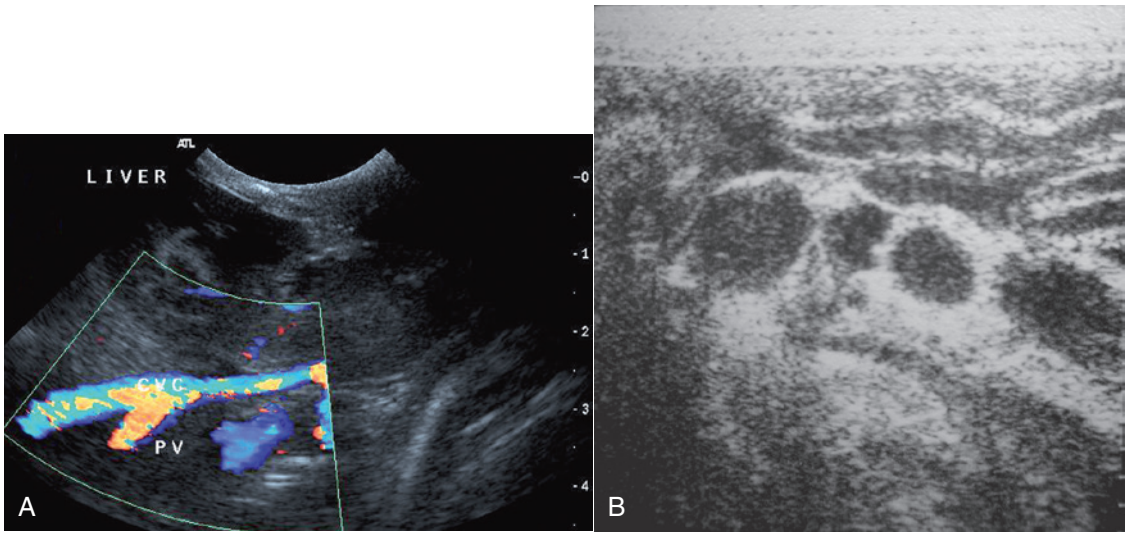

FIG 34.12
(A) Doppler ultrasonographic findings of a congenital extrahepatic portocaval shunt in a young English Springer Spaniel. **(B)** Ultrasonographic appearance of multiple extrahepatic acquired portosystemic shunts in a 6-year-old German Shepherd with noncirrhotic portal hypertension. *CVC,* Caudal vena cava; *PV,* portal vein. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

follows that acute cases of pancreatitis, which classically show these features, are more often visible ultrasonographically than low grade, chronic forms with little edema. US is also useful to assess for concurrent pancreatic masses, abscesses, or pseudocysts and to detect associated cholangitis and small intestinal wall thickening. An animal with acute pancreatitis usually shows a characteristically focal area of pain as the ultrasound probe is positioned over the pancreas.

COMPUTED TOMOGRAPHY

CT is increasingly available in veterinary medicine and can be used to image a variety of hepatic diseases and masses. It is most commonly indicated in imaging PSS and has now largely replaced contrast radiography in identifying PSS and giving detailed anatomic information (Nelson and Nelson, 2011). CT requires a general anesthetic but is less invasive than contrast radiography. US can be performed under sedation and is less expensive than CT. Therefore, if a shunt can be accurately identified with plain or bubble US, a CT is not necessarily indicated. However, with complex shunts of unclear anatomy on US, CT can provide invaluable information before surgery (Fig. 34.13).

Abdominal CT has so far proved largely disappointing for the diagnosis of pancreatitis in dogs and cats, although a recent study suggested it might be more reliable than ultrasound, particularly to allow visualization of the entire pancreas and for diagnosis of associated portal vein thrombosis.

FIG 34.13
CT angiogram with three-dimensional mapping of a 2-year-old neutered female Border Terrier with a congenital portosystemic shunt of unusual anatomy. The shunting vessel can be seen leaving the left gastric vein cranial to the kidney and then coursing cranially in a tortuous path over the liver, finally entering the caudal vena cava just caudal to the diaphragm. (Courtesy Dr. Paddy Mannion, Cambridge Radiology Referrals, Cambridge, England.)

With acute pancreatitis, dogs had an enlarged, homogenously to heterogeneously attenuating and contrast-enhancing pancreas with ill-defined borders, as has been reported in humans (Adrian et al., 2015).

MAGNETIC RESONANCE IMAGING

MRI is used frequently in human medicine for imaging of the biliary tract and pancreatic ducts. MR cholangiopancreatography allows accurate imaging of duct abnormalities without any need for contrast. There are no reports yet of its clinical use in dogs and cats, but a recent study in normal cats showed promise for future clinical use (Marolf et al., 2011; Marolf 2017).

SCINTIGRAPHY

Scintigraphy is used in hepatobiliary disease in cats and dogs most frequently to diagnose PSS. The isotope selected is technetium-99m (^{99m}Tc). The isotope has a short half-life (6 hours); thus although the animal must be relatively isolated for 24 to 48 hours, and urinary and fecal waste stored until radioactivity has fallen to background levels, there is minimal radiation hazard to the animal or involved personnel. For diagnosis of PSS in dogs, after placement of ^{99m}Tc-pertechnetate into the descending colon, the vascular path taken by the isotope after absorption is plotted. Time-activity curves determine whether the isotope arrived in the liver first, which is normal, or in the heart and lungs, which is compatible with any type of portal venous bypass of the liver. This approach has the advantage of specifically evaluating the portal blood supply rather than the hepatic mass, which may or may not be reduced in animals with congenital PSS or primary hepatobiliary disease and acquired PSS. The test results do not provide anatomic detail but only evidence of the presence or absence of congenital or acquired portosystemic shunting and is largely being replaced by CT angiography, which provides more precise anatomic information.

BIOPSY AND CYTOLOGY

LIVER CYTOLOGY

Fine-needle aspiration of the liver for cytologic analysis is rarely advisable because of low diagnostic yield and often misleading results. The exceptions to this are aspirating bile for culture and cytology, and for quick diagnosis of hepatic lipidosis in cats and aspiration for suspected neoplasia (Fig. 34.14). One study showed that cytology had a high positive predictive value for hepatic neoplasia (round cell tumors and carcinoma) but a low positive predictive value for inflammatory disease (Bahr et al., 2013). In addition, a negative result on cytology should not exclude neoplasia because the same study showed that only 50% of patients with a histologic diagnosis of neoplasia had a positive cytology. An overall correlation of only 30% in dogs and 51% in cats was found in another study comparing the cytologic diagnosis with the histopathologic diagnosis of a variety of liver diseases (Wang et al., 2004).

FIG 34.14
A 4-year-old spayed female domestic short-haired cat with suspected hepatic lipidosis positioned in right lateral recumbency for blind, fine-needle aspiration for cytology. With care taken to avoid the spleen, the needle is directed craniomedially into the liver.

LIVER BIOPSY: INDICATIONS

For most primary hepatobiliary diseases of cats and dogs, a hepatic biopsy is needed to establish a final diagnosis and prognosis, and to guide treatment. It is usually impossible to make a definitive diagnosis and reach a logical decision about management without a liver biopsy. Without a biopsy, therapy of liver disease in dogs and cats will be at best nonspecific, and at worst dangerous and counterproductive. Therefore some type of biopsy should be obtained wherever possible, and certainly steroid, copper-chelating, and antifibrotic therapies should not be used without biopsy confirmation of disease and stage. Biopsy is indicated to do the following: (1) explain abnormal results of hepatic status and/or function tests, especially if they persist for longer than 1 month; (2) explain hepatomegaly of unknown cause; (3) determine hepatic involvement in systemic illness (although biopsy is not always necessary for this); (4) stage neoplastic disease; (5) objectively assess response to therapy; or (6) evaluate progress of previously diagnosed, not specifically treatable disease. It is much easier to justify a liver biopsy clinically for the diagnosis of disease (indications 1-4) than for assessing response to therapy (objectives 5 and 6). A liver biopsy is an invasive procedure and should only be performed if it is in the best interests of the patient—that is, will affect treatment or prognosis. Sequential biopsies to assess response to treatment are of limited usefulness unless the treatment will be altered on the basis of the results. In addition, sampling artifact is often observed in biopsies of diffuse liver disease; small biopsies tend to yield differing results, even if taken at the same time, because of the small sample size and patchy nature of the pathology. This makes the results of sequential liver biopsies difficult to interpret. Are they different because the disease has progressed or simply because they sampled a different part of the liver? Several approaches for liver biopsy are available, and the choice is dictated by patient and operator considerations (Box 34.4). In addition, in most cases of hepatic disease, the accuracy of histologic diagnosis is better with larger (surgical or laparoscopic wedge) rather than smaller (needle) biopsies.

BOX 34.4

Patient and Operator Considerations for Hepatic Biopsy

Patient

1. Characteristics of the suspected hepatobiliary disorder—liver size (small, normal, enlarged); texture (fibrotic or friable); focal, multifocal, or diffuse distribution; presence of abdominal effusion
2. Clinical stability and suitability for anesthesia
3. Coagulation status and platelet count

Operator

1. Available equipment
2. Experience with chosen technique
3. Complication rate for chosen technique
4. Size of specimen needed
5. Access to reliable veterinary pathology laboratory
6. Cost of procedure and client finances
7. Predicted accuracy of results

LIVER BIOPSY: TECHNIQUES

All cats and dogs undergoing hepatic biopsy are fasted for at least 12 hours, regardless of the approach selected.

In an especially small and/or firm fibrotic liver, it is difficult to obtain a biopsy specimen by percutaneous needle methods; small, fragmented specimens that are challenging to interpret are often the result (Fig. 34.15). There is less than a 40% correlation between 18-gauge needle biopsy and wedge biopsy for certain hepatobiliary diseases (e.g., chronic hepatitis or cirrhosis, cholangitis, portovascular anomaly, fibrosis). If a needle technique is selected, the largest available instrument is used (preferably, 14 gauge; minimum, 16 gauge) and multiple samples are taken to ensure that there are enough samples for examination. Pathologists suggest that at least six portal triads should be examined to allow an accurate diagnosis, and in humans up to 12 to 15 triads are recommended. However, needle biopsy specimens often have fewer than this (see Fig. 34.15).

The animal's coagulation status is determined before a liver biopsy is performed, regardless of the approach. Hemorrhage is the major risk of liver biopsy in dogs and cats. However, it remains unclear and controversial which markers of coagulation status, if any, are predictive of perioperative bleeding. Ideally, a complete coagulation profile (one-stage prothrombin time [OSPT], APTT, fibrin degradation products, fibrinogen content, platelet count) is obtained; a platelet count and an activated clotting time in a glass tube, as a screening test of the intrinsic coagulation cascade, are also

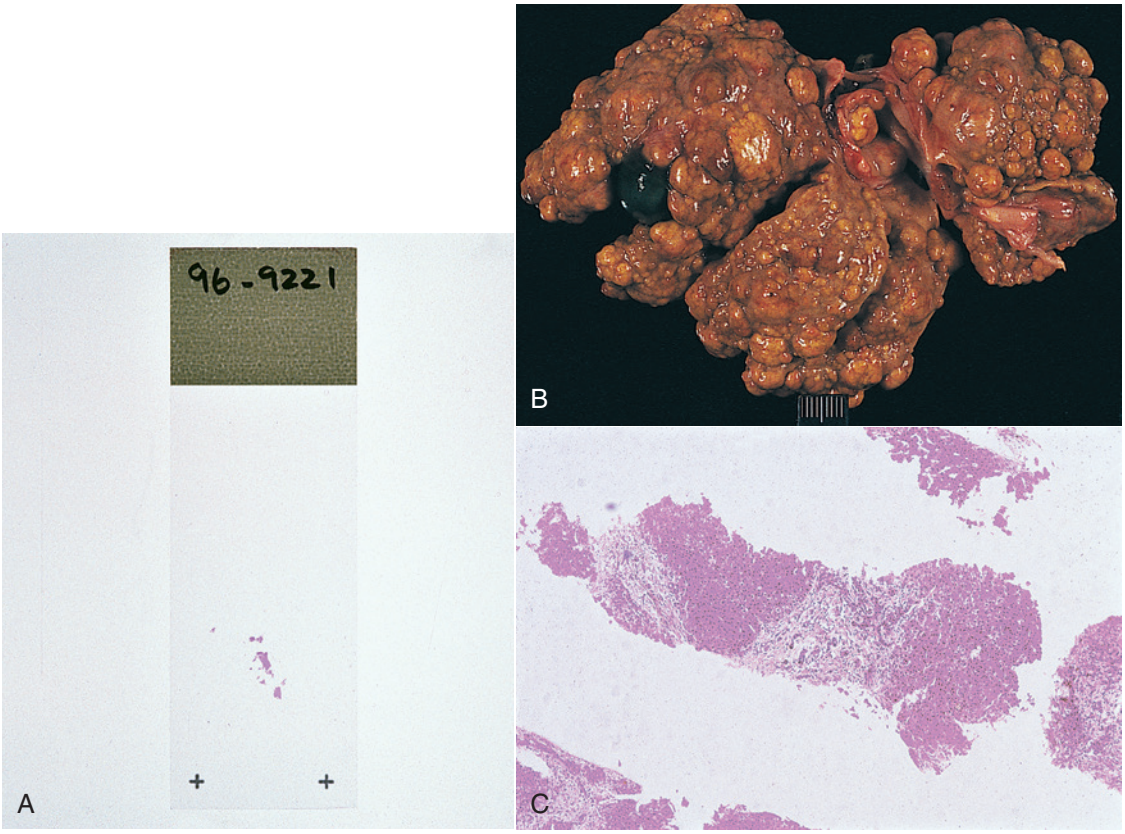

FIG 34.15
(A) Liver specimen obtained percutaneously (with ultrasound guidance) from a dog with hepatic fibrosis and nodular regeneration. **(B)** The specimen was difficult to obtain because the liver was firm and rubbery in texture. **(C)** The resultant sample was difficult to interpret histologically.

acceptable. One study showed that bleeding after US-guided biopsy is more likely if the platelet count is less than 80,000 cells/μL or if the OSPT (dogs) or APTT (cats) is prolonged (Bigge et al., 2001), but these results were not repeated in other studies. If possible, von Willebrand factor is measured in susceptible breeds in advance of biopsy because results of standard coagulation tests are usually normal in affected dogs. A buccal mucosal bleeding time test provides indirect assessment of platelet function (see Chapter 87). In dogs with von Willebrand disease, desmopressin acetate (DDAVP) is given (1-4 μg/kg SQ) before surgery to enhance the shift of von Willebrand factor activity from endothelial cells to the plasma.

Mild abnormalities in coagulation test results do not preclude liver biopsy. Results of routine coagulation tests may not correlate with liver bleeding times. Liver biopsy should be delayed if there is clinical evidence of bleeding or marked abnormalities in coagulation test results. Because animals with complete EBDO may be vitamin K–deficient (manifested by prolongation of OSPT and APTT), treatment with vitamin K_1 (0.5-1 mg/kg [maximum, 10 mg] subcutaneously every 12 hours for three treatments) is indicated for 1 or 2 days before surgery. This is particularly true in cats. Dogs with EBDO may in fact be hypercoagulable (see previous section), so vitamin K supplementation may not be indicated in them. Vitamin K supplementation can also improve coagulation times in animals with other liver disease, particularly cats. Repeating the OSPT and APTT within 24 hours after the administration of vitamin K_1 should demonstrate normal or near-normal values. If not, the dose can be adjusted and the procedure delayed. If bleeding is excessive during or after biopsy and cannot be controlled locally with direct pressure or application of a clot-promoting substance, fresh whole blood or plasma is given (see Chapter 80 for transfusion guidelines).

TECHNIQUES

The preferred techniques for liver biopsy are laparoscopy or laparotomy with wedge biopsy. These are preferred over transcutaneous Tru-Cut–type needle biopsies (US-guided or blind) because wedge biopsies give a more reliable diagnosis. The diagnostic accuracy of needle biopsies was compared with wedge biopsies of liver from the same patients, and there was agreement in the diagnoses only 48% of the time (Cole et al., 2002). This is likely because of the greatly increased risk of sampling artifact with needle biopsies (see earlier). US-guided transcutaneous Tru-Cut biopsies are, however, less invasive than laparotomy or laparoscopy, can

be taken under heavy sedation or general anesthesia, and are better than no biopsy at all. However, they are often too small and nonrepresentative (see Fig. 34.15), and it is not possible to obtain enough tissue for quantitative copper measurement by Tru-Cut needle biopsy. Multiple biopsies should be taken with as large a Tru-Cut needle as possible to maximize the chances of obtaining diagnostic samples. The animal should be monitored carefully for hemorrhage afterward (preferably hospitalized overnight), which although uncommon, can develop unnoticed in these animals and can be life-threatening.

Laparotomy is much more invasive but allows examination of other abdominal organs (e.g., pancreas, small intestine), observation of the liver, and careful biopsy. The risk of hemorrhage is, therefore smaller than with Tru-Cut biopsies because any bleeding can be seen and dealt with at the time of surgery. The biopsies obtained are generally bigger and more diagnostic except that focal lesions deep in the parenchyma may be missed if US has not been used as well. If one part of the liver looks normal and another part abnormal, biopsies should be obtained from both areas because the apparently normal part may be the diseased area. Laparotomy is clearly indicated if there is a mass that could be resected (Fig. 34.16). Laparoscopy is less invasive than laparotomy and has similar advantages. It is the preferred method of obtaining diagnostic liver biopsies if there is access to equipment and operator experience (Fig. 34.17), and has been shown to have a low complication rate, even in dogs with advanced liver disease and coagulopathies (McDevitt et al., 2016). Recovery is much quicker than with laparotomy, and animals can usually be sent home on the same day as the procedure. With laparotomy and laparoscopy, consideration should be given to obtaining a bile sample by aspiration and examining and taking biopsies from other organs such as the pancreas at the same time, as indicated in the

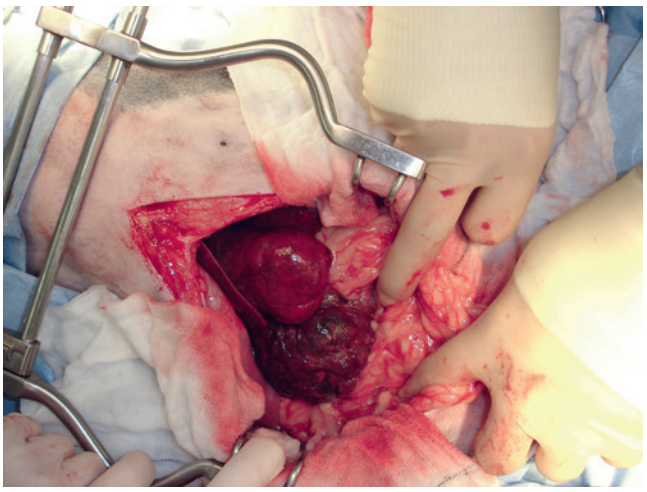

FIG 34.16
Laparotomy for resection of a hepatic mass in a dog. A diagnosis of hepatocellular carcinoma was made on histopathology. (Courtesy Dr. Laura Owen, Soft Tissue Surgery Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

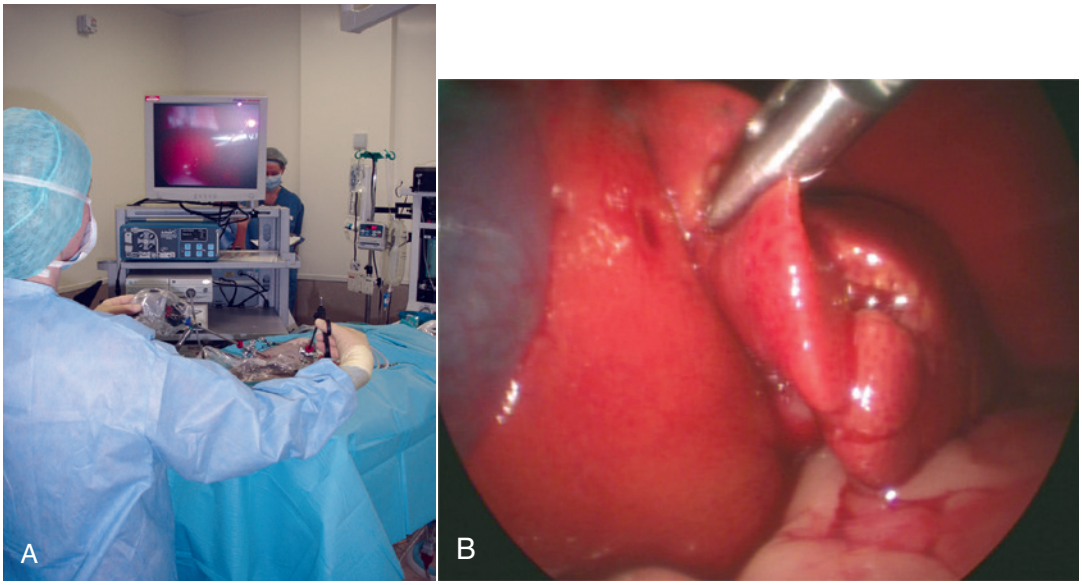

FIG 34.17
(A) Laparoscopic liver biopsy performed in a 7-year-old female cross-breed dog with a history of vomiting, anorexia, and increased liver enzyme levels. The final histologic diagnosis was idiopathic chronic hepatitis. **(B)** Biopsy being taken from a liver lobe. The gallbladder is visible on the left. A gallbladder aspirate was also taken using a transcutaneous needle under laparoscopic visualization. animal's previous investigations. Serious consideration should also be given to placing a feeding tube at the same time to avoid a second anesthetic for feeding tube placement at a later date should this prove necessary.

Laparotomy and laparoscopy require a general anesthetic. A few dogs with end-stage chronic hepatitis and cats with acute hepatic lipidosis are very poor anesthetic risks and likely to die if anesthetized for any procedure. These cases should have fine-needle aspiration or Tru-Cut biopsies under careful sedation or supportive care until their clinical condition improves enough to allow the use of a safe general anesthetic.

US-guided Tru-Cut biopsies may be performed under sedation or general anesthesia. If a concurrent gallbladder aspirate is being obtained, a general anesthetic is preferred to allow breath-holding during the procedure. Biopsy can be performed blindly if the cat or dog has generalized hepatomegaly and the operator is confident of the path of the needle. The most common needle biopsy instruments are the Tru-Cut (Cardinal Health, Dublin, Ohio) and Jamshidi Menghini (Cardinal Health, Kormed, Seoul, Korea) needles. The Jamshidi Menghini biopsy needles can be operated with one hand, and aspiration is used to sever and contain the specimen within the barrel of a 6- or 12-mL syringe. The Tru-Cut needle requires two hands to operate and relies on the tissue falling into the specimen trough and then being severed by the sharp outer cannula (Fig. 34.18). One-handed, semiautomatic (e.g., Tenmo Evolution biopsy needle, Cardinal Health; Vet-core biopsy needle, Smiths Medical, Dublin, Ohio; Global Veterinary Products, Amarillo, Tex) and automatic (e.g., Pro-Mag Ultra Automatic biopsy instrument, Angiotech, Wheeling, Ill; Bard Biopty biopsy instrument and Bard Biopty-Cut biopsy needle, Bard Biopsy Systems, Tempe, Ariz) versions of this instrument are also available. These biopsy needles are intended for single use. The automatic biopsy instrument or semiautomatic biopsy needle device can be used to obtain liver biopsies in dogs, but only the semiautomatic biopsy needle device should be used in cats. One study identified a high risk of fatal complications (unexpected fatal shock reaction) when an automatic biopsy instrument was used to obtain liver biopsies in cats (Proot and Rothuizen, 2006).

Biopsy can be done of any palpably enlarged lobe as long as care is taken to angle the needle to avoid puncturing the gallbladder. Usually the animal is placed in right lateral recumbency for this purpose, and biopsy of the left lateral lobe is done. Elevating the head and thorax slightly may assist in presenting the liver to the operator. Two or three complete core specimens are obtained; if indicated, one core specimen is placed in a sterile container for culture and sensitivity testing. Each of the remaining core specimens is placed on a piece of stiff paper (e.g., filter paper) in correct orientation (Fig. 34.19) before immersion in fixative for histologic examination and/or special testing.

After biopsy, a small bandage is applied to keep the site clean during recovery, and the animal is placed in a position to allow its body weight to compress the region of the biopsy sites in the liver (e.g., left lateral recumbency). Consideration should be given to postoperative analgesia; puncture of the liver capsule can be painful. The animal should be monitored carefully for any evidence of hemorrhage for several hours after the procedure. As long as the biopsy procedure proceeded smoothly and without unpleasant surprises (animal awake and struggling), only basic monitoring of mucous

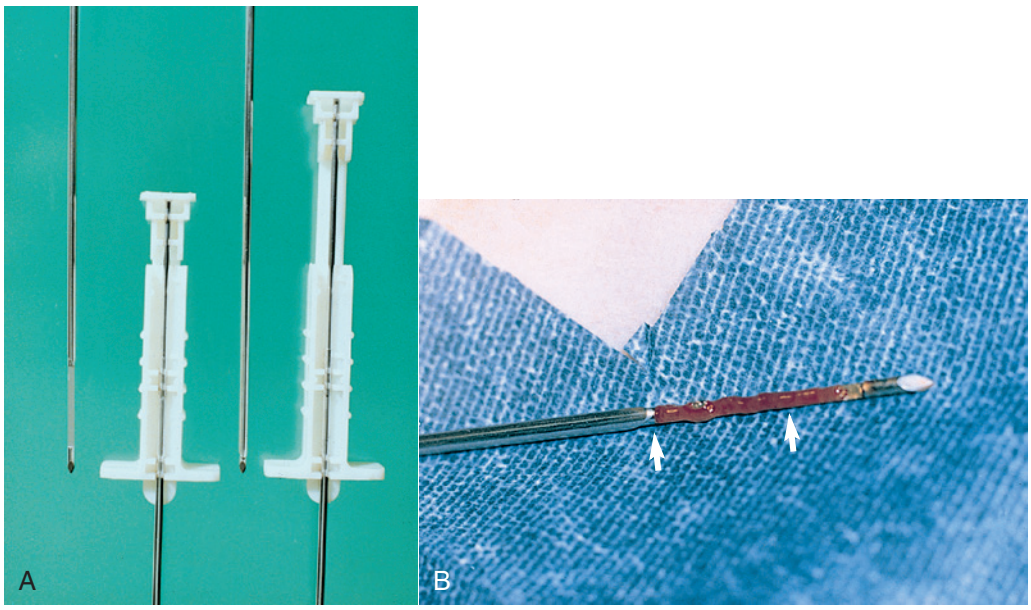

FIG 34.18

membrane color, heart rate, and the skin puncture site is needed. Naturally, if excessive hemorrhage or damage to other organs occurs with this blind technique, detection and treatment may be delayed.

Aspiration of the gallbladder for cytologic analysis and culture can be accomplished with US guidance or by laparoscopy. Bile leakage may occur, even if a small-gauge needle is used, so attempts are made to evacuate the gallbladder completely; the needle should be placed in the gallbladder through the liver parenchyma to help prevent leakage. Some surgeons prefer to obtain bile during laparotomy when a purse-string suture can be applied to the aspiration site to prevent seepage. Large-volume abdominal effusion hinders direct inspection of the liver and associated structures and must be removed before laparoscopic biopsy is attempted. This is best achieved slowly with diuretics while the biopsy procedure is delayed. Rapid removal at the time of surgery can result in a marked decrease in blood albumin concentration unless accompanied by a plasma transfusion.

Liver tissue specimens taken by any technique are submerged in buffered 10% formalin at a ratio of at least 10 parts formalin to 1 part tissue. Samples for copper histochemical staining or tissue quantification are harvested and fixed or preserved according to the specifications of the pathology laboratory selected to do the assays. A portion of the specimen can be frozen or stored in RNA later (see https://www.thermofisher.com) or a similar preservative for molecular studies (e.g., polymerase chain reaction for organisms or tumor clonality). The liver sections should be sent to a veterinary pathologist with a specialty in liver disease. Appropriate stains should be used for copper, fibrous tissue, and other samples, and their use should be discussed with the attending pathologist. Stains recommended for every liver biopsy are hematoxylin and eosin; a fibrosis stain and a copper stain. Other histologic stains are then used according to need (Webster et al., 2019).

PANCREATIC BIOPSIES

Pancreatic biopsy is the only definitive way of making a diagnosis but is not recommended in most cases. For any biopsy to be justified clinically, the benefits should outweigh the risks. Ultimately, the results should alter outcome in the case, and this usually means they should alter treatment decisions. In small animals, there are situations where a biopsy might give prognostic rather than treatment information and also alter outcome (for example, the owner may decide on euthanasia as a result of finding a pancreatic tumor). If the biopsy doesn't do either of these things, then it is difficult to justify ethically. It is difficult to biopsy a pancreas noninvasively, and the procedure usually requires laparotomy or laparoscopy. Fine needle aspiration cytology of the pancreas has been described and shows some promise in helping differentiate pancreatitis from neoplasia in dogs (Bjorneby and Kari, 2002) although the author's experience suggests this is as challenging as prostatic cytology and requires a cytologist experienced at looking at pancreatic aspirates to differentiate hyperplasia from neoplasia.

The gold standard for diagnosis of pancreatitis is biopsy and histopathologic examination, but even histology of a pancreatic biopsy is not 100% sensitive because the lesions of pancreatitis are patchy particularly early in the disease process, so a small surgical biopsy may miss the disease. To diagnose the disease definitively needs multiple large sections taken throughout the organ (Newman et al., 2004), and this is clearly only possible postmortem.

There are no clearly defined veterinary guidelines about when to biopsy the pancreas. However, if we reflect the human situation quite closely, the single biggest reason to biopsy a pancreas is to rule in or out neoplasia. In this case, there is often a justification to undertake a laparotomy or laparoscopy and obtain a biopsy. Nodules in the pancreas are as likely to be inflammatory as neoplastic, particularly in Cocker Spaniels with IgG4+ chronic pancreatitis (see Chapter 37), so a biopsy is required to definitively diagnose neoplasia, and dogs and cats with pancreatic masses should NOT be euthanized on the table without histology.

The indications for biopsy in pancreatitis are less clear. Generally, the cause of pancreatitis in dogs and cats is unknown so the treatment is supportive and nonspecific, and a biopsy will not change that. There is one exception, which is the multisystemic immune-mediated disease in English Cocker spaniels, described in Chapter 37. But even in this disease, diagnosis can be made presumptively on the basis of immune-mediated disease in other organs, and a pancreatic biopsy is not necessary. Undertaking a general anesthetic and laparotomy or laparoscopy in a dog or cat with acute disease is dangerous; these dogs or cats have systemic inflammatory response and multiorgan dysfunction, and need stabilizing before surgery. Mortality in dogs and cats with pancreatitis is usually as a result of multiorgan failure, not the localized pancreatitis itself, and undertaking a GA and laparotomy in a dog that is already unstable is likely to make things worse. There are no studies in dogs assessing the risk of mortality with early surgery in acute

pancreatitis, but in humans there is clear evidence that early surgery in acute pancreatitis actually increases mortality compared with delaying surgery for 2 to 4 weeks after symptom onset, and thus this is avoided unless there is a high suspicion of malignant neoplasia (McKay et al., 2004; Wittau et al., 2010).

However, bearing all these factors in mind, it is still well worthwhile taking a careful pancreatic biopsy in any animal that is having an exploratory laparotomy or surgery for another reason, and pancreatitis is a possibility. In the past, these were discouraged because of a fear of postoperative pancreatitis. However, this appears to be a theoretical rather than real concern as long as the surgeon only takes a small biopsy and preserves pancreatic blood supply.

Pancreatic biopsy appears to be safe and does not carry a high risk of postoperative pancreatitis, provided that the pancreas is handled gently and the blood supply is not disrupted. A study of pancreatic biopsy in 27 normal dogs showed elevations in some pancreatic enzyme levels postbiopsy but not in cPLI, and there were no clinical signs of pancreatitis after surgery (Cordner et al., 2010).

CHAPTER 35

Hepatobiliary Diseases in the Cat

GENERAL CONSIDERATIONS

The causes, clinical signs, and prognosis of hepatobiliary tract diseases in cats are very different from those of dogs. Primary and secondary causes of liver disease in cats are outlined in Table 35.1. Cats typically have hepatobiliary disease or acute hepatic lipidosis, but chronic parenchymal disease is uncommon in this species; in addition, feline liver disease rarely progresses to cirrhosis, as is sometimes the case in dogs. The clinical signs of hepatobiliary disease in cats are generally nonspecific and similar to the signs of inflammatory bowel disease (IBD) and pancreatitis; the three conditions may coexist, further confusing diagnosis. Hepatic lipidosis presents with more classic signs of liver disease, including jaundice and encephalopathy. The most important differences between feline and canine hepatobiliary diseases are outlined in Table 35.2.

The feline hepatopathies in this chapter are described approximately in order of their frequency in clinical practice in the United States. Historically, hepatic lipidosis has been most common in the United States and cholangitis most common in Europe, but lipidosis is becoming increasingly common in Europe, and cholangitis is now commonly recognized in the United States.

HEPATIC LIPIDOSIS

Etiology and Pathogenesis

Feline hepatic lipidosis may be primary or secondary to another disease, but in either case it is associated with a high mortality unless the cat is intensively fed.

PRIMARY HEPATIC LIPIDOSIS

Primary or idiopathic hepatic lipidosis usually affects obese cats and remains the most common hepatic disease of cats in North America; it is also now emerging as an increasingly common problem in Europe and Israel (Bayton et al., 2018; Kuzi et al., 2017). It is effectively an acute hepatopathy with a massive accumulation of fat in hepatocytes leading to acute loss of hepatocyte function, which is reversible if the fat can be mobilized (Fig. 35.1). The reason for the differences in prevalence in different countries is unknown but intriguing. Some researchers suggest environmental differences (e.g., differences in outdoor or indoor lifestyle or feeding habits), genetic differences among cats, or both.

The pathogenesis of primary hepatic lipidosis remains incompletely understood, but it seems to involve a combination of excessive peripheral lipid mobilization to the liver, deficiency of dietary proteins and other nutrients that would usually allow fat metabolism and transport out of the liver, and concurrent primary disturbances in appetite. Excessive mobilization of peripheral fat occurs particularly during periods of anorexia or stress in previously overweight cats. Concurrently, anorexia results in deficiencies of dietary proteins and other nutrients; cats are particularly susceptible to these problems because of their high dietary requirements (see Table 35.2). Some of these nutrients are important in fat metabolism and mobilization, particularly methionine, carnitine, and taurine, so deficiencies in these nutrients are implicated as contributing to the pathogenesis of the disease. Methionine is an important precursor in the synthesis of an important hepatic antioxidant, glutathione, and hepatic concentrations of glutathione may decrease markedly in cats with hepatic lipidosis. Relative arginine deficiency will contribute to the resultant hepatic encephalopathy (HE) caused by decreased urea cycle activity. Concurrent primary appetite disturbances result in persistent and marked anorexia, which is likely caused by disturbances in the complex neurohormonal control of appetite. Recent studies have suggested that peripheral insulin resistance does not play a relevant role in the disease, unlike in human nonalcoholic fatty liver disease.

SECONDARY HEPATIC LIPIDOSIS

Secondary hepatic lipidosis is also common in cats; its pathogenesis is similar to that of the primary disease but is complicated by the more marked neuroendocrine responses to stress. Secondary lipidosis can therefore be seen in cats that are less obese than those presenting with the primary

TABLE 35.1

Clinically Relevant Hepatobiliary Diseases in Cats

PRIMARY	SECONDARY
Common	
Idiopathic lipidosis	Secondary lipidosis
Neutrophilic cholangitis	Hyperthyroidism
Lymphocytic cholangitis	Pancreatitis Diabetes mellitus
Uncommon or Rare	
Congenital portosystemic shunt	Secondary neoplasia (less common than primary)
Extrahepatic bile duct obstruction	Biliary stasis associated with extrahepatic sepsis
Liver flukes (except common in hunting cats in endemic areas)	Hepatic abscess
Primary neoplasia	
Infections (see Box 35.5)	
Drug- or toxin-induced hepatopathy	
Biliary cysts	
Sclerosing cholangitis/biliary cirrhosis	
Congenital ductal plate abnormalities	
Primary copper-associated hepatopathy	
Hepatic amyloidosis	
Intrahepatic arteriovenous fistula	

disease and even in cats with a normal or thin body condition. Any anorexic cat with concurrent disease must therefore be regarded as being at high risk of hepatic lipidosis, and appropriate feeding support should be instituted as rapidly as possible. Secondary lipidosis may occur in association with any disease causing anorexia, but has been most commonly recognized in cats with pancreatitis, diabetes mellitus (DM), other hepatic disorders, IBD, and neoplasia.

Clinical Features

Most affected cats are middle-aged, but they can be of any age or sex. In a recent study from Israel, 99% of affected cats were neutered and 66% were female (Kuzi et al., 2017). There is no reported breed predilection. Cats with primary lipidosis are commonly obese, are housed indoors, and have experienced a stressful event (e.g., introduction of a new pet into the household, abrupt dietary change) or an illness that has caused them to become anorexic and lose weight rapidly. The initiating event is not always known. Secondary lipidosis may affect cats of normal or thin body condition as well as obese animals, and the clinical signs are complicated by those of the concurrent disease. For example, the clinical signs of acute diabetic ketoacidosis are similar to those of developing hepatic lipidosis.

Clinical signs are typical of an acute (reversible) loss of hepatocyte function and of hepatocyte swelling, with resultant intrahepatic cholestasis. Cats are usually jaundiced and have intermittent vomiting and dehydration. They may also have diarrhea or constipation. There is usually palpable hepatomegaly on physical examination. HE, most often manifested as depression and ptyalism, is related to severe hepatocellular dysfunction and relative arginine deficiency to which the anorexic cat is predisposed. Previously obese cats have extensive loss of muscle mass but maintain certain fat stores, such as those in the falciform ligament and inguinal region (Fig. 35.2).

Diagnosis

The only truly definitive and reliable method of diagnosing and identifying concurrent and causative conditions is histopathology of a wedge biopsy of liver obtained at laparotomy or laparoscopy or (less reliably) a Tru-Cut-type biopsy taken under ultrasonographic guidance. However, all of these procedures require a general anesthetic, and most cats with hepatic lipidosis are too ill on presentation to be safely anesthetized. Therefore using fine-needle aspiration (FNA) cytology of the liver performed blindly or under ultrasonographic guidance in an awake or sedated cat can yield a preliminary diagnosis; this will allow intensive management and tube feeding for a few days to stabilize the patient before anesthesia is considered for a more definitive diagnosis. Because coagulopathies are common in cats with lipidosis, a few days of therapy will help correct them before considering surgery. The clinician must be aware, however, that FNA cytology, although useful for emergency diagnosis and management, can be misleading in cats, and hepatic parenchymal disease can be misdiagnosed as lipidosis using this technique. In addition, concurrent diseases of the liver and other organs, including the pancreas and small intestine, will be overlooked without a laparoscopic or surgical biopsy. It is important to differentiate mild to moderate lipid accumulation in hepatocytes, which is common in sick and anorexic cats and causes no clinical problems, from clinically severe lipidosis on cytology (see Fig. 35.1).

FNA can be performed under ultrasonographic guidance while the cat is being evaluated or obtained blindly if there is palpable hepatomegaly. The procedure is performed in a similar way to aspiration of a mass. The enlarged liver is palpated, and the abdominal wall overlying it is clipped and prepped. A 22-gauge needle is passed through the skin into the liver from ventrally on the left side, which prevents inadvertent puncturing of the gallbladder, and gentle suction is applied to a 5-mL syringe two or three times, before withdrawing and gently expressing the needle contents onto a slide (see Fig. 34.14). Analgesia is recommended for either procedure because puncture of the liver capsule is painful. Opiate partial agonists, such as buprenorphine, are a good

TABLE 35.2

Important Differences Between Cats and Dogs With Hepatobiliary Disease

PARAMETER	CATS	DOGS	REASON FOR DIFFERENCE
Disease spectrum	Cats have a higher prevalence of hepatobiliary diseases than dogs. Chronic parenchymal disease, fibrosis, cirrhosis, and portal hypertension are much less common than in dogs. Concurrent biliary tract disease, pancreatitis, and inflammatory bowel disease are possible in either species but are more common in the cat. Ascending infections of the bile duct are also proposed to be more common in cats. Cats are particularly susceptible to clinically serious hepatic lipidosis (primary or secondary).	Chronic parenchymal disease is the most common, usually progressing to fibrosis and cirrhosis, with portal hypertension. Biliary tract disease (acute and chronic) does occur but is uncommon. Secondary hepatic lipidosis can develop in association with other diseases but is not usually a clinical problem.	Unknown. It has been proposed that the high prevalence of biliary tract disease is caused by differences in anatomy, but this has not been proved. In most cats, the bile duct joins the single major pancreatic duct before entering the small intestine at the major duodenal papilla, whereas in most dogs the bile duct enters the duodenum separately from two pancreatic ducts. Underlying cause of hepatic lipidosis in cats is not fully elucidated (see text) but likely caused by differences in metabolism.
Ability to metabolize drugs or toxins	Cats have a relative deficiency of glucuronyl transferase, reducing their ability to metabolize drugs and toxins and making them more susceptible to oxidant toxins. However, cats are pickier with their food and therefore less likely to scavenge toxins.	Because dogs are generally more likely to scavenge, they may have more access to hepatotoxins. Dogs generally have no deficiency of enzymes, but there are some breed variations (e.g., Doberman Pinschers that have an impaired ability to detoxify potentiated sulfonamides).	Cats are less likely than dogs to have toxic liver damage associated with environmental toxins. However, cats are generally less able to metabolize toxins than dogs and are therefore more susceptible than dogs to toxic liver damage caused by many potentially hepatotoxic drugs.
Isoenzymes of alkaline phosphatase (ALP) and steroid hepatopathies	Cats do not produce a steroid-induced isoenzyme of alkaline phosphatase (ALP) and the half-life of ALP is very short in cats (6 hours). Hyperadrenocorticism (HAC) is rare in cats.	Dogs have a steroid-induced isoenzyme of ALP and ALP that has a long half-life; the half-life of hepatobiliary ALP is 66 hours and the half-life of glucocorticoid-induced ALP is 74 hours. Hyperadrenocorticism is common in dogs.	Even mild increase in ALP levels in cats suggests a significant ongoing problem. ALP level does not increase with steroid therapy (or HAC before the development of diabetes mellitus) in cats. Steroid treatment and HAC are major differentials for high ALP levels in dogs.
Hepatic metabolism of glucose and protein	Adapted to high-protein diet—postprandial hepatic gluconeogenesis from protein and constantly high activity of protein catabolizing enzymes in the liver, which cannot be downregulated. High dietary requirement for arginine for the hepatic urea cycle. Taurine is an essential dietary requirement, and bile salts are all conjugated with taurine.	Adapted to use dietary starch; postprandial insulin release results in glucose storage. Dogs can downregulate hepatic protein, metabolizing enzymes as necessary when the diet is low in protein. Lower arginine requirement than cats. No obligate dietary taurine requirement provided diet contains enough sulfur amino acids.	Cats will rapidly develop protein-calorie malnutrition and start breaking down their own body protein if fed a protein-restricted diet in liver disease. Arginine deficiency can contribute to the development of hyperammonemia in cats with liver disease if the cat is fed a diet deficient in arginine (e.g., dairy protein). Taurine, arginine, and protein deficiency can contribute to the pathogenesis of hepatic lipidosis in cats.

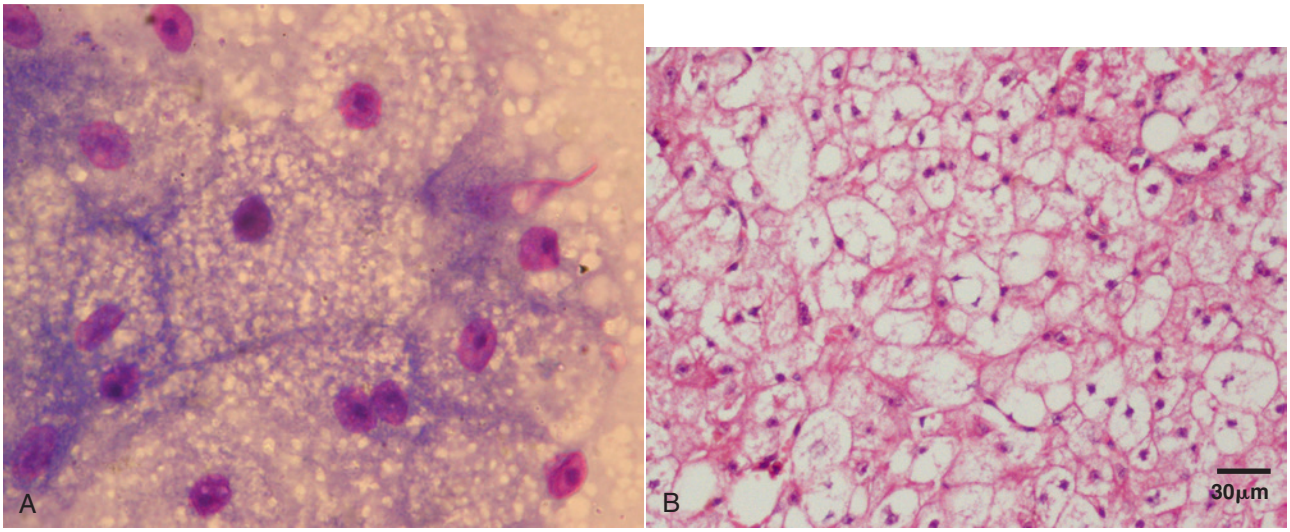

FIG 35.1
(A) Cytology of feline hepatocytes with hepatic lipidosis showing marked swelling of hepatocytes with lipid. **(B)** Histologic section of liver from a cat with hepatic lipidosis. Note marked swelling of hepatocytes with fat (H&E stain). Bar = 30 μm. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

choice; buprenorphine appears to be more effective than butorphanol as an analgesic in cats.

Clinically relevant hepatic lipidosis is usually easily recognizable on routine Giemsa or Diff-Quik staining of cytology samples or routine hematoxylin and eosin (H&E)–stained histology samples (see Fig. 35.1). It is possible to use special staining procedures with Oil Red O stain applied to snap-frozen biopsy samples to confirm that hepatocellular vacuolation is indeed lipid, but these procedures are not practical in a private practice setting. In addition, glycogen accumulation is uncommon in feline (as opposed to canine) hepatocytes.

Clinicopathologic findings reflect cholestasis and marked hepatocellular dysfunction. Hyperbilirubinemia is present in more than 95% of cases, and levels of the hepatocellular enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are also markedly elevated in most cats. Alkaline phosphatase activity (ALP) is also markedly increased in more than 80% of cases; this is particularly relevant in cats, in which this enzyme has a short half-life and no steroid induction (see Table 35.2). In cats with classic primary (idiopathic) lipidosis, a particular hallmark of the disease is an inappropriately low γ-glutamyl transferase (GGT) level, which is only mildly increased in the face of marked increase in the concentration of the other cholestatic markers (i.e., bilirubin and ALP). This is in contrast to cats with primary biliary tract disease or extrahepatic bile duct obstruction (EBDO) in which both GGT and ALP levels are usually high. However, in cats with secondary lipidosis associated with an underlying primary hepatopathy or pancreatic disease, the GGT level may be high as well. Therefore finding a high GGT level does not rule out hepatic lipidosis but should stimulate the search for an underlying cause. Blood urea nitrogen (BUN) concentration is low in more than half of the cats with lipidosis, reflecting generalized hepatocyte dysfunction. Electrolyte abnormalities are relatively common and can contribute to mortality if not addressed. Up to one third of cats are hypokalemic, and hypophosphatemia has been reported in 17% of cases; hypomagnesemia has also been reported in cats with lipidosis. Hypokalemia was a poor prognostic indicator in one study (Center et al.,

1996) and a more recent study identified hypoproteinaemia, hypoalbuminaemia, increased serum creatine kinase activity, hypocholesterolaemia, and hepatic failure at presentation as significantly associated with mortality. In addition, worsening hypoalbuminaemia, hyperammonaemia, hyperbilirubinaemia, or electrolyte disorders during hospitalization were also associated with mortality (Kuzi et al., 2017). There is no value in measuring serum bile acid levels as an indication of hepatic function in these cats because they will be high as a result of the concurrent cholestasis. Fasting cholesterol and glucose concentrations may also be high, and sometimes hyperglycemia is so marked that it results in glucosuria. This is usually a metabolic stress response and typically resolves after appropriate therapy. However, some cats may become diabetic as a result of an underlying disease process, or DM may be the cause of their lipidosis; therefore blood and urine glucose and ketone levels should be monitored carefully. The appearance of ketonuria in addition to glycosuria in a hyperglycemic cat is highly suggestive of overt DM. Serum ketone concentrations do increase in cats with hepatic lipidosis, but urine ketones are reported to be normal (Gorman et al., 2016).

Hemostatic abnormalities are common in cats with lipidosis, occurring in 20% to 60% of cases. Anemia is present in about 25% of cats, and there are often Heinz bodies in their red blood cells. Neutrophilia is not characteristic but may occur as a result of comorbidities, such as pancreatitis.

Radiographs show diffuse hepatomegaly; abdominal effusion is uncommon (see Fig. 35.2). Ultrasonography helps differentiate parenchymal from biliary tract disease and also allows assessment of other abdominal organs to detect underlying disease, particularly of the pancreas and intestine. Characteristically, the lipidotic liver appears hyperechoic, although this is not a specific finding and can also be seen in cats with other generalized parenchymal diseases, such as lymphoma or hepatic amyloidosis, and also in clinically normal obese cats.

Additional diagnostic tests should be performed to determine the presence of comorbidities that could be causing protracted anorexia and secondary hepatic lipidosis. Tests should be selected according to clues in the history, physical examination, and clinicopathologic and ultrasonographic evaluations. For example, serum feline specific pancreatic lipase immunoreactivity should be evaluated in cats suspected of having pancreatitis (see Chapter 34).

Treatment and Prognosis

Treatment recommendations for cats with hepatic lipidosis are outlined in Box 35.1. The single most important factor in reducing mortality is early and intensive feeding of a high-protein diet. In all cases, this requires some form of tube feeding. If the cat is very ill at presentation, a nasoesophageal tube can be placed for the first few days while the cat is stabilized (Box 35.2; Fig. 35.3), and an esophagostomy or gastrostomy tube may then be placed for long-term feeding (Fig. 35.4; see Bexfield and Lee: *BSAVA Guide to Procedures in Small Animal Practice, edition 2* for more details). The advantages of esophagostomy or gastrostomy tubes over nasoesophageal tube are longer-term support, better tolerated by the animal, and it is possible to feed thicker food. They are also easier to manage and could be managed by the owner at home. However, it is necessary to use a general anesthetic for placement. For gastrostomy tubes, the tube must be in at least 5 to 7 days for surgical tubes and 14 to 21 days for endoscopically placed tubes to allow adhesions to form between the stomach and body wall.

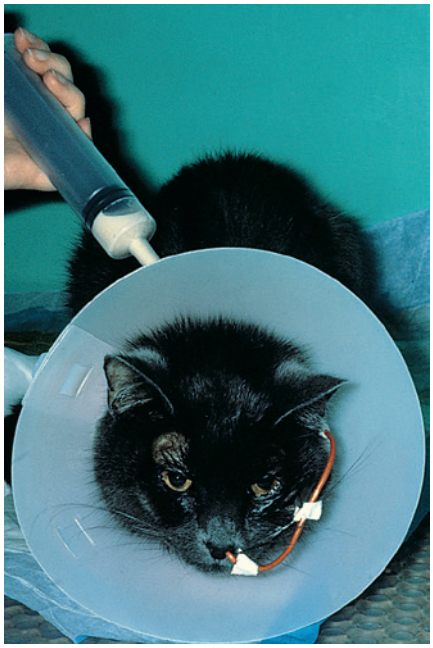

FIG 35.3
Nasoesophageal tube in place in a cat being fed a liquid enteral diet.

Most cats need 4 to 6 weeks of tube feeding, but many cats can be sent home with an esophagostomy or gastrostomy tube in place for home feeding once they have stabilized. A high-protein diet, such as those manufactured for feline intensive care patients, is ideal (e.g., Royal Canin Feline and canine convalescence support, Royal Canin USA, St Charles, Mo; Hill's a/d diet, Hill's Pet Nutrition, Topeka, Kan; or Fortol liquid feed, Arnolds, Amsterdam, New York). In some cats, however, a high-protein diet will worsen signs of encephalopathy during the first few days of therapy. Attempts should be made to control this by other methods, such as by feeding smaller amounts more frequently or infusion feeding slowly, rather than by reducing the protein content of the diet. Concurrent pancreatitis does not alter the dietary management; the current recommendations in cats with pancreatitis are to feed them as soon as possible and not to restrict fat (see Chapter 37).

Fluid and electrolyte abnormalities should also be addressed effectively in the first few days, and antiemetics should be used if necessary. Occasionally, cats with lipidosis may develop refeeding syndrome when oral nutrition is introduced, with a marked decrease in serum phosphate and potassium concentrations leading to hemolysis (Brenner et al., 2011). It is important to identify and treat this

BOX 35.1

Outline of Treatment of Hepatic Lipidosis in Cats

1. **Treat any identifiable underlying cause** but also start other treatments (steps 2 and 3) concurrently do not rely on—treating the cause alone to resolve the disease in secondary cases
2. **Institute fluid therapy as soon as possible**
   a. IV fluid support initially—maintenance rates plus replacement for any fluid lost, e.g., in vomiting. Normal saline with added potassium chloride as necessary is ideal. Avoid dextrose because it may worsen hyperglycemia.
   b. Measure and replace any electrolyte deficits, particularly potassium and phosphate. Carefully monitor blood glucose and electrolyte levels, particularly potassium and phosphate, which may become low during treatment. There is no evidence that adding insulin to the fluids is helpful; in fact, it increases the risk of serious hypokalemia and hypophosphatemia.
   c. After the first few days, fluid and electrolyte needs can be supplied via the feeding tube.
3. **Institute nutritional support as soon as rehydrated.**
   a. **How?** A nasoesophageal tube can be used for temporary support for the first few days before general anesthetic for more permanent tube placement. A gastrostomy or esophagostomy tube will usually be required long term because feeding will be necessary for 4 to 6 weeks in most cases.
   b. **What?** A diet as high in protein as possible should be given, preferably managing any resultant encephalopathy by other means, such as feeding small amounts often or if possible continuous infusion rather than bolus feeding. A diet such as Royal Canin Convalescence support canine and feline or Hill's a/d diet would be suitable. Some clinicians add extra nutrients such as taurine, arginine, B vitamins, or carnitine to the tube feed, but there is no firm evidence that any of these are necessary if a balanced feline diet is used. However, additional vitamins are necessary in some specific cats; cobalamin (vitamin B_{12}) may be deficient, particularly in cats with concurrent pancreatic and/or ileal disease (see Chapter 34) and should then be supplemented parenterally. Vitamin K–responsive coagulopathies are very common in cats with lipidosis, and some recommend supplementation in all cats at the start of treatment with 0.5 mg/kg IM q12h for three doses.
   c. **How much**? Start conservatively with the resting energy requirement (RER) because cats have had prolonged anorexia and complications of feeding are more common in the first few days. Start with 20% of RER on day 1 and build up gradually over a few days because of the risk of refeeding syndrome (see text). Start with small amounts frequently (or even slow-rate constant infusion) and gradually build up to higher volumes and lower frequency over the first week. The calorie intake can then be gradually increased to the metabolic energy requirement (MER).

$$\text{RER} = 50\ \text{Kcal} \times \text{BW Kg}$$

$$\text{MER} = 70 - 100\ \text{Kcal} \times \text{BW Kg}$$

(70 for neutered, indoor cats; 100 for lean active adult cats)

   d. Appetite stimulants are not recommended because they are of limited efficacy and potentially hepatotoxic.
4. **Antioxidant supplementation:** Particularly S-adenosylmethionine (20 mg/kg or 200 mg total, PO, once daily) on the basis of limited but supportive evidence in cats. Also vitamin E 100 iu/day (see text).
5. **Additional therapeutic support as necessary:** Antiemetics and promotility agents such as maropitant (1 mg/kg once a day SC or IV intravenously slowly over 1-2 minutes for up to 5 days) and ranitidine (2 mg/kg PO or IV twice a day) may be necessary if the cat is vomiting or has delayed gastric emptying with reflux of food up the feeding tube. There is currently no evidence supporting the use of ursodeoxycholic acid in cats with lipidosis.

BW, Body weight.

syndrome: phosphate can be supplemented by administering potassium phosphate (0.01-0.03 mM/kg/h intravenously until the serum phosphate concentration normalizes), and the food should be introduced more gradually.

Many cats require vitamin K therapy for the management of coagulopathies, 0.5 mg/kg of vitamin K_1 (phytomenadione) subcutaneously or intramuscularly q12h for 3 days; clinicians should not place any central catheters or invasive feeding tubes until hemostasis is normalized. There is the potential for serious and undetected bleeding around a central venous catheter in a cat with a coagulopathy. Antioxidant therapy is also indicated for cats with lipidosis because of the associated glutathione depletion in many cats. Vitamin E and S-adenosylmethionine supplementation should be considered: S-adenosylmethionine, 20 mg/kg orally (PO), once daily, given whole on an empty stomach, cats and dogs; or 100- to 400-mg total dose daily in cats. The ideal dose of vitamin E in a cat is unclear, but we use 100 IU daily.

Prognosis for recovery in cats with hepatic lipidosis is good as long as feeding is rapidly and effectively instituted. Studies have reported between 55% and 80% survival in intensively fed cats, whereas mortality is very high without supportive feeding. One large study (Center et al., 1996) suggested that older age was a poor prognostic indicator for

BOX 35.2

Placement of Nasoesophageal Feeding Tubes

This is used for short-term nutritional support (<1 wk) while stabilizing the cat before the placement of an esophagostomy or gastrostomy tube.

Placement

1. Premeasure tube to allow placement in caudal esophagus, not stomach; this minimizes gastric reflux. Premeasure to seventh intercostal (IC) space from nose or 75% of distance from nose to last rib if animal is so obese that ribs cannot be counted (orogastric—ninth IC space or 90% of distance from nose to last rib). Mark tube with pen or piece of tape.
2. Apply local anesthetic to nose. Mild sedation may occasionally also be necessary, preferably with buprenorphine or butorphanol.
3. Lubricate tube and advance into the ventral meatus; it is important not to advance into the middle or dorsal meatus or the tube will lodge at the ethmoturbinates. It may be helpful to raise the cat's head slightly to do this.
4. Hold the cat's head normally as you approach the pharynx to prevent tracheal intubation. Allow the cat to swallow, and advance the tube to a measured mark or tape.
5. To check that the tube is correctly positioned, instill water and air and auscultate over the left flank for bubbling in the stomach. If still uncertain, perform radiography. If the tube does not have a radiodense line, first inject some iodine-containing contrast material into the tube.
6. Pass the tube over the top of the cat's head, and suture or glue the tapes at the level of the nares and top of the head; be careful to avoid interfering with the cat's whiskers.
7. Put on an Elizabethan collar.
8. Flush regularly with warm water before and after feeds.

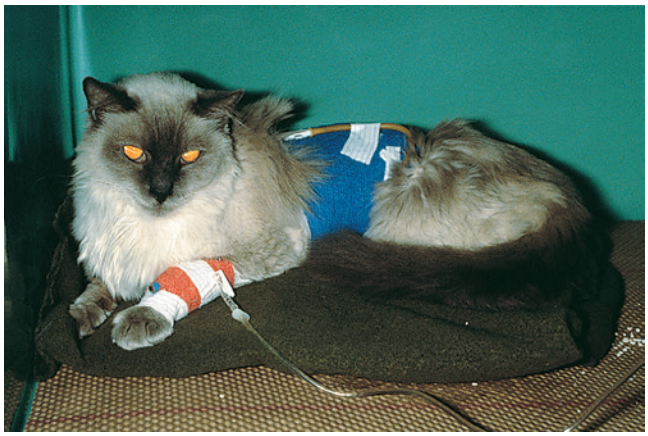

FIG 35.4
Cat with gastrostomy tube to permit long-term feeding.

survival and that cats with secondary hepatic lipidosis may do slightly worse than those with primary disease. However, the differences were not significant, which suggests that it is worth treating cats with secondary lipidosis as aggressively as those with primary disease.

BILIARY TRACT DISEASE

Biliary tract diseases are the second most common disorders of the feline liver in the United States and the most common feline liver disease in Europe (see Table 35.1). This contrasts with dogs, in which parenchymal diseases are most common. All disorders of the biliary tract in cats can present with similar clinical signs, including lethargy, anorexia, and jaundice. Clinical, clinicopathologic, and diagnostic imaging findings do not allow differentiation of the types of diseases; in most cases, cytology, bile culture, and histopathology of the liver are necessary for accurate diagnosis and most effective treatment as detailed in Table 35.3.

CHOLANGITIS

Cholangitis refers to inflammation of the biliary tract, which in some (but not all) cats may also extend to the surrounding hepatic parenchyma (cholangiohepatitis). It is more common in cats than in dogs, and it is typically divided into three categories, likely associated with different etiologies—neutrophilic cholangitis, lymphocytic cholangitis, and chronic cholangitis associated with liver fluke infestation. The nomenclature of feline biliary tract disease has been standardized by the World Small Animal Veterinary Association (WSAVA; Rothuizen et al., 2006; see Table 35.3). However, there is ongoing debate about the overlap between lymphocytic cholangitis and chronic neutrophilic cholangitis, and it has been suggested that these two categories should be combined into a broader non–suppurative cholangitis-cholangiohepatitis group (Warren et al., 2011). A wide variety of alternative names have been used in the literature in the past, sometimes blurring the categories and making comparisons between studies difficult. It is likely that there are several chronic forms of the disease with different etiologies and that increased understanding in the future will lead to improved nomenclature (see Table 35.3).

Cats with inflammatory biliary tract disease also often have concurrent pancreatitis and/or intestinal disease (often termed *triaditis*, Fragkou et al., 2016). It has been proposed that this is a reflection of the anatomy of their pancreatic and bile ducts, which usually join before entering the proximal duodenum through a common outflow tract. It has been suggested that this increases the likelihood of intestinal contents being refluxed up the pancreatic and bile ducts during vomiting. It is also possible that sphincter of Oddi spasm secondary to IBD, which has been reported in cats (Furneaux, 2010), blocks the pancreatic and bile ducts in some cats. However, it is likely that the reasons are multifactorial and that the disease associations also reflect common causative agents or events independent of anatomy in this species.

TABLE 35.3

Current World Small Animal Veterinary Association Classification of Feline Biliary Tract Disease

NAME OF DISEASE	NAMES PREVIOUSLY USED IN THE LITERATURE	CAUSE OF DISEASE	FINDINGS ON LIVER PATHOLOGY	RECOMMENDED DIAGNOSTIC PROCEDURES
Neutrophilic cholangitis, acute phase	Suppurative or exudative cholangitis-cholangiohepatitis.	Likely ascending bacterial infection from small intestine.	Neutrophils in lumen and/or epithelium of bile ducts. May also be edema and neutrophils in periportal area, parenchyma, and occasionally hepatic abscess.	Cytology and culture of bile aspirates are necessary for diagnosis. Ultrasound and histopathology can be suggestive but are not obligatory, and changes may be absent on either of these.
Chronic neutrophilic cholangitis (included in the neutrophilic cholangitis category by the WSAVA, but overlap with lymphocytic cholangitis category)	Some reported cases of "lymphocytic" or "chronic" cholangiohepatitis would now fall into this category.	Unknown. Some cases may be chronic persistent bacterial infections, and some cases may have the same etiology(ies) as lymphocytic cholangitis.	Mixed inflammatory infiltrate in portal areas, including neutrophils, lymphocytes, plasma cells, and sometimes some fibrosis and bile duct proliferation.	Liver histopathology necessary for diagnosis. Changes may be found on ultrasound and bile cytology but sensitivity limited; will not yield definitive diagnosis.
Lymphocytic cholangitis	Lymphocytic cholangiohepatitis, lymphocytic portal hepatitis, chronic cholangiohepatitis, nonsuppurative cholangitis, but note overlap of these definitions with the chronic phase of neutrophilic cholangitis.	Unknown; may be immune-mediated disease.	Infiltration of small lymphocytes into portal regions. Variable portal fibrosis and bile duct proliferation. Lymphocytes may also be present in biliary epithelium. Occasional plasma cells, eosinophils may be seen. Difficult to differentiate some cases from well-differentiated lymphoma.	Liver histopathology necessary for diagnosis. Changes may be found on ultrasound and bile cytology but sensitivity limited; will not yield definitive diagnosis.
Chronic cholangitis associated with liver fluke	—	Liver fluke	Dilated larger bile ducts with papillary projections and marked periductal and portal fibrosis. Slight to moderate inflammation of portal areas and ducts with neutrophils, macrophages, limited numbers of eosinophils. Flukes, eggs may be seen in ducts.	Ultrasonography of dilated bile ducts + history of possible exposure + demonstration of fluke eggs in feces or bile aspirates (see text). Histopathology supportive.

Adapted from Rothuizen J et al: *WSAVA standards for clinical and histological diagnosis of canine and feline liver diseases,* Oxford, England, 2006, Saunders Elsevier.

Neutrophilic Cholangitis

Neutrophilic cholangitis is also known as suppurative cholangitis, exudative cholangitis-cholangiohepatitis, and acute cholangitis-cholangiohepatitis.

Pathogenesis and Etiology

This process is believed to be caused by an ascending bacterial infection originating in the small intestine. The most common organism isolated is *Escherichia coli,* although *Streptococcus* spp., *Klebsiella* spp., *Pseudomonas* spp., *Enterococcus* spp., *Clostridium* spp., and even occasionally *Salmonella* spp. may be involved. Concurrent pancreatic and intestinal disease is common (see earlier). The result is a neutrophilic infiltrate in the lumen of the bile duct and often infiltration of the bile duct walls with neutrophils, and edema and neutrophils within the portal areas (Fig. 35.5). Occasionally, an associated hepatic abscess may develop. Cholecystitis (inflammation of the gallbladder) may occur concurrently, or the two conditions may occur separately. A more chronic stage of neutrophilic cholangitis is also recognized; in these cases there is a mixed inflammatory infiltrate in the portal areas consisting of neutrophils, lymphocytes, and plasma cells. Some of these cases are thought to represent more chronic, persistent infection of the biliary tract, although a recent study using fluorescence in situ hybridization failed to find more bacteria in these cases than in control cats (Warren et al., 2011). There is significant overlap between cats with chronic neutrophilic cholangitis and cats with lymphocytic cholangitis; the rest of this section describes only acute neutrophilic cholangitis.

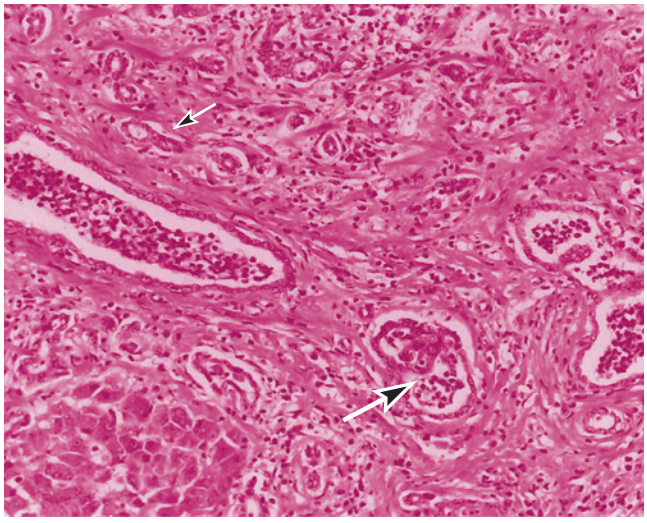

FIG 35.5
Photomicrograph of liver specimen from a cat with neutrophilic cholangitis. Note the neutrophilic and histiocytic inflammation in and around the bile ducts *(large arrow)*. Biliary ductular hyperplasia is also present *(small arrow)* (H&E stain Bar = 100·m). (Courtesy Pathology Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

Clinical Features

Cats of all ages and breeds can be affected, but acute cholangitis is most often seen in young to middle-aged cats. It usually presents acutely (less than 1 month's history), although it may be present longer. Cats typically have signs of biliary stasis and sepsis with lethargy, pyrexia, and jaundice.

Diagnosis

Clinicopathologic and imaging findings overlap with those in other diseases of the biliary tract, so a definitive diagnosis of neutrophilic cholangitis cannot be made simply from a characteristic history and clinicopathologic findings. However, cats with this acute disease tend to have higher segmented and band neutrophil counts, ALT activities, and total bilirubin concentrations than cats with lymphocytic cholangitis. Rather surprisingly, a recent study documented that some cats with acute neutrophilic cholangitis had normal white blood cell counts and liver enzyme levels, and there was significant overlap in clinicopathologic values among cats with acute neutrophilic cholangitis, chronic neutrophilic cholangitis, and lymphocytic cholangitis. Therefore clinicopathologic findings were neither sensitive nor specific for the disease (Callahan Clark et al., 2011). Also, hepatic ultrasonography is neither sensitive nor specific. Affected cats may have an enlarged hyperechoic liver on ultrasonography and may develop dilated biliary tracts more chronically, but cats with the acute disease usually have no dilation of the biliary tract on ultrasonography, and the hepatic parenchyma may appear normal (Callahan Clark et al., 2011; Marolf et al., 2012). Pancreatic abnormalities are also commonly seen on ultrasound in cats with neutrophilic cholangitis, supporting the presence of triaditis in some affected cats.

An accurate diagnosis of neutrophilic cholangitis caused by acute ascending infection requires cytology and culture of bile. Histopathology of the liver alone is not enough in this particular disease because in many cases the disease is confined to the biliary tract, and changes on liver pathology are mild and nonspecific. Samples of bile for bacterial culture can be taken carefully from the gallbladder during laparotomy or laparoscopy or under ultrasonographic guidance. There is a small but definite risk of bile leakage, particularly if the gallbladder wall is devitalized and/or there is increased intravesical pressure. In a study of six cats with neutrophilic cholecystitis, one cat developed gallbladder rupture and bile peritonitis after ultrasound-guided cholecystocentesis (Brain et al., 2006). However, in one study of transcutaneous gallbladder aspiration in 12 normal cats (Savary-Bataille et al., 2003) and in another study of 83 cats (Byfield et al., 2017), there were no cases of gallbladder rupture. If the clinician has a concern about the integrity of the gallbladder wall, it might be safer to obtain a sample at laparotomy or laparoscopy rather than under ultrasonographic guidance. In the latter case, a general anesthetic is strongly recommended to prevent patient movement while the needle is in the gallbladder, which greatly increases the risk of bile leakage. Some clinicians place the needle in the gallbladder through the hepatic parenchyma to further reduce the risk of leakage.

The cat should be monitored carefully for any leakage of bile after the procedure; any suspicion of leakage and bile peritonitis warrants surgery. Cytology of bile usually shows bacteria and neutrophils, and culture and sensitivity tests should be performed.

Treatment and Prognosis

Cats should be treated for 4 to 6 weeks with an appropriate antibiotic on the basis of the results of culture and sensitivity tests. Amoxicillin is a good initial choice at a dose of 15 to 20 mg/kg PO q8h. Ursodeoxycholic acid may be given as an additional choleretic and antiinflammatory agent at a dose of 15 mg/kg PO q24h, although there are no studies demonstrating its benefit in cats with neutrophilic cholangitis. Septic or extremely sick cats may require hospitalization for IV fluid and IV antibiotic administration during the initial stages of therapy. Careful attention should be paid to feeding anorexic cats to prevent the concurrent development of hepatic lipidosis, which was found in one third of the cats with cholangitis in a recent study (Callahan Clark et al., 2011); a high-protein diet designed for critical care use, as outlined in the lipidosis section, is more appropriate for these animals than a protein-restricted liver diet. The prognosis is generally good, and these cats usually recover completely provided they are treated early and appropriately. It is thought that some cases of the more chronic form of neutrophilic cholangitis may represent long-term persistence of a low-grade infection in untreated or only partially treated cats.

Lymphocytic Cholangitis

Lymphocytic cholangitis is also termed *lymphocytic cholangiohepatitis, lymphocytic portal hepatitis,* and *nonsuppurative cholangitis*. Some cases of chronic neutrophilic cholangitis as defined by the WSAVA may also overlap with lymphocytic cholangitis.

Pathogenesis and Etiology

Lymphocytic cholangitis is a slowly progressive chronic disease characterized by infiltration of the portal areas of the liver with small lymphocytes. Occasionally, plasma cells and eosinophils can be seen. The presence of neutrophils might change the name of the disease to chronic neutrophilic cholangitis, but some authors include a predominantly lymphocytic disease with a small number of neutrophils in the lymphocytic chronic cholangitis category. Histologic changes vary among cases, probably reflecting a variety of as yet unknown etiologies. In the largest study on the histology of the disease (Warren et al., 2011), many cats had biliary hyperplasia and peribiliary fibrosis, but a small number of cases showed ductopenia (loss of bile ducts). The lymphocyte infiltrate was predominantly of T cells, but portal B-cell aggregates seemed to be a particular feature of the disease. Bile duct targeting by inflammatory cells was common. In severe cases the main differential diagnosis on histology is lymphoma, and in some cases, differentiating the two diseases can be difficult. The cause is unknown, and the variety of clinical and histologic presentations suggests more than one cause. Some researchers have suggested an immune-mediated etiology, but the disease does not resolve with immunosuppressive medication. Other studies have suggested possible infectious etiologies, such as *Helicobacter* or *Bartonella* spp. (Boomkens et al., 2004; Greiter-Wilke et al., 2006; Kordick et al., 1999), although recent work has not supported infectious causes (Warren et al., 2011). However, the use of immunosuppressive medication in all these cases is subject to question.

Clinical Features

Cats with lymphocytic cholangitis were previously reported to be typically young to middle-aged, and Persians appeared to be overrepresented, but recent studies report it in older cats with no obvious breed predisposition (Callahan Clark et al., 2011; Warren et al., 2011). Affected cats tend to have a long history (months to years) of waxing and waning low-grade illness. Many become jaundiced, and they often lose weight and have intermittent anorexia and lethargy, but they are less likely to be pyrexic than cats with neutrophilic cholangitis. About one third of cats may also present with a high-protein ascites, reportedly most commonly in the United Kingdom. This makes differentiation from feline infectious peritonitis (FIP) important. Ultimately, the differentiation in these cats can be made only on histopathology.

Diagnosis

Diagnosis in these cases relies ultimately on hepatic histopathology, although ultrasonographic and clinicopathologic findings can support a presumptive clinical diagnosis. Increases in liver enzyme levels are mild to moderate and tend to be less marked than in cats with neutrophilic cholangitis. Peripheral blood neutrophilia is less common than in cats with the acute disease but may be present. A particular feature of most cats with lymphocytic cholangitis is an increase in γ-globulin concentration, which again may cause confusion with FIP. However, some cats have normal white blood cell counts and liver enzyme levels, so these findings are neither sensitive nor specific (Callahan Clark et al., 2011). Radiographic signs are also nonspecific; there may be hepatomegaly (which is often caused by enlargement of the larger bile ducts) and in some cases abdominal effusion but radiographs are often normal (Fig. 35.6). Ultrasonography is more helpful and reveals dilation of the biliary tract in some patients (see Fig. 34.11). The common bile duct typically appears dilated, and there may be dilation of the gallbladder and sludge in it. The main differential diagnosis for these cats is EBDO; the ultrasonographer should attempt to rule this out by carefully imaging the surrounding pancreas, small intestine, and mesentery, although it can be difficult to rule out EBDO completely particularly if it is caused by an echolucent lesion or sphincter of Oddi spasm.

It is very important to evaluate a hemostasis profile before performing a liver biopsy in view of how commonly coagulation times are prolonged in cats with liver disease. Vitamin K should be given before the biopsy (0.5 mg/kg of vitamin

K_1 SC or IM, q12h for 3 days) if there is any concern about hemostasis; fresh-frozen plasma should be available to manage potential postbiopsy bleeding. The author routinely administers vitamin K for 2 to 3 days before liver biopsy in all cats. It is recommended that biopsies be taken from multiple lobes because histologic findings can vary considerably among liver lobes (Callahan Clark et al., 2011; Warren et al., 2011). Bile aspiration is not necessary unless the disease is more acute and there is a possibility of neutrophilic cholangitis. Histology is important to rule out FIP (see Chapter 96) and lymphoma (see Chapter 79). Hepatic lymphoma shows a predilection for portal areas in cats, so it is an important differential diagnosis in these cats. Large cell lymphomas are relatively easy to diagnose, but small cell lymphomas appear similar cytologically and histologically to lymphocytic cholangitis. Features suggesting lymphoma include a dense lymphocytic infiltrate extending beyond the limiting plate, an absence of peribiliary fibrosis, and evidence of lymphoma in other tissues, such as the intestine and abdominal lymph nodes. The polymerase chain reaction (PCR) for antigen receptor rearrangement (PARR) assay (see Chapter 79) may be helpful in distinguishing lymphoma from inflammatory disorders. The typical hepatic lesion in cats with FIP is a multifocal pyogranulomatous reaction with evidence of vasculitis or perivasculitis, which is distinct from the periportal lymphocytic infiltrate seen in cats with lymphocytic cholangitis (Fig. 35.7). Serology or PCR assay for *Bartonella* spp. might be considered, although the importance of this organism in the naturally occurring disease is unclear.

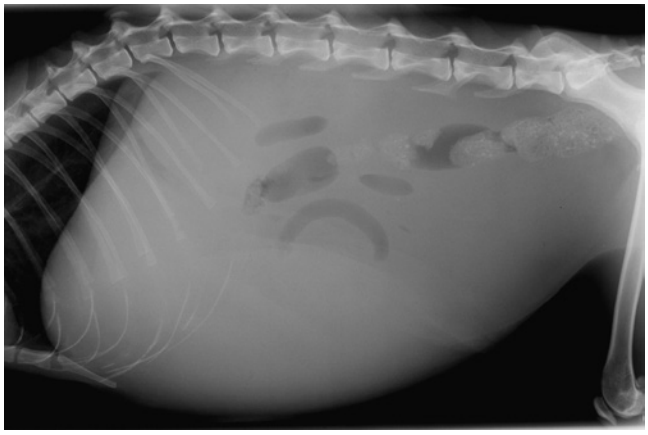

FIG 35.6
Lateral abdominal radiograph from a cat with lymphocytic cholangitis and associated ascites. The major differential diagnosis in this case would be feline infectious peritonitis. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

Treatment and Prognosis

Researchers disagree on the recommended therapy for this disease, which likely reflects uncertainty about its etiology. Several authors recommend immunosuppressive doses of corticosteroids. However, although these tend to ameliorate the acute flare-ups of the disease, they do not lead to resolution of signs, and the condition invariably recurs. Antibiotic therapy is wise, at least early in treatment, until an infectious etiology has been ruled out. There is a logical reason to use ursodeoxycholic acid (15 mg/kg PO q24h) in these cats for its choleretic and antiinflammatory effects, as well as its effect on modulating the bile acid pool and reducing toxic bile acids. Use of antioxidants such as S-adenosylmethionine (20 mg/kg or 200-400 mg total, once daily on an empty

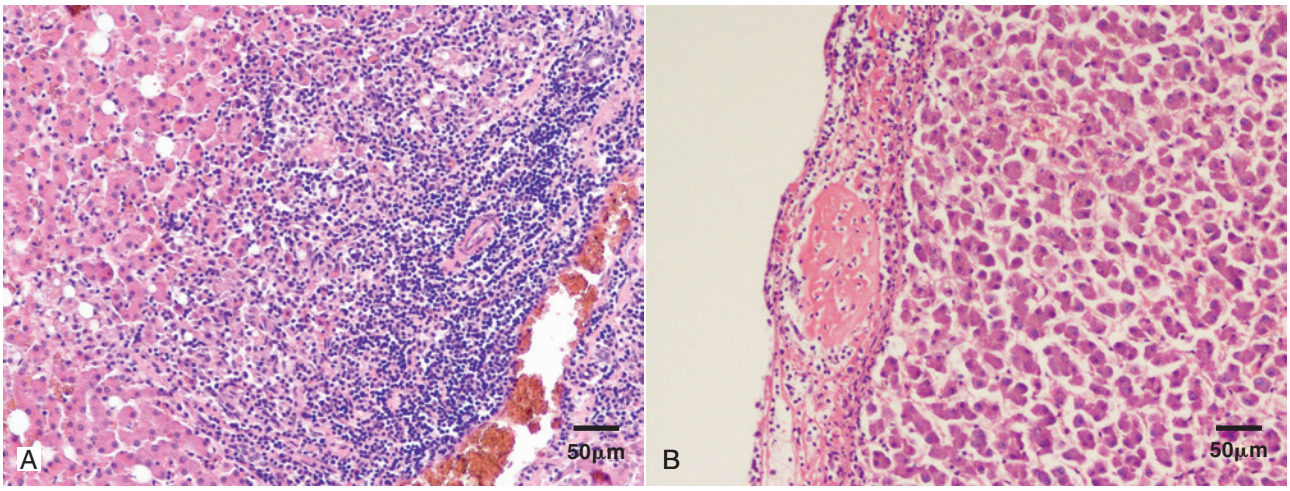

FIG 35.7
(A) Photomicrograph of liver specimen from a cat with severe lymphocytic cholangitis. There is an intense mononuclear cell infiltration surrounding the portal tract. **(B)** Photomicrograph of liver specimen from a cat with feline infectious peritonitis. Note the pyogranulomatous perivascular inflammation along the liver capsule (left-hand edge) (**A** and **B,** H&E stain). Bar = 50 µm. (Courtesy Pathology Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

stomach) and vitamin E (≈100 IU daily) is also logical because bile is a potent oxidizing toxin in the liver. A recent retrospective study of 26 cats with lymphocytic cholangitis, with a preponderance of older male cats and Norwegian Forest cats, suggested that cats had a longer survival time when given prednisolone alone than when given ursodeoxycholic acid alone (Otte et al., 2013). Further prospective studies are necessary to evaluate these therapies individually and together in a wider range of ages and breeds before the results can be generalized to all cats with lymphocytic cholangitis. Again, it is important to ensure that affected cats eat to prevent the development of concurrent hepatic lipidosis; as discussed earlier, a highly digestible, high-quality diet without protein restriction is indicated. A diet formulated for feline intestinal disease (e.g., Eukanuba feline intestinal, Procter & Gamble, Cincinnati, Ohio; Royal Canin feline selected protein; or Hill's i/d) might be the most appropriate because of the relatively high prevalence of concurrent IBD. Tube feeding should be considered if necessary (see earlier, "Hepatic Lipidosis"). Cats with more acute signs, particularly associated with concurrent intestinal and/or pancreatic disease, may require hospitalization and IV fluid therapy.

The prognosis for cure appears to be poor because the disease appears to wax and wane chronically in spite of treatment. However, few cats with lymphocytic cholangitis die as a result of their disease and those that do die have a high prevalence of concurrent pancreatic and intestinal disease, which may explain their poor outcome (Callahan Clark et al., 2011). This is likely because, as opposed to dogs, the disease does not generally progress to end-stage cirrhosis.

Sclerosing Cholangitis

Sclerosing cholangitis, or biliary cirrhosis, involves an end-stage fibrotic liver and is uncommon in cats except in association with liver fluke. Cats appear to be very resistant to hepatic fibrosis. The condition is characterized histologically by diffuse proliferative fibrosis of the bile duct walls spreading to involve the hepatic lobules and disrupting their architecture and circulation. It is thought in most cases to represent an end stage of chronic biliary tract disease, usually complete obstruction or chronic severe liver fluke infestation (see the next section). It is unusual for neutrophilic or lymphocytic cholangitis to progress to sclerosing cholangitis in cats. Some cases of ductal plate abnormality may be misdiagnosed as sclerosing cholangitis in cats (see later section). Affected cats present with typical clinical signs of chronic biliary tract disease (see previous "Cholangitis" and later "Extrahepatic Biliary Tract Obstruction"). Affected cats may also develop chronic portal hypertension, with the resultant development of ascites, gastrointestinal ulceration, and/or an acquired portosystemic shunt (PSS) and HE (see Chapter 33). Acquired PSSs are much less common in cats than in dogs. Sclerosing cholangitis is diagnosed on hepatic biopsy; again, it is very important to evaluate hemostasis profiles before biopsy and to administer vitamin K_1 (0.5 mg/kg SC or IM q12h for up to 3 days) as necessary because vitamin K deficiency is common in cats with chronic biliary tract obstruction. It should be noted that cats with sclerosing cholangitis may have hepatomegaly on radiography, which is unexpected; cirrhosis usually results in a small liver in dogs. Presumably, this reflects the biliary tract dilation and florid peribiliary fibrosis in these cases. Treatment is supportive, with treatment of only the clinical signs associated with portal hypertension, as outlined in Chapter 36.

Liver Fluke Infestation

Etiology and Pathogenesis

Liver fluke infestation is regularly observed in cats from areas endemic for the family Opisthorchiidae *(Platynosomum* spp., and occasionally *Amphimerus pseudofelineus* and *Metametorchis intermedius).* It is estimated that, in Florida and Hawaii, the prevalence of *Platynosomum fastosum* (the most common feline liver fluke) is as high as 70%; the clinical feline disease is referred to as lizard poisoning. The flukes require two intermediate hosts: water snails and lizards, amphibians, geckos, or fish, depending on the species. The cat is the final host and is infested by ingesting the metacercariae in the second intermediate host. The immature flukes migrate from the intestine to the liver via the bile ducts and become adult and patent by 8 to 10 weeks. Eggs can then be found in the feces (inconsistent) or bile aspirates (more reliable). The severity of associated disease seems to depend on the parasite load and on individual responses. Many cases are mild. In some cases the pancreas may also be affected. The clinical signs are caused by peribiliary inflammation and fibrosis in the liver, culminating, in severe cases, in an obstructive jaundice. In experimental infestations, hepatic lesions are visible histologically starting approximately 3 weeks postinfestation. There is an initial distention of proximal bile ducts and a neutrophilic and eosinophilic inflammatory response, which progresses chronically to adenomatous duct hyperplasia and surrounding florid fibrosis. Eosinophils may be absent in the later stages of disease, and flukes and eggs may not be seen on histology.

Clinical Signs

Commonly, cats with low-grade infestations remain asymptomatic. However, heavy infestations can be associated with severe and often fatal disease (Haney et al., 2006; Xavier et al., 2007). In these cases clinical signs are typically those of posthepatic jaundice combined with those of inflammatory liver disease (e.g., jaundice, anorexia, depression, weight loss, lethargy). Diarrhea and vomiting have been features of clinical cases but do not occur in experimental cases; affected cats may also have hepatomegaly and ascites.

Diagnosis

Diagnosis is made after a history of exposure (cats often have a history of hunting lizards), combined with finding the flukes or eggs in feces or bile. Supportive findings are high liver enzyme levels typical of cholestasis; ALT, AST, and bilirubin concentrations are particularly high, but the ALP level is surprisingly often only mildly increased. Eosinophilia is inconsistent. Ultrasonography reveals changes typical of

biliary tract disease, such as dilation of the bile ducts. In one case fluke infestation also caused acquired polycystic disease of the biliary system (Xavier et al., 2007).

Ova may be found in the feces using the formalin-ether sedimentation method (Box 35.3). However, shedding of eggs is sporadic; also, eggs will not be present if the fluke infestation has resulted in a complete biliary obstruction. The most reliable way of demonstrating flukes and eggs is with bile aspirates.

Treatment

The ideal and most effective treatment regimen for feline liver flukes remains controversial. Currently, the most commonly recommended treatment is praziquantel (20 mg/kg SC q24h for 3 days). The prognosis for recovery in severely affected cats is poor.

CHOLECYSTITIS

Cholecystitis refers to inflammation of the gallbladder. Neutrophilic cholecystitis is frequently seen in cats but rarely in dogs. It may occur alone or in combination with neutrophilic cholangitis. Ultrasonographically, the gallbladder wall often appears thickened and sometimes irregular; there may be sludging of the bile and/or choleliths. Clinical signs, diagnosis, and treatment are similar to those of neutrophilic cholangitis (see earlier). Chronic thickening of the gall bladder wall may be an indications for surgical cholecystectomy since bacterial infections recur in these patients. Lymphocytic cholecystitis is also occasionally recognized and is treated like lymphocytic cholangitis (see earlier).

EXTRAHEPATIC BILE DUCT OBSTRUCTION

Pathogenesis and Etiology

EBDO is a syndrome associated with several different underlying causes. These may be categorized as extraluminal compressive or intraluminal obstructive lesions, but diseases often cause EBDO through a combination of these mechanisms; for example, cholangitis may result in a combination of extraluminal compression by associated edema and inflammation and intraluminal obstruction by inspissated bile. Therefore it is more practically helpful to divide the causes into common and less common causes (Box 35.4). Several studies have shown inflammation of the small intestine, pancreas, biliary tract, or a combination of these (known as triaditis) to be the most common cause of EBDO in cats; neoplasias of the biliary tract or pancreas are the next most common cause. Dysfunction of the sphincter of Oddi because of adjacent duodenal inflammation or neoplasia has also been recently reported in cats and may be more common than appreciated because of difficulties in diagnosis (Furneaux, 2010). Choleliths are uncommon in cats. Those reported in the literature are usually cholesterol or calcium salts, or a mixture of these, and are associated with cholangitis. They are variably radiodense depending on the amount of calcium in the stone, but they are easily visualized using ultrasonography (Fig. 35.8). Two of the three cases of bilirubin choleliths reported in the literature were from Somali cats with pyruvate kinase deficiency, and it was assumed that they were secondary to chronic hemolysis (Harvey et al., 2007). Therefore finding bilirubin choleliths in a cat should stimulate a search for underlying hemolytic disease.

BOX 35.3

Formalin-Ether Sedimentation Technique for Detecting *Platynosomum concinnum* Ova in Feces

1. Mix 1 g of feces in 25 mL saline; filter through a fine mesh screen.
2. Centrifuge solution for 5 min at 1500 rpm; discard the supernate.
3. Resuspend the pellet with 7 mL of 10% neutral buffered formalin; let stand for 10 min.
4. Add 3 mL of cold ether on top of solution and shake vigorously for 1 min. Centrifuge for 3 min at 1500 rpm.
5. Discard the supernate, resuspend the pellet in several drops of saline, and prepare slide of solution to examine microscopically.

From Bielsa LM et al: Liver flukes *(Platynosomum concinnum)* in cats, *J Am Anim Hosp Assoc* 21:269, 1985.

BOX 35.4

Causes of Extrahepatic Bile Duct Obstruction in Cats

Common Causes

One or a combination of inflammation of pancreas, duodenum, or biliary tree (most common)
Neoplasia, particularly of the biliary tree or pancreas (second most common)

Less Common Causes

Stricture of bile duct after inflammation, surgery, or trauma
Sphincter of Oddi dysfunction
Diaphragmatic with involvement of the gallbladder or common bile duct and subsequent compression
Cholelithiasis
- Usually cholesterol and/or calcium salts concurrent with cholangitis
- Occasionally bilirubin, associated with pyruvate kinase deficiency–induced hemolysis in Somali cats

Cysts (congenital or acquired) compressing biliary tree
Liver flukes
Foreign body

Note: Sepsis distant to the liver can produce an associated biliary stasis, which may appear clinicopathologically to be very similar to extrahepatic bile duct obstruction (EBDO). Also, biliary tract rupture (usually traumatic) produces clinicopathologic findings similar to those of EBDO but the cat is usually much sicker.

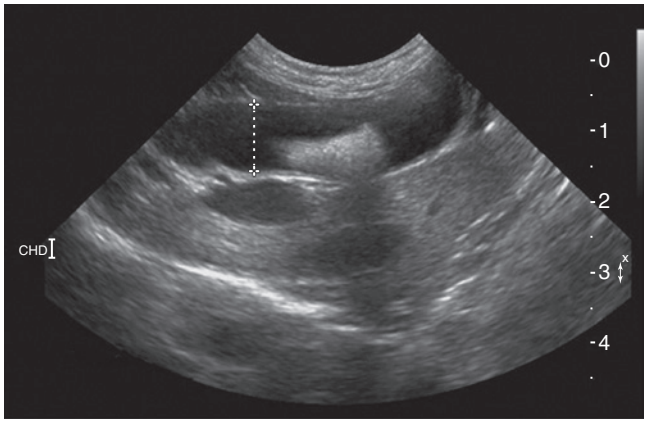

FIG 35.8
Ultrasound image of the common bile duct in a cat with choleliths causing extrahepatic biliary obstruction. Note that the bile duct is markedly dilated and contains a radiodense cholelith with distal acoustic shadowing. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

Clinical Features

In cats with EBDO, clinical signs, clinicopathologic findings, and survey radiographic findings are indistinguishable from those associated with other severe cholestatic hepatopathies; jaundice, anorexia, depression, vomiting, and hepatomegaly are the main presenting features. Cats with biliary obstruction can also be painful, and the clinician should be aware of subtle signs because cats tend to hide their pain. If biliary obstruction is complete, feces will be pale or acholic. There may be a cranial abdominal mass on palpation because of a very distended gallbladder or underlying neoplasia, but often abdominal palpation is normal (other than the hepatomegaly). Cats with EBDO are at particular risk of malabsorption of fat-soluble vitamins, including vitamin K, because of the lack of intestinal bile salts reducing fat digestion. This is compounded in many cases by the concurrent intestinal and/or pancreatic disease, which further reduces fat absorption. As discussed previously, it is very important in these cases to assess coagulation times before performing biopsies or surgery and to supplement vitamin K parenterally as necessary. However, to the author's knowledge, no correlation between the results of hemostasis profiles and development of postbiopsy bleeding has been established.

Diagnosis

Ultrasonography is the most useful diagnostic tool to differentiate EBDO from other biliary tract diseases in cats; sometimes, the cause of EBDO is determined. Clinicopathologic findings are nonspecific; the high concentrations and activities of hepatocellular and biliary enzymes, bilirubin, and cholesterol resulting from cholestasis are indistinguishable from those in cats with other cholestatic hepatopathies. Ultrasonography will usually reveal dilation of the gallbladder and extrahepatic and intrahepatic biliary trees (see Fig. 35.8), although gallbladder dilation is not a consistent or essential finding. A search should then be conducted for a possible cause of obstruction by carefully examining the small intestine, liver, and pancreas for evidence of inflammation or neoplasia. Biliary tract rupture can present in a similar way and should be ruled out by identifying and analyzing any free abdominal fluid; cats with biliary rupture have a high concentration of bilirubin in the fluid. FNA of bile from the gallbladder under ultrasonographic guidance should be avoided or approached with great care if EBDO is suspected or confirmed because of the high risk of leakage caused by the increased pressure. In these cats it is preferable to aspirate bile during surgery. It may be necessary to undertake an exploratory laparotomy to assess bile duct patency and the cause of the obstruction. Hemostatic function should be assessed first, and vitamin K therapy given (0.5 mg/kg of vitamin K_1 SC or IM q12h for 3 days). The liver, pancreas, and small intestine should be carefully inspected and biopsied as necessary.

Treatment

Treatment depends on the underlying cause of the EBDO and whether the obstruction is complete or partial. The prognosis for partial obstructions is surprisingly good when using medical management, and surgery may not be necessary in all cases. Studies of EBDO in acute-on-chronic pancreatitis in humans suggest that medical management rather than surgery or stenting is the treatment of choice in most cases and that there are usually no long-term sequelae (Abdallah et al., 2007). Similar studies have not been reported in cats.

If the feces are not acholic and there is some evidence of bile flow into the duodenum and no pain, cats can be managed medically with a choleretic (ursodeoxycholic acid, 15 mg/kg PO q24h) and an antioxidant (e.g., S-adenosylmethionine, 20 mg/kg, or 200-400 mg daily on an empty stomach) to protect the hepatocytes against bile-induced oxidant damage. The underlying disorder should also be treated as outlined in the preceding section. However, if the cat does not improve after several days or signs of complete obstruction develop, such as acholic feces, surgical intervention is indicated. Major biliary tract surgery in the cat carries a high morbidity and mortality, and should be undertaken only when necessary to relieve complete obstruction. More minor procedures such as sphincterotomy, cholecystectomy, and stent placement are better tolerated.

DUCTAL PLATE ABNORMALITIES

The ductal plate is the distinct layer of cells surrounding the developing portal triad in the fetus. Abnormalities in the development of this cause a variety of congenital disorders particularly affecting intrahepatic bile ducts including biliary cysts (see later) and congenital hepatic fibrosis. Although uncommon, these are reported in cats. Cats with inherited polycystic kidney disease often also have cysts within the liver. In some cases, these are associated with the classic

mutation for polycystic kidney disease, and in others, they are not (Guerra et al., 2015). Congenital hepatic fibrosis has also been reported in cats, and Persian cats appear to be over-represented (Bosje et al., 1988; Zandvliet et al., 2005). Affected cats usually present with signs of portal hypertension including ascites, lethargy and vomiting, and HE. Alternatively, lesions may be discovered incidentally on ultrasound. Portal hypertension is unusual in cats and should raise the suspicion of ductal plate abnormality particularly in areas where liver fluke is not endemic. Inexperienced pathologists may erroneously diagnose some cases of ductal plate abnormality as biliary cirrhosis. Cytokeratin staining of liver sections helps highlight the classic marked proliferation of small bile ducts seen in the bridging fibrosis in congenital hepatic fibrosis.

Affected cats are treated symptomatically for portal hypertension (see Chapter 36 for more details). Prognosis can be good with life-long treatment.

BILIARY CYSTS

Most cystic lesions in the feline liver are of bile duct origin and may be congenital or acquired. Congenital cysts are usually multiple and often present as part of a congenital ductal plate abnormality as described earlier, polycystic disease of several organs, including the kidneys. The cystic contents are clear. Persian cats and Persian crosses are at increased risk. Cysts may be an incidental finding on imaging, particularly if they are small, but large cysts can cause clinical signs as a result of destruction of hepatic tissue and also compression of surrounding bile ducts resulting in signs of biliary tract obstruction (see earlier). Treatment is not indicated if they are small and nonprogressive, but if they are large and causing problems, they may be treated surgically by removal or omentalization (Friend et al., 2001).

Acquired hepatic cysts may be single or multiple and may be small or very large. The contents may be clear, bloody, or bilious. They may occur secondary to trauma, inflammation, or neoplasia (including biliary cystadenomas; Fig. 35.9) or in rare cases caused by liver flukes. Therapy depends on the cause, but surgical management may be necessary if they are large. Cysts may also occur in the form of large, irregular sacculations of the extrahepatic bile duct (choledochal cysts).

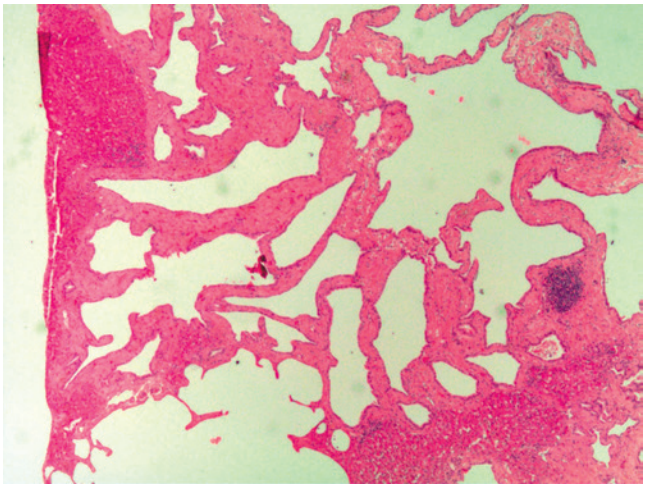

FIG 35.9

HEPATIC AMYLOIDOSIS

Etiology

Hepatic amyloidosis is an uncommon but apparently emerging cause of liver disease in cats. Historically, amyloidosis was usually recognized as a familial disease in Abyssinian cats, which predominantly affects the kidneys although liver involvement is not uncommon. However, amyloidosis in Siamese cats is predominantly hepatic. Hepatic amyloidosis has also been reported in domestic shorthairs, oriental shorthairs, and a Devon Rex cat (Beatty et al., 2002). The amyloid in familial and sporadic cases is amyloid A (inflammatory), and in sporadic cases there is usually an underlying chronic inflammatory process in another organ (e.g., chronic gingivitis), which is thought to be the driving force for the formation of the inflammatory amyloid.

Clinical Signs

Affected cats usually present with signs of anemia and hypotension related to rupture of the hepatic capsule and hemoabdomen. These cats are predisposed to hepatic rupture because the liver is enlarged and rigid, and therefore easily damaged with normal trauma, such as jumping. Affected cats usually exhibit lethargy, anorexia, pale mucous membranes, bounding pulse, and heart murmur secondary to the anemia but rarely any specific signs of liver disease. There may be hepatomegaly on abdominal palpation.

Diagnosis

Diagnosis relies on histopathology of a liver biopsy; although clinicopathologic and ultrasonographic findings are supportive, it is important to rule out the major differential diagnoses of FIP, hepatic lipidosis, and hepatic lymphoma. The transient anemia resolves as blood is reabsorbed from the abdomen (autotransfusion). There are mild to marked increases in ALT activity and globulin concentration, but there are rarely increases in ALP and GGT levels, which helps differentiate amyloidosis from biliary tract disease and lipidosis. On ultrasonography, amyloidosis can resemble lymphoma and lipidosis, with hepatomegaly and a generalized increase in hepatic parenchymal echogenicity or a mixed hypoechoic and hyperechoic appearance (Beatty et al., 2002), but no dilation of the biliary tract. FNA cytology is not helpful because amyloid does not appear on the aspirate. Therefore hepatic biopsy, after careful evaluation of hemostasis profiles, is the recommended method of diagnosis.

Treatment and Prognosis

Treatment is supportive because there is no specific antiamyloid medication. Colchicine is of uncertain efficacy and is not indicated for cats because of its potential toxicity. Instead, the focus should be on reducing or eliminating the underlying inflammatory disorder driving the amyloid deposition and supportive care with antioxidants and vitamin K supplementation as necessary (0.5 mg/kg SC or IM every 7-20 days). Blood transfusions may be necessary in cats with acute hemoabdomen. The long-term prognosis is poor, and most cats die as a result of intraabdominal bleeding.

FELINE COPPER STORAGE DISEASE

Primary and secondary accumulation of copper is much less common in feline liver disease than in dogs (see Chapter 36), however, it has been reported (Whittemore et al., 2012; Hurwitz et al., 2014). It is therefore important to consider staining feline liver biopsies for copper.

Primary copper storage disease has been reported in cats with typical centrilobular distribution of copper on histology and a high dry weight concentration of copper on analysis of liver (Hurwitz et al., 2014). Affected cats can be any sex or breed but tended to be young (median 2 years). Clinical, clinicopathologic, and imaging findings overlap other feline hepatobiliary disorders, particularly cholangitis. All cats had elevated ALT and, in some affected cats, the elevation was marked. Diagnosis was on the basis of histopathology and on measurement of copper > 700 μg/g of liver sample dry weight. Cats were treated with a low copper diet (Prescription Diet L/D Feline Hepatic Health, Hills Pet Nutrition Inc, Topeka, Kansas or Veterinary Diet Feline Hepatic, Royal Canin, St Charles, MO.) and chelation with penicilliamine 10 to 15 mg/kg per os every 12 hours. Close monitoring is necessary because one cat developed hemolytic anaemia during treatment, which resolved with cessation of penicillamine. Alternatively, elemental zinc (2-4 mg per os every 24 hours) could be used instead of chelation, although the relative efficacy is unclear. It is important not to use zinc concurrently with penicillamine as zinc will compete with the copper for chelation. Administration of antioxidants is also wise (vitamin E and SAMe).

NEOPLASIA

Etiology

Primary liver tumors are uncommon in cats but appear to be more common than in dogs. Hepatic tumors are much less common in both species than in humans, possibly because two of the predisposing factors for development of liver tumors (hepatitis virus infection and α-protease inhibitor deficiency) have not been recognized in small animals. Cirrhosis also predisposes to liver tumors in humans but is rare in cats. Liver tumors represent 1% to 3% of all neoplasms in cats (Liptak, 2007) but up to 7% of the nonhematopoietic tumors. No predisposing factors have been identified except possibly primary copper storage disease (Hurwitz et al., 2014). In cats, in contrast to dogs, benign tumors are more common than malignant tumors; they are frequently an incidental finding during workup for other diseases.

An unusual benign tumor occasionally found in cats is the myelolipoma, which has a suggested association with chronic hypoxia and hepatic involvement in diaphragmatic hernias. Biliary carcinomas are the most common malignant tumors in cats, which may mirror the high prevalence of biliary tract disease in this species. Trematodes are also a predisposing cause in humans and possibly in some cats, but bile duct carcinomas also occur in cats outside the range of liver fluke infestations, so there are other factors involved. Also in contrast to dogs, primary hepatobiliary tumors are more common than metastatic neoplasia in cats. Secondary tumors include particularly hematopoietic tumors, such as lymphoma and, less commonly, leukemias, histiocytic tumors, and mast cell tumors, as well as metastases from other organs (e.g., pancreas, mammary glands, gastrointestinal tract). Hemangiosarcomas in the liver may be primary or secondary, and sometimes the origin is difficult to ascertain if multiple organs are involved, although primary hepatic hemangiosarcomas appear to be more common in cats than in dogs.

The common feline primary liver tumors recognized and their behavior are outlined in Table 35.4.

Clinical Features

Primary malignant tumors of the liver are usually seen in older cats (mean age, 10-12 years), and there is no obvious gender predisposition reported. The presenting clinical signs and clinicopathologic findings are indistinguishable from those in cats with other types of primary liver diseases. There may be lethargy, vomiting, weight loss, ascites, or jaundice. Some affected cats may have palpable hepatomegaly, ascites, or liver masses on abdominal palpation. However, at least 50% of cats with liver tumors are asymptomatic.

Diagnosis

Diagnosis relies on a combination of diagnostic imaging, cytology, and histology. A suspicion may be gained from the clinical findings, but given that more than half of affected cats have no clinical signs, the liver mass may be a serendipitous finding while the cat is being evaluated for another reason. On clinical pathology, high liver enzyme activity and bile acid concentration and mild anemia and neutrophilia are common but nonspecific findings. Jaundice is uncommon but can occur. Liver function is usually normal because the tumor must involve more than 70% of the liver mass before resulting in a reduction in liver function. The exception to this is a diffuse hematologic malignancy (e.g., lymphoma), which can result in a significant disturbance of hepatocyte function (including coagulopathies). The functional defects often resolve when the tumor is cytoreduced by chemotherapy.

TABLE 35.4

Primary Liver Tumors in Cats

TYPE OF TUMOR	BEHAVIOR
Bile Duct Tumor	
Biliary carcinoma (including cystadenocarcinoma) Biliary adenoma Gallbladder tumors	Most common primary liver tumor in cats (>50%) Biliary carcinoma most common malignant feline liver tumor Aggressive behavior—diffuse intraperitoneal metastases in 67%-80% of cases
Hepatocellular Tumor	
Hepatocellular carcinoma (HCC) Hepatocellular adenoma (hepatoblastoma; very rare)	Recognized but less common than biliary tumors Adenoma more common than carcinoma
Neuroendocrine Tumor	
Hepatic carcinoid	Very rare but very aggressive
Primary Hepatic Sarcoma	
Hemangiosarcoma, leiomyosarcoma, others	Uncommon Most locally aggressive, high metastatic rate Hemangiosarcoma most common primary hepatic sarcoma in cats

Note: Benign tumors are more common than malignant tumors in this species.

Radiographs may show hepatomegaly; the liver may have an irregular border or focal enlargement of one lobe. There may be also involvement of other organs (e.g., lymphadenopathy in cats with lymphoma), and thoracic radiographs may reveal evidence of metastases. However, radiographs may also be normal. Some malignant hepatic tumors commonly seed the peritoneum and metastasize to local lymph nodes or lungs. As in other diseases of the liver, ultrasonography is more helpful in identifying a hepatic mass and evaluating for metastases; it also allows for FNA of the mass(es). Hepatic tumors can also be cystic, particularly cystadenocarcinomas (see Fig. 35.9). Cats, unlike dogs, rarely have benign nodular hyperplasia in the liver, so this is not a likely differential diagnosis for a hepatic mass. Diffuse hepatic tumors (e.g., lymphoma) may show a diffuse change in echogenicity, or the liver may appear normal on ultrasonography. Important differential diagnoses for diffuse hepatic tumors are FIP, lipidosis, and amyloidosis. A thorough abdominal ultrasonographic examination should be undertaken to search for evidence of metastases. It should be kept in mind that, because benign tumors are more common than malignant tumors in cats, no animal should be euthanized on the basis of finding a hepatic mass with no evidence of metastases on ultrasonography.

A definitive diagnosis is usually obtained using cytology or histopathology; as mentioned earlier, cats with hepatic lymphoma may have ultrasonographically normal-appearing livers, so FNA should always be performed in these patients. In some cases FNA may be diagnostic, but in others they may be difficult to interpret, particularly in cats with benign hepatocellular tumors, in which the cells are indistinguishable from normal hepatocytes. Ultrasonography-guided Tru-Cut–type biopsies are usually diagnostic; alternatively, biopsies can be obtained during laparoscopy or laparotomy. In the case of an apparently single lesion, the clinician may elect to proceed straight to surgical removal and an excisional biopsy. Hemostasis profiles should be evaluated before performing a biopsy. It is unusual for the one-stage prothrombin time and activated partial thromboplastin time to be prolonged in cats with primary liver tumors, but they can be markedly prolonged in cats with diffuse hepatic infiltration with lymphoma or other diffuse secondary tumors (e.g., mast cell tumors). Biopsies should not be considered in these cases until clotting factors have been replenished with a fresh-frozen plasma transfusion.

Treatment

Treatment of primary hepatic tumors relies on surgical removal if they are resectable. This is advisable even in cats with benign tumors, including biliary adenomas. Treatment of diffuse, nodular, or metastatic tumors may be difficult. Primary hepatic tumors generally have a poor response to chemotherapy. It has been suggested that this is because hepatocytes, normal and transformed, have high expression of the multidrug resistance membrane-associated P-glycoprotein and that hepatocytes are naturally high in detoxifying enzymes. Radiotherapy is not wise because normal liver tissue is very radiosensitive. For additional information, please see Chapter 79 (the section on lymphoma) and Chapter 81 (the section on mast cell tumors).

Prognosis

The prognosis of benign tumors is good after resection but poor for cats with any type of malignant liver tumor. However, most cats with lymphoma of the liver respond to chemotherapy (see Chapter 78).

CONGENITAL PORTOSYSTEMIC SHUNTS

Etiology and Pathogenesis

PSSs are abnormal vascular communications between the portal and systemic circulations. They may be congenital or acquired secondary to portal hypertension. The latter are usually multiple vessels and are very rare in cats because they usually occur secondary to congenital hepatic fibrosis (see earlier) and cirrhosis, both uncommon in cats. Acquired PSS secondary to a congenital hepatic arteriovenous (AV) fistula

has been reported in a young cat but is very rare (McConnell et al., 2006).

Most cases of PSS in cats are therefore congenital, but even these are recognized less commonly than in dogs. Congenital PSSs are usually single or, at most, double vessels and may be intrahepatic or extrahepatic (Lipscomb et al., 2007). Extrahepatic PSSs represent abnormal communications between the portal vein or one of its contributors (e.g., left gastric, splenic, cranial, or caudal mesenteric or gastroduodenal vein) and the caudal vena cava or azygos vein. Intrahepatic PSSs may be left-sided, in which case they are believed to represent a persistence of the fetal ductus venosus after birth (patent ductus venosus [PDV]; White et al., 2001), or they may be right-sided or centrally located in the liver, in which case they are believed to be anomalous vessels.

The pathophysiology of congenital PSS largely relates to the shunting of unfiltered blood directly into the systemic circulation, resulting in hyperammonemia and HE. The pathophysiology of HE is outlined in Chapter 33. The shunting vessel acts as a low-resistance pathway for some of the portal blood, bypassing the higher resistance intrahepatic portal vasculature. Portal pressure is therefore lower than normal in cats with congenital PSS, which is an important distinguishing feature from (rare) cases of acquired shunting, in which there is portal hypertension and therefore increased portal pressure. Concurrent hepatic microvascular dysplasia or portal vein hypoplasia, which can confuse this differentiation, occurs in some dogs (see Chapter 36) but has only been reported in one cat (Sugimoto et al., 2018). Shunting may also allow bacteremia and potentially infections of hematogenous origin that may present as so-called pyrexia of unknown origin, although this is rare. Additional effects of portal blood bypassing the liver are hepatic atrophy and a reduction in the metabolic activity of the liver, which contributes to inefficient use of dietary components, poor growth, and loss of lean body mass.

Liver atrophy (microhepatia) and changes in hepatic organelle function are partly caused by changes in hepatic perfusion. The portal blood usually provides about 50% of the liver's oxygen requirement, but this is obviously reduced in cats with PSS. Cats with PSS typically have arteriolar hyperplasia in an attempt to compensate for the reduced portal flow, but they often still have some degree of hepatic underperfusion. In addition, PSS results in reduced delivery of hepatotrophic factors, such as insulin, to the liver, which further contributes to hepatic atrophy.

Clinical Features

Persian and Himalayan cats were reported to be at increased risk for congenital PSS in a small case series, and another series noted that purebred cats in general were overrepresented; however, cats of any breed, including mixed-breed cats, can be affected. Both sexes appear to be equally at risk. There is no reported association between breed and shunt types (unlike in dogs), although in one study 6 of 13 cats with an intrahepatic PSS were Siamese (Lipscomb et al., 2007). Most cases present before 2 years of age; many are younger than 1 year, but old cats with congenital PSSs are frequently recognized.

The typical clinical signs in cats with congenital PSS are gastrointestinal, urinary, or neurologic (HE), although the latter tend to predominate in cats and, anecdotally, are often more severe than in dogs. Cats typically present with a history of waxing and waning neurologic signs consistent with HE rather than a sudden acute HE crisis. The typical signs of HE are outlined in Box 33.3. Hypersalivation is a common sign of HE in cats but is rare in dogs. There is sometimes an association between signs of HE and feeding, which may relate to glutamine metabolism by enterocytes releasing ammonia; however, not all cats display these signs. Cats in acute crisis may present comatose or with seizures; cats appear to be more susceptible to seizures than dogs, preoperatively and postoperatively. The reason for this is unknown, although it has been suggested that sudden changes in the concentrations of ammonia and other metabolites in the blood after surgery or sudden changes in medical management may destabilize neurotransmitters in cats more than dogs. Drug intolerance is common, particularly prolonged recovery from routine anesthesia for spaying or neutering. Animals with PSS may also show intermittent vomiting and/or diarrhea. Urinary tract signs are caused by cystitis associated with urate calculi and polyuria or polydipsia, but they are less common in cats than in dogs. It is important to note that as opposed to dogs, many cats with urate stones in the bladder do not have a PSS. In one study from a large U.S. stone center, only 7 of 159 cats with urate stones had a diagnosis of a congenital PSS (Dear et al., 2011). Cats with congenital PSS also often show signs of poor growth compared with their litter mates (Fig. 35.10). There has been a reported high prevalence of copper-colored irises

FIG 35.10
A 6-month-old kitten with a congenital portosystemic shunt, demonstrating very small size for its age and also copper-colored irises, which are often noted in kittens with portosystemic shunts.

in cats with PSS (see Fig. 35.10), but this is not a consistent feature.

Because of the low portal pressure, ascites is not a feature in cats, which helps in distinguishing congenital PSS from the rare feline cases of acquired PSS, in which ascites is expected because of portal hypertension.

Diagnosis

A suspicion for congenital PSS can be gained from the history of recurrent neurologic signs combined with high fasting and/or postprandial bile acid or ammonia concentration in a young cat. Traditional ammonia tolerance tests are not recommended because they can precipitate severe HE. Postprandial ammonia or bile acid determinations are safer alternatives. Serum bile acid levels should be measured before and 2 hours after feeding (see Box 34.3). If the ammonia level is measured instead, the postprandial sample should be taken 6 hours after feeding (Walker et al., 2001). Other typical (but not pathognomonic) clinicopathologic findings in some cats include a low serum urea concentration, mildly increased liver enzyme levels, and microcytosis. Notable differences from dogs are that decreases in total protein or albumin levels, hypoglycemia, and anemia are much less common in cats. Urine specific gravity is low in many dogs but occurs in fewer than 20% of affected cats. If fasting bile acid concentrations are very high, it is not necessary to obtain a postprandial sample, but the diagnostic sensitivity of doing both is higher than only measuring fasting concentrations. If biliary stasis (which also causes high bile acid concentrations) is ruled out and the cat does not have hepatic lipidosis (which causes hepatocellular failure and HE, with increases in bile acid and ammonia concentration in many cases), it is likely that the cat has a congenital PSS because other causes of HE and high bile acid concentrations are uncommon in cats. A recent case report noted significant increases in postprandial ammonia and bile acid concentrations in a cat with congenital hypothyroidism, which resolved with treatment of the hypothyroidism. The reason for this was unknown, but this is an important, albeit rare, differential diagnosis for PSS in a young cat (Quante et al., 2010). Hypocobalaminemia can also cause signs of HE with elevated ammonia but normal bile acids. This is more common in dogs but has been reported in a cat (Simpson et al., 2012). Abdominal radiographs show a small liver in 50% of cases (Lamb et al., 1996) but, for definitive diagnosis, the shunting vessel must be visualized.

Visualization of the shunting vessel is achieved by ultrasonography, portal venography, or computed tomography (CT) angiography (see Chapter 34). A liver biopsy should be taken at the time of surgery or portovenography, after evaluation of hemostasis profiles, to rule out other or concurrent conditions. This shows histologic features similar to those in dogs, typical of portal venous hypoperfusion, with loss of smaller portal veins, increased numbers of arterioles, hepatocellular atrophy with lipogranulomas, and sometimes periportal sinusoidal dilation but minimal inflammation.

Treatment

Treatment involves complete or partial ligation of the shunting vessel using one of several methods, including silk or cellophane, or ameroid constrictors; however, a detailed explanation is beyond the scope of this text. The procedure is best reserved for referral centers, particularly in cats, which are more prone to complications than dogs. The postoperative mortality in cats appears to be higher than in dogs, which is often caused by intractable, severe neurologic signs. Pretreatment with phenobarbital has been attempted, but too few cases have been reported to assess its value. Propofol infusions are often used for HE-associated seizures in dogs, but care must be taken in cats because of their susceptibility to Heinz body hemolytic anemia when they are given propofol infusions.

Cats should be managed medically before surgery and for a period of about 2 months after surgery while the portal vasculature and liver mass recover. This involves careful dietary management (see later) with additional antibiotics (usually amoxicillin, 15-20 mg/kg PO q8h) and sometimes also a soluble fiber source such as lactulose (2.5-5 mL PO q8h, to effect). Some anecdotal data suggest that changes in medical management should be made more gradually in cats than in dogs to prevent the risk of seizures (e.g., change the diet first, add antibiotics after 1 week or more, and then add the soluble fiber source later). Details of the medical management of HE are given in Chapter 36. Cats do not tolerate marked dietary protein restriction because of their high obligate protein requirement, and in fact dietary protein restriction is no longer indicated in affected animals. Little and often feeding of a highly digestible diet is recommended. A diet manufactured for cats with gastrointestinal disease (e.g., Hill's i/d or Royal Canin intestinal) is appropriate and, unlike in dogs, homemade diets based on dairy protein should be avoided in cats because dairy protein is relatively deficient in arginine, which is essential for the urea cycle. Such a deficiency will further predispose to hyperammonemia. Medical management alone is effective in some dogs long term (see Chapter 36) and anecdotally, some cats do well with medical treatment of congenital PSS, although this is less common than in dogs probably because of their high obligate protein metabolism; this would make them more susceptible to hyperammonemia, regardless of the diet fed.

Prognosis

The prognosis appears to be good if the PSS can be ligated. Medical management is worth attempting if the client declines surgery although insufficient cases have been reported to assess the long-term prognosis with either medical or surgical management in cats. However, clients should be warned that the short-term mortality rate after surgery is relatively high.

HEPATOBILIARY INFECTIONS

Several infectious organisms can infect the liver as a primary target or as part of a more generalized infection (Box 35.5).

BOX 35.5

Infectious Diseases With Hepatic Involvement in Cats

Disseminated mycobacterial infections
Histoplasmosis
Infection with *Cytauxzoon felis*
Infection with *Streptococcus* groups B and G in neonates
Leptospirosis (extremely rare)
Liver fluke (see text for details)
Feline infectious peritonitis
Toxoplasmosis
Bartonellosis
Salmonellosis
Tularemia *(Francisella tularensis)*
Tyzzer disease

Note: Neutrophilic cholangitis is often caused by ascending bacterial infection from the gut. *Bartonella* spp. may be involved in the etiology of some cases of lymphocytic cholangitis.

In addition, neutrophilic cholangitis likely has a primary infectious cause in most cats (see earlier).

Hepatic involvement is common in the dry and effusive forms of FIP (see Chapter 96). Because cats with effusive FIP can present with the same signs as cats with lymphocytic cholangitis, it is an important differential diagnosis for this disease. A liver biopsy may be necessary to distinguish them; one study suggested that Tru-Cut-type biopsy or FNA cytology of the liver is more sensitive than biopsy or aspiration of the kidney for diagnosis of FIP in cats (Giordano et al., 2005).

Disseminated toxoplasmosis is uncommon in cats, but when it occurs, the liver is usually involved with intracellular growth of *Toxoplasma gondii* during the active clinical disease, resulting in cell death. Effects of delayed hypersensitivity reactions and immune complex vasculitis also contribute to clinical illness. Trophozoite infection of the lungs, liver, and central nervous system (including the eyes) is usually responsible for clinical signs. As expected, high serum ALT levels and hyperbilirubinemia commensurate with the degree of hepatocellular necrosis are the typical serum biochemical findings in cats with liver involvement. Cholangiohepatitis resulting from infection of the biliary epithelium has been noted occasionally in experimental and spontaneously occurring cases of toxoplasmosis in cats. The distribution of affected tissues in disseminated histoplasmosis often includes the lung, eye, bone marrow, spleen, lymph node, skin, bone, and liver. Infection with *Bartonella* spp. can cause cholangitis in cats.

TOXIC HEPATOPATHY

Pathogenesis and Etiology

By definition, toxic hepatopathy refers to a hepatic injury directly attributable to exposure to environmental toxins or certain therapeutic agents. Any therapeutic agent might be hepatotoxic as a result of an idiosyncratic reaction, but only a limited number of toxicities due to the use of drugs have been reported in cats (Box 35.6) in addition to reported environmental hepatotoxins. Cats are particularly sensitive to phenol toxicity because of their limited hepatic glucuronide transferase activity. A variety of essential oils used topically have been reported to be hepatotoxic for cats. Essential oils are absorbed rapidly, both orally and dermally, and are metabolized by the liver to glucuronide and glycine conjugates; it is believed that cats are more sensitive than dogs to their hepatotoxic effects (Means, 2002).

Complete information that could support meaningful conclusions about the frequency, character, and substances that consistently cause hepatotoxicity in cats is not available. Clinicians therefore must rely on anecdotal reports, clinical observations, and data accumulated by central agencies such as the ASPCA Animal Poison Control Center (888-426-4435; $65 per case via credit card; https://www.aspca.org/pet-care/animal-poison-control) and the U.S. Food and Drug Administration (FDA) Center for Veterinary Medicine, in Washington, DC (suspected adverse drug experiences can be reported to 1-888-FDA-VETS), and in the UK

BOX 35.6

Causes of Clinically Relevant Hepatic Toxicity in Cats: Therapeutic Agents or Environmental Toxins

Therapeutic Agents

Acetaminophen, >50-100 mg/kg, but any dose potentially toxic
Amiodarone
Aspirin, >33 mg/kg/day
Diazepam
Essential oils
Griseofulvin
Ketoconazole
Megestrol acetate
Methimazole
MTP inhibitors (off-label use; see text)
Nitrofurantoin
Phenazopyridine
Stanozolol
Tetracycline

Environmental Toxins

Aflatoxin
Amanita phalloides (mushroom)
Dry-cleaning fluid (trichloroethane)
Inorganic arsenicals (lead arsenate, sodium arsenate, sodium arsenite)
Phenols
Pine oil + isopropanol
Thallium
Toluene
White phosphorus
Zinc phosphide

the Veterinary Poisons Information Service (https://vpisglobal.com/our-research/). In general, drug- or toxin-induced hepatic injury in cats is extremely uncommon, and most reactions are acute, occurring within 5 days of exposure. The character and severity of the toxic reaction depend on the characteristics of the substance, dose, and duration of exposure.

Three therapeutic agents have been reported to be hepatotoxic in some cats—tetracycline, diazepam, and stanozolol. Veterinarians have used these agents for years without known deleterious effects. For each drug, clinical and clinicopathologic signs of hepatotoxicosis developed within 2 weeks of daily oral administration at recommended dosages. The adverse hepatic reaction to tetracycline was serious but nonlethal, and the cat recovered completely after drug discontinuation and 6 weeks of supportive care (Kaufman et al., 1993). Histologic findings in the liver included centrilobular fibrosis, mild cholangiohepatitis, and mild lipid deposition in hepatocytes. In the cats that experienced diazepam-associated hepatic failure, the outcome was death in 16 of 17 despite intensive treatment. The oral dosages of diazepam that cats received, primarily for inappropriate urination, ranged from 1 mg every 24 hours to 2.5 mg every 12 hours. The histologic lesions in the liver were similar to those observed in the cat with tetracycline-associated hepatic injury but more severe: massive, predominantly centrilobular necrosis; suppurative cholangitis; and mild lipid vacuolation in some cats. Because of the severity of the lesions reported in cats apparently susceptible to diazepam-associated hepatic necrosis, serum liver enzyme levels should be evaluated during the window of days 3 to 5 of administration in cats given diazepam by mouth. Until there is more information to improve the understanding of this lethal and unpredictable hepatic reaction, use of other agents for control of behavior and elimination problems in cats is recommended. Cats that experienced an adverse reaction to stanozolol were healthy or had chronic renal failure (14 of 18 cats) or gingivitis or stomatitis (2 of 3 cats; Harkin et al., 2000). Serum ALT levels were markedly increased in most cats given 1 mg PO every 24 hours for several months or 4 mg PO every 24 hours (and 25 mg IM once) for 3 weeks; all but one survived after the drug was discontinued, and intensive supportive care was instituted. The histologic lesions were moderate to marked diffuse centrilobular lipidosis and evidence of intrahepatic cholestasis—accumulation of bile and lipofuscin in hepatocytes and Kupffer cells.

The discriminatory eating habits of cats may account for the relatively uncommon occurrence of hepatotoxicity from ingested environmental toxins such as pesticides, household products, and other chemicals. It is certainly possible that many adverse hepatic reactions to drugs or toxic chemicals go unnoticed in cats because the first clinical signs of illness are vomiting and diarrhea, after which the medication is stopped. If the signs resolve, there usually is no further evaluation, and the medication is not readministered to prove that the substance caused the reaction.

Diagnosis

Clinical evidence that suggests drug- or toxin-induced hepatic damage includes the following: supportive history (e.g., known exposure); normal liver size to mild generalized tender hepatomegaly; laboratory test results consistent with acute liver injury (e.g., high serum ALT and/or AST levels, hyperbilirubinemia); and, if the exposure was nonlethal, recovery with discontinuation of the agent and specific or supportive care. There are no pathognomonic histologic changes in the liver, although necrosis with minimal inflammation and lipid accumulation are considered typical findings. In many cases, all clinical and clinicopathologic markers of a toxic liver insult are present, but the inciting chemical cannot be identified. In the case of hepatotoxicity from therapeutic agents, idiosyncratic reactions can occur that are not dose-related, although drug overdose is usually the reason for liver injury.

Treatment

In cats with suspected acute hepatotoxicity, the basic principles for treatment of toxicoses are applied:

- Preventing further exposure and absorption
- Managing life-threatening cardiopulmonary and renal complications
- Hastening elimination of the substance
- Implementing specific therapy if possible
- Providing supportive care

Because few hepatotoxins have specific antidotes, the success of recovery often relies on time and aggressive supportive care. More guidance on supportive treatment of acute toxic hepatopathy is provided in Box 36.4.

Acetaminophen is one of the few toxins with a specific antidote. Acetaminophen is particularly toxic to cats, in which the usual hepatic detoxification pathways of sulfation and glucuronidation are particularly limited. Acetaminophen is oxidized to a toxic metabolite that causes methemoglobinuria within hours of ingestion and Heinz body anemia, hemolysis, and liver failure within 2 to 7 days of ingestion. *N*-acetylcysteine is a specific antidote that binds the toxic metabolite and increases the glucuronidation process. It should be administered at a dose of 140 mg/kg IV or PO as a loading dose and then continued at 70 mg/kg q6h for a total of seven treatments, or for up to 5 days. There is also evidence that additional S-adenosylmethionine (20 mg/kg, or 200-400 mg total daily) is beneficial in cats with acetaminophen toxicity because it replenishes glutathione, which inactivates the toxic metabolite (Webb et al., 2003). In addition, a recent study suggested that silymarin was beneficial for treating experimental acetaminophen toxicity in cats. A single dose of 30 mg/kg PO given to cats at the same time as acetaminophen or 4 hours later was as effective at preventing elevation in liver enzymes, bilirubin, and methemoglobin levels as a single dose of *N*-acetylcysteine (Avizeh et al., 2010). It is unclear how to extrapolate these findings to the clinical setting, but the use of *N*-acetylcysteine,

silymarin, and S-adenosylmethionine would be a logical step.

HEPATOBILIARY MANIFESTATIONS OF SYSTEMIC DISEASE

Several feline systemic illnesses have hepatic manifestations that may be identified by physical, clinicopathologic, and/or radiographic examination, but the major clinical signs can be attributed to another disease (see Table 35.1). In such cases the hepatic lesion should recede with satisfactory treatment of the primary illness.

Metastatic neoplasia could be the underlying reason for abdominal enlargement resulting from hepatomegaly or, rarely, malignant abdominal effusion, although primary neoplasia is more common than metastatic neoplasia in the feline liver. Some of the signs of hyperthyroidism, especially occasional vomiting, diarrhea, and weight loss, can resemble those of primary hepatobiliary disease. Thyrotoxic cats commonly have high liver enzyme levels; more than 75% of affected cats have high serum AP levels (2-12 times higher), although in cats it is not known whether this is of liver or bone origin or, as is true for hyperthyroid human patients, both. More than 50% of hyperthyroid cats have high serum ALT or AST levels (2-10 times higher). More than 90% of affected cats have high serum levels of at least one of the AP, ALT, or AST enzymes. Approximately 3% are hyperbilirubinemic. Histopathologic changes are minimal, and there appears to be little functional disturbance. It is thought that malnutrition, hepatocellular hypoxia, and the direct effects of thyroid hormone on liver cells are responsible for these liver-related abnormalities. Hepatomegaly associated with mild to moderate lipid deposition is a common physical examination finding in cats with DM; a small number of cats may also be icteric. Mild to moderate increases in liver-specific enzyme levels are typical. More severe clinicopathologic abnormalities might be expected in cats with more severe hepatic lipidosis. Hyperadrenocorticism is rare in cats and, unlike in dogs, obvious liver involvement is unusual. The liver is usually normal in size on radiographs, and it is unusual to find high serum AP and ALT levels in hyperadrenocorticoid cats. Unlike dogs, cats do not have a steroid-induced isoenzyme of ALP, and an increased ALT level, when recognized, is probably related to intercurrent DM.

CHAPTER 36

Hepatobiliary Diseases in the Dog

GENERAL CONSIDERATIONS

There are marked differences between dogs and cats in the causes, types, and presentations of liver disease (see Table 35.2). In dogs, chronic liver disease is more common than acute disease and, notably, chronic parenchymal disease (chronic hepatitis) is much more common in dogs than in cats; it almost invariably leads to progressive fibrosis and cirrhosis. This contrasts with cats, in which primary biliary tract disease is more common but fibrosis and cirrhosis are extremely uncommon. The clinical signs of liver disease in dogs therefore tend to be even more nonspecific than in cats. Jaundice is less commonly associated with parenchymal disease and, because of the enormous reserve capacity of the liver, signs may not be evident until 75% of the liver mass is lost. The cause of chronic hepatitis in dogs is usually unknown, with a few notable exceptions, and treatment focuses on attempting to slow progression of the disease and treating the clinical signs. Dogs with chronic hepatitis often develop portal hypertension, and treatment of the associated complications is central to treatment of disease in dogs, whereas portal hypertension is very uncommon in cats. Both congenital and acquired portosystemic shunts (PSSs) are more commonly recognized in dogs than in cats; in addition, vacuolar and secondary hepatopathies are very common in dogs and can be confused with primary liver disease on presentation. The most common primary and secondary liver diseases in dogs are outlined in Table 36.1.

CHRONIC HEPATITIS

Chronic hepatitis is predominantly a histologic definition. It is essential to take a liver biopsy before making a diagnosis of chronic hepatitis in dogs, because reactive (secondary) hepatopathy is much more common than primary liver disease in this species (see later). Chronic hepatitis is defined by the World Small Animal Veterinary Association (WSAVA) Liver Standardization Group as being characterized by hepatocellular apoptosis or necrosis, a variable mononuclear or mixed inflammatory cell infiltrate, regeneration, and fibrosis (Van den Ingh et al., 2006; Fig. 36.1). The histologic definition says nothing about temporal chronicity, but this is impossible to judge because many dogs with chronic hepatitis have few or no clinical signs before biopsy, and elevated liver enzymes are often not detected unless a blood sample is taken for another reason such as preanesthetic check.

Chronic hepatitis is common in dogs and shows some noticeable breed predilections, suggesting a genetic basis to the disease. Box 36.1 lists dog breeds reported to have a high prevalence of chronic hepatitis, and Box 36.2 lists possible causes for genetic increases in susceptibility, all of which have been demonstrated in humans with chronic hepatitis and some of which have been recognized in other diseases in dogs. The only one that has been confirmed as a cause of chronic hepatitis in dogs is the mutation of a gene involved in metal storage in dogs with copper storage disease (see later). The others have been suspected but not proven, although increases in major histocompatibility complex (MHC) class II antigen haplotypes in some breeds suggest genetic susceptibility to autoimmune disease (see later).

Young to middle-aged dogs are most commonly affected, and the sex ratio varies among breeds. Dalmatians, Doberman Pinschers, and English Springer Spaniels with chronic hepatitis are typically younger than Labrador Retrievers, English Cocker Spaniels, and Cairn Terriers. It should also be noted that there are some notable geographic differences in breed-related liver diseases, which likely reflect differences in breeding in different countries; diseases common in the United States may be unusual in the United Kingdom, and vice versa. It is also important to remember that chronic hepatitis can affect mixed-breed and purebred dogs, and that recognition of one cause in a breed does not necessarily mean that chronic hepatitis in all dogs of that breed has the same cause. For example, in many Doberman Pinschers and West Highland White Terriers, chronic hepatitis is caused by copper accumulation, but in others it is not. In many cases of canine chronic hepatitis, the cause is unknown. This contrasts with the situation in humans, in whom most cases of chronic hepatitis are viral and some have defined and often effective treatments that can reverse the disease process. In dogs, chronic viral causes have not been convincingly demonstrated, but the histology in some cases is suggestive of this

TABLE 36.1

Liver Diseases in Dogs

PRIMARY	SECONDARY
Chronic hepatitis	Steroid-induced hepatopathy
Copper storage disease	Hepatic steatosis (lipidosis) (secondary to diabetes mellitus or hypothyroidism)
Congenital portosystemic shunt	Congestion: heart failure or heartworm disease
Drug- or toxin-induced hepatopathy	Idiopathic vacuolar hepatopathy in Scottish Terriers and others Reactive hepatitis (e.g., secondary to pancreatitis, inflammatory bowel disease) Metastatic neoplasia
Uncommon or Rare	
Biliary tract disease, all types	Hepatocutaneous syndrome
Hepatic infections (see text)	
Portal vein hypoplasia, microvascular dysplasia	
Ductal plate abnormality	
Hepatic arteriovenous fistula	
Acute fulminant hepatitis (all causes)	
Hepatic abscess	
Primary neoplasia	

BOX 36.1

Dog Breds Wih Reported Increased Risk of Chronic Hepatitis*

American and English Cocker Spaniels (worldwide, males > females)
Bedlington Terrier (worldwide, copper storage disease)
Cairn Terrier (United Kingdom)†
Dalmatian (United States, copper storage disease; United Kingdom, pathophysiology not reported†)
Doberman Pinschers (worldwide, some with copper storage disease and some without; Scandinavian reports suggest immune-mediated component, see text; females > males)
English Springer Spaniels† (United Kingdom, Norway; females > males)
Great Dane (United Kingdom)†
Labrador Retrievers (worldwide; copper storage disease in United States and Holland; not copper-associated in United Kingdom; females > males)
Samoyed (United Kingdom)†
West Highland White Terriers (worldwide; some copper-associated and some not)
Standard Poodle (Anecdotal USA not copper associated).

*No reported sex ratio unless stated.
†Data for recently reported UK breeds from Bexfield NH, et al: Breed, age, and gender distribution of dogs with chronic hepatitis in the United Kingdom, *Vet J* 193:124, 2012.
Note previously reported hepatitis in Skye Terriers is now believed to be a congenital ductal plate abnormality (see later in chapter).

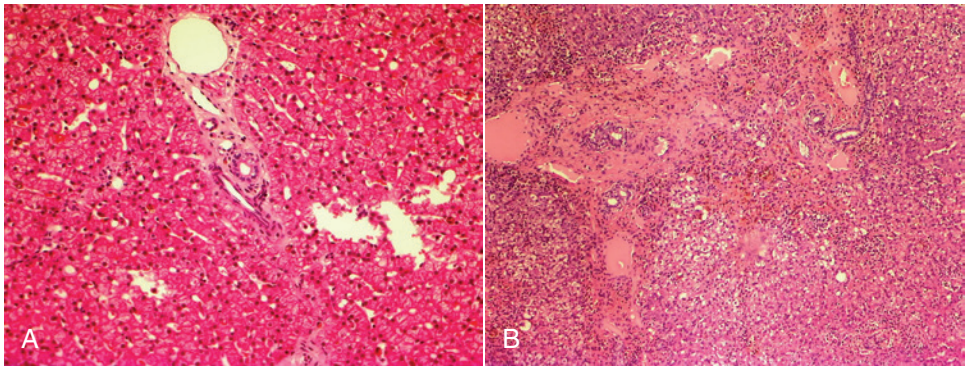

FIG 36.1
(A) Histopathology of normal liver from a middle-aged Yorkshire Terrier. Note the normal portal triad with hepatic portal vein, artery, and bile duct and hepatocytes arranged in neat cords with sinusoids in between (white holes in *bottom right* are a sectioning artifact) (H&E, ×200). **(B)** Histopathology of liver in a 3-year-old female English Springer Spaniel with severe chronic hepatitis. There is marked distortion of the normal lobular structure (compare to **A**), with inflammation, fibrosis, and hepatocyte vacuolation and necrosis. There is also some ductular hyperplasia and disruption of the limiting plate (H&E, ×100). (Courtesy Pathology Department, Veterinary Medicine, University of Cambridge, Cambridge, England.)

BOX 36.2

Possible Causes of Breed-Related Liver Disease

- Increased susceptibility to infectious causes of chronic hepatitis and/or chronicity of infection
- Mutation in gene involved in metal storage or excretion
- Mutation in gene involved in other metabolic processes (e.g., protease inhibitor production)
- Increased susceptibility to toxic hepatitis (e.g., impaired detoxification of drugs)
- Susceptibility to immune-mediated disease

and the search for infectious agents continues. Most cases therefore remain a nonspecific diagnosis of chronic hepatitis, and the treatment remains nonspecific and symptomatic. However, in a few notable exceptions, such as copper storage disease, some cases of granulomatous hepatitis, and toxic hepatitis, the cause may be known and treated specifically. These are outlined in separate sections of this chapter.

IDIOPATHIC CHRONIC HEPATITIS

Potential Etiology

The potential causes of canine chronic hepatitis are reviewed in Webster et al., 2019. Idiopathic chronic hepatitis likely represents an unidentified viral, bacterial, or other infection, an unidentified previous toxic event, or, in some cases, immune-mediated disease. However, because criteria for diagnosis of immune-mediated chronic hepatitis have not yet been agreed in dogs, immunosuppressive drugs should be used only cautiously when other potential causes have been ruled out as much as possible and the histology is suggestive of an immune-mediated disease. It is also very important to rule out primary or secondary copper buildup in all dogs with chronic hepatitis by staining liver biopsies for copper (see later). More details of when to suspect immune-mediated hepatitis are described in later sections ("Granulomatous Hepatitis" and "Infectious Causes of Canine Chronic Hepatitis").

Primary chronic hepatitis caused by infectious agents is uncommon in dogs, although there may be a yet-unidentified infectious cause in some dogs with what appears to be idiopathic chronic hepatitis. Clinicians should keep this possibility in mind before prescribing immunosuppressive medication. Granulomatous hepatitis is an uncommon histologic diagnosis in which there is a prominent histiocytic component to the inflammatory infiltrate. This is usually associated with either a foreign body-type reaction to increased copper in the liver or a chronic infectious cause, which should trigger a search for these potential etiologies.

To date, there has been no convincing demonstration of a viral cause of canine chronic hepatitis, although it has been suspected in several cases. The most common viral cause of chronic hepatitis in people is hepatitis B virus, a hepadnavirus. Similar hepadnaviruses associated with hepatitis have been identified in woodchucks, ground squirrels, tree squirrels, and ducks, but attempts to identify hepadnaviruses by polymerase chain reaction (PCR) assay in the liver of dogs with chronic hepatitis or hepatocellular carcinoma have failed. Hepatitis C virus, a *Hepacivirus,* is another increasingly common cause of chronic hepatitis in humans. The recent discovery of a hepatitis C–like virus in dogs created excitement with the possibility that this might also be associated with canine chronic liver disease (Kapoor et al., 2011). However, the virus was isolated from the respiratory tract, and subsequent studies have failed to associate the virus with chronic hepatitis in dogs (Bexfield et al., 2013). Two other viruses have been suggested as a possible cause of canine chronic hepatitis: canine adenovirus type 1 (CAV-1) and canine acidophil cell hepatitis virus. CAV-1 causes acute fulminant hepatitis in immunologically naive dogs but can also cause chronic hepatitis experimentally in partially immune dogs. However, its importance in naturally occurring chronic hepatitis is unclear, and studies are conflicting. An alternative viral cause of canine acute, persistent, and chronic hepatitis was proposed in Glasgow by Jarrett and O'Neil in 1985 and termed *canine acidophil cell hepatitis virus* pending isolation and identification. The virus appeared to be transmissible by subcutaneous (SC) injection of liver homogenate and serum, and was apparently capable of producing a chronic hepatitis marked by fibrosis and hepatocyte necrosis but sparse inflammatory changes (Jarrett and O'Neil, 1985; Jarrett et al., 1987). It was proposed at the time that this was the most important cause of hepatitis in Glasgow. However, there have been no further published studies by these or other workers regarding the identity or significance of this virus, so its identity and role remain unknown.

Bacterial infections have been sporadically reported as a cause of canine chronic hepatitis, but their importance is unclear. Bile-tolerant *Helicobacter* spp. can cause hepatitis centered on the bile ducts in rodents; there was one report of necrotizing hepatitis associated with *Helicobacter canis* infection in a pup (Fox et al., 1996). However, no further work has been reported in dogs, and a clear association between *Helicobacter* infection and liver disease has yet to be demonstrated.

Leptospiral infections may be a clinically relevant and underestimated cause of chronic hepatitis in dogs. Most dogs in the United States are vaccinated regularly against *Leptospira interrogans* serovars *canicola* and *icterohaemorrhagiae* (bivalent vaccine), and the new quadrivalent vaccine also protects against *L. interrogans* serogroup Australis serovar Bratislava and *L.kirschneri* serogroup Grippotyphosa serovar Bananal/Lianguang, so it is assumed that leptospiral infection is now a rare disease. However, recent studies have shown an emergence of diseases associated with both vaccinal and other serovars; in addition, there is little immunologic cross-reaction with the vaccine serovars. Typically, acute *leptospiral* infections cause both liver and kidney disease. However, more chronic infections can cause chronic hepatitis alone. Infection with predominantly vaccinal serovars was recently reported in a case series of 10 dogs

with chronic granulomatous hepatitis without renal involvement from the UK (McKallum et al., 2019). Nine dogs were vaccinated. Infection with atypical leptospires, particularly *Leptospira grippotyphosa,* can cause a chronic hepatitis with ascites, particularly in young dogs, but azotemia is uncommon in these dogs. Histologically, the livers of dogs with confirmed leptospire infection have portal and intralobular inflammation (i.e., mainly lymphocytic-plasmacytic, with variable amounts of neutrophils and macrophages). Some dogs have very prominent histiocytic (i.e., macrophage-rich) inflammation. There may also be periportal and portoportal fibrosis that could disrupt the hepatic architecture. The organisms are sparse and difficult to find with conventional staining techniques, so it is possible that some cases of leptospiral hepatitis are misdiagnosed as immune-mediated disease on the basis of their histologic appearance. There is also often a poor serologic response in affected dogs, further complicating diagnosis. In one study, only three out of nine dogs tested were positive on serology, and only one was positive on blood PCR, but none were positive on urine PCR (McKallum et al., 2019). The cases were diagnosed with fluorescent in-situ hybridization and PCR speciation from histology blocks.

Adamus et al. (1997) noted the similarity in age bias (6–9 months) and histologic appearance between leptospiral hepatitis and lobular dissecting hepatitis, and it has been suggested that undiagnosed infections may be a cause of lobular dissecting hepatitis in some young dogs (see later). There have also been sporadic reports of *Bartonella henselae* and *Bartonella clarridgeiae* in dogs with chronic liver disease, but again their significance as a cause of the disease is unclear. Peliosis hepatitis, rather than chronic hepatitis, is the more typical histologic appearance associated with *Bartonella* spp. infection in humans and was reported in one dog (Kitchell et al., 2000). Serology, culture, or PCR assay for *Bartonella* spp. is available (see Chapter 94).

One study (Boomkens et al., 2005) evaluated 98 liver samples from dogs with chronic hepatitis using nested PCR for Hepadnaviridae, *Helicobacter, Leptospira,* and *Borrelia* spp.; hepatitis A, C, and E viruses; canine adenovirus; and canine parvovirus, and failed to find evidence of infection in any of the dogs. Another more recent study also failed to find CAV-1, canine parvovirus, canine herpesvirus, and pathogenic *Leptospira* spp. in English Springer Spaniels with chronic hepatitis in England (Bexfield et al., 2011). More work is needed before potentially infectious causes of chronic hepatitis in dogs can be completely ruled out. However, the clinician would be wise to consider further testing in any dog with a marked pyogranulomatous component to their chronic hepatitis on serology. Submission of the histology block for eubacterial fluorescent in-situ hybridization would be wise in these cases.

Lobular Dissecting Hepatitis

Lobular dissecting hepatitis is an idiopathic inflammatory disorder recognized predominantly in young dogs; it has a typical histologic appearance of fibrotic dissection of lobular parenchyma into individual and small groups of hepatocytes. It has been reported in several breeds, including families of Standard Poodles and Finnish Spitzes. It has been proposed that lobular dissecting hepatitis does not represent a distinctive disease but is a response of the juvenile liver to various insults. Infectious etiologies have been suggested, although not proven, and the age of onset and histologic appearance bear a striking resemblance to atypical leptospiral infection in dogs. Treatment recommendations are similar to those for canine chronic hepatitis (see later).

Immune-Mediated Chronic Hepatitis

Some cases of canine chronic hepatitis are likely to be immune-mediated, although it is difficult for the clinician and pathologist to confidently make this diagnosis. Diagnostic criteria used in humans, including measurement of circulating autoantibodies and ruling out viral causes, have not been validated in dogs. Any dog with a prominent lymphoplasmacytic infiltrate on histology may have immune-mediated disease, but other causes of this inflammation, including infectious and reactive disease, should be ruled out before considering immunosuppressive therapy because of other potential causes of lymphoplasmacytic inflammation, including secondary (reactive) liver disease (see later) and chronic infections (see earlier). The presence of a mild inflammatory infiltrate should prompt consideration of reactive hepatopathy, particularly if there is no associated hepatocellular apoptosis or necrosis. The presence of concurrent pyogranulomatous inflammation should prompt a search for copper or an infectious cause (see earlier).

Immune-mediated chronic hepatitis is suspected in some Doberman Pinschers and also some English Springer Spaniels on the basis of associations with certain MHC class 2 antigen haplotypes. There are a few papers investigating the use of immunosuppressive medications in affected dogs, which are detailed in the treatment section later that also support an immune-mediated pathogenesis in some dogs.

Toxic Causes of Chronic Hepatitis

Toxins and drug reactions generally cause acute necrotizing hepatitis rather than chronic disease. Phenobarbital or primidone can cause acute or chronic hepatotoxicity (see later). Lomustine (CCNU) can also cause delayed, cumulative, dose-related chronic hepatotoxicity that is irreversible and can be fatal. Concurrent treatment with SAM-e appeared to be partly protective against hepatotoxicity from CCNU in a recent study in dogs (Skorupski et al., 2011). Another occasional reported cause of chronic liver damage is phenylbutazone. Carprofen can also be associated with acute and chronic liver disease in dogs. Most other reported hepatotoxic drugs and toxins cause an acute hepatitis (see later, "Acute Hepatitis"; Box 36.5). Certain mycotoxins, including aflatoxins, can cause acute or chronic liver disease in dogs, depending on the dose ingested and period of exposure. Dogs scavenge and eat contaminated food more often than humans do, so it is possible that some cases of canine chronic hepatitis are caused by acute or chronic ingestion

of unidentified toxins. In addition, although poorly documented, it is very possible that herbal and nutraceutical supplements could cause chronic liver disease in some dogs. Daily ingestion of cheap, poorly quality-controlled joint supplements based on shellfish has been associated with chronic liver disease in humans, likely due to a contaminating toxin. Reports of joint supplement hepatotoxicity in dogs have only been seen with a large overdose, but chronic low-dose toxicity remains possible. Because a wide variety of drugs and herbals have been reported as causing hepatic adverse reactions in humans and dogs, a drug reaction should be considered in any dog with chronic hepatitis that is also on long-term therapy of any type, and a careful history of supplement use should be obtained, although care should be taken not to overdiagnose drug reactions. Chronic hepatitis should be considered as possibly being drug-related only when there is a clear temporal relationship with drug intake and likely alternative causes have been excluded.

Shared Pathogenesis of All Forms of Chronic Hepatitis

The pathogenesis of chronic hepatitis relates to the loss of hepatic mass resulting in loss of function and, late in the disease process, development of portal hypertension. In many cases hepatocyte swelling, fibrosis, and portal hypertension also contribute to cholestasis and jaundice. Ongoing inflammation may also result in bouts of pyrexia and hepatic pain with associated gastrointestinal (GI) and other signs, and many dogs with chronic hepatitis develop negative nitrogen balance and protein-calorie malnutrition. Loss of hepatic function accounts for coagulopathies and adverse drug reactions in affected dogs.

Portal hypertension is an important consequence of chronic hepatitis and fibrosis, and its effects contribute to the clinical signs and death of many affected animals. It causes a typical triad of clinical signs of ascites, GI ulceration, and hepatic encephalopathy (HE). In a healthy dog the pressure in the portal vein is lower than the pressure in the caudal vena cava. However, in association with obstruction and disruption of the sinusoids by fibrosis and hepatocyte swelling, portal pressure rises until it exceeds that in the caudal vena cava (portal hypertension). This results in splanchnic congestion, with splenic congestion, gut wall edema, and eventually ascites. The mechanisms of ascites formation in dogs with liver disease are complex but involve activation of the renin-angiotensin-aldosterone system (RAAS), with sodium retention in the kidneys and increased circulating fluid volume (see Chapter 33).

If the rise in portal pressure is sustained, multiple acquired PSSs will develop by the opening up of previously nonfunctional vessels; this allows for some of the portal blood to bypass the liver and enter the portal vein directly (Fig. 36.2). These acquired PSSs differ from congenital PSSs in that they are multiple and exist in the presence of increased portal pressure, whereas in patients with congenital PSSs, the portal pressure is low. Acquired PSSs lead to HE by a mechanism similar to that for congenital PSS (see Chapter 33). However, the HE must be medically treated because the ligation of acquired PSSs is contraindicated (see section on treatment of PSS later). This is because acquired PSSs are important escape valves to allow dissipation of some of the portal hypertension; therefore any attempt to ligate them will result in fatal splanchnic congestion. Acquired PSSs in humans are also recognized to reduce the risk of serious GI ulceration associated with portal hypertension. Because of this, they are sometimes created surgically in humans with cirrhosis to reduce the risk of serious bleeds. The same is likely to be true in dogs; GI ulceration is one of the most common causes of death in dogs with chronic hepatitis, and acquired PSSs will help reduce this risk.

Clinical Features of All Forms of Chronic Hepatitis

Dogs of any age or breed can be affected with chronic hepatitis, but there is an increased suspicion in middle-aged dogs of the breeds listed in Box 36.1. Some of these breeds may also be affected by copper storage disease, granulomatous hepatitis, or immune-mediated hepatitis (see earlier and later sections). The functional and structural reserve capacity of the liver implies that dogs with chronic hepatitis usually have no clinical signs until late in the disease process, when more than 75% of liver function has been lost. By this stage, there is already extensive destruction of liver mass, and treatment will be less effective than it would have been earlier in the disease (Fig. 36.3). It is therefore beneficial to diagnose the disease earlier, and dogs with persistently high liver

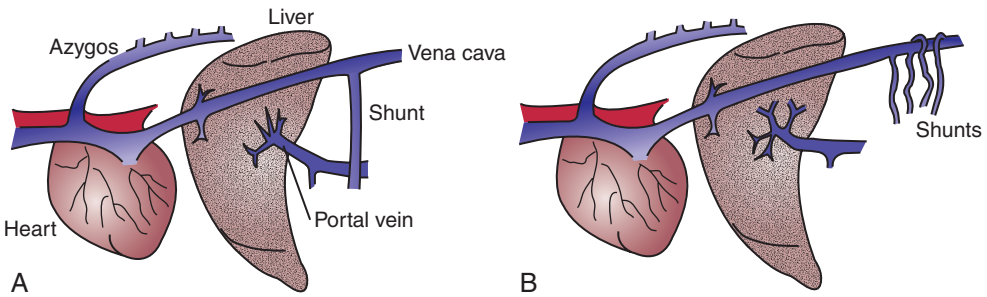

FIG 36.2
Diagrammatic representation of congenital and acquired portosystemic shunts. **(A)** Congenital portocaval shunt. **(B)** Multiple acquired shunts. These develop only if the pressure in the portal vein is higher than the pressure in the vena cava.

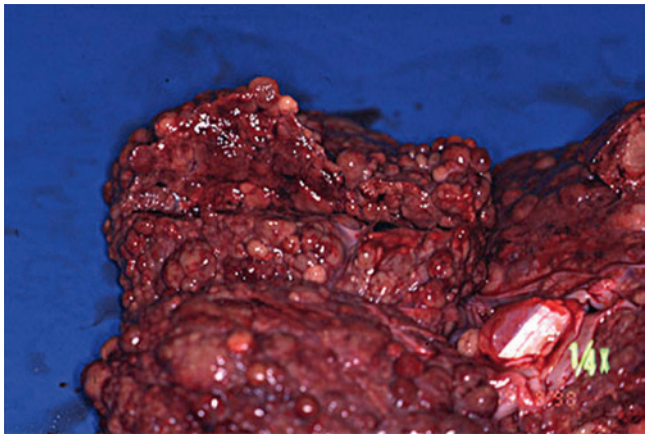

FIG 36.3
Liver from a 6-year-old Bearded Collie that had shown clinical signs for only 1 month before dying from end-stage liver disease. The diagnosis was chronic hepatitis with macronodular cirrhosis and very little normal liver tissue remaining.

enzyme activities (particularly hepatocellular enzymes such as alanine aminotransferase [ALT]) should not be ignored. If liver enzyme activities are high for several months and other causes have been ruled out (see later, "Secondary Hepatopathies"), a liver biopsy should be obtained. This is even more important in breeds at high risk and in those predisposed to treatable diseases, such as copper storage disease.

Once dogs have lost a significant amount of liver mass, they will display clinical signs, but these are typically low-grade, waxing and waning, and nonspecific, making differential diagnosis from other diseases a challenge. Vomiting and diarrhea, anorexia, and polyuria-polydipsia (PU-PD) are common. Jaundice and ascites occur in some dogs at presentation and develop later in others but not in all cases. Ascites at presentation has been identified as a poor prognostic indicator in humans and in two studies in dogs (Poldervaart et al., 2009; Raffan et al., 2009) because it may represent more advanced disease with secondary portal hypertension. Poldervaart et al. (2009); Gómez Selgas et al. (2014) also identified jaundice as a negative prognostic factor in dogs with idiopathic chronic hepatitis. HE is uncommon and usually seen only in dogs with end-stage disease. The presence of HE strongly suggests the development of an acquired PSS. Dogs with chronic hepatitis usually have some degree of protein-calorie malnutrition as a result of chronic hepatic functional impairment and concurrent GI signs (see Chapter 33). They are often overtly thin. They may be depressed but are also often surprisingly alert considering the severity of their disease.

Diagnosis

Ultimately, a definitive diagnosis requires a liver biopsy, but disease is suspected from the clinical signs and clinicopathologic features. Clinical signs, clinicopathologic findings, and imaging may be supportive of chronic hepatitis but are not specific. A serum biochemical profile may show a combination of high activities of hepatocellular enzymes (ALT and aspartate aminotransferase [AST]) and cholestatic enzymes (alkaline phosphatase [ALP] and γ-glutamyltransferase [GGT]) and evidence of decreased parenchymal liver function (low urea, low albumin, and sometimes high bilirubin and bile acid concentrations). Persistent increases in ALT levels are the most consistent finding in dogs with chronic hepatitis but can also be found in other primary and secondary hepatopathies. A high ALP activity is much less specific in dogs, particularly because there is a steroid-induced isoenzyme. Hepatocellular enzymes can become normal in end-stage disease because of a lack of liver mass, but by that stage function test results (e.g., ammonia and bile acid concentrations) will be abnormal, and the dog may even be jaundiced.

Radiographic findings are nonspecific. Dogs with chronic hepatitis often have a small liver (contrasting with cats, in which hepatomegaly is more common), but the liver may also appear small in normal dogs, and the assessment of liver size is further confused by the variations in the gastric axis in deep-chested dogs. If ascites is present, radiographs are not helpful because the fluid obscures all abdominal detail. Ultrasonography is much more useful for assessing hepatic architecture (see Chapter 34). Dogs with chronic hepatitis often have a small, diffusely hyperechoic liver on ultrasonography, although the liver may look ultrasonographically normal in some cases. In other cases it may appear nodular because of macronodular cirrhosis and/or concurrent benign nodular hyperplasia (see later). It is impossible to definitively differentiate benign from malignant nodules on ultrasonographic appearance alone; cytology or biopsy is essential to obtain a definitive diagnosis.

End-stage chronic hepatitis with cirrhosis may appear very similar to noncirrhotic portal hypertension or congenital ductal plate abnormality from a diagnostic standpoint, yet the treatment of the latter is very different, and the long-term prognosis is much more favorable than with cirrhosis. Therefore a liver biopsy is necessary for a definitive diagnosis and appropriate treatment. Hemorrhage is the most significant risk of liver biopsy, and therefore it is the consensus amongst veterinary hepatologists to obtain a hemostasis profile (one-stage prothrombin time, activated partial thromboplastin time, and platelet count) before obtaining a biopsy and to address any coagulopathies or thrombocytopenia before the procedure. However, publications fail to show a clear association between any one measure of hemostasis and the risk of bleeding complications postbiopsy. Fine-needle aspiration (FNA) cytology is of limited value in the diagnosis of chronic hepatitis; the most representative biopsies are wedge biopsies obtained during laparotomy or laparoscopy. Ultrasonographically guided Tru-Cut–type needle biopsies can be of some benefit but are often misleading (see Chapter 34 for more details on biopsy techniques).

Treatment

The goals of treatment of dogs with chronic hepatitis include treating any identified underlying cause, slowing progression of the disease if possible, treating clinical signs such as ascites and HE, and supporting liver function and the animal's nutritional and metabolic needs.

Treatment of Underlying Cause

If an infectious cause is identified, this should be treated appropriately. Any significant copper buildup should be chelated (see later) and managed with a low copper diet. Any suspected hepatotoxic drug or nutraceutical should be removed and replaced as necessary with a safe alternative. This can be particularly difficult in the case of a dog with chronic hepatitis and concurrent life-limiting degenerative joint disease where the continued use of nonsteroidal anti-inflammatory drugs (NSAIDs) is contraindicated.

Diet

Dietary management is always an important part of treatment for patients with liver disease because the liver is the first stop for nutrients on their way from the gut to the systemic circulation, and it is intimately involved in the metabolism of nutrients. This metabolism is compromised in patients with liver disease; in addition, dogs with chronic hepatitis typically have protein-calorie malnutrition, so excessive restriction of nutrients can be harmful.

The nutritional requirements for dogs with liver disease are outlined in Table 36.2. The most important consideration is dietary protein concentration. It is now recognized in humans and dogs with liver disease that, to avoid a negative nitrogen balance, dietary protein should not be restricted. However, it is important to feed a high-quality, highly digestible protein to reduce hepatic work and decrease the amount of undigested protein that reaches the colon, where it is converted to ammonia. Most ammonia reaching the systemic circulation in the portal blood of animals with congenital and acquired PSSs originates not from dietary protein but from enterocyte catabolism of glutamine as their main source of energy. This cannot be avoided without starving the enterocytes, so other means of controlling HE are recommended in addition to dietary restriction (see later). Most prescription diets available for dogs with liver disease (Hill's l/d diet, Hill's Pet Nutrition, Topeka, KS; Royal Canin Hepatic Formula, Royal Canin USA, St Charles, MO) are ideally formulated, except that they have lower protein than is ideal for a dog with chronic hepatitis. Therefore these diets should be fed as a baseline in small amounts and often with the addition of high-quality protein to the food. Dairy and vegetable protein produce the best results in humans and dogs with liver disease; cottage cheese is a good choice to add to the diet. The amount to add to the food is difficult to estimate. It is advisable to start with 1 or 2 tablespoons of cottage cheese per meal, monitor clinical signs and blood protein levels, and for gastrointestinal disease such as Hill's ID diet or Royal Canin gastrointestinal or a clinical diet formulated adjust accordingly. Alternatively, a clinical diet formulated for liver disease with a less restricted protein content can be used, such as Purina HP.

Drugs

Drug support in dogs with idiopathic chronic hepatitis is nonspecific, and attempts to slow the progression of disease and control clinical signs. Specific drug treatments are reserved for patients with an identified underlying cause. Without a biopsy, nonspecific treatment should consist of choleretics, antioxidants, and diet. The use of glucocorticoids and copper chelators must be reserved for biopsy-confirmed cases only.

Choleretics

Ursodiol is widely and commonly used in dogs with chronic hepatitis. It is a synthetic hydrophilic bile acid that is choleretic and modulates the bile acid pool in biliary stasis, making the bile less toxic to hepatocytes. It also has antiinflammatory and antioxidant properties, and studies suggest that it is synergistic with SAM-e and vitamin E. The only absolute contraindication is complete biliary obstruction, which is very rare in dogs and would usually result in obvious acholic feces. It can be used in any dog with chronic hepatitis, particularly in those associated with biliary stasis, and can safely be used without a biopsy. However, as with other drugs used for the treatment of canine liver disease, there is limited, although encouraging, evidence about its efficacy. It may be more helpful in some diseases than others, but this has not yet been determined for dogs. The recommended dose is 10 to 15 mg/kg orally (PO) q12h (or divided into two doses given q12h).

Antioxidants

A variety of antioxidants are used in dogs with chronic hepatitis. The best documented are vitamin E and SAM-e. Vitamin E appears to be beneficial at a dosage of 400 IU/day PO for a 30-kg dog, given as a water-soluble preparation once a day. Dosages for smaller dogs are scaled appropriately. SAM-e is a glutathione precursor and is of particular benefit for dogs with toxic hepatopathy (see earlier) and those with biliary stasis because bile is a potent oxidant. It is synergistic with vitamin E and ursodiol, and an argument could be made for it being beneficial in any dog with chronic hepatitis. The recommended dose is 20 mg/kg PO q24h. There are some studies documenting its use in dogs, but more research is needed to define in which diseases it is most useful. SAM-e is a very unstable molecule because it is a methyl donor and must therefore be carefully packaged and given on an empty stomach. The pharmacokinetics and GI availability in dogs have been published for the pure preparation (Denosyl, Nutramax Laboratories, Edgewood, MD; Center et al., 2005). However, SAM-e is increasingly being marketed as a polypharmacy nutraceutical in preparations with other nutraceuticals and vitamins combined. Pharmacokinetic and absorption data should be sought from the manufacturers of these products to ensure that the SAM-e is absorbed in effective amounts.

Another antioxidant commonly used in dogs with chronic hepatitis is milk thistle *(Silybum marianum)*. The active ingredients are flavonoids, commonly referred to as silymarin; the most effective of these is believed to be silybin. There are few studies on the use of flavonoids in dogs, and the only clinical studies are in regard to acute toxic hepatitis. Silybin may have the potential to be a helpful adjunct to therapy in some cases, but much more information on absorption, availability, and ideal dosage is necessary. Silybin

TABLE 36.2

Dietary Considerations for Dogs With Liver Disease*

DIETARY COMPONENT	RECOMMENDATIONS
Protein	Normal amount – avoid low and high protein foods High-quality (optimal amounts of all essential amino acids) Highly digestible Ideal protein source may be dairy or vegetable (Reduced aromatic amino acids and increased branched-chain amino may reduce hepatic encephalopathy—evidence lacking.) Ornithine aspartate may reduce hepatic encephalopathy—one small pilot study in dogs (Ahn et al., 2016) Proprietary liver diets or GI diets or hypoallergenic diets are ideal
Fat	No special advice for liver disease—fat restriction usually unnecessary even with biliary tract disease. Optimizing omega-3–omega-6 may help reduce inflammation (more research is needed).
Carbohydrate	No special advice for liver disease except highly digestible as a calorie source, reducing the need for hepatic gluconeogenesis from fat and protein.
Fiber	Ideal is moderate amount of mixed fiber source Fermentable fiber (e.g., lactulose) may reduce hepatic encephalopathy (conflicting evidence in humans, little evidence in dogs)—broken down to short-chain fatty acids in the colon, trapping ammonia as ammonium, increasing nitrogen incorporation into bacteria and reducing ammonia production. Nonfermentable fiber prevents constipation, a potential predisposing factor for development of encephalopathy
Minerals	
Zinc	Zinc indicated in copper storage disease—reduces copper absorption from gut and copper availability in the liver. Do not supplement when dog is on copper chelators as zinc will compete with copper for chelation. Zinc supplementation may be helpful in chronic hepatitis with hepatic encephalopathy—extrapolated from humans and no evidence in dogs
Copper	Animals with copper storage disease should be maintained on a low-copper, high-zinc diet.
Vitamins	
Fat-soluble	Vitamin E supplementation may be cytoprotective, especially in copper toxicity, because of its antioxidant effect. Vitamin K supplementation may be necessary if clotting times are prolonged, especially in cats and particularly if considering biopsies. Vitamins A and D should not be supplemented. Vitamin A can cause hepatic damage, and vitamin D supplementation can cause calcification in tissues.
Water-soluble	B vitamins may be supplemented because there is potential increased loss in polydipsia/polyuria associated with liver disease. Vitamin C should not be supplemented because ascorbate can increase the tissue damage associated with copper and iron in liver disease.

*The diet should be fed little and often (four to six times daily) and needs to be palatable. A good and sufficient diet is essential for hepatic regeneration and optimal hepatic function.

is included in many nutraceuticals marketed for dogs with liver disease. One study (Filburn et al., 2007) showed that it had very poor absorption alone but was more bioavailable when complexed with phosphatidylcholine. Denamarin (Nutramax Laboratories) contains both SAM-e and silybin in reportedly bioavailable forms, although published data supporting this are currently lacking.

Antioxidant nutraceuticals have great potential benefits for the treatment of chronic liver disease in dogs as well as vacuolar and toxic hepatopathies in dogs and cats, and can be safely used without a biopsy. However, the clinician must be aware of the emerging nature of the information about their bioavailability and efficacy, and choose products carefully with this in mind.

Copper chelators

Any dog with chronic hepatitis and an excess of copper on biopsies should be treated with copper chelators and a low copper diet (see "Copper Storage Disease" section for

more details). Pathologists may describe a copper distribution suggestive of secondary rather than primary copper buildup (predominantly zone 1, periportal) but nevertheless, copper within the liver is toxic and has the potential to worsen the disease and should be removed. As a guideline, if copper buildup is described as moderate to marked on histology, and is associated with raised ALT and histologic evidence of hepatitis, it should be chelated. Antioxidants should also be used (SAM-e and Vitamin E).

Glucocorticoids

Glucocorticoids are commonly used in dogs with idiopathic chronic hepatitis but should never be used without having the results of a biopsy available and a strong suspicion of autoimmune etiology. Biopsies are necessary not only to confirm the presumptive diagnosis but also to rule out any contraindications. Glucocorticoids have traditionally been used in this context for their putative antiinflammatory and antifibrotic actions, rather than as immunosuppressives. However there is very little evidence for their efficacy as nonspecific antifibrotics, and their use should be confined to suspected autoimmune hepatitis cases (see earlier). The most effective antifibrotic and antiinflammatory intervention in chronic hepatitis is to remove the underlying cause (Fig. 36.4), and nonspecific use of glucocorticoids in unrecognized chronic infectious, toxic, or metabolic cases of chronic hepatitis may do more harm than good in perpetuating or worsening the cause.

In suspected autoimmune hepatitis, prednisone/prednisolone should be dosed at 1 to 2 mg/kg once a day, with a gradually reducing dose over weeks to months while monitoring efficacy with repeat liver enzyme measurements. Effective treatment should be accompanied by a reduction in ALT levels, but ALP may increase due to steroid induction. Nevertheless, in one study of the efficacy of steroid treatment in English Springer Spaniels with suspected immune-mediated hepatitis, successful treatment was accompanied by a surprising reduction in ALP as well as ALT (Bayton et al., 2018). Some dogs can be weaned slowly off all therapy, whereas other dogs require long-term maintenance at a lower dose.

Glucocorticoids are contraindicated later in the disease, when there is portal hypertension and end-stage fibrosis, or in conditions with noninflammatory fibrosis (e.g., noncirrhotic portal hypertension), in which there is no rationale for their use. In these circumstances they are also likely to shorten the life expectancy by increasing the risk of serious GI ulceration. Hence, glucocorticoids should never be used without a histopathologic diagnosis and staging of disease.

Other immunosuppressive drugs

Other immunosuppressive drugs are sometimes used in dogs with suspected autoimmune hepatitis. Cyclosporine has been reported to be efficacious in one study of dogs with chronic hepatitis and is the author's first choice as an alternative to prednisolone. Cyclosporine is particularly indicated for long-term management in animals that cannot be weaned off steroids and also in dogs where the adverse effects of steroid therapy are a problem, for example, dogs with portal hypertension and ascites but suspected ongoing autoimmune hepatitis. As with corticosteroids, cyclosporine should never be used without biopsy confirmation of suspected autoimmune hepatitis. Azathioprine has been used alone or in combination with prednisolone, and mycophenolate mofetil has also been used in dogs with chronic hepatitis. However, there is no evidence in support of the use of these two potent drugs in dogs with chronic hepatitis, and the author would

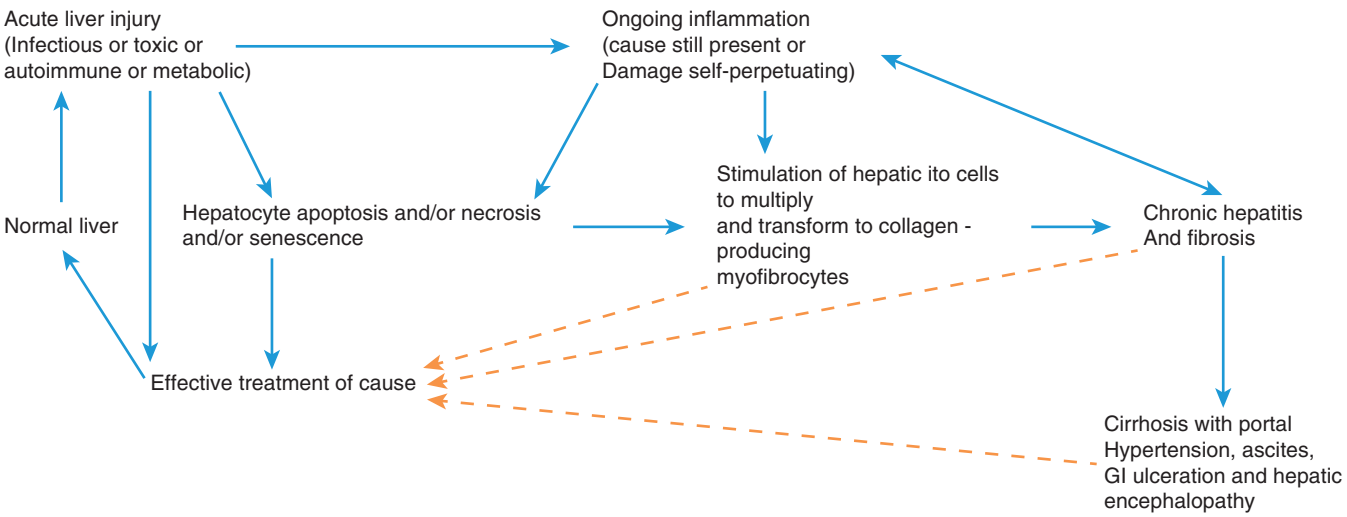

FIG 36.4
Chain of events in acute and chronic liver disease. In the face of ongoing inflammation and insult, progressive fibrosis will lead to cirrhosis and liver failure. However, if the inciting cause is effectively treated, fibrosis and even early cirrhosis might be reversed as indicated by orange arrows. This has been convincingly demonstrated in humans but not yet dogs.

generally avoid them because of the lack of evidence and potential side effects.

Antifibrotics

The most effective antifibrotic treatment in the context of chronic hepatitis is to effectively treat the underlying cause. Fig. 36.4 illustrates the potential for reversal of fibrosis and even early cirrhosis if the underlying cause is treated. This has been well described in human medicine but poorly documented in canine chronic hepatitis. Later in the disease process, when there is extensive fibrosis, the direct antifibrotic agent colchicine can be used. However, the author does not recommend its use as there is no good evidence of efficacy and it has a high incidence of side effects. It is difficult to believe that colchicine is an effective antifibrotic in the liver of dogs given that no effective hepatic antifibrotic has been identified in humans, in spite of years of research (Friedman, 2010). Spironolactone may also have some antifibrotic activity. This has been demonstrated in rats with chronic hepatitis, so there is an argument to use it.

Antibiotics

There is a primary indication for the use of antibiotics in dogs with ascending biliary tract infections or suspected bacterial infection as a cause of chronic hepatitis. The latter is rarely proven, but if an atypical leptospiral infection might be present (e.g., if chronic granulomatous hepatitis is seen in a dog with access to sources of infection, such as rivers or ditches), a course of appropriate antibiotics would be wise to rule this out. The recommended therapy for leptospiral infections is to start with intravenous (IV) amoxicillin, 22 mg/kg q12h, to terminate replication and reduce potentially fatal liver and kidney complications. If leptospiral infection is subsequently confirmed by rising titers on serology, dark field microscopy, PCR assay of the urine or blood for organisms, or fluorescent in-situ hybridization of live biopsies, this should be followed by doxycycline therapy (5 mg/kg PO q12h, for 2 weeks) once liver function has normalized to eliminate the chronic renal carrier state. For additional information on leptospirosis, see Chapter 94. *Bartonella* spp. have occasionally been associated with chronic liver disease in dogs, but the optimal treatment for *Bartonella* infection in dogs has not been established. Macrolides (e.g., erythromycin) or alternatively fluoroquinolones or doxycycline have been shown to have some efficacy against some *Bartonella* spp. in dogs. It has been suggested that 4 to 6 weeks of treatment might be necessary to eliminate infection (see Chapter 94).

Antibiotics are also used as part of supportive treatment in dogs with HE caused by acquired PSS in end-stage chronic hepatitis; they are given in a similar way as to dogs with congenital PSS to reduce toxin absorption from the gut and risk of systemic infections (see later). Ampicillin or amoxicillin is often used long term in these cases, 10 to 20 mg/kg PO q8-12h.

As with other drugs, the clinician should avoid any antibiotics that increase hepatic work or the risk of hepatotoxicity. Thus tetracyclines, potentiated sulfonamides, nitrofurantoin, and erythromycin should be avoided unless necessary (e.g., with confirmed leptospirosis or bartonellosis) because they are potentially hepatotoxic.

Treatment of portal hypertension

Dogs with chronic hepatitis presenting with clinical signs of portal hypertension (ascites, gut wall congestion, and potentially acquired PSS) have specific management considerations. The treatment of HE associated with acquired PSS is the same as the treatment of HE associated with congenital PSS (see later in this chapter).

The treatment of ascites associated with portal hypertension in chronic hepatitis revolves around the use of diuretics, first aldosterone antagonists (spironolactone, 1-2 mg/kg PO q12h) and then the addition of furosemide (2 mg/kg PO q12h) if necessary in refractory cases. The reason spironolactone is the diuretic of choice in these dogs is due to the underlying pathophysiology with increase in aldosterone and fluid retention described in Chapter 33. Spironolactone usually takes 2 or 3 days to reach full effect, and the resolution of ascites can be monitored by weighing the patient daily; any acute changes in weight will be caused by fluid shifts. Dietary sodium restriction has also been recommended, although it is unclear how effective or important this is. However, it is certainly wise to refrain from feeding the patient high-salt snacks and treats.

It is important to monitor serum electrolyte concentrations, mainly sodium and potassium, daily during the first few days of treatment and every few weeks to months thereafter, depending on how stable the dog and drug doses are. Hypokalemia should be avoided because it can precipitate HE (see later), but it is less likely in a dog on aldosterone antagonists and loop diuretics than in a dog on furosemide alone. Hyponatremia can also occur; if it is marked, the diuretics should be stopped and the patient given careful IV replacement until the sodium level is normalized. Therapeutic paracentesis is indicated only for patients with ascites that is severe enough to compromise breathing. This is actually unusual and is manifested by severe ascites with a tense abdomen and the dog is unable to settle and lie down. Paracentesis should be accompanied by concurrent IV administration of a colloid plasma expander, plasma, or albumin; removal of a large volume of fluid containing albumin can result in a precipitous hypoalbuminemia and decrease in oncotic pressure, leading to pulmonary edema. This is a real problem in dogs with chronic liver disease in which the liver's capacity to manufacture albumin is reduced.

Dogs with portal hypertension are at risk of GI ulceration due to splanchnic congestion, as described earlier and in Chapter 33. The clinician must be aware that GI ulceration may occur acutely in dogs with splanchnic congestion, and serious clinical deterioration may occur before melena is apparent because it takes several hours for the blood to pass from the small to large intestine. Before this occurs, it is possible for the animal to show sudden onset and marked signs of HE because blood is a high-protein meal in the small intestine (see earlier) or even for the ulcer to perforate and cause peritonitis (Fig. 36.5).

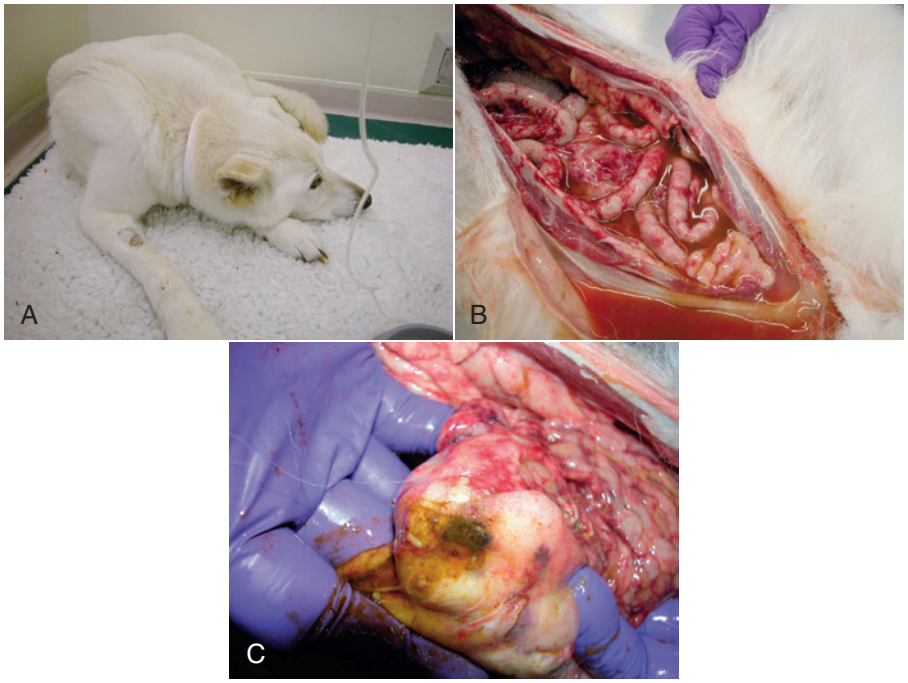

FIG 36.5
(A) Nine-year-old neutered female German Shepherd dog with previously stable noncirrhotic portal hypertension treated medically for 8 years presented very depressed, with a week-long history of anorexia (same dog as Fig. 36.13). **(B)** and **(C)** In spite of immediate institution of tube feeding on admission, the dog rapidly developed fatal septic peritonitis as a result of rupture of an ulcer at the gastroduodenal junction. It was found that the dog had developed asymptomatic pyelonephritis. The referring veterinarian had recognized the hepatic encephalopathy but tried to manage it by starvation for a week, which likely increased rather than decreased ammonia production through breakdown of muscle and also increased the risk of GI ulceration because of a lack of intraluminal gut nutrition.

Treatment of GI ulceration largely revolves around its prevention (i.e., avoiding triggers as much as possible, such as prolonged fasting and the use of steroids or NSAIDs, and avoiding hypotension during any surgery). It is particularly important that any dog with portal hypertension that undergoes a prolonged period of anorexia is fed because they will be at high risk of GI ulceration if they do not receive nourishment (see Fig. 36.5). Parenteral nutrition is not an effective alternative in these dogs because it does not supply luminal nutrients for enterocyte healing—upper GI ulceration is a common adverse effect of total parenteral nutrition in humans, even in those without portal hypertension, and some form of enteral support should be instituted as soon as possible. The use of gastric acid secretory inhibitors (H_2 blockers or proton pump inhibitors) is of questionable benefit in patients with portal hypertension because it is usually the duodenum that is ulcerated (rather than the stomach); also, there have been reports that the gastric pH in dogs with liver disease may already be higher than normal as a result of changes in gastrin metabolism, although a recent study of dogs with newly diagnosed liver disease found no difference in gastrin concentration compared with control dogs (Mazaki-Tovi et al., 2012). However, in the face of active ulceration and melena, gastric acid secretory inhibitors are often used in the hope that they will help. In these circumstances, cimetidine is contraindicated because of its effect on hepatic P450 enzymes; therefore ranitidine (2 mg/kg administered orally or via slow IV administration q12h) or famotidine (0.5-1 mg/kg administered PO q12-24h) are recommended. The proton pump inhibitor omeprazole is likely to be more effective in the face of overt bleeding and should be dosed at 1 mg/kg q12h. Likewise, sucralfate (Carafate™) is of questionable efficacy; it is most effective against gastric ulceration (i.e., in association with a low pH), but it is often used (at a dosage of 500 mg-1 g per dog PO q8h). Hemostasis profiles should also be evaluated, and any coagulopathy treated with vitamin K (see the later section on coagulopathy) or plasma transfusions.

Treatment of coagulopathies

Despite the presence of hemostatic abnormalities, spontaneous bleeding is uncommon in patients with chronic liver disease but relatively common in those with acute disease (see later). Because dogs with portal hypertension and GI hemorrhage (see previous section) may also have a coagulopathy predisposing to their bleeding, they should be thoroughly evaluated. However, the risk of hemorrhage increases

after a challenge to hemostasis, such as liver biopsy; therefore it is very important to evaluate hemostasis before performing liver biopsy. If coagulation times are prolonged, it is worth trying vitamin K1 (phytomenadione) therapy (0.5–1 mg/kg SC × 3 doses at 12 hour intervals). However, this is much less effective in dogs than cats, so administration of fresh or fresh frozen plasma may be indicated to replenish depleted clotting factors. A starting dose of 10 mL/kg given slowly is recommended; the dose of plasma is titrated on the basis of the results of the one stage prothrombin time (OSPT) and activated partial thromboplastin time (APTT).

COPPER STORAGE DISEASE

Pathogenesis and Etiology

Copper storage disease has been recognized as a cause of acute and chronic hepatitis in several breeds, the best researched of which is the Bedlington Terrier (see Box 36.1). Other breeds in which copper storage disease has been reported are Dalmatians (in the United States and Canada), Labrador Retrievers (in the United States and Holland), and some Doberman Pinschers (in Holland), although individual members of all these breeds have also been reported with chronic hepatitis without copper accumulation. In addition, copper storage disease has been suspected but not extensively investigated in West Highland White Terriers. The previously reported copper storage disease in Skye Terriers is now believed to be a congenital ductal plate abnormality (see later). In one study of several dog breeds in Holland, hepatitis was ascribed to copper storage disease in 36% and was idiopathic and not copper associated in 64% of 101 dogs studied with acute and chronic liver disease (Poldervaart et al., 2009). It is also possible for seemingly normal dogs without a recognized copper storage disease to develop copper-associated chronic hepatitis if fed a diet very high in copper, such as dry calf feed (Van den Ingh et al., 2007).

Copper is excreted in the bile and can build up as a secondary phenomenon in any type of chronic hepatitis associated with cholestasis. In these cases, the accumulation is usually mild, often in zone 1 (peribiliary), and the amount of copper does not correlate with the severity of the disease. An early study demonstrated that dogs were resistant to copper accumulation in cholestasis unless they were also copper-loaded in the diet (Azumi, 1982). Copper buildup in the liver is therefore likely to be an interaction between genetic susceptibility and environment (i.e., dietary copper concentration and concurrent biliary stasis). Dietary copper concentration heavily affects hepatic copper accumulation in all breeds, not just those predisposed to copper storage disease. An increase in hepatic copper has been observed in dogs since the 1980s, and it is hypothesized this is due to the change in formulation of copper added to commercial food to a more bioavailable chelate (Gagne et al., 2013). The peribiliary distribution and lack of correlation between amount of copper buildup and clinical signs helps distinguish these cases from "true" copper storage disease, in which the copper accumulation is the cause rather than an epiphenomenon of the disease, and accumulation is usually marked, progressive, correlated with disease severity, and in zone 3 (perivenous; see Fig. 33.7 for an explanation of hepatic zonation). Copper chelation is recommended in any dog with chronic hepatitis with significant copper buildup, whether it is primary or secondary, because copper is a potent oxidizing toxin. Therefore distinguishing primary from secondary copper accumulation may not change treatment recommendations, except for informing a search for an underlying primary cause other than the copper.

True copper storage disease likely represents a genetic defect in copper transport and/or storage. The breed in which this has been best defined is the Bedlington Terrier. In this breed it is inherited as an autosomal recessive trait, and up to 60% of Bedlington Terriers in some countries have been affected in the past, although the prevalence is now decreasing as a result of selective breeding. The disease is confined to the liver, and there appears to be a specific defect in hepatic biliary copper excretion, probably in transport from the hepatocyte lysosomes to the biliary tract. Studies have identified at least one genetic defect associated with the disease, a deletion in the *MURR1* gene (now *COMMD1;* Van de Sluis et al., 2002), which codes for a protein of unknown function. However, Bedlington Terriers with copper storage disease but without a *COMMD1* deletion have been reported in the United States, United Kingdom, and Australia (Coronado et al., 2003; Haywood, 2006; Hyun et al., 2004), suggesting that there are additional mutations involved in the breed. A recently published study identified an association between copper storage disease in Bedlington Terriers and an alternative mutation in metal transporter ABCA 12, which is functionally similar to the ATPase 7B that is mutated in humans with Wilson's disease (Haywood et al., 2016).

In Labrador Retrievers, a missense mutation in the ATPase 7B gene itself has been associated with copper accumulation, whereas a missense mutation in ATPase 7A protects against copper accumulation (Fieten et al., 2016).

Clinical Features

Affected Bedlington Terriers can present with acute or chronic clinical signs, depending on individual factors, such as the amount of copper in the diet, and other possible factors, including concurrent stress and disease. If there is rapid and marked buildup, dogs may present with acute fulminant hepatic necrosis and no previous clinical signs. This is usually seen in young to middle-aged dogs and is often accompanied by acute intravascular hemolytic anemia caused by the rapid release of copper into the circulation. The prognosis is poor, and most animals die within a few days. Fortunately, this is uncommon; most dogs have a more chronic, protracted course, with several years of copper buildup and persistently high ALT activity, culminating in the development of chronic hepatitis with piecemeal necrosis, inflammation, and bridging fibrosis. Clinical signs are therefore recognized in these individuals only late in the disease process and are usually those of canine chronic

hepatitis. These dogs usually present at about 4 years of age, but may be younger (Fig. 36.6). Eventually, if not treated, affected dogs will develop cirrhosis.

The clinical signs and progression in other breeds with copper storage disease are similar to those in Bedlington Terriers. The disease in Dalmatians is associated with acute onset, rapid progression, and very high levels of hepatic copper in the absence of significant clinical, clinicopathologic, or histologic evidence of cholestasis. Affected dogs usually present as young adults with acute onset of GI signs and PU-PD, by which time severe liver disease is already present. Labrador Retrievers with copper storage disease have an average age at presentation of 7 to 9 years (range, 2.5–14 years). The clinical signs are relatively mild and include anorexia, vomiting, and lethargy. Doberman Pinschers appear to have a long phase of subclinical disease culminating, in untreated cases, in an acute-on-chronic disease and rapidly progressive deterioration. However, it is unclear how many of the clinically affected Doberman Pinschers described in the literature had copper storage disease and how many had idiopathic or potentially immune-mediated chronic hepatitis, so the actual presenting signs of copper storage disease in this breed are unclear. Most published studies on copper storage disease in Doberman Pinschers have described the diagnosis and treatment of subclinical disease.

Occasionally, dogs with copper storage disease also present with renal signs typical of Fanconi syndrome with normoglycemic glycosuria and proteinuria. This has not been reported in Bedlington Terriers but in a variety of breeds including two West Highland White Terriers (Appleman et al., 2008; Hill et al., 2008) and nine Labrador Retrievers (Langlois et al., 2013). Most but not all cases have been associated with increased copper accumulation in the kidneys on histology.

FIG 36.6
Bedlington Terrier with copper storage disease. (From Hall EJ et al., editors: *BSAVA manual of canine and feline gastroenterology,* ed 2, Gloucestershire, United Kingdom, 2005, British Small Animal Veterinary Association.)

Diagnosis

The magnitude of increase in liver enzyme activities and the diagnostic imaging findings in dogs with chronic copper storage disease are very similar to those of dogs with idiopathic chronic hepatitis. Therefore a definitive diagnosis requires a liver biopsy and determination or estimation of the copper concentration in the liver. This can be done qualitatively on formalin-fixed sections using rhodanine or rubeanic acid staining to detect copper; correlations between the quantitative and qualitative estimations of copper accumulation have been published (Shih et al., 2007). Digital scanning of rhodanine-stained sections is a more objective qualitative measure of hepatic copper (Center et al., 2013). The finding of large accumulations of copper in hepatocytes on cytology with rubeanic acid is also suggestive of copper storage disease (Fig. 36.7; Teske et al., 1992). Quantitative measurement of copper content can also be performed, but this requires a large biopsy specimen carefully taken and stored in copper-free tubes. The concentration of copper that is considered pathologic is controversial but > 1000 µg/g dry weight liver is generally considered significant. The clinician should also be aware that there can be considerable variation in copper concentration between liver lobes due to patchy fibrosis and regeneration. Further details on diagnosis of copper storage disease can be found in Webster et al., 2019. In addition to estimating copper content, the liver biopsy will give an indication of the chronicity and extent of liver damage, which will affect treatment decisions similarly to that for chronic hepatitis. Bedlington Terriers can be tested for the *COMMD1* deletion before breeding or when newly acquired to assess their risk for this disease, but an absence of the *COMMD1* deletion does not guarantee that the dog

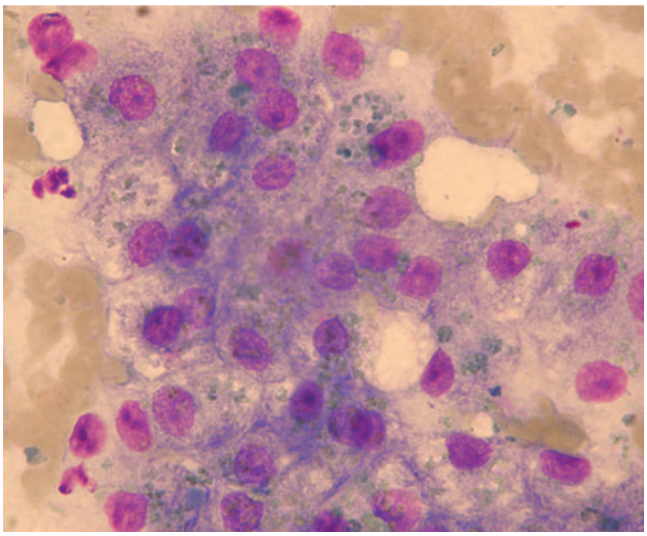

FIG 36.7
Cytology of hepatocytes from Bedlington Terrier with copper storage disease demonstrating copper granules (rubeanic acid stain). (Courtesy Elizabeth Villiers; from Hall EJ et al., editors: *BSAVA manual of canine and feline gastroenterology,* ed 2, Gloucestershire, United Kingdom, 2005, British Small Animal Veterinary Association.)

will not be affected. The genetic test is currently offered via mouth swabs at the Animal Health Trust in Newmarket, England (details at https://www.ahtdnatesting.co.uk) and by VetGen in the United States (www.vetgen.com). To rule out copper storage disease through a liver biopsy in a breeding animal, clinicians should obtain a biopsy when the dog is about 12 months old, by which time there will be sufficient copper buildup to diagnose the disease. In much older animals, cirrhosis with nodular regeneration can develop, and the nodules will have a lower copper content than the rest of the liver, confusing diagnosis if a regenerative nodule is inadvertently biopsied.

A genetic test for copper storage disease in Labrador Retrievers has recently become available in the United States (https://www.vetgen.com/canine-ct-lab.html). This is based on the ATP7B mutation. However, the laboratory notes that the prevalence of this mutation is high in Labradors so they do not recommend breeding away from it completely but rather avoiding homozygous pairings.

Treatment

The ideal treatment for a dog known to be affected is prevention. Bedlington Terriers homozygous for the *COMMD1* mutation should be fed a low-copper, high-zinc diet. The proprietary liver diets formulated for dogs (Royal Canin Hepatic Support or Hill's canine l/d) have low copper and high zinc concentrations but are also moderately protein-restricted, so it would be wise to supplement with a low-copper protein source (e.g., cottage cheese) in growing dogs. Purina Proplan Veterinary HP hepatic diet (Produits Nestlé SA, Vevey, Switzerland), available in Europe but not the United States, has low copper with a slightly higher protein concentration than the other diets. It is also important to avoid giving the dog tap water from copper pipes in soft water areas; bottled water should be used instead. Box 36.3 lists common high-copper foods that should be avoided and high-zinc foods that could be supplemented.

Dogs that present with an acute crisis should be treated with intensive support in exactly the same way as dogs with acute hepatitis (Box 36.4). Blood transfusion may be necessary if hemolysis is severe, but until cupremia is controlled, the patient will likely continue to hemolyze the transfused red blood cells. Copper chelation is unlikely to be beneficial acutely, but chelation with 2,2,2-tetramine (trientine) could be considered (or 2,3,2-tetramine if obtainable) because this can chelate rapidly. Trientine is available as a drug licensed for humans (Syprine, Valeant Pharmaceuticals, Bridgewater, NJ). The recommended dose in dogs is 10 to 15 mg/

BOX 36.3

Foods Rich in Copper and Zinc

Copper

- Shellfish*
- Liver*
- Kidney, heart
- Cereals
- Cocoa
- Legumes
- Soft tap water (copper pipes)

Zinc

- Red meat
- Egg yolks
- Milk
- Beans, peas
- Liver
- Whole grains, lentils
- Rice
- Potatoes

*Particularly high in copper.

BOX 36.4

Treatment Recommendations for Acute Fulminant Hepatitis

- Identify and treat cause, if possible:
  - Remove drugs implicated.
  - Treat leptospirosis.
  - Treat acetaminophen toxicity: give *N*-acetylcysteine (150 mg/kg by IV infusion in 200 mL 5% glucose over 15 min, followed by 50-mg/kg IV infusion in 500 mL over 4 hours, then 100-mg/kg IV infusion in 1000 mL over 16 hours), ± cimetidine (5–10 mg/kg IV, IM, or PO, q8h)
- Fluids:
  - Careful IV fluid therapy—dextrose saline with added potassium often most appropriate.
  - Measure blood glucose and electrolyte concentrations every few hours and adjust appropriately.
  - Use peripheral catheter and monitor renal function; use central catheters only when confirmed that there is no coagulopathy or high risk of unnoticed bleeding around catheter.
  - Monitor carefully. Ensure adequate urine output and reversal of dehydration, but do not overinfuse or worsen fluid retention.
- Treat coagulopathy as necessary. Consider fresh-frozen plasma and vitamin K (see text).
- Treat acute hepatic encephalopathy (see text later in chapter). Consider propofol infusions and lactulose-neomycin enemas. Regularly monitor blood glucose and potassium levels, and supplement as necessary.
- Treat any gastrointestinal ulceration. Consider acid secretory inhibitors (ranitidine or omeprazole).
- Treat any ascites with spironolactone ± furosemide.
- Consider antibiotics in all cases to protect against infectious complications, particularly septicemia of gut origin. Give antibiotics to all pyrexic cases intravenously. Use broad-spectrum agents that are safe in liver disease such as amoxicillin-clavulanate.
- Food—nothing by mouth for first 1–2 days until fluid balance has been restored and dog can swallow; then feed diet based on dairy or soy protein, high-quality protein, not restricted. Tube feed if necessary.

kg PO q12h, 30 minutes before a meal. 2,3,2-Tetramine is difficult to obtain. Penicillamine is not helpful in an acute crisis because chelation takes weeks to months. However, it should be noted that there is much less information available about the pharmacokinetics, drug interactions, and toxicity of trientine in dogs than there is for D-penicillamine. Reported adverse effects include nausea, gastritis, abdominal pain, melena, and weakness. On recovery, the animal should continue on long-term treatment, as outlined in the following sections.

Treatment of dogs that already have high hepatic copper concentrations documented by biopsy but are not in an acute crisis consists of active copper chelation, zinc supplementation once chelation is completed, and a low-copper diet and additional supportive therapy. The chronic hepatitis secondary to copper storage disease should be treated the same way as in dogs with idiopathic chronic hepatitis, using antioxidants, ursodiol, and other supportive medication (see earlier, "Idiopathic Chronic Hepatitis"). There is a particular role for antioxidants such as vitamin E and SAM-e in metal-induced liver injury. Chelation can be achieved using D-penicillamine or trientine. D-Penicillamine takes months to have a significant effect on the copper content of the liver but is easily available and its pharmacokinetics and toxicity in dogs are well documented; it also has weak antifibrotic and antiinflammatory properties. The recommended dosage is 10 to 15 mg/kg PO q12h, 30 minutes before meals. Starting at the lower end of the dosage range and increasing the dose after 1 week (or dividing the dose and giving it more frequently) can reduce the common adverse effects of vomiting and anorexia. It has also been reported rarely to cause nephrotic syndrome, leukopenia, and thrombocytopenia in dogs, so a complete blood count (CBC) and urine samples should be monitored regularly during therapy. A decrease in liver copper content of about 900 µg/g dry weight/year can be anticipated in dogs treated with D-penicillamine. Trientine (2,2,2-tetramine) is another efficacious copper chelator that may be used; it can remove copper from the liver more rapidly than D-penicillamine. Details of dosage and potential adverse effects have been presented earlier.

Copper chelation treatment is continued until a normal liver copper concentration is reached; this is best determined by liver biopsy and copper quantification or cytologic estimate. An alternative is to monitor serum liver enzyme activities every 2 to 3 months until they return to normal. Treatment should then be stopped to prevent copper deficiency, which can occur after prolonged, overzealous copper chelation and can result in severe effects of copper deficiency, with weight loss and hematemesis. The regimen can then be changed to a preventive protocol consisting of a copper-restricted diet and zinc administration throughout the animal's life span.

ACUTE HEPATITIS

Etiology and Pathogenesis

Acute hepatitis is much less common than chronic hepatitis in dogs but, when severe, carries a much poorer prognosis. Treatment focuses on providing supportive measures and allowing the liver to recover. Dogs with acute hepatitis are at high risk of disseminated intravascular coagulation (DIC). Severe loss of liver function is also fatal because it cannot be replaced artificially while awaiting recovery; there is no such treatment as liver dialysis. However, because of the remarkable regenerative capacity of the liver, animals that survive the acute phase of the disease can recover completely, with no permanent hepatic injury, as long as they are fed and supported properly.

Most causes of acute fulminating hepatitis in dogs are infectious or toxic (see Box 36.5). In unvaccinated dogs, CAV-1 and leptospira are important differential diagnoses. Dogs with copper storage disease can present acutely, often associated with high serum copper concentration in addition to acute hepatic necrosis. Xylitol, an artificial sweetener, has been reported to cause acute hepatic necrosis and an associated coagulopathy in dogs (Dunayer et al., 2006), with a high mortality. Aflatoxin in contaminated food has also caused acute and subacute hepatitis with a high mortality in dogs (Newman et al., 2007). The most common drugs implicated in causing acute hepatic necrosis in dogs

BOX 36.5

Potential Causes of Acute Fulminant Hepatitis in Dogs

Infections

- Canine adenovirus type 1
- Neonatal canine herpesvirus
- *Leptospira interrogans* (various serovars)
- Endotoxemia
- *Yersinia*
- Sarcocystic hepatitis (neospora; sarcocystitis and hammondia) rarely (Irvine et al., 2016).

Thermal

- Heat stroke

Metabolic

- Acute necrosis associated with copper storage disease in Bedlingtons, Dalmatians, and some Labradors and Dobermans (see Box 36.1)

Toxic or Drug-Induced

- Acetaminophen
- Phenobarbital or primidone
- Carprofen (especially Labrador Retrievers)
- Mebendazole
- Thiacetarsamide
- Mercury
- Potentiated sulfonamides
- Mebendazole
- Cyanobacteria (blue-green algae) in seawater and fresh water
- Xylitol
- Aflatoxin
- Nitrofurantoin
- Lomustine (CCNU)

are listed in Box 36.5, but any drug could cause idiosyncratic hepatic necrosis in an individual dog. A case of destructive cholangitis (termed *disappearing bile duct syndrome*) was reported in a dog as a suspected drug reaction to amoxicillin-clavulanate, amitraz, and milbemycin oxime or a combination of these (Gabriel et al., 2006); the author has seen this in a clinical case likely caused by an idiosyncratic reaction to amoxicillin-clavulanate.

Clinical Features

The clinical features of acute fulminating hepatitis, independent of the cause, relate to the acute loss of hepatic function together with the effects of generalized cell necrosis and release of inflammatory cytokines and tissue factors. Dogs usually present with an acute onset of one or more of the following—anorexia, vomiting, PD-PU, dehydration, HE with depression progressing to seizures and/or coma, jaundice, fever, cranial abdominal pain, coagulopathy with petechiae and possible hematemesis and melena, and, in some cases, ascites and splenomegaly resulting from acute portal hypertension. In dogs and cats with severe acute liver disease, spontaneous bleeding may result from depletion of clotting factors or from DIC. Renal failure is a severe complication in some cases, with both prerenal and intrinsic renal components. In humans with acute hepatic failure, hypotension, cardiac arrhythmias, cerebral and pulmonary edema, and pancreatic inflammation also have been reported; these may occur in some dogs, although they have not been specifically reported.

Diagnosis

The diagnosis is usually made on the basis of history, clinical signs, and clinicopathologic findings. Liver histopathology should be confirmatory, but results are often not obtained until recovery (or postmortem) because of the severe, acute nature of the disease. A history of recent drug or toxin exposure is important in implicating these as a cause; vaccination status is an important consideration for infectious causes.

On clinical pathology, dogs with acute hepatitis often have early marked increases in hepatocellular enzyme ALT and AST activities (10-fold to >100-fold). Jaundice and increases in markers of cholestasis may also occur; the rare cases of destructive cholangitis are characterized by early severe jaundice, marked increases in ALP activities, and hyperbilirubinemia. Hypoglycemia and hypokalemia are common in dogs with acute hepatitis, and azotemia is seen in some cases as a result of both prerenal and renal causes. Hemostatic abnormalities, with prolonged clotting times and thrombocytopenia, are frequently present and can be a sign of developing DIC (see Chapter 87). In patients with DIC, APTT and OSPT may be prolonged, but it is impossible to distinguish this from reduced hepatic production of clotting factors. However, measurement of increased D-dimers and/or fibrin degradation products, combined with decreases in platelet count and schistocytosis, increases the index of suspicion for DIC. D-dimer concentrations are often mildly to moderately increased in dogs with liver disease because of reduced clearance in the liver, and this does not necessarily mean that the dog has a thrombus or DIC. More marked elevations are suggestive of DIC. Diagnostic imaging is not usually helpful in dogs with acute hepatitis. There may be hepatomegaly and a diffuse change in hepatic echogenicity; in some cases there may be splenic congestion and/or ascites, but these changes are not specific and do not help define the cause or extent of the damage. In some patients, the ultrasonographic examination is unremarkable.

Treatment and Prognosis

Treatment of acute fulminant hepatitis in dogs is largely supportive, outlined in Box 36.4. Every attempt should be made to identify and treat the primary cause at the same time that supportive therapy is instituted. Corticosteroid treatment is not indicated in these cases and may worsen the prognosis by increasing the risk of GI ulceration and thrombosis. DIC is a high risk in these cases, and the treatment of DIC is difficult and usually unsuccessful. The most effective treatment is to remove the inciting cause, which in acute liver failure in humans means rapid liver transplant. Without this option in dogs and cats, the mortality in DIC of acute fulminant hepatitis is likely to be 100%. Recommended therapies include plasma transfusion to replace depleted clotting factors and careful heparin therapy during the hypercoagulable phase. However, the efficacy of heparin therapy in DIC has recently been called into question in humans, and there are no clinical data supporting its use in dogs and cats (see Chapter 87).

The owner should be warned of the poor prognosis for recovery in spite of intensive support, and in severe cases, early referral to an intensive care unit should be considered. However, dogs that recover from the acute phase have a good chance of complete recovery. Some research in humans and animals has suggested that chronic liver lesions are less likely to develop if a single-protein milk or soybean-based diet is fed during the recovery phase.

BILIARY TRACT DISORDERS

Biliary tract disorders are less common in dogs than in cats, but primary biliary tract disorders and extrahepatic bile duct obstruction (EBDO) are recognized in dogs. In addition, destructive cholangitis caused by drug reactions leading to severe cholestasis and icterus has been recognized occasionally in dogs but not cats. Dogs occasionally develop congenital hepatic and renal cysts, similar to Caroli's disease in humans, which are discussed in the section on ductal plate disorders later.

CHOLANGITIS AND CHOLECYSTITIS

Primary cholangitis has been considered to be less common in dogs than in cats, although recent reports suggest it has been underestimated (Tamborini et al., 2016; Harrison et al., 2018). Histologically, cholangitis is defined as inflammation confined to the portal region with either inflammatory cell infiltration of the bile duct wall or within the lumen of the bile duct. The clinical signs and diagnostic evaluation are

similar to those in cats with neutrophilic cholangitis (see Chapter 35). Dogs can be of any age or breed, and the typical presentation is acute onset of anorexia, jaundice, and vomiting, with or without pyrexia, although not all affected dogs are jaundiced. In some cases there may have been a previous history of acute enteritis or pancreatitis, suggesting a potential cause for ascending biliary infection from the gut. Mechanical obstruction and gallbladder mucocele (see later) should be ruled out first, usually by ultrasonography, and then liver and bile and/or gallbladder mucosa specimens should be obtained for histopathology and microbial culture and sensitivity testing, preferably before antibiotic treatment is initiated. Concurrent cholecystitis is common in those cases in which it is investigated (Harrison et al., 2018).

Liver biopsies and bile samples can be obtained by direct visualization during surgery, laparoscopy, or ultrasonographic guidance. The latter method carries a greater risk of bile leakage; to minimize this, a 22-gauge needle attached to a 12-mL syringe is used for cholecystocentesis (bile retrieval), and an attempt is made to evacuate the gallbladder. The procedure is best performed under general anesthesia rather than heavy sedation to minimize the chance of patient motion during aspiration. The risk of iatrogenic bile or septic peritonitis is low but greatest with patients with a severely diseased gallbladder wall (determined ultrasonographically); surgical treatment is necessary if bile peritonitis occurs. Enteric organisms similar to those found in cats are usually found; the most common isolate in several studies is *Escherichia coli.* Other organisms reported are all of gut origin and include *Enterococcus, Klebsiella, Clostridium,* fecal *Streptococcus, Corynebacterium,* and *Bacteroides* spp. *Clostridium* may be a gas-forming species causing emphysematous changes in the gallbladder wall visible radiographically or ultrasonographically. Antibiotic resistance is relatively common among isolates and can also develop during therapy, underscoring the importance of obtaining bile samples for culture and sensitivity whenever possible. Choleliths can be found in association with cholecystitis or cholangitis; the cause and effect relationship is not always clear.

Treatment involves 4 to 6 weeks of antibiotics, preferably based on the results of culture and sensitivity, together with antioxidants and choleretics. As in cats, amoxicillin is a good initial choice at a dose of 15 to 20 mg/kg PO q8h combined with ursodeoxycholic acid at a dose of 15 mg/kg PO every 24 hours or split into two doses q12 hours. One recent study showed cholecystectomy reduced the risk of death in affected dogs, so this should be seriously considered, particularly when gallbladder abnormalities are found on ultrasound (Harrison et al., 2018).

GALLBLADDER MUCOCELE

Gallbladder mucocele has been reported as a common cause of clinical signs of biliary tract disease in dogs (Fig. 36.8). The cause is unclear, but it is most common in middle-aged to older dogs; there appears to be a breed predisposition in Shetland Sheepdogs in the United States. Other suggested breed associations are Cocker Spaniels and Miniature Schnauzers. There is a suggested association with endocrinopathies, particularly hypothyroidism, hyperadrenocorticism, and hyperlipidemia, and affected dogs show a variety of metabolic changes (Gookin et al., 2015; Gookin et al., 2018). Prior use of imidacloprid also shows an association in one study (Gookin et al., 2015). Sterile or septic inflammation of the gallbladder wall and/or disordered gallbladder

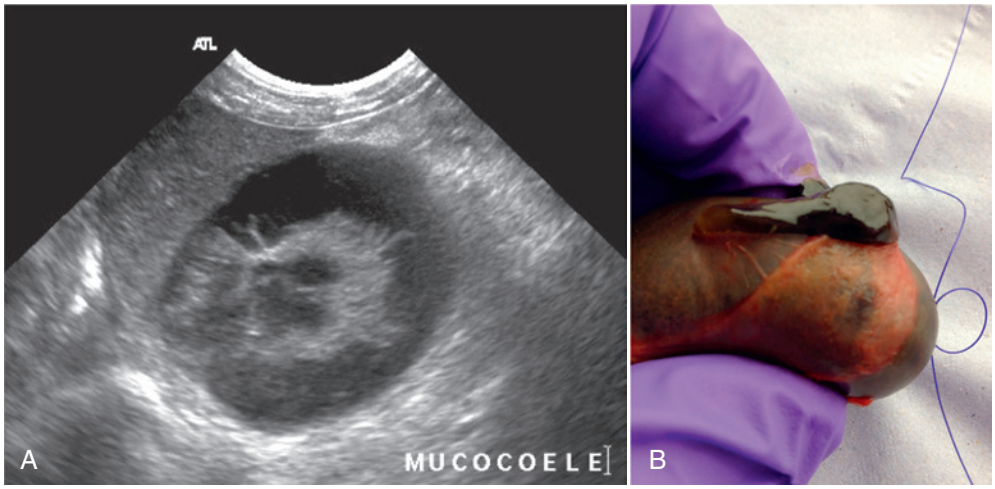

FIG 36.8

(Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.) **(B)** Appearance of the gallbladder with mucocele after surgical removal from a Border Terrier. Note gelatinous material exuding from cut surface. (Courtesy Queen's Veterinary School Hospital, University of Cambridge, England.)

motility may also predispose to mucocele formation. A mutation in biliary phosphatidylcholine transporter was proposed as a cause in affected Shetland Sheepdogs and also a few dogs of other breeds with mucocele (Mealey et al., 2010) but later disputed (Cullen et al., 2014).

Clinical signs vary. In some dogs mucocele is clinically silent and is an incidental finding on abdominal ultrasonography (see Fig. 36.8). In others nonspecific clinical signs are seen, similar to those of other biliary tract diseases with anorexia, lethargy, vomiting, and icterus. Some dogs present acutely because of gallbladder rupture and bile peritonitis. A recent study demonstrated that ultrasonography has a high specificity but low sensitivity of only 56% for gallbladder rupture and bile peritonitis for dogs with mucocele (Jaffey et al., 2018). Therefore, if gallbladder rupture is suspected clinically, surgery should be undertaken even if the ultrasound is negative.

Treatment is usually surgical for clinically affected dogs; cholecystectomy with or without biliary diversion is the technique of choice. Biliary diversion increases perioperative mortality and is rarely necessary. Gallbladder rupture also increases the risk of death. However, those that survive the perioperative period have a good long-term prognosis. Medical management of subclinical mucoceles has been reported in two dogs with hypothyroidism that were successfully treated (Walter et al., 2008) and in Shetland Sheepdogs (Aguirre et al., 2007). In the shelties, medical management consisted of a low-fat diet (e.g., Hill's i/d low fat; Royal Canin Waltham Gastrointestinal Low Fat; Eukanuba Intestinal Diet, Procter & Gamble Pet Care, Mason, OH) with a choleretic (ursodeoxycholic acid, 10–15 mg/kg PO total daily dosage, preferably split twice) and antioxidant (SAM-e, 20 mg/kg PO q24h). In one dog this resulted in resolution of the mucocele; in two dogs the mucocele remained static; one dog died as a result of gallbladder rupture and one as a result of pulmonary thromboembolism, both within 2 weeks of diagnosis; and two dogs were lost to follow-up. It would also seem sensible to address the underlying cause of the dyslipidemia in all cases, whether surgically or medically managed.

EXTRAHEPATIC BILE DUCT OBSTRUCTION

The causes of EBDO in dogs are similar to those in cats (see Box 35.4) with the exception of liver flukes, which are uncommon in dogs. The most common cause of EBDO in dogs is extraluminal obstruction from acute-on-chronic pancreatitis (see Chapter 37), but intestinal foreign bodies, neoplasia, bile duct involvement in a diaphragmatic hernia, and other processes can also cause EBDO (Fig. 36.9). Bile duct injuries that heal and result in stricture formation several weeks later are also seen in dogs; the common bile duct (CBD) may be compressed when carried with the liver into the thorax in dogs with diaphragmatic hernia. Extraluminal compressive lesions, such as pancreatic, biliary, or duodenal neoplasms, are less common causes, and cholelithiasis as a cause of EBDO is rare. To be considered as EBDO, a pathologic process must exist at the level of the CBD that impedes bile flow into the duodenum. Only if bile flow has been completely interrupted for several weeks are acholic feces, vitamin K–responsive coagulopathy, and repeated absence of urobilinogen in properly processed urine specimens found. If obstruction is incomplete, these features are not present and the constellation of signs and clinicopathologic test results resembles those of other, nonobstructive biliary tract disorders.

Clinical Features

Presenting clinical signs and clinicopathologic and physical examination findings of all these disorders may not differ greatly unless the underlying condition has caused EBDO or bile peritonitis. Regardless of the underlying disorder, typical clinical signs are jaundice, acute or chronic vomiting, anorexia, depression, weight loss, and occasionally vague cranial abdominal pain. Because of the protected location of the gallbladder in the abdomen, it is rarely possible to be

FIG 36.9

able to palpate it in a dog with EBDO unless the gallbladder is greatly enlarged.

Diagnosis

Affected dogs often show hyperbilirubinemia, high serum ALP, GGT, fasting and postprandial serum bile acid (SBA), and cholesterol concentrations, and less severe changes in serum ALT activity. SBA concentrations increase early in dogs with biliary stasis; in these circumstances, the degree of SBA level elevation gives no indication of liver function. Generally, more severe cholestatic lesions are associated with more severe clinicopathologic changes. Radiographically, there may be evidence of hepatomegaly and a mass effect in the area of the gallbladder on survey abdominal films. Gas shadows associated with the gallbladder and other biliary tract structures could be ascribed to ascending infection with gas-forming organisms. The cause of cholelithiasis in dogs is unclear, and they may also be found in asymptomatic dogs. These concretions are radiolucent unless they contain calcium, which occurs about 50% of the time. Inflammatory abdominal effusion is expected in dogs with bile peritonitis but not in those with most causes of EBDO, except for effusions associated with pancreatitis or pancreatic cancer.

Ultrasonography helps differentiate medical from surgical causes of EHBO, although this imaging modality is certainly not foolproof. Dilated and tortuous hepatic bile ducts and CBD, as well as gallbladder distention, are convincing ultrasonographic evidence of EBDO at the CBD or sphincter of Oddi. When dilated biliary structures are seen, it might be difficult to distinguish EBDO that requires surgical intervention from resolving transient EBDO associated with severe acute-on-chronic pancreatitis or from nonobstructive biliary disease (e.g., bacterial cholecystitis or cholangitis) unless a source of obstruction is specifically identified (e.g., pancreatic mass, cholelith in the CBD). Prolonged fasting causes gallbladder enlargement because of delayed evacuation and should not be overinterpreted. In addition, cystic hyperplasia and epithelial polyp formation are common lesions in older dogs and should not be confused with choleliths in the gallbladder. A stellate appearance to the contents of the gallbladder is characteristic of gallbladder mucocele (see Fig. 36.8). Monitoring the serum bilirubin concentration to determine when to intervene surgically is not worthwhile because it begins to decline over days to weeks, without relief of obstruction, in cats and dogs with experimentally induced EBDO. Conversely, in some dogs a significant proportion of bilirubin becomes irreversibly bound to albumin in the circulation (biliprotein), resulting in delayed clearance and continued elevation of the serum bilirubin concentration for up to 2 weeks after the initial insult has resolved.

Treatment and Prognosis

If the distinction between medical and surgical causes of jaundice is not clear, it might be safer to proceed surgically to avoid excessive delays in diagnosis, particularly if bile peritonitis is suspected. The previously established principle is that cases with complete, persistent EBDO should be operated on as quickly as possible because of the fear that refluxed bile acids will inevitably lead to cirrhosis unless the obstruction is relieved rapidly. However, more recent evidence suggests that medical management can be safely undertaken in otherwise clinically well dogs for days to weeks while transient biliary tract obstruction resolves, and clinicians should not be too quick to go in surgically in a dog with EBDO secondary to pancreatitis. There is no evidence in the veterinary literature to guide clinicians on how often cirrhosis ensues and how long a complete biliary obstruction should be allowed to continue before surgical intervention. However, in a review of biliary tract obstruction caused by chronic pancreatitis (CP) in humans, Abdallah et al. (2007) pointed out that as few as 7% of cases developed subsequent biliary cirrhosis. Biliary obstruction caused by CP in humans is considered to be transient if it resolves within 1 month; most cases are transient because the biliary obstruction resolves as the edema of the acute-on-chronic inflammation resolves. In the absence of marked pain or a mass, the patient will be monitored for 1 month and only treated surgically if the jaundice is persistent after this or there is suspicion of neoplasia.

As with any other form of liver disease, it is important to stabilize the patient with fluids and electrolytes, and to perform a hemostasis profile and platelet count before surgery. Prolonged coagulation times may respond to vitamin K_1 injections 0.5–1 mg/kg SC × 3 doses at 12-hour intervals prior to surgery (to be consistent with earlier recommendations), but if not, a fresh-frozen plasma transfusion is advisable before surgery to replace clotting factors. If the site of obstruction or biliary injury is not identified, at least tissue (e.g., liver, gallbladder mucosa) and bile specimens can be obtained for histopathologic and cytologic evaluation, bacterial culture, and sensitivity testing. Any abdominal fluid should be analyzed cytologically and cultured for aerobic and anaerobic bacteria. A liver biopsy specimen should also be obtained in all cases. Typical hepatic histopathologic findings in dogs with early EBDO are canalicular bile plugs and bile ductular proliferation, with degrees of periportal inflammation and fibrosis in chronic cases. Confounding biliary infection can incite a stronger inflammatory reaction in the periportal region. However, it is impossible to diagnose a primary biliary tract infection from a liver biopsy alone.

Surgical goals are to relieve biliary obstruction or leakage and restore bile flow. Reconstructive procedures to divert bile flow can be performed if the cause of EBDO cannot be corrected. However, because these carry a poor long-term prognosis, less invasive procedures such as stenting are preferred whenever possible.

In cases without complete biliary obstruction (e.g., some choleliths) or with transient obstruction (e.g., most cases of acute-on-chronic pancreatitis), medical management alone is indicated. The choleretic ursodiol is indicated as treatment in these cases, provided that complete EBDO has been ruled out. Choleliths may also move using this drug. The recommended dosage is 10 to 15 mg/kg total, PO daily, preferably split into two doses. In addition, all cases (both medical and

surgical) should receive antioxidant therapy, preferably with vitamin E (400 IU PO for a 30-kg dog, scaled appropriately to the size of the dog; tablets usually come as 100, 200, or 400 IU) and SAM-e (20 mg/kg PO q24h) because it has been demonstrated that bile reflux in the liver is a potent oxidant toxin. Dogs should be fed a high-quality diet that is not protein-restricted: usually, a diet designed for critical care feeding is more appropriate than a manufactured liver support diet because the dog is suffering an inflammatory and/or septic process, but hepatocyte function is usually good.

The prognosis for dogs with EBDO depends on the underlying cause. If the cause can be addressed without surgical reconstruction, the prognosis is fair to good. If extensive biliary reconstruction is needed, the prognosis is guarded.

Bile Peritonitis

Bile peritonitis usually results from abdominal trauma damaging the CBD (e.g., penetrating injury, horse kick, automobile accident) or pathologic rupture of a severely diseased gallbladder, particularly with gall bladder mucocele but also which sometimes occurs after diagnostic ultrasonography-guided aspiration. Early signs of bile peritonitis are nonspecific, but with progression, jaundice, fever, and abdominal effusion are seen. When bile, which is normally sterile, comes into contact with the peritoneal surface, there are resultant cell necrosis and changes in permeability, which predispose to infection with bacteria that move across the intestinal wall. Hypovolemia and sepsis may occur in animals with undetected bile peritonitis. Surgery is essential in bile peritonitis, both to identify and treat the cause and to lavage the abdomen. Presurgical considerations are the same as for EBDO. If surgery for bile peritonitis is to be delayed, peritoneal drainage should be established to remove noxious, bile-containing abdominal fluid and for lavage.

CONGENITAL VASCULAR DISORDERS

Congenital disorders of hepatic vasculature, intrahepatic and extrahepatic, are more common in dogs than in cats. There are some breed-related tendencies, suggesting a genetic basis to some disorders, but it is also assumed that most of them result from some type of (as yet undefined) insult in utero. Experimental reduction in flow in the umbilical vein in sheep and other species can result in the development of PSSs and asymmetry of hepatic lobular and vascular supplies; this is likely also true in dogs. This would explain why it is relatively common to see dogs with more than one coexistent congenital vascular disorder in the liver (e.g., a congenital PSS combined with intrahepatic portal vein hypoplasia or microvascular dysplasia [MVD]) and would also explain why dogs with congenital PSSs have a higher prevalence of other congenital defects, such as cryptorchidism and cardiac disorders.

For ease of categorization, and because they have different clinical presentations, congenital vascular disorders have been divided into disorders associated with low portal pressure and those with high portal pressure. However, it is important to remember than when two or more congenital hepatic defects occur concurrently, the differentiation will be less obvious.

DISORDERS ASSOCIATED WITH LOW PORTAL PRESSURE: CONGENITAL PORTOSYSTEMIC SHUNT

Etiology and Pathogenesis

Congenital PSSs are the most common congenital portovascular disorder in dogs. The etiology and pathogenesis are similar to those in cats; see Chapter 35 for more details. Many different types of congenital portovascular anomalies have been reported in dogs; sometimes they coexist with intrahepatic or extrahepatic portal vein hypoplasia or intrahepatic MVD (see later). However, a distinguishing feature of isolated congenital PSS is that it results in a low portal pressure because some blood is shunted away from the sinusoidal circulation by the shunting vessel(s). Dogs with isolated congenital PSS therefore do not present with ascites unless they are severely hypoalbuminemic. This allows differentiation from the congenital vascular disorders associated with increased portal pressure and therefore acquired PSS (see later) in which portal hypertension and associated ascites are common at presentation.

Canine congenital PSSs can be extrahepatic or intrahepatic. Extrahepatic PSSs are anomalous vessels connecting the portal vein or one of its contributors (left gastric, splenic, cranial or caudal mesenteric, or gastroduodenal vein) to the caudal vena cava or azygos vein. They are most commonly recognized in small-breed dogs and have a high prevalence in Cairn Terriers, Yorkshire Terriers, West Highland White Terriers, Maltese, Havanese, other terriers, and Miniature Schnauzers (Fig. 36.10). Intrahepatic PSSs may be left-sided, in which case they are thought to represent persistence of the fetal ductus venosus, or they can be right-sided or central, in which case they likely have a different embryologic origin. An intrahepatic PSS is usually seen in large-breed dogs, but Collies tend to have extrahepatic PSSs, despite being large dogs. Increased breed prevalence suggests a genetic basis to the disease, but this has only been investigated in Irish Wolfhounds, in which an inherited basis of patent ductus venosus has been demonstrated, in Cairn Terriers with extrahepatic PSSs, in which an autosomal polygenic inheritance or monogenic inheritance with variable expression is suspected (van Straten et al., 2005), and in Maltese dogs, in which a partially penetrant recessive mode of inheritance has been proposed (O'Leary et al., 2014). Affected Irish Wolfhounds tend to have smaller litters and can also produce more than one puppy with a PSS in a litter.

One study reported that dogs from breeds that were not usually recognized as having a high risk of PSS were more likely to present with unusual anatomic forms of PSS that were less often amenable to surgical management (Hunt, 2004).

Clinical Features

Clinical signs are similar to those in cats; neurologic, GI, and urinary tract signs predominate (see Chapter 35 for more details). About 75% of dogs present before 1 year of age, but some present at an older age, with some as old as 10 years before signs are recognized. There is a spectrum of severity of neurologic signs, ranging from severely affected young puppies that persistently circle, become centrally blind, and can even have seizures or become comatose, to very mildly affected or asymptomatic individuals. It is likely that this variation reflects differences in shunt fraction and dietary and other environmental differences among dogs. Concurrent inflammation is an important trigger for HE in affected dogs, so clinicians should look carefully in affected animals for inflammatory disease such as urinary tract infections. PU-PD with hyposthenuric urine are relatively common; this is probably multifactorial in etiology and partly caused by reduced renal medullar concentrating gradient (see Chapter 33). Urate uroliths are also common and can be cystic or renal. Anecdotally, urate renal calculi seem to be more common in terriers, and dogs presenting with calculi often do not have prominent neurologic signs. On physical examination, animals are often but not always smaller than their litter mates and may have nonlocalizing neurologic signs and, in some cases, palpable renomegaly. The latter is caused by circulatory changes and is not a reflection of renal disease or uroliths; it is of no clinical significance and regresses after shunt ligation. Other congenital defects may be apparent, particularly cryptorchidism, which is reported in up to 50% of male dogs with congenital PSSs.

Diagnosis

The diagnosis of congenital PSS in dogs is the same as in cats (see Chapter 35) and relies on visualizing the shunting vessel ultrasonographically, with computed tomography (CT) angiography or portovenography (Fig. 36.11, or

grossly at surgery. Scintigraphy can demonstrate shunting but is not helpful for differentiating congenital from acquired PSS, so some other imaging method is necessary for treatment decisions. See Chapter 34 for more information on imaging PSSs.

If possible, it is important to try to estimate how well developed the remaining hepatic portal vasculature is by repeating the portovenography after ligation and/or by evaluating the histologic findings on liver biopsies taken at the time of ligation. This is a work in progress, but there is a strong suspicion that the postligation prognosis may depend on the potential for the intrahepatic vasculature to open up after surgery, and dogs that do poorly postoperatively may have concurrent portal vein hypoplasia and/or MVD (see later).

Nonspecific clinicopathologic findings in more than 50% of affected dogs, regardless of the type of vascular anomaly, are microcytosis, hypoalbuminemia, mild increases in serum AP and ALT activities, hypocholesterolemia, and low blood urea nitrogen concentration. Fasting bile acid concentrations may be normal or high, but postprandial bile acid concentrations are high in all cases. However, this does not distinguish congenital PSS from acquired PSS or early cholestasis, which also causes increases in bile acid concentration. The postprandial ammonia concentration can also be measured and will be high, whereas fasting ammonia concentration may be high or normal (see Box 34.3 for details of how to perform an ammonia challenge test). Ammonia tolerance or challenge tests are potentially dangerous because they can precipitate an encephalopathic crisis. Other tests have been evaluated for their sensitivity and specificity in the diagnosis of PSS. The level of protein C, a liver-derived anticoagulant, is also decreased in dogs with PSS and increases after ligation; this can help differentiate PSS from MVD.

Puppies of high-risk breeds could be screened for congenital PSS by measuring bile acid or ammonia concentrations before they are placed into homes, but there are potential false-positives with both of these tests; no puppy should be euthanized or labeled as having a definite congenital PSS on the basis of a high bile acid and/or ammonia concentration without further evidence. Normal Irish Wolfhounds can have a transiently high blood ammonia concentration between the ages of 6 to 8 weeks; this normalizes at 3 to 4 months of age. Zandvliet et al. (2007) have demonstrated that this is caused by a clinically insignificant urea cycle defect. Postprandial bile acid concentrations can be falsely elevated in Maltese puppies without PSS for unknown reasons, again confusing any efforts at screening tests in this breed (Tisdall et al., 1995).

On diagnostic imaging, the liver is frequently but not always small. Ultrasonography now has a high sensitivity and specificity for the diagnosis of both intrahepatic and extrahepatic PSS; furthermore, their anatomy can usually also be described ultrasonographically. Bubble studies may help visualization of a PSS with ultrasonography (Gómez-Ochoa et al., 2011). If the shunting vessel cannot be fully visualized or characterized by ultrasonography, CT angiography is now the imaging technique of choice, replacing portovenography wherever possible (see Chapter 34 for more details).

Overview of Treatment Options and Prognosis

Surgical occlusion of the anomalous vessel to restore normal portal circulation has long been recommended as the treatment of choice. In many cases this will restore normal or near-normal liver function. However, owners need to be aware of the small but definite risk of postoperative mortality as a result of portal hypertension and/or refractory seizures, and of the potential that the PSS may be only partially and not totally ligated. It is more common to be able to ligate the PSS partially at the first surgery, because the portal vasculature cannot initially accommodate all the shunting blood. In some cases it is possible to repeat the surgery at a later date to ligate the PSS further, but this is often unnecessary to control clinical signs. A few dogs with partially ligated shunts develop portal hypertension and multiple acquired PSSs with a recurrence of their clinical signs. There are several different surgical procedures described for ligation of PSS, but they are outside the scope of this text. In addition to surgical ligation, a PSS may be attenuated with ameroid constrictors (Fig. 36.12) or embolized with coils. Laparoscopic ligation of PSS has been reported in two dogs (Miller et al., 2006). As a general rule, ligation of a PSS requires an experienced surgeon.

Medical treatment is required to stabilize the patient before surgery and for about 8 weeks after surgery while the hepatic vasculature and mass recover. This involves careful dietary management combined, in many cases, with antibiotics and soluble dietary fiber. In some cases medical management may continue successfully over the course of

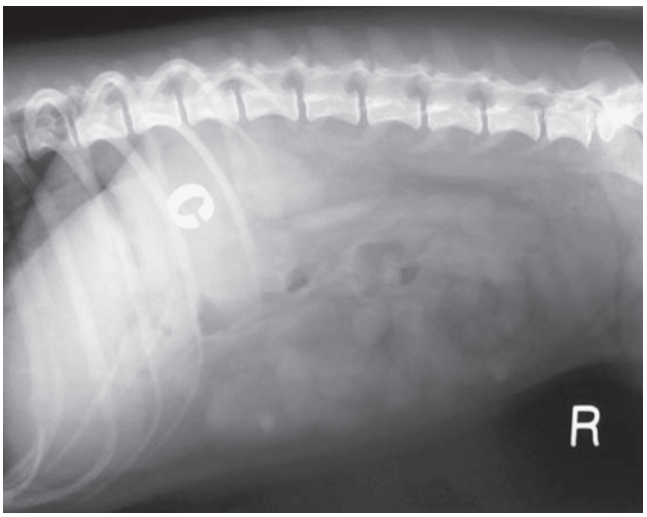

FIG 36.12

Note that the ameroid is visible as a radiodense ring in the craniodorsal abdomen. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

the patient's life as an alternative to surgery. This is usually because the client cannot afford referral, is unhappy about the risks associated with surgery, or because the patient has multiple or intrahepatic shunts. Mildly affected and older animals are good candidates for medical management, but generally these are dogs with smaller shunting fractions. Dogs (particularly terriers) that present at an older age with urate stones but no neurologic signs are also good candidates for medical management alone. In addition, dogs with concurrent portal vein hypoplasia and/or MVD tend to have a higher surgical risk and are best managed medically. Medical management does not reverse the underlying disorder but can result in good long-term results. A recent prospective study of 126 dogs with congenital PSSs comparing surgical with medical management found that surgically managed dogs had a higher probability of survival over the course of the study (Greenhalgh et al., 2010). However, only 18 dogs had died by the end of the study, and survival time was long for the dogs remaining alive in both groups (mean, 729 days). Age at the time of surgery did not appear to affect prognosis. Once the dog has reached adulthood, there is no evidence that the liver progressively atrophies throughout life. Ultimately, more studies are needed to identify the factors that are most important in determining prognosis after medical and/or surgical management and to help preoperatively identify the small number of animals that will have a poor outcome after surgery. The specific details of medical management of hepatic encephalopathy are given below.

Management of Hepatic Encephalopathy

Whether caused by congenital or acquired PSS, the treatment of HE in dogs is similar (Fig. 36.13). The main difference is that acquired PSSs are usually the result of portal hypertension, so treatment of its other manifestations and the underlying liver disease will also be necessary in these cases (see earlier). Controlled trials have not been conducted in animals to determine the optimal treatment for HE and for each stage (mild, moderate, severe) of HE. Therefore current recommendations are based on human studies and on anecdotal reports in dogs.

The goal of treatment in dogs with HE is to restore normal neurologic function by decreasing the formation

FIG 36.13
Female German Shepherd Dog with noncirrhotic portal hypertension. **(A)** At 14 months of age, with ascites and in poor body condition, but remarkably alert. **(B)** 5 years later on medical management only—very stable and in good body condition, with no detectable ascites. The dog lived for 8 years with a good quality of life before developing a gastroduodenal ulcer (see Fig. 36-5). **(C)** Drugs that the dog received long term, in addition to dietary management. of gut-derived and peripherally derived encephalotoxins, eliminating precipitating factors, and correcting acid-base and electrolyte abnormalities. A variety of encephalotoxins are implicated as causes of HE (see Chapter 33), but the most important from the point of view of treatment is ammonia. It was once believed that the most important source of ammonia was undigested protein in the colon metabolized by gut bacteria, but emphasis has now shifted to interorgan metabolism of ammonia and small intestinal enterocyte glutamine catabolism in patients with HE rather than production of ammonia in the large intestine from dietary protein itself, which is considered a less important source (see Chapter 33 for more details). There are high amounts of ammonia in the portal circulation, particularly after a meal, but the main source is obligate catabolism of glutamine by small intestinal enterocytes as their main energy source; intestinal glutaminase concentrations seem to increase for unknown reasons in humans with cirrhosis, increasing gut ammonia production. There are no published studies showing the relative contribution of small and large intestine–derived ammonia to HE in dogs, but the observed tendency for dogs to show signs of HE 1 to 2 hours after feeding would support a small intestinal origin. Dogs with experimental PSS and animals and humans with acquired PSS actually have a higher dietary protein requirement than do normal animals or people. Inflammatory mediators are also thought to be important precipitators of HE. It is known that clinically relevant episodes of HE in dogs with congenital or acquired PSS are often precipitated by stress and infections, not just by feeding, emphasizing the role of hypermetabolism, inflammation, and breakdown of body protein in the development of HE (see Chapter 33). HE is also triggered by negative nitrogen balance and breaking down of muscle mass (see Fig. 36.5), particularly in dogs with acquired PSS and protein-calorie malnutrition, and in these cases starvation and protein restriction will worsen the HE.

A combination of careful dietary manipulation, locally acting agents that discourage the formation of readily absorbable ammonia and hasten evacuation of the intestinal tract (lactulose), antibiotics to suppress bacterial populations that generate ammonia and other gut-derived encephalotoxins, and treatment of any precipitating cause is the standard approach for the long-term management of chronic HE (Box 36.6). Dietary management and treatment of the

BOX 36.6

Long-Term Medical Management of Hepatic Encephalopathy

Dietary Management

- Feed normal amounts (if possible) of high-quality, highly digestible protein to minimize the chance that any protein will reach the colon to be converted into NH_3. Some veterinarians recommend increasing branched chain amino acids and reducing aromatic amino acids such as tryptophan, but there is no evidence that changing the dietary levels affects cerebrospinal fluid levels. Consider adding ornithine aspartate, which provides substrates for conversion of NH_3 to urea (ornithine) and glutamine (aspartate). Restrict protein only if absolutely necessary to control neurologic signs and monitor muscle mass and blood protein concentrations carefully.
- Prevent protein-calorie malnutrition by avoiding prolonged fasting and/or excessive protein restriction because this will lead to hyperammonemia from the breakdown of body protein.
- Feed small amounts often to reduce the amount of liver work required, reduce energy demands and thus glutamine metabolism in small intestine, and lessen the potential for undigested food to reach the colon.
- Fat needs no special recommendations, although it should be fed in normal amounts and not restricted unless clinical steatorrhea develops (rare). Avoid diets that are very high in fats, particularly with cholestasis or portal hypertension, in which GI signs may be exacerbated.
- Carbohydrates should be highly digestible as a primary calorie source, reducing the need for hepatic gluconeogenesis from fat and protein.
- Fermentable fiber reduces hepatic encephalopathy in the same way as lactulose. Nonfermentable fiber is also important because it prevents constipation and therefore reduces contact time for colonic bacteria to act on feces and produce ammonia.
- Zinc supplementation may reduce encephalopathy because zinc is used in many metalloenzymes in the urea cycle and in the muscle metabolism of ammonia.

Lactulose

- Lactulose is a soluble fiber that acidifies colonic contents, reducing ammonia absorption, and also increases colonic bacterial cell growth, therefore incorporating ammonia into the bacterial cell walls. Cats should be given 2.5–5 mL PO q8h, and dogs, 2.5–15 mL PO q8h. Start at the low dose, and titrate to effect (two or three soft stools daily).

Antibiotics

- Give amoxicillin (22 mg/kg PO q12h) to reduce gastrointestinal flora and also protect against bacteremia.

Identify and Treat Concurrent Infections and Inflammation

- Pay particular attention to identifying and treating any urinary tract infections (pyelonephritis or cystitis).

underlying cause are the most important approaches, but guidelines have changed over the last few years with respect to protein restriction, and it is now clear that many dogs with congenital or acquired PSS have higher protein requirements than do normal animals. Long-term feeding of a protein-restricted diet is contraindicated and will result in protein-calorie malnutrition. The emphasis has shifted to feeding a digestible protein in small amounts and often to reduce the work of the small intestine and thus glutamine metabolism. There is preliminary evidence that soybean or dairy protein may be preferable to other protein sources.

Most, if not all, dogs with congenital or acquired PSS can tolerate normal protein concentrations if other measures are also implemented, as outlined later and in Box 36.6. A few require more marked restriction in the short term, but every effort should be made to increase to a normal protein concentration over the long term. The body condition score and serum protein concentrations should be carefully monitored to avoid negative nitrogen balance.

Lactulose (β-galactosidofructose) is a semisynthetic disaccharide that is not digestible by mammals and therefore passes into the colon, where it is degraded by bacteria into short-chain fatty acids (SCFAs), particularly lactic and acetic acid. These SCFAs help control signs of HE by acidifying the intestinal contents, which traps ammonium ions in the colon, and by promoting osmotic diarrhea. In addition, SCFAs are used as an energy source by colonic bacteria, allowing them to grow and thus incorporate colonic ammonia into their own bacterial protein, which is subsequently lost with the bacteria in the feces (a type of bacterial ammonia trap).

The dose is adjusted until there are two to three soft stools per day (see Box 36.6); overdosing results in watery diarrhea. There are no known complications of chronic lactulose use in animals other than diarrhea. However, the efficacy of lactulose has never been critically evaluated in dogs and cats with HE. Recent studies in humans have been contradictory with one meta-analysis suggesting no benefit, but a more recent meta-analysis suggested some benefit in HE. Lactulose can also be given by enema in animals with acute HE (see Box 36.7). Many dogs object strongly to the sweet taste of lactulose; an attractive alternative is lactitol (β-galactosidosorbitol), which is related to lactulose and can be used as a powder (500 mg/kg/day in three to four doses, adjusted to produce two to three soft stools daily). Currently, lactitol is available in the United States as a food sweetener but has not been studied in dogs with HE.

If dietary therapy alone or in combination with lactulose is insufficient to control signs of HE, antibiotics may be added. Usually, amoxicillin is used at 22 mg/kg PO q12h. Traditionally, antibiotic therapy was believed to work simply by reducing colonic bacterial metabolism. However, recent studies implicating inflammatory mediators in triggering HE provide an alternative explanation for the efficacy of antibiotics in some animals with HE where they may also be treating undetected urinary tract or other infections. Antibiotics effective for gram-negative, urea-splitting organisms (neomycin sulfate, 20 mg/kg PO q12h) may also be used, although neomycin is more useful for acute HE rather than long-term use because intestinal bacteria tend to become resistant to neomycin. In addition, it is not systemically absorbed and remains in the GI tract, which will not help any systemic infection.

Other therapeutic strategies investigated in humans with chronic HE include ornithine aspartate supplementation (see Box 36.6) and probiotics to increase the numbers of beneficial bacteria. These may show benefit in dogs in the future, but there are currently no published studies documenting their use in small animals.

Certain conditions are known to accentuate or precipitate HE and should be avoided or treated aggressively when detected (see Box 33.2). In many cases it is the precipitating factors, rather than the diet, that are most important in triggering HE. It is particularly important to identify and treat any concurrent inflammatory disease that can trigger HE episodes in susceptible animals.

Management of Acute Hepatic Encephalopathy

Acute HE is a true medical emergency. Fortunately, it is much less common than chronic waxing and waning HE. Animals may present in status epilepticus or comatose, and although HE initially causes no permanent brain damage, prolonged seizures, status epilepticus, or coma will; prolonged severe HE by itself may lead to serious cerebral edema as a result of accumulation of the osmolyte glutamine (from ammonia detoxification) in astrocytes. In addition, the systemic effects of acute HE, particularly hypoglycemia, can be fatal if not recognized and treated. The treatment of acute encephalopathic crises is outlined in Box 36.7. Intensive management is required. However, treatment is worthwhile because some animals can go on to complete recovery and successful long-term medical management, particularly if the acute crisis was triggered by a definable event (e.g., acute GI bleeding in a dog with chronic liver disease and portal hypertension). Nothing by mouth (NPO), administration of enemas, and IV fluid therapy constitute the basic therapeutic approach. Warm water cleansing enemas may be useful simply by removing colonic contents and preventing absorption of intestinal encephalotoxins. Lactulose or dilute vinegar may be added to acidify the colon and decrease absorption of ammonia. The most effective enema contains three parts lactulose to seven parts water at a total dose of 20 mL/kg. The solution is left in place, with the aid of a Foley catheter, as a retention enema for 15 to 20 minutes. For lactulose to be beneficial, the pH of the evacuated colon contents must be 6 or lower. These enemas can be given every 4 to 6 hours. Because lactulose is osmotically active, dehydration can occur if enemas are used too aggressively without careful attention to fluid intake. Fluids chosen for the replacement of losses, volume expansion, and maintenance should not contain lactate, which is converted to bicarbonate, because alkalinizing solutions may precipitate or worsen HE by promoting the formation of the more readily diffusible form of ammonia. Half-strength (0.45%) saline solution in 2.5% dextrose is a good empirical

BOX 36.7

Treatment of Acute Encephalopathic Crisis

- Remove or treat any identified precipitating cause.
- Give nothing by mouth for 24–48 hours and IV fluids.
- Avoid fluid overload; measure central venous pressure or monitor carefully clinically.
- Avoid or treat hypokalemia (triggers hepatic encephalopathy).
- Avoid or treat hypoglycemia (monitor blood glucose level every 1–2 hours, particularly in small breeds, in which hypoglycemia is common and can cause permanent cerebral damage).
- Monitor body temperature, and warm gently or cool as necessary if hyperthermic after seizures.
- Administer enemas to remove ammonia from colon—warm water, lactulose, or dilute vinegar.
- Instill a neomycin retention enema after the colon is clear and administer IV ampicillin.
- Treat any seizures:
  - Carefully rule out treatable causes (e.g., electrolyte imbalances, hypoglycemia, hypertension, idiopathic epilepsy).
  - Maintain other intensive care measures (as earlier).
  - Treat with anticonvulsant—exact protocol controversial. Options are:
    - Levetiracetam 20 mg/kg bolus. Repeat as necessary every 20 minutes to maximum 60 mg/kg followed by 20 mg/kg tid. Unlikely to work for postligation seizures if dog already on levetiracetam.
    - Propofol bolus (3.5 mg/kg dogs; 1 mg/kg cats) followed by infusions (0.1–0.25 mg/kg/min) often effective.
    - Phenobarbitol, ketamine, or dexmedetomidine may also be used.
    - Diazepam of very limited efficacy.

choice, with potassium added according to its serum concentration. Serum electrolyte concentrations in dogs with HE are extremely variable; until the results become available, 20 mEq KCl/L in the fluids administered is a safe amount to add. Seizuring dogs can be stabilized with a loading dose of levetiracetam intravenously (see Box 36.7) or low-dose propofol infusions (Fig. 36.14). The dose of propofol is calculated by giving an initial bolus to effect, usually about 1 mg/kg, timing how long it takes for the animal to show mild signs of seizures, such as mild limb paddling again, and then dividing the dose by the time required to calculate an infusion rate. For example, if after a bolus of 1 mg/kg of propofol the dog shows signs of seizure activity again after 10 minutes, the infusion rate would be 1/10 = 0.1 mg/kg/min. In practice, the dose of propofol to be given by constant rate infusion is usually about 0.1 to 0.2 mg/kg/min. Dogs sometimes need to remain on the infusion for hours or days, but the rate can be gradually reduced to control seizures while still allowing the dog to regain consciousness—in some cases, even

FIG 36.14

enough to start eating. Propofol infusions can result in Heinz body hemolytic anemia in dogs and cats. Levetiracetam has been reported to be effective at reducing the risk of postoperative seizures and death in dogs undergoing surgical attenuation of extrahepatic PSS with ameroid constrictors when the dogs were pretreated with 20 mg/kg PO q8h, for a minimum of 24 hours before surgery (Fryer et al., 2011). However, a recent large multicenter study did not support the use of preoperative levetiracetam as protective against seizures, leaving clinicians unclear as to whether to use it or not (Mullins et al., 2019). There are no studies describing the use of levetiracetam IV in dogs with PSS that are already seizuring, but there are anecdotal reports of its efficacy in this situation.

In spite of some early promising reports, there is still no convincing evidence in support of other pharmacologic treatments for HE, apart from antibiotics and lactulose, so other drugs cannot currently be recommended for use in dogs. Trials of the benzodiazepine receptor antagonist flumazenil in human patients with refractory acute HE have had mixed results. Although flumazenil has been studied in animals for its ability to reverse the action of benzodiazepine tranquilizers, there have been no clinical studies on its use in acute HE in animals.

DISORDERS ASSOCIATED WITH HIGH PORTAL PRESSURE

There are a number of less common congenital vascular disorders of the liver in dogs that present with normal or high portal pressure, rather than the low portal pressure seen in association with a congenital PSS. Because of the portal hypertension, the affected dog may present with the constellation of typical clinical signs (see Chapter 33), including ascites, and the potential for GI ulceration in addition to multiple acquired PSSs and HE. With the exception of arteriovenous fistulae, none of these conditions can be treated surgically, but some of them have a good long-term prognosis with medical management.

Primary Hypoplasia of the Portal Vein, Microvascular Dysplasia, and Noncirrhotic Portal Hypertension

Etiology and Pathogenesis

There have been several reports of vascular disorders in young dogs associated with portal hypertension, usually ascites, and characteristic histopathologic changes in the liver, including a reduction in smaller portal vein branches, increased numbers of arterioles, and a variable amount of mild fibrosis. There are some reports of overt hypoplasia of the extrahepatic portal vein, but most studies of noncirrhotic portal hypertension and MVD appear to describe portal vein hypoplasia confined to the intrahepatic vasculature. These diseases may all be different abnormalities or may represent different spectra of the same abnormalities, but their clinical presentation, treatment, and prognosis are similar. A lack of intrahepatic or extrahepatic portal vein branches results in portal hypertension, with the same potential consequences as those of chronic hepatitis (see earlier), including ascites, gut wall edema, and often GI ulceration and acquired PSSs (Fig. 36.13). Dogs with MVD often do not present with notable portal hypertension; despite this, MVD has been grouped with these diseases by the World Small Animal Veterinary Association (WSAVA) Liver Standardization Group (Cullen et al., 2006). Dogs reported with MVD typically have shunting at the level of the hepatic lobule but no clinical signs of overt portal hypertension.

Any breed can be affected, but MVD particularly affects small-breed dogs; Yorkshire Terriers and Cairn Terriers show a particularly high prevalence, whereas noncirrhotic portal hypertension often affects large-breed dogs.

Clinical Signs

Dogs with all these conditions typically present at a young age with a combination of signs of portal hypertension and PSS, the severity of which depends on that of their lesions. Because of the acquired PSS seen in these patients, some of the clinical signs and clinicopathologic findings overlap with those of congenital PSS, particularly because all these disorders typically present in young dogs. Therefore the presence of other signs of portal hypertension (e.g., ascites) is an important clinical clue that one of these disorders with acquired PSS may be present, rather than a congenital PSS.

Dogs with portal vein hypoplasia or idiopathic noncirrhotic portal hypertension typically present between 1 and 4 years of age and are often purebreds of either gender; large breeds predominate. Early reports of congenital or juvenile hepatic fibrosis in German Shepherd Dogs may also have represented a form of noncirrhotic portal hypertension. Presenting signs are typically those of portal hypertension, with abdominal distention associated with effusion, GI signs, polydipsia, weight loss, and, less consistently, signs of HE. Dogs are often surprisingly alert (Fig. 36.14).

Dogs with MVD present with similar clinicopathologic findings but usually without overt evidence of portal hypertension or ascites. MVD tends to affect terriers and thus overlaps with breeds at high risk for congenital PSSs. In addition, some dogs may have both congenital PSS and MVD or portal vein hypoplasia, further confusing the diagnosis. Cairn Terriers and Yorkshire Terriers in particular have been reported with MVD. In one breed (Cairn Terrier), the site of anatomic abnormality has been identified as the terminal portal veins. In this breed it is believed to be an autosomal inherited trait, but the specific mode of inheritance has not been established. Typical signs include vomiting, diarrhea, and signs of HE, although the clinical signs, particularly the HE, are notably milder in dogs with MVD than in those with congenital PSS unless both disorders occur concurrently. Dogs with only MVD are somewhat older, and many have mild to no signs of illness. In the case of young purebred dogs that have been screened for congenital PSS before sale or that are ill for nonhepatic reasons, a high SBA concentration may be the only finding.

Diagnosis

The diagnosis of MVD or intrahepatic portal vein hypoplasia and noncirrhotic portal hypertension relies ultimately on liver biopsy findings of intrahepatic portal vein hypoplasia in the absence of a grossly demonstrable shunting vessel. The liver biopsy findings alone can be indistinguishable from the changes that occur secondary to congenital PSSs, so the clinical findings of concurrent portal hypertension and ruling out a shunting vessel are important parts of the final diagnosis. Clinicopathologic findings are similar to those in dogs with congenital PSS and include evidence of hepatic dysfunction (e.g., hypoalbuminemia) and hyposthenuria.

Microcytosis is much less common with MVD than with congenital PSS. One study suggested that having a normal protein C concentration (>70% activity) had a high sensitivity and specificity for differentiating MVD from a congenital PSS, in which the protein C concentration is usually low (Toulza et al., 2006). Microhepatia and hypoechogenic abdominal fluid are the notable abdominal ultrasonographic findings in dogs with noncirrhotic portal hypertension; it may be possible to visualize multiple acquired PSSs ultrasonographically. Dogs with MVD alone tend not to have ascites and have less marked increases in SBA concentrations than dogs with a true congenital PSS.

The most important aspects of identifying a dog with MVD, portal vein hypoplasia, and/or noncirrhotic portal hypertension are ruling out a surgically correctable PSS, identifying portal hypertension (which requires treatment; see earlier), and obtaining a liver biopsy for confirmation or exclusion of other hepatopathies. Portal vein hypoplasia is similar clinically, on clinical pathology, and on diagnostic imaging to end-stage chronic hepatitis with cirrhosis; the only way to differentiate the two is on liver histology. In general, portal vein hypoplasia–noncirrhotic portal hypertension carries a much better long-term prognosis than cirrhosis, so the differentiation is important prognostically.

Treatment and Prognosis

The prognosis for all these conditions appears to be relatively good, provided that the clinical signs can be controlled. They are nonprogressive, and there is no surgical treatment for any

of them. Symptomatic therapy for HE, ascites, and GI ulceration (if present) is usually successful (see earlier). It should be noted that glucocorticoid therapy is absolutely contraindicated in these dogs and is likely to worsen the outcome because of the associated portal hypertension and high risk of GI ulceration. This underlines the importance of liver biopsy in these dogs, allowing differentiation from chronic hepatitis.

One study of dogs with noncirrhotic portal hypertension concluded that affected dogs might live as long as 9 years after diagnosis with appropriate symptomatic therapy (Bunch et al., 2001). A few dogs were euthanized because of problems related to persistent portal hypertension (e.g., duodenal ulceration). Dogs with MVD tend to have milder clinical signs than dogs with congenital PSSs and can be managed medically with success over the long term. Affected dogs seem to live comfortably, in good to excellent condition, for at least 5 years.

Congenital Ductal Plate Abnormalities

Etiology

Ductal plate abnormalities are congenital diseases of the liver causes by abnormalities in development of the ductal plate (see later). There are a variety of phenotypes depending on the stage in embryologic development when the abnormality occurs, and there may be some overlap with portal vein abnormalities. Traditionally, these conditions were considered rare in dogs, but with increasing awareness of the condition, more cases are being identified. The commonest phenotypes in dogs are Caroli's disease, where bile ducts are large, and cystic and congenital hepatic fibrosis, where there are multiple small bile ductules and associated fibrosis. The latter can be confused with cirrhosis on pathology and hence potential underdiagnosis. The differentiation is important because dogs with congenital hepatic fibrosis generally have a better prognosis than those with cirrhosis if appropriately treated.

The ductal plate is the embryonic precursor of the interlobular and intralobular bile ducts. It is a double layer of embryonic epithelium surrounding the portal veins. Bile duct development involves many signaling molecules, and abnormalities in this development result in a wide variety of presentations in human medicine, with persistence of embryonic bile ducts and varying amounts of periportal fibrosis. The drivers of fibrosis in this context remain incompletely understood. There are a variety of genetic mutations involved in humans, many of them autosomal dominant, and affected individuals may have concurrent renal cysts or skeletal abnormalities. The disease phenotype in the liver depends on which bile ducts are affected; maturation arrest of small interlobular bile ducts results in congenital hepatic fibrosis, whereas maturation arrest of medium intrahepatic bile ducts results in Caroli's disease. The genetics of ductal plate anomalies are currently unknown in dogs. The first report of congenital hepatic fibrosis in dogs in the veterinary literature was in 2010 (Brown et al., 2010). Since that time, cases have been reported in Boxer dogs and Skye Terriers and anecdotally in other breeds. Pillai et al. in 2016 reported 30 Boxer dogs with ductal plate malformations, suggesting an increased prevalence in this breed. Interestingly, there was a high prevalence of concurrent congenital hepatic abnormalities such as atrophy of liver lobes or gallbladder or vascular abnormalities. Two dogs also had Caroli's disease. Recent work at the University of Cambridge in the UK suggests that Skye Terrier hepatitis may in fact also be a congenital ductal plate abnormality.

Clinical Features

Dogs with congenital hepatic fibrosis usually present at a young age, with most being under 1 year of age at presentation, but occasionally dogs present as old as 10 years of age. Clinical signs are typical of portal hypertension (see earlier) including ascites, vomiting, and diarrhea, and also in some cases melena. Some dogs present with HE.

Diagnosis

Clinicopathologic abnormalities are very similar to chronic liver disease. Affected dogs usually have elevated liver enzymes but very rarely elevated bilirubin. Bile acids are often elevated, associated with development of acquired PSSs. Some dogs have microcytic red cells. Diagnostic imaging findings are generally indistinguishable from cirrhosis: dogs usually have a small hyperechoic liver and free abdominal fluid. Some cases may have other congenital abnormalities such as atresia of the gallbladder or a liver lobe, or large liver cysts that would increase the index of suspicion of ductal plate abnormality. However, confirmation of diagnosis requires a liver biopsy. Congenital hepatic fibrosis typically appears as abnormal, expanded portal tracts with multiple small bile duct profiles and bands of fibrosis both periportally and extending into the liver. These tracts of fibrosis can sometimes resemble lobular dissecting hepatitis. There may also be areas of fibrosis and multiple small bile ducts underneath the liver capsule, similar to Meyenburg complexes reported in humans. Bile ducts typically have cuboidal rather than columnar epithelium. Increased copper accumulation is common in affected boxers and Skye Terriers, and is assumed to be secondary to abnormal excretion. The disease is often patchy affecting individual liver lobes more than others.

Treatment and Prognosis

Treatment of affected animals is symptomatic because there is no cure for the congenital abnormality. Nonetheless, many dogs have a good long-term prognosis with supportive care; a reported median survival in one study in Boxers was 8.8 years in dogs without acquired PSS and 7.5 years in dogs with PSS. Anecdotally, Skye Terriers and other breeds can also do well long term. Management is the same as for dogs with portal hypertension, with symptomatic treatment of ascites with spironolactone and careful dietary and other management for HE (see Box 36.6). It is particularly important that affected dogs are fed sufficient dietary protein for maintenance because long-term survival is anticipated.

Arterioportal Fistula

Intrahepatic arterioportal fistula, causing marked volume overload of the portal circulation and resulting in portal hypertension, acquired PSSs, and ascites, is seen occasionally. Abdominal Doppler ultrasonography can frequently detect the tortuous tubular structures representing the connection between an artery and overperfused portal vein or veins; sometimes the turbulent blood flow through the fistula can be auscultated through the body wall. If only one lobe of the liver is affected, the lobe containing the arterioportal fistula can be removed surgically. Assuming that there is adequate intrahepatic portal vasculature, acquired PSSs regress once portal overcirculation subsides. More often, multiple liver lobes are involved, making surgical treatment impossible.

FOCAL HEPATIC LESIONS

ABSCESSES

Etiology

Hepatic abscesses are usually the result of septic embolization from an intraabdominal bacterial infection. In puppies they are frequently a consequence of omphalophlebitis, whereas in adult dogs they arise most often subsequent to inflammatory conditions of the pancreas or hepatobiliary system. Adult dogs with certain endocrine diseases (e.g., diabetes mellitus, hyperadrenocorticism) are also at risk. Hepatic abscesses have also been reported secondary to liver fluke infection in a dog (Lemetayer et al., 2016). Occasionally, infection arising from a location other than the abdominal cavity, such as the endocardium, lung, or blood, may disseminate to the liver, causing abscessation.

The most common isolates in published studies are aerobic gram-negative organisms, particularly *E. coli,* which can be multiresistant, and the anaerobic *Clostridium* spp. *Staphylococcus* spp. have also been identified.

Clinical Features

The typical signalment and physical examination findings in dogs with hepatic abscesses depend on the underlying cause. Dogs older than 8 years are most often affected because the predisposing causes of liver abscesses are seen more commonly in older dogs. Regardless of the initiating event, anorexia, lethargy, and vomiting are consistent presenting complaints. Expected physical examination findings include fever, dehydration, and abdominal pain. Hepatomegaly may be detected in dogs with diabetes mellitus or hyperadrenocorticism and in some dogs with primary hepatobiliary disease.

Diagnosis

Neutrophilic leukocytosis with a left shift, with or without toxic changes, and high serum ALP and ALT activities are dependable but nonspecific clinicopathologic abnormalities. Survey abdominal radiographs may reveal evidence of an irregular hepatomegaly, mass, or gas opacities within the area of the hepatic parenchyma (Fig. 36.15), but ultrasonography is the imaging modality of choice. One or more hypoechoic or anechoic hepatic masses and perhaps a hyperechoic rim surrounding the mass or masses are characteristic findings. If there are multiple masses that would preclude surgical removal, or if the owner declines surgery, FNA

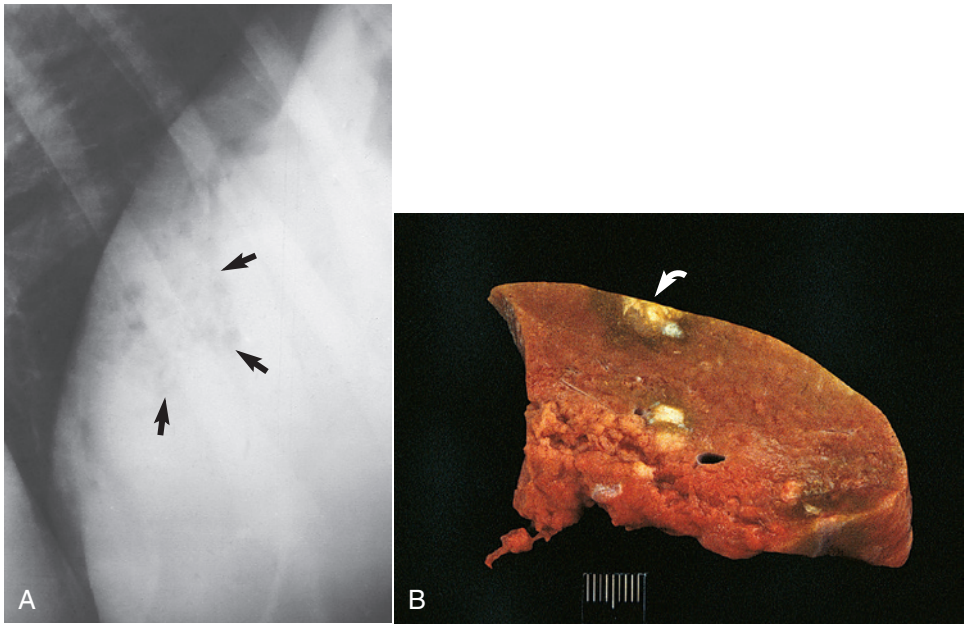

FIG 36.15

cytology analysis of the contents of a representative lesion will distinguish an abscess from nodular hyperplasia, neoplasm (e.g., hemangiosarcoma), or granuloma. Ideally, material should be obtained for cytologic analysis and aerobic and anaerobic bacterial cultures from a representative lesion deep in the liver parenchyma to prevent abscess rupture and abdominal contamination. Abscess material should also be obtained by this approach during surgery so that antibiotic treatment can be initiated postoperatively. Ultrasound-guided drainage of the abscess can also be used as treatment in combination with appropriate antibiotics (see later). Results of the preliminary clinicopathologic and radiographic evaluation should be scrutinized for evidence of previously noted comorbidities.

Treatment and Prognosis

Treatment for liver abscesses consists of surgical removal of infected tissue, administration of appropriate antibiotics, supportive care, and resolution of underlying predisposing conditions. Infected liver tissue should be removed, if possible, and submitted for histopathologic examination and bacterial culture if this was not done preoperatively. Fluid, electrolyte, and acid–base abnormalities are addressed. Administration of a combination of antibiotics with a gram-negative and anaerobic spectrum is initiated until culture and sensitivity test results are available. Because staphylococci and clostridia are the most common isolates, amoxicillin (10–20 mg/kg IV q8h) combined with metronidazole (10 mg/kg PO q12h, or 7.5 mg/kg PO q12h for dogs with hepatic dysfunction) or clindamycin (10 mg/kg IV or PO q12h) is a good empiric choice. Surgery is not indicated for animals with multiple abscesses; ultrasound-guided centesis and abscess evacuation may be a reasonable adjunct to treatment. This has been described combined with saline lavage and alcohol infusion. For more details, see Lemetayer et al. (2016). Antibiotic treatment is continued on a long-term basis, usually for 6 to 8 weeks or until clinicopathologic and ultrasonographic indicators of abscessation are resolved. From the limited information available about this rare condition, it seems that with aggressive medical and surgical treatment, the prognosis for dogs with liver abscesses may not be as poor as once thought.

NODULAR HYPERPLASIA

Hepatic nodular hyperplasia is a benign condition of older dogs that does not cause clinical illness; clinicians should be aware of it, however, because hyperplastic nodules may be misinterpreted as a more serious condition, such as primary or metastatic malignancy or regenerative nodules associated with cirrhosis. The prevalence increases with age, and as many as 70% to 100% of dogs older than 14 years have some microscopic or macroscopic hyperplasia. Affected dogs have high serum ALP activities (usually a 2.5-fold elevation but possibly as high as 14-fold), which prompts an investigation for hyperadrenocorticism. There is no evidence of hepatic dysfunction on serum biochemical analysis. Many dogs have multiple macroscopic nodules found ultrasonographically or at surgery, ranging in size from 2 to 5 cm in diameter; some dogs have a single nodule.

Micronodular changes occur much less frequently and are identified only in liver biopsy specimens. The lesion consists of increased numbers of normal to vacuolated hepatocytes with more mitotic figures and fewer binucleate cells than expected in normal liver; components of normal lobular architecture (e.g., portal tracts, central vein) remain. The adjacent parenchyma is compressed by growth of the nodules; fibrosis, necrosis, inflammation, and bile ductule hyperplasia are absent. Because the prognosis for each of these nodular conditions is different and the margin of the lesion with adjacent hepatic tissue is important to establish a diagnosis, a wedge biopsy is recommended. Needle specimens are likely to be too small to confidently differentiate nodular hyperplasia from primary hepatocellular carcinoma or adenoma. The cause of this lesion is unknown; on the basis of the experimental development of nodular hyperplasia in rodent species, some have speculated a dietary role (low protein).

NEOPLASIA

Etiology

Primary hepatic neoplasms are rare in dogs, accounting for fewer than 1.5% of all canine tumors. Unlike in cats, malignant tumors are more common than benign tumors, and metastatic tumors are 2.5 times more common than primary tumors in dogs. Metastases particularly arise from primary neoplasms in the spleen, pancreas, and GI tract (Fig. 36.16); the liver can also be involved in systemic malignancies such as lymphoma, malignant histiocytosis, and mastocytosis.

Although certain chemical agents can induce hepatic neoplasms experimentally, and chronic hepatitis, steatohepatitis, and chronic biliary tract disease are also predisposing causes in other species, the cause of naturally occurring canine hepatic neoplasms is unknown. The types of primary

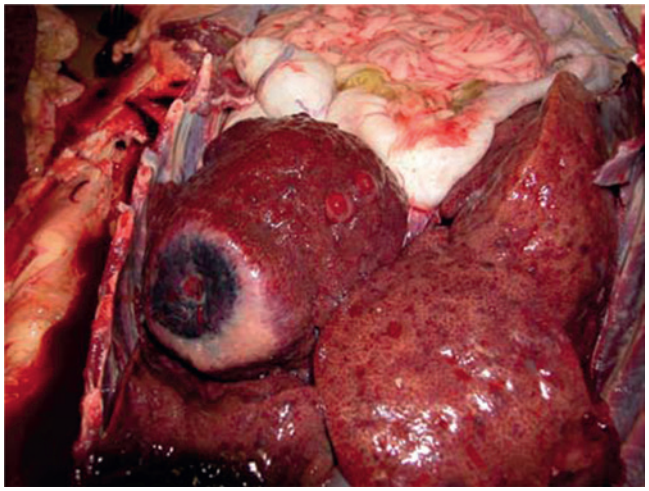

FIG 36.16
Gross appearance of liver postmortem from a 2-year-old male Siberian Husky with a metastatic carcinoma.

hepatic tumors seen in dogs and their relative importance and metastatic potential are outlined in Table 36.3.

Clinical Features

Clinical signs and physical examination findings in dogs with primary or secondary liver tumors are nonspecific, except for diffuse or nodular hepatomegaly. Even this can be confused with other conditions, such as macronodular cirrhosis or benign nodular hyperplasia, which are also common in older dogs. Therefore no dog should be euthanized on the basis of a presumptive diagnosis of a liver mass on clinical examination or diagnostic imaging without supportive histology. The left liver lobes are often affected by hepatocellular carcinoma, which can occur in three different patterns—massive (single, large nodule; most common), nodular (multiple smaller nodules), and diffuse (indistinct nodules throughout). The behavior of each type of tumor tends also to be different, as outlined in Table 36.3.

Clinicopathologic abnormalities are similarly not specific for neoplasia, and blood test results may be normal, even in dogs with extensive involvement. Dogs with lymphoma infiltrating the liver usually have marked increases in ALT and ALP activities but are rarely jaundiced; moreover, although the liver usually looks abnormal on ultrasonography, they may have normal liver echotexture. The authors occasionally see dogs with marked hepatic involvement with large cell lymphoma that have normal liver enzyme activities. Hypoglycemia has been described in association with hepatocellular carcinoma in dogs and can be caused by paraneoplastic production of insulin-like growth factor. Cytology usually allows the distinction of solitary hepatocellular carcinomas from nodular hyperplasia. Massive forms of hepatocellular carcinoma have a low metastatic rate. Metastases from other diffuse and nodular forms of hepatocellular carcinoma or biliary carcinoma usually occur early; the most common sites are the liver, regional lymph nodes, lung, and peritoneal surfaces. Hepatocellular adenoma (hepatoma) is a benign tumor that usually occurs as a single mass that is typically smaller than the massive form of hepatocellular carcinoma but can be multifocal. Histologic features of hepatocellular adenoma are similar to those of nodular hyperplasia (or normal liver), except for the presence of a fine rim of reticulin surrounding the adenoma and lack of apparent normal architecture—that is, few portal tracts and no central veins.

TABLE 36.3

Primary Liver Tumors in Dogs*

TYPE OF TUMOR	COMMENTS
Hepatocellular Tumors	
Hepatocellular carcinoma (HCC)	HCC most common primary liver tumor in dogs (50%)
Hepatocellular adenoma, hepatoma	Most are massive; some nodular or diffuse
Hepatoblastoma—very rare	Miniature Schnauzers, male dogs may be at increased risk MR, 0%–37% for massive forms, 93%–100% for nodular and diffuse forms Adenoma uncommon and usually incidental
Biliary Tract Tumors	
Biliary carcinoma (including cystadenocarcinoma)	Bile duct carcinomas second most common primary tumor in dogs (22%–41% of malignant canine liver tumors)
Biliary adenoma	Labrador Retrievers, females may be at increased risk
Gallbladder tumors	Usually aggressive MR up to 88% Adenomas uncommon, gallbladder tumors very rare
Neuroendocrine Tumor	
Hepatic carcinoid	Very rare, but always diffuse or nodular, and very aggressive
Primary Hepatic Sarcomas	
Hemangiosarcoma, leiomyosarcoma, gastrointestinal stromal tumors, others	Uncommon Most locally aggressive, diffuse, or nodular; high MR

MR, Metastatic rate.
*Note that malignant tumors are more common than benign tumors and that metastases to the liver are more common than primary liver tumors in dogs.

Treatment and Prognosis

When a single large hepatic mass is identified, it can be difficult to distinguish a well-differentiated hepatocellular carcinoma from nodular hyperplasia and hepatocellular adenoma from ultrasonography, CT imaging, or gross appearance; however, as noted, cytology is usually helpful. Surgical resection is the treatment of choice for primary hepatic neoplasms and massive hepatocellular carcinoma. In the latter, it usually carries a good prognosis provided the tumor can be fully resected because these have a lower metastatic rate than the more diffuse and nodular forms of the tumor, and the local recurrence rate after liver lobectomy is reportedly less than 13%. Long-term (2- to 3-year) survival rates after surgical resection are common in dogs with massive hepatocellular carcinoma. Surgical excision is therefore the treatment of choice for single tumors involving one liver lobe because this allows diagnosis and, in many cases, cure.

The prognosis for diffuse and nodular hepatocellular carcinomas and other forms of primary malignant liver tumors

is poor because there is no effective therapy. Hepatic tumors also respond poorly to chemotherapy, likely partly because of the development of rapid drug resistance by neoplastic hepatocytes. The response of secondary (metastatic) liver tumors depends on the type and location of the primary tumor; responses in dogs with hepatic lymphoma as part of the multicentric form are very good to excellent, whereas presumed primary hepatic lymphoma had a poor response to chemotherapy in one recent study, with dogs not achieving complete remission and dogs with a low serum albumin concentration having particularly poor responses (Dank et al., 2011). Hemangiosarcoma metastases respond well to vincristine, doxorubicin, and cyclophosphamide (VAC) chemotherapy (see Chapter 81). Metastatic carcinomas or carcinoids of the liver rarely respond to chemotherapy. (See "Oncology" for additional information on metastatic tumors.)

HEPATOCUTANEOUS SYNDROME AND SUPERFICIAL NECROLYTIC DERMATITIS

Etiology and Pathogenesis

Hepatocutaneous syndrome (also known as *superficial necrolytic dermatitis, metabolic epidermal necrosis*, and *necrolytic migratory erythema*) is a skin condition reported in association with certain liver diseases that usually carries a poor prognosis. The pathophysiology and underlying causes in dogs remain unclear, and it is likely multifactorial. It occurs in association with certain typical findings on hepatic ultrasonography and histopathology, and often no underlying cause is found. However, because it is likely that many cases represent a hepatic reaction to an underlying endocrine tumor or disorder, superficial necrolytic dermatitis represents an intermediate disorder between primary liver disease and secondary hepatopathies.

The underlying pathogenesis in the skin appears to be caused by abnormally low circulating amino acid concentrations and thus malnutrition of the skin, particularly in areas of poor blood supply, such as the extremities. Zinc deficiency may also be involved because the histologic appearance of the skin is similar to that in dogs with zinc-responsive dermatosis; fatty acid deficiencies have also been implicated. In humans the disorder is usually associated with a glucagon-secreting tumor of the pancreas. However, glucagonomas are rarely reported in affected dogs, and circulating glucagon concentrations are usually normal, although they may be occasionally high. Plasma amino acid concentrations have been reported to be very low in all affected dogs in which they have been measured, both in dogs with pancreatic tumors and dogs without. It has been proposed that canine superficial necrolytic dermatitis represents a metabolic hepatopathy with increased hepatic catabolism of amino acids, which decreases their peripheral availability.

Superficial necrolytic dermatitis secondary to chronic phenobarbital administration for epilepsy has been reported in 11 dogs (March et al., 2004). The median age of the affected dogs was 10 years, and the median duration of phenobarbital therapy was 6 years. No other underlying cause could be found. Plasma amino acid concentrations were markedly decreased in the only dog in which they were measured.

Whatever the underlying pathogenesis, dogs with superficial necrolytic dermatitis are at high risk of becoming diabetic, which is reported in 25% to 40% of cases. This is easy to explain if blood glucagon concentrations are high, because glucagon is a diabetogenic hormone but is difficult to explain on the basis of simple amino acid level changes.

Clinical Findings

Idiopathic superficial necrolytic dermatitis is usually reported in older dogs of small breeds; in one study 75% of the affected dogs were male (Outerbridge et al., 2002). Most dogs present because of their skin disease rather than their primary liver disease. Typically, there is erythema, crusting, and hyperkeratosis affecting the footpads, nose, and periorbital, perianal, and genital areas, and often pressure points on the limbs. The paw lesions can be extremely painful because of associated fissures and may result in lameness and secondary infection. Signs of liver disease may also be present, although not usually, and diabetes mellitus often develops later in the disease process, especially if the animal is given diabetogenic drugs such as glucocorticoids in an attempt to control the skin disease.

Diagnosis

Definitive diagnosis is based on skin biopsy findings that are characteristic and unique. The only syndrome with a similar appearance on skin histopathology is zinc-responsive dermatosis. There is a marked parakeratotic hyperkeratosis with intercellular and intracellular edema and hyperplastic basal cells, producing a characteristic red, white, and blue appearance on hematoxylin and eosin (H&E) staining.

The associated hepatic findings are more nonspecific, except for the ultrasonographic findings. There are usually increases in liver enzyme activities, and there may be hypoalbuminemia in some cases. In dogs that are diabetic, there is hyperglycemia and glycosuria. The typical ultrasonographic appearance is a so-called Swiss cheese liver consisting of multiple hypoechoic regions with hyperechoic borders (Fig. 36.17). Hepatic histology in all cases is remarkably similar, showing what has been described as a distinctive form of macronodular cirrhosis. The liver is divided into regenerative hyperplastic nodules with fibrous septa and bordered by characteristic ballooned vacuolated hepatocytes but with minimal or no inflammation or necrosis.

Treatment and Prognosis

The prognosis is very poor unless the underlying cause can be identified and treated; most dogs live for less than 6 months. There have been reports of disease resolution if a pancreatic tumor is identified and removed. Dogs with phenobarbital-associated hepatocutaneous syndrome may

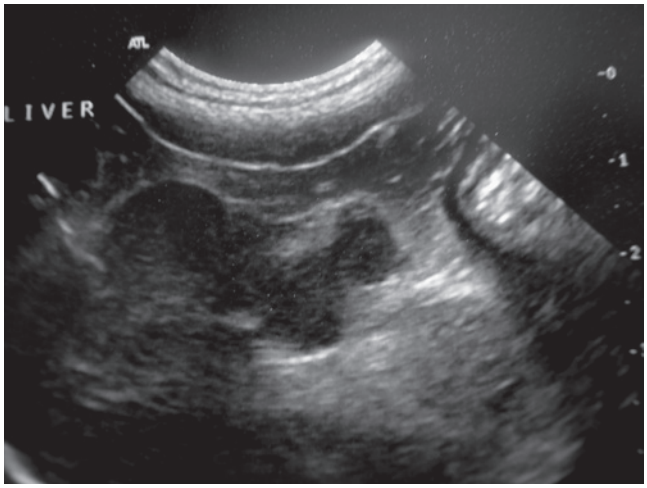

FIG 36.17
Ultrasonographic appearance of the liver of a 6-year-old Border Terrier with hepatocutaneous syndrome secondary to chronic phenobarbital medication for idiopathic epilepsy. Note the typical hypoechoic holes in the liver parenchyma on the left. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

improve when the drug is withdrawn, although this has not yet been demonstrated. An alternative nonhepatotoxic therapy for their epilepsy will need to be instituted; potassium bromide might be an alternative choice, but it takes weeks to reach a steady state. Imepitoin is another alternative choice. Gabapentin might also be used, although this is only effective in some dogs and does undergo some hepatic metabolism. For more details, see Chapter 62.

When an underlying cause cannot be identified and treated, therapy is symptomatic and supportive. The most important aspect is amino acid and protein supplementation; in a few cases this may lead to long-term survival. There are single case reports of humans with resolution of the disease after amino acid infusions and/or regular dietary supplementation of egg protein; feeding egg yolks has also been reported as resulting in a clinical improvement in some dogs. It is unclear whether eggs are beneficial simply because they are a high-quality amino acid supplement or whether there are other beneficial micronutrients in the eggs. Dogs with hepatocutaneous syndrome should not be fed proprietary diets for liver disease because these are protein-restricted. Other supportive therapy includes antibiotics for secondary skin infections (e.g., cephalexin, 20 mg/kg PO q12h) and antioxidants (see earlier, "Chronic Hepatitis: Treatment"). In addition, zinc and fatty acid supplementation may be helpful in some cases. Glucocorticoids should be avoided because they will precipitate diabetes mellitus. Our group has treated two dogs with hepatocutaneous syndrome that survived for several years on a high-quality digestible diet, marketed for GI disease, with extra egg and vitamin E and SAM-e supplementation with antibiotics; however, one dog did become diabetic 1 month after diagnosis.

SECONDARY HEPATOPATHIES

Secondary (reactive and vacuolar) hepatopathies are common in dogs. In pathology studies it is clear that they are more common than primary hepatic disease. Many of these hepatopathies result in elevations in liver enzyme activities, but usually the liver changes are not clinically relevant and do not result in compromised liver function. However, they are often confused with primary liver disease, and it is important to rule out secondary hepatopathies as much as possible in the workup of dogs with elevated liver enzyme activities to allow identification and treatment of the underlying primary disease (e.g., endocrine disease or inflammatory disease elsewhere in the splanchnic bed). High liver enzyme activities in older dogs have many other causes in addition to primary liver disease, and it is also important to resist the urge to put them on a protein-restricted diet and other medications for liver disease before working up the case properly. Many dogs with secondary hepatopathies will not have hepatic histopathology performed because the primary cause will be identified with other tests. However, it is convenient from a classification point of view to split secondary hepatopathies into three groups on the basis of their appearance histopathologically—secondary hepatopathies associated with hepatocyte swelling and/or vacuolation, hepatic congestion or edema, and reactive hepatitis.

HEPATOCYTE VACUOLATION

Secondary hepatopathies associated with hepatocyte vacuolation are divided into steroid-induced hepatopathy and hepatocellular steatosis (lipidosis, fatty changes). Steroid-induced hepatopathy is characterized by hepatocellular glycogen accumulation, which is distinctive from steatosis, in which fat (rather than glycogen) accumulates in hepatocytes. The difference can be demonstrated with special stains (periodic acid–Schiff for glycogen and Oil Red O or Sudan black for fat), but there are also some differences on routine H&E staining that help with differentiation. Glycogen vacuoles tend not to displace the nucleus from the center of the cell and often contain strands of eosinophilic material, whereas classic steatosis is associated with clear empty vacuoles because the fat is lost in processing, and the nucleus is often displaced to the edge of the cell (Fig. 36.18).

Both types of vacuolar hepatopathies are reversible when the underlying cause is eliminated. The most common causes are endocrine diseases (see Table 36.1). Steroid-induced hepatopathy is seen in hyperadrenocorticism and dogs being given exogenous corticosteroids. It has also been associated with other hormone therapies and the administration of some other drugs, such as D-penicillamine or barbiturates. There have been reports of idiopathic vacuolar hepatopathy in Scottish Terriers causing marked elevations in ALP levels, but the underlying cause is unknown. A large study of Scottish Terriers with vacuolar hepatopathy at Cornell (Sepesy et al., 2006) suggested that these dogs had an overproduction of androgenic hormones, perhaps as a result of a genetic defect in 21-hydroxylase. It is worrisome that 30% of the Scottish Terriers in that study also developed

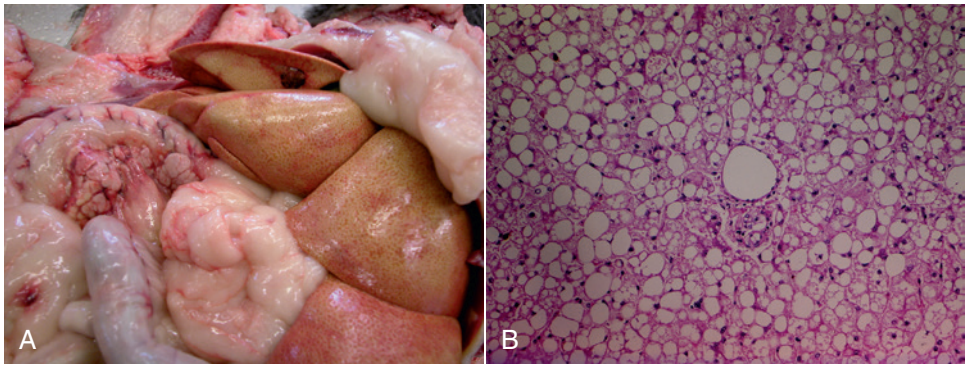

FIG 36.18
Gross **(A)** and histologic **(B)** appearance of the liver postmortem in a middle-aged Miniature Poodle with poorly controlled diabetes mellitus. Note the pale yellowish appearance of the liver associated with generalized hepatic steatosis. Histologically, the hepatocytes are markedly swollen with fat that displaces the nuclei to the edge of the cells. The portal triad is seen in the center (H&E, ×200). (Courtesy Pathology Department, Veterinary Medicine, University of Cambridge, Cambridge, England.)

hepatocellular carcinoma, suggesting that chronic vacuolar hepatopathy may predispose to tumors in dogs as it can in humans. The vacuolation seen as part of the hepatocutaneous syndrome looks similar to glycogen vacuolation. Steatosis is generally associated with diabetes mellitus in dogs, in which it starts centrilobularly and then spreads. It has also been reported in juvenile hypoglycemia of small-breed dogs. However, although hepatic steatosis can sometimes appear very marked in dogs, it does not appear to become a clinically significant disease in its own right, unlike in cats, in which primary or secondary hepatic lipidosis are important clinical syndromes (see Chapter 35).

HEPATIC CONGESTION AND EDEMA

Hepatic congestion is a common finding with right-sided congestive heart failure and other causes of posthepatic venous congestion, such as heartworm disease. Again, this results in elevation in liver enzyme levels. It is usually reversible, but in a few chronic cases of congestion associated with heart disease, it can result in fibrosis and permanent compromise (so-called cardiac cirrhosis).

NONSPECIFIC REACTIVE HEPATITIS

Nonspecific reactive hepatitis is a nonspecific hepatic response to a number of extrahepatic processes, particularly inflammatory processes in the splanchnic bed, such as pancreatitis and inflammatory bowel disease. There is a mild inflammatory infiltrate in the sinusoids and portal areas and/or parenchyma but no associated hepatocyte necrosis or fibrosis and therefore no evidence of primary (significant) hepatitis. This could be viewed as the hepatic equivalent of a reactive lymph node and should prompt a search for an underlying cause.

Diagnosis

The diagnosis of all types of secondary hepatopathies relies on diagnosing the underlying cause. The clinical signs will be those of the primary cause and are not related to the liver. However, sometimes there will be an overlap in clinical signs, notably with hyperadrenocorticism or diabetes mellitus in which the PU-PD and abdominal enlargement, together with raised liver enzyme levels, might increase the suspicion of primary liver disease. Recognizing that there is a secondary hepatopathy involves initial pattern recognition of the enzyme level elevation and clinical signs—for example, in a dog with PU-PD, a potbelly, dermatologic signs, a pattern of a very marked elevation in the ALP activity, and a less marked elevation in the ALT activity should raise the suspicion of hyperadrenocorticism. This is followed by appropriate diagnostic tests for the underlying condition. Liver biopsies are usually not indicated. However, there will inevitably be cases with mild or nontypical changes of the primary condition in which liver biopsies will be taken on suspicion of primary hepatopathy. Finding nonspecific secondary changes in the liver should then stimulate a repeat search for an underlying cause.

CHAPTER 37

The Exocrine Pancreas

GENERAL CONSIDERATIONS

The pancreas is located in the cranial abdomen, with the left limb positioned between the transverse colon and the greater curvature of the stomach, and the right limb running next to the proximal duodenum. Any or all of these neighboring structures can be affected when there is pancreatic inflammation. The exocrine acini make up about 90% of pancreatic tissue, and the endocrine islets interspersed among the acini make up the remaining 10% (Fig. 37.1). The close anatomic association between the acini and islets allows subtle signaling between them to coordinate digestion and metabolism, but it also means that there is a complex cause and effect relationship between diabetes mellitus (DM) and pancreatitis. The major function of the exocrine pancreas is to secrete digestive enzymes, bicarbonate, and intrinsic factor (IF) into the proximal duodenum. Pancreatic enzymes are responsible for the initial digestion of larger food molecules and require an alkaline pH to function—hence the concurrent bicarbonate secretion by pancreatic duct cells. The pancreas secretes several proteases, phospholipases, ribonucleases, and deoxyribonucleases as inactive precursors (zymogens), and α-amylase and lipase as intact molecules. The pancreas is the only significant source of lipase, and hence steatorrhea (fatty feces) is a prominent sign of exocrine pancreatic insufficiency (EPI). Trypsin is central to the pathogenesis of pancreatitis, as discussed later, and inappropriate early activation of the zymogen trypsinogen to trypsin within the pancreatic acini is the final common pathway triggering pancreatic inflammation. In the normal animal, pancreatic secretion is triggered by the thought of food and stomach filling, and most potently by the presence of fat and protein in the small intestinal lumen. The vagus nerve, local enteric nervous system, and hormones secretin and cholecystokinin from the small intestine stimulate pancreatic secretion. Trypsinogen is activated in the small intestine by the brush border enzyme enterokinase, which cleaves a peptide (the trypsin activation peptide [TAP]) from trypsinogen. Activated trypsin then activates the other zymogens within the intestinal lumen. IF, which is necessary for vitamin B_{12} absorption in the ileum, is secreted only by the pancreas in the cat. In the dog the pancreas is the main source of IF, but a small amount is also secreted by the gastric mucosa.

Diseases of the exocrine pancreas are relatively common but often misdiagnosed in dogs and cats because of nonspecific clinical signs, relative difficulty in accessing the organ for diagnostic imaging and biopsies, and lack of sensitive and specific clinicopathologic tests. Pancreatitis is the most common disease of the exocrine pancreas in cats and dogs; EPI, although less common, is also recognized frequently. Uncommon diseases of the pancreas include pancreatic abscess, pseudocyst, and neoplasia.

Recent advances in the understanding of the pathophysiology, prevalence, and potential causes of pancreatitis in dogs and cats may provide clues about treatment in the future, although treatment of acute pancreatitis remains largely nonspecific and supportive in all species.

Important differences in the anatomy of the pancreas and associated areas between the dog and cat are outlined in Table 37.1.

PANCREATITIS

Pancreatitis may be acute or chronic. As with acute and chronic hepatitis, the difference is histologic and not necessarily clinical (Table 37.2; Fig. 37.2), and there is often clinical overlap between the two. Chronic disease may present initially as an acute-on-chronic episode; in postmortem studies of fatal acute pancreatitis in dogs and cats, up to half of the cases were actually acute-on-chronic disease. Differentiation of acute disease from an acute flare-up of chronic disease is not important for initial management, which is the same in all cases, but is important to allow recognition of the potential long-term sequelae of chronic disease (see later). The causes of acute and chronic pancreatitis may be different, but there may also be some overlap between them.

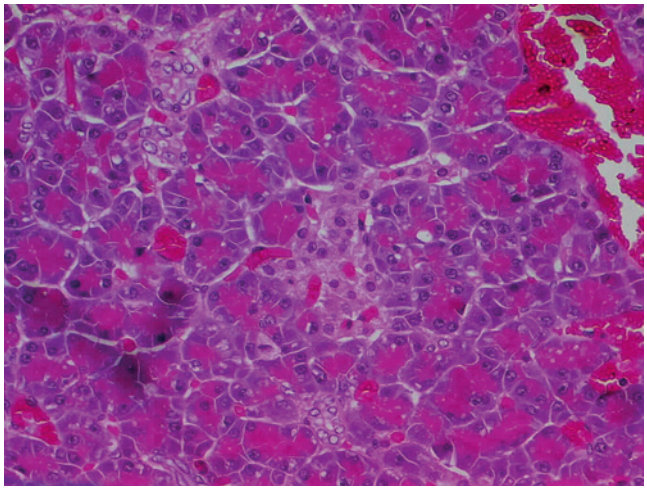

FIG 37.1
Histopathology of a section of normal canine pancreas showing two paler staining islets of Langerhans and exocrine acini surrounding them. Note that the islets make up only 10% to 20% of the volume of the pancreas.

ACUTE PANCREATITIS

Etiology and Pathogenesis

Understanding of the pathophysiology of acute pancreatitis in humans has increased in recent years with the discovery of hereditary mutations of trypsin, which predispose to pancreatitis; the pathophysiology of this disease is believed to be similar in dogs and cats. The final common pathway in all cases is the inappropriate early activation of trypsinogen in the pancreas as a result of increased autoactivation of trypsinogen and/or reduced autolysis of prematurely activated trypsin. Trypsin is the major protease secreted by the pancreas, and inappropriate early activation in the acinar cells would obviously cause autodigestion and severe inflammation. Protective mechanisms therefore exist to prevent early activation. Trypsin is stored in zymogen granules in the pancreatic acini as the inactive precursor trypsinogen. Up to 10% of trypsinogen gradually autoactivates normally within the granules but is inactivated by the action of other trypsin molecules and by the cosegregating protective molecule, pancreatic secretory trypsin inhibitor (PSTI; also known as serine protease inhibitor Kazal type 1, or *SPINK1*). Genetic mutations of trypsinogen, which make it resistant to hydrolysis, and/or of PSTI predispose to pancreatitis in people and are also likely to occur in some dogs (Table 37.3). A variety of mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene also predispose to pancreatitis in humans. Studies of mutations predisposing to acute pancreatitis in dogs have focused on Miniature Schnauzers. Initial studies showed no mutations in the cationic trypsinogen gene in individuals with pancreatitis in this breed but did find variations in the gene coding *SPINK1* (Bishop et al., 2004, 2010). However, a more recent study questioned the significance of this finding because *SPINK1* mutations were found in Miniature and Standard Schnauzers, both with and without pancreatitis (Furrow et al., 2012). Another study identified several mutations of the canine CFTR gene in dogs both with and without pancreatitis but no significant association with disease (Spadafora et al., 2010). More studies are necessary to elucidate the role of mutations in pancreatitis in dogs.

If too much trypsin autoactivates in the pancreas, the protective mechanisms are overwhelmed and a chain reaction occurs whereby activated trypsin activates more trypsin and the other enzymes in the pancreas. This results in pancreatic autodigestion, inflammation, and peripancreatic fat necrosis, which leads to focal or more generalized sterile peritonitis. There is an associated systemic inflammatory response (SIR) in even the mildest cases of pancreatitis. Many other organs may be involved, and in the most severe cases there is multiorgan failure (MOF) and diffuse intravascular coagulation (DIC). The circulating protease inhibitors α_1-antitrypsin (α_1-protease inhibitor) and α-macroglobulin play a role in removing trypsin and other proteases from the circulation. Saturation of these protease inhibitors by excessive amounts of circulating proteases contributes to the systemic inflammation, but generalized neutrophil activation and cytokine release are probably the primary cause of SIR.

The previous paragraph has described the final common pathway of acute pancreatitis in dogs and cats, but the underlying cause of the disease is often unknown (see Table 37.3). There appears to be a strong breed relationship for pancreatitis in dogs, so hereditary causes are likely to be a factor. Many of the previously reported supposed causes in dogs are likely triggers for disease in genetically susceptible individuals.

Clinical Features

Acute pancreatitis typically affects middle-aged dogs and cats, although very young and very old individuals may also be affected. Terrier breeds, Miniature Schnauzers, and domestic short-haired cats appear to be at increased risk for acute pancreatitis, although any breed or cross-breed can be affected. Some dog breeds appear to be underrepresented in clinical studies, particularly large and giant breeds, although Labrador Retrievers and Husky types (the latter particularly in Australia) are often affected. Breed relationships suggest an underlying genetic tendency, mirroring the situation in humans. It is likely that the disease is multifactorial, with a genetic tendency and superimposed triggering factors. For example, eating a high-fat meal may be a trigger for a susceptible terrier. Some studies suggest a slight increase in risk in female dogs, whereas others show no gender predisposition. Obesity has been suggested as a predisposing factor in dogs, but it is unclear whether this is a cause or whether it is cosegregating with disease (i.e., breeds at high risk for acute pancreatitis may coincidentally also be breeds with a high risk for obesity). In some cases in cats there is a recognized association with concurrent cholangitis, inflammatory bowel disease, and renal disease. Cats with acute pancreatitis are also at high risk for hepatic lipidosis.

The history in dogs often includes a trigger such as a high-fat meal or engorging (see Table 37.3). Recent drug therapy

TABLE 37.1

Differences in Pancreatic Structure, Function, and Diseases in Dogs and Cats

FEATURE	DOGS	CATS
Anatomy (but many variations; some dogs are like cats, and vice versa)	Usually two pancreatic ducts—large accessory duct from right limb to minor papilla in duodenum, small pancreatic duct from left limb to major duodenal papilla in duodenum next to (but not joining) bile duct Sphincter of Oddi unlikely to be of clinical significance	Usually single major pancreatic duct joining common bile duct before entering duodenum at duodenal papilla 3 cm distal to pylorus 20% of cats have second, accessory duct; occasionally ducts remain separate Sphincter of Oddi may be as important as in humans
Pancreatic function	Intrinsic factor secreted largely by pancreas but also some in stomach; vitamin B_{12} deficiency common in exocrine insufficiency but sometimes normal	Intrinsic factor secreted entirely by pancreas so vitamin B_{12} deficiency very common in exocrine insufficiency; vitamin K deficiency also common because of concurrent liver and intestinal disease further reducing absorption
Pancreatitis—disease associations	Common association between pancreatitis and endocrine disease (see text) Association with liver and small intestinal disease not recognized Emerging association in some breeds with immune-mediated diseases, particularly keratoconjunctivitis sicca and glomerulonephritis (see text)	Common association with cholangiohepatitis and/or inflammatory bowel disease High risk of concurrent hepatic lipidosis May also be associated with renal disease
Exocrine pancreas, other pathology	Incidental pancreatic nodular hyperplasia common	Incidental pancreatic nodular hyperplasia common
Pancreatitis		
Spectrum of disease	Most cases acute at presentation Low-grade chronic disease increasingly recognized and more common than acute on postmortem studies	Most cases low-grade, chronic interstitial disease, challenge to diagnose Acute severe cases also recognized
Diagnosis (see Chapter 34)	Histology is gold standard Variety of catalytic and immunoassays available Ultrasonography quite sensitive Obvious or suggestive clinical signs in acute cases	Histology is gold standard Most catalytic assays no help Immunoassays more helpful Ultrasonography less sensitive than in dogs Clinical signs usually low grade and nonspecific, even in acute disease
Causes of exocrine pancreatic insufficiency	Often pancreatic acinar atrophy—increased prevalence in certain breeds (especially German Shepherd Dogs) End-stage chronic pancreatitis also common, underrecognized, particularly in middle-aged to older dogs of specific breeds (see text)	Most cases end-stage chronic pancreatitis Pancreatic acinar atrophy rare Occasionally due to raccoon pancreatic fluke (*Eurytrema procyonis*) in eastern United States.

TABLE 37.2

Differences Between Acute and Chronic Pancreatitis in Dogs and Cats

PARAMETER	ACUTE PANCREATITIS	CHRONIC PANCREATITIS
Histopathology	Varying degrees of acinar necrosis, edema, inflammation, with neutrophils and peripancreatic fat necrosis Potentially completely reversible, with no permanent pancreatic architectural or functional changes	Characterized by lymphocytic inflammation and fibrosis, with permanent disruption of architecture Possible to have acute-on-chronic cases with concurrent neutrophilic inflammation and necrosis
Clinical appearance	Spectrum from severe and fatal (usually necrotizing) to mild and subclinical (less common)	Spectrum from mild, low-grade intermittent gastrointestinal signs (most common) to acute-on-chronic episode indistinguishable from classic acute pancreatitis
Diagnostic challenge	Higher sensitivity of enzyme tests and ultrasonography than in chronic disease	Lower sensitivity of enzyme tests and ultrasonography than in acute disease: diagnosis much more challenging
Mortality and long-term sequelae	High immediate mortality but no long-term sequelae	Low mortality except acute-on-chronic bouts High risk of eventual exocrine and endocrine insufficiency

TABLE 37.3

Causes of Acute Pancreatitis in Dogs and Cats

RISK FACTOR	CAUSE
Idiopathic, 90%	Unknown (some may be hereditary or inherited susceptibility to environmental trigger)
Duct obstruction ± hypersecretion ± bile reflux into pancreatic duct	Experimental; neoplasia; surgery ± cholangitis + role in chronic pancreatitis
Hypertriglyceridemia	Inherent abnormal lipid metabolism (breed-related—e.g., Miniature Schnauzers) Endocrine—diabetes mellitus, hyperadrenocorticism, hypothyroidism
Breed, gender (?)	Increased risk in terriers ± spayed females—may reflect risk of hypertriglyceridemia in some (also Miniature Schnauzers; see above) and potentially other mutations (see text)
Diet	Dietary indiscretion, high-fat diet Malnutrition, obesity (?)
Trauma	Road traffic accident, surgery, high-rise syndrome
Ischemia, reperfusion	Surgery (not just pancreas), gastric dilation, volvulus; shock, severe immune-mediated hemolytic anemia (common association if anemia severe)
Hypercalcemia	Experimental (more common in cats than dogs); hypercalcemia of malignancy (uncommon association clinically); primary hyperparathyroidism
Drugs, toxins	Organophosphates, azathioprine, asparaginase, thiazides, furosemide, estrogens, sulfa drugs, tetracycline, procainamide, potassium bromide, clomipramine
Infections	Toxoplasma, others (uncommon)

Adapted from Villiers E, Blackwood L, editors: *BSAVA manual of canine and feline clinical pathology*, ed 2, Gloucestershire, Britain, 2005, British Small Animal Veterinary Association.

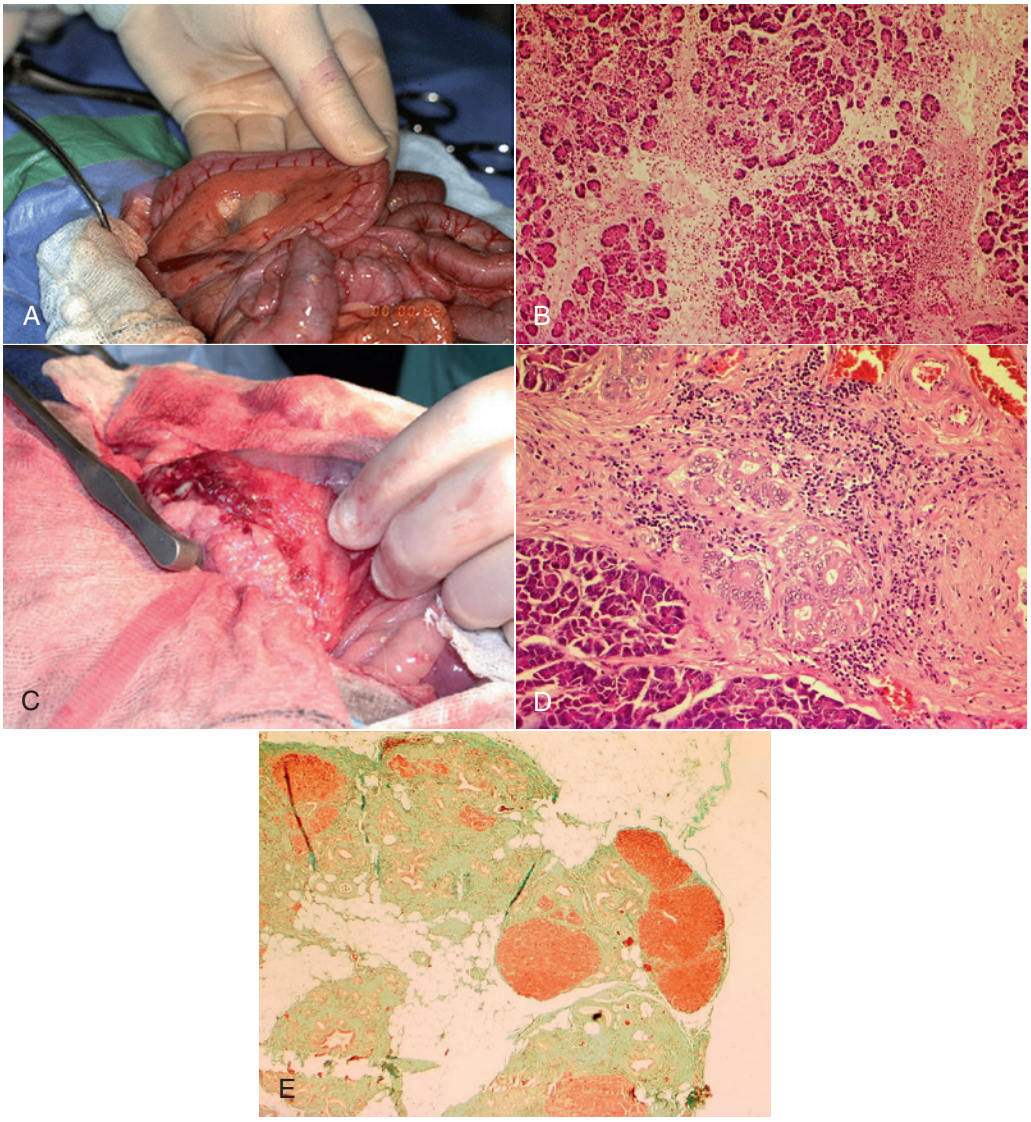

FIG 37.2
(A) Gross appearance of acute pancreatitis in a cat at laparotomy demonstrating generalized hyperemia. It is also possible for acute pancreatitis to appear normal grossly. **(B)** Histopathologic appearance of acute pancreatitis in a young adult female West Highland White Terrier. Note prominent edema and inflammation disrupting the acini. This case was fatal, but it would have been potentially completely reversible if the dog had survived the acute phase (hematoxylin and eosin [H&E], ×100). **(C)** Gross appearance of chronic pancreatitis in a middle-aged Jack Russell Terrier. Note the nodular appearance of pancreas and extensive adhesions to the duodenum obscuring the mesentery. It is also possible for chronic pancreatitis to appear normal grossly. **(D)** Histologic appearance of chronic pancreatitis from a 10-year-old male Cavalier King Charles Spaniel. Note fibrosis, mononuclear inflammatory cells, and ductular hyperplasia (H&E, ×200). **(E)** Histologic appearance of end-stage chronic pancreatitis in an 11-year-old neutered female Cavalier King Charles Spaniel with diabetes mellitus and exocrine pancreatic insufficiency. Note extensive fibrosis *(green)* and small islands of remaining acini *(red)* (Masson's trichrome, ×40). (**A** and **C,** From Villiers E, Blackwood L, editors: *BSAVA manual of canine and feline clinical pathology,* ed 2, Gloucestershire, Britain, 2005, British Small Animal Veterinary Association.)

may also be a trigger, particularly potassium bromide, azathioprine, or asparaginase in dogs. Concurrent endocrine diseases such as hypothyroidism, hyperadrenocorticism, or DM increase the risk of severe fatal pancreatitis in dogs; therefore it is important to identify these in the history. In cats the history may include features of concurrent cholangiohepatitis, inflammatory bowel disease, hepatic lipidosis, or any combination of these.

The clinical signs in dogs vary with the severity of the disease, from mild abdominal pain and anorexia to acute abdomen and potential MOF and DIC. Dogs with severe acute disease usually present with acute onset of vomiting, anorexia, marked abdominal pain, and varying degrees of dehydration, collapse, and shock. The vomiting is initially typical of delayed gastric emptying resulting from peritonitis, with emesis of undigested food a long time after feeding, progressing to vomiting only bile. The main differential diagnoses in these cases are other causes of acute abdomen, particularly intestinal foreign body or obstruction; the vomiting may be so severe that the dog may undergo an unnecessary laparotomy for a suspected obstruction if a careful workup was not performed first. Some patients may show the classic so-called praying stance, with the forelegs on the floor and the hind legs standing (Fig. 37.3), but this is not pathognomonic for pancreatitis and can be seen in association with any painful condition in the cranial abdomen, including hepatic, gastric, or duodenal pain. By contrast, cats with severe, fatal, necrotizing pancreatitis usually have surprisingly mild clinical signs, such as anorexia and lethargy; vomiting and abdominal pain occur in fewer than half of the cases. Unlike dogs, cats often demonstrate remarkably little abdominal pain on examination in spite of severe peritonitis.

At the milder end of the spectrum, dogs and cats may present with mild gastrointestinal signs, typically anorexia and sometimes some mild vomiting, followed by the passage of some colitic-like feces (e.g., tenesmus, hematochezia, frequent bowel movements) accompanied by some fresh blood because of local peritonitis in the area of the transverse colon. Inflammatory bowel disease, low-grade infectious enteritis, chronic food intolerance, and chronic hepatitis are major differential diagnoses for this presentation in dogs and cats. Animals that are still eating may show prominent postprandial discomfort.

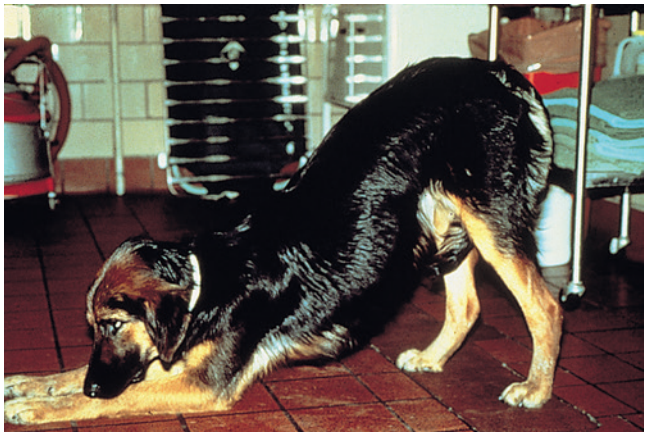

FIG 37.3
Dog exhibiting evidence of cranial abdominal pain by assuming the so-called position of relief. (Courtesy Dr. William E. Hornbuckle, Cornell University, College of Veterinary Medicine, Ithaca, NY.)

Cats and dogs with acute pancreatitis can present with jaundice at initial examination or often developing a few days later, when the initial acute signs are resolving. Most, if not all, animals with pancreatitis and jaundice have acute-on-chronic disease (see later, "Chronic Pancreatitis").

Careful clinical examination should focus on the identification of the degree of dehydration and shock, careful assessment for any concurrent diseases (particularly endocrine disease), and careful abdominal palpation. In severe cases, petechiae or ecchymoses suggestive of DIC may be identified, and there may be respiratory distress associated with acute respiratory distress syndrome. Careful clinical and clinicopathologic assessment of the degree of shock and concurrent organ damage is important for prognosis and treatment decisions (see later). Abdominal palpation should identify pancreatic pain and rule out, if possible, any palpable foreign bodies or intussusceptions, although abdominal imaging may be required to rule these out with confidence. In severe cases, generalized peritonitis will result in generalized unmistakable abdominal pain in dogs, whereas in milder cases careful palpation of the cranial abdomen is required to identify a focus of abdominal pain (Fig. 37.4); in cats, pain may not be apparent. Occasionally, a cranial abdominal mass representing a focus of fat necrosis may be palpated, particularly in cats.

Diagnosis

The clinician should be aware that there are many other diseases that produce similar clinical presentations to acute pancreatitis, and some of these might also be associated with elevations in pancreatic enzymes. Some form of diagnostic imaging is recommended together with blood sampling to rule out more serious primary diseases, such as a perforating foreign body.

Routine clinical pathology

Routine laboratory analysis (i.e., complete blood count [CBC], serum biochemical profile, and urinalysis) typically does not help in arriving at a specific diagnosis, but it is very important to perform these in all but the mildest cases because they provide important prognostic information and aid in effective treatment (see later). Typical clinicopathologic abnormalities in dogs and cats with acute pancreatitis are shown in Table 34.3.

Specific pancreatic enzyme assays

More specific tests for the pancreas are the catalytic assays for amylase and lipase, the new catalytic assay DGGR lipase and the immunoassays for trypsin-like immunoreactivity (TLI) and pancreatic lipase immunoreactivity (PLI). More

FIG 37.4
Carefully palpating a Cocker Spaniel for cranial abdominal pain. **(A)** The clinician should palpate craniodorsally under the rib cage for evidence of focal pancreatic pain, as shown in this dog by turning of the head. **(B)** With deep-chested dogs it helps to ask an assistant to elevate the head of the dog to displace the pancreas caudally (effectively achieving the opposite of the dog in Fig. 37.3).

details on these tests including the sensitivity and specificity in dogs and cats are found in Chapter 34 and Table 34.2. Overall, PLI has the highest sensitivity and likely the highest specificity in both species. DGGR lipase is also of diagnostic utility in both dogs and cats. Classical lipase has some usefulness in dogs but none in cats.

Prognostic indicators

Blood tests can give some prognostic indication in both species. TAP, the peptide removed from trypsin in the small intestine to activate it, is well conserved among species, so human enzyme-linked immunosorbent assays (ELISAs) can be used for dogs and cats. Elevations in plasma or urine TAP levels are no more sensitive or specific than currently available blood tests for the diagnosis of pancreatitis in dogs and cats, but do have some prognostic value. Of the individual diagnostic tests, the following were found to be negative prognostic indicators in dogs: high urinary TAP-to-creatinine ratio, marked increases in serum lipase activity, marked increases in serum creatinine and phosphate concentrations, and low urine specific gravity. A recent study identified hypothermia and metabolic acidosis as negative prognostic indicators in dogs with pancreatitis (Pápa et al., 2011), and another recent study also identified very marked elevations in canine PLI, thrombocytopenia, high urea or creatinine, and increased C-reactive protein concentrations on days 3 and 4 but not days 1 and 2 after admission as negative prognostic indicators in dogs with suspected but not confirmed acute pancreatitis (Sato et al., 2017). A clinical severity index with prognostic utility in dogs has been published, which takes into account renal and hepatic function, presence or absence of DM, blood pressure, and other local and systemic complications (Mansfield et al., 2008). In cats, the negative prognostic indicators found were low ionized calcium levels and leukopenia. Urinary or plasma TAP levels do not appear to be prognostically useful in cats, and neither does the degree of elevation of TLI in cats or dogs.

Diagnostic imaging

The most sensitive and easily accessible way to image the canine and feline pancreas noninvasively is by ultrasonography. Endoscopic ultrasound may be more sensitive but is only available in a small number of centers. Abdominal radiographs in patients with pancreatitis usually show mild or no changes, even in those with severe disease (Fig. 34.8). However, in patients with acute disease, abdominal radiography plays an important role in ruling out acute intestinal obstruction, which would result in obvious changes, primarily dilated, gas-filled, stacking loops of intestine and the presence of radiopaque foreign bodies. Typical radiographic changes in dogs and cats with acute pancreatitis are described in Chapter 34.

The most sensitive imaging modalities in humans with pancreatitis are magnetic resonance imaging (MRI), computed tomography (CT), and endoscopic ultrasonography (EUS). In addition, endoscopic retrograde cholangiopancreatography (ERCP) is performed in humans to image the ducts and enable tiny pancreatic biopsies to be taken via a small endoscope.

CT has so far proved disappointing in dogs and cats as detailed in Chapter 34. EUS is not widely available, although a recent study in Beagles indicated that the technique could visualize most of the pancreas, except the distal third of the right limb, and could be used to obtain fine-needle aspiration (FNA) samples (Kook et al., 2012). ERCP has been described in normal Beagles and in dogs with chronic gastrointestinal disease (Spillmann et al., 2004, 2005) but is technically difficult in dogs weighing less than 10 kg and carries a risk of worsening pancreatitis. Because all these techniques require general anesthesia, they may never become widely used in small animal patients with severe acute pancreatitis. Transcutaneous ultrasonography has a high specificity for pancreatic disease—if a lesion is found, it usually is real—but a variable sensitivity, depending on the skill of the operator and severity of the disease. Ultrasonography has a higher

sensitivity for typical acute pancreatitis in dogs and cats because associated edema and peripancreatic fat necrosis result in visible interfaces. The sensitivity is much lower for chronic and low-grade acute pancreatitis in cats and dogs (Fig. 37.5).

Fluid analysis

Some dogs and cats with pancreatitis have abdominal effusion. Fluid analysis usually reveals serosanguineous sterile exudates, although modified transudates and chylous effusions have also been reported in cats. Amylase and lipase concentrations in the fluid may be higher than in the serum, and high lipase concentrations in the effusion can be diagnostically helpful (Guija de Arespacochaga et al., 2006). Pleural effusions also occur in a small number of dogs with acute pancreatitis as a result of generalized vasculitis. More details are found in Chapter 34.

Histopathology

Definitive diagnosis of acute pancreatitis can be achieved only via histopathology of a pancreatic biopsy, but this is invasive and not indicated in most cases. However, if the animal has a laparotomy during the investigation, the clinician should always remember to inspect the pancreas visually and, preferably, to obtain a small biopsy. The pancreas usually appears grossly inflamed and may have a mass-like appearance. The latter is usually caused by fat necrosis and/or fibrosis and not neoplasia; therefore no animal should be euthanized on the basis of a tumor-like appearance in the pancreas without supportive cytology or pathology because large masses in the pancreas are very rarely tumors. Pancreatic neoplasia is usually so malignant that it will have metastasized widely and caused the animal's death before the mass becomes large. Indications and techniques for pancreatic biopsy are reviewed in Chapter 34.

However, in most cases, a biopsy will not be performed, and diagnosis is based on a combination of clinical suspicion, specific enzyme tests, and diagnostic imaging. No one noninvasive test is 100% sensitive and specific for pancreatitis in dogs and cats; in a few cases of even severe disease, all the tests may be negative.

Treatment and Prognosis

The treatment and prognosis of dogs and cats with acute pancreatitis depends on the severity of the condition at presentation. Severe acute pancreatitis is a very serious disease, has a very high mortality, and requires intensive management, whereas more moderate disease can be managed with intravenous (IV) fluids and analgesia, and patients with mild disease can sometimes be managed on an outpatient basis.

Cats with severe disease are more difficult to assess because of their mild clinical signs. It therefore seems prudent to assume that all cats have severe disease unless proved otherwise and treat them intensively, with the intent of preventing hepatic lipidosis and other fatal complications.

The inciting cause of the pancreatitis should be treated or removed in the few cases for which it is known (e.g., hypercalcemia or drug-induced), and every effort should be made during treatment to avoid further potential triggers, as outlined in Table 37.3. Most cases of pancreatitis are, however, idiopathic, and treatment is largely symptomatic. The one exception is chronic pancreatitis in English Cocker Spaniels, which may be an immune-mediated disease in which steroids and other immunosuppressive drugs may be indicated as a specific treatment (see later, "Chronic Pancreatitis," for more details). Occasionally, Cocker Spaniels with chronic pancreatitis present with acute clinical signs, and judicious corticosteroid therapy might be considered for them. However, there is no evidence that corticosteroid therapy is beneficial for other breeds of dogs, including Terriers; the

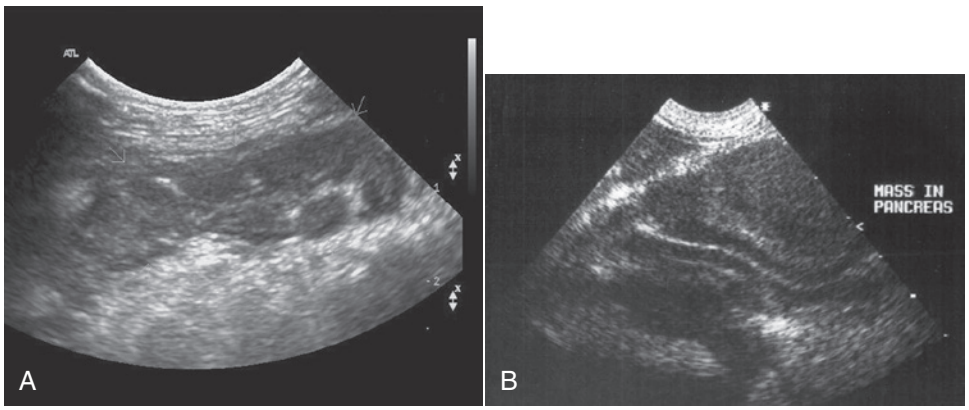

FIG 37.5
(A) Typical ultrasonographic appearance of acute pancreatitis in a Miniature Schnauzer with a diffusely hypoechoic pancreas *(gray arrows)* with surrounding hyperechoic mesentery. **(B)** Typical ultrasonographic appearance of chronic pancreatitis in an English Cocker Spaniel. There is a mass-like effect displacing the duodenum. Many dogs and cats with chronic pancreatitis have an unremarkable abdominal ultrasound. (Courtesy Diagnostic Imaging Department, Queen's Veterinary School Hospital, University of Cambridge, Cambridge, England.)

use of such drugs in them might actually worsen the prognosis by increasing the risk of gastric ulceration and reducing the activity of the reticuloendothelial system in the removal of circulating α_2-macroglobulin–protease complexes. In some cases, a dog or cat might need corticosteroid therapy for a concurrent condition, such as immune-mediated hemolytic anemia or inflammatory bowel disease, in which case the benefits of corticosteroids may outweigh their potential deleterious effects.

Severe, necrotizing pancreatitis carries a poor to very poor prognosis in cats and dogs. These patients have severe fluid and electrolyte abnormalities associated with systemic inflammatory disease, renal compromise, and a high risk of DIC. Intensive management is required, including plasma transfusions in many cases and enteral tube feeding or total parenteral nutrition (TPN) in some (see next section). These patients will likely benefit from referral to a specialist. If referral is not an option, intensive therapy can be attempted in the practice, but the owner must be warned of the very poor prognosis and expense of treatment. Severe acute pancreatitis also carries a poor prognosis in humans, but the mortality has been reduced in the last 5 years by a combination of early and aggressive IV fluid therapy and early feeding.

At the other end of the spectrum, patients with very mild pancreatitis may simply need hospitalization for 12 to 24 hours of IV fluid therapy if they are vomiting and dehydrated; if they are alert and well hydrated, they may be managed at home with 24 to 48 hours of pancreatic rest (fluids only by mouth) and analgesia, followed by long-term feeding of an appropriate diet.

It is important to give consideration to the following aspects of treatment in all patients: IV fluid and electrolyte replacement; analgesia; nutrition; and other supportive therapy, as indicated, such as antiemetics and antibiotics (see Box 37.1).

Intravenous fluids and electrolytes

IV fluid therapy is very important in all but the mildest cases of pancreatitis to reverse dehydration, address electrolyte imbalances associated with vomiting and fluid pooling in the hypomotile gastrointestinal tract, maintain adequate pancreatic circulation, and maintain effective peripheral circulation in the presence of the associated SIR. It is vital to prevent pancreatic ischemia associated with reduced perfusion because it contributes to necrosis. Replacement fluids (e.g., lactated Ringer's or Plasmalyte) are usually used at rates and volumes that depend on the degree of dehydration and shock—twice the maintenance rates (100-120 mL/kg/day) are adequate for mild to moderately affected animals (grades 0 and 1), but more severely affected animals may need initial shock rates (90 mL/kg/h for 30-60 minutes) followed by synthetic colloids. It is important to measure urine output concurrently. Rapid crystalloid infusion in severely affected animals that have a pathologic increase in vascular permeability carries an increased risk of pulmonary edema, so patients should be closely monitored; central venous pressure ideally should be measured in the most severely affected dogs and the fluid rate adjusted accordingly to maintain normal central venous pressure.

Serum electrolyte concentrations should be carefully monitored. Potential electrolyte abnormalities are outlined in Table 34.3, but the most clinically relevant is hypokalemia caused by vomiting and reduced food intake. Hypokalemia can significantly impair recovery and contribute to mortality because it causes not only skeletal muscle weakness but also gastrointestinal atony, which will contribute to the clinical signs of the disease and delay successful feeding. Aggressive fluid therapy further increases renal potassium loss, particularly in cats, so it is important to measure serum potassium concentrations frequently (at least daily while the patient is vomiting) and add supplemental potassium chloride to the fluids as necessary. A scaled approach is best, based on the degree of hypokalemia. Lactated Ringer's or Plasmalyte contains only 4 mEq/L potassium, and most cases require supplementing at least to replacement rates (20 mEq/L). Even if the serum potassium concentration cannot be measured, a vomiting anorexic dog with no evidence of renal failure should receive replacement rates of potassium in the fluids. More severely hypokalemic dogs should be supplemented more as long as serum concentrations can be measured regularly and infusion rates carefully controlled. A dog or cat with a serum potassium concentration of 2.0 mEq/L or less should receive between 40 and 60 mEq/L in the fluids at a controlled infusion rate. As a general rule, the infusion rate of potassium should still not be increased above 0.5 mEq/kg/h.

A plasma transfusion is likely indicated in dogs and cats with severe pancreatitis to replace α_1-antitrypsin and α_2-macroglobulin. It also supplies clotting factors and may be combined with heparin therapy in animals at high risk of DIC, although the efficacy of heparin therapy in DIC in humans and animals has been questioned, and there are currently no controlled trials that either support or refute its use for pancreatitis in dogs and cats (see Chapter 87).

Analgesia

Pancreatitis is usually a very painful condition. Hospitalized patients should be monitored carefully for pain, and analgesia should be administered as necessary. In practice, analgesia is indicated for almost all patients with pancreatitis and should be given routinely to cats with pancreatitis

BOX 37.1

Pillars of Treatment in Severe Acute Pancreatitis (see text for more details)

- Early, aggressive intravenous fluid therapy (monitor urine output and electrolytes)
- Analgesia (early and effective—assume pain unless proven otherwise)
- Early enteral feeding (as soon as rehydrated)

because their pain is difficult to assess. Morphine agonists or partial agonists are often used, particularly buprenorphine or butorphanol. Butorphanol also has antiemetic properties. These partial opiate agonists are effective for mild to moderate pain, but full opioid agonists are preferred in more severe pain. Morphine, methadone, meperidine, and fentanyl (IV or patches) can be used (Table 37.4). Concerns that the effects of opiates on the sphincter of Oddi might exacerbate disease have often been cited with regard to dogs and humans, but more recent studies have suggested minimal clinically relevant effects, except when high and repeated doses of morphine are used. These drugs are regularly used now in humans with pancreatitis, with no obvious problems. Fentanyl patches take time to achieve effect (on average, 24 hours in dogs and 7 hours in cats), so concurrent use of an opiate for the first few hours after application is recommended.

TABLE 37.4

Analgesics Used for Acute Pancreatitis

ANALGESIC	INDICATIONS AND CAUTIONS	DOSAGE AND ROUTE		COMMENTS
		DOGS	CATS	
Buprenorphine	Most generally useful analgesic in hospitalized patient May be dosed transmucosally at home in both dogs and cats but dog dose much higher	IV, SC, IM, 0.01-0.02 mg/kg Oral transmucosal dose 0.12 mg/kg	IV, SC, IM same as for dogs Oral transmucosal dose 0.01-0.03 mg/kg*	Concerns about effects on sphincter of Oddi largely unfounded
Butorphanol	Author has limited experience with its use; other opiates preferred in acute pancreatitis because of butorphanol's limited analgesic effect and potentially negative cardiovascular effects (see notes); however, additional antiemetic effect may be beneficial	0.05-0.6 mg/kg IM, SC, IV, q6-8h; 0.1-0.2 mg/kg/h as CRI Oral—0.5-1 mg/kg q6-12h	Same as for dogs	At analgesic doses in humans, increases pulmonary artery pressure and cardiac work, unlike other analgesics in the table, so other opiates preferred
Meperidine (Demerol)	Meperidine by injection only, hence hospitalized animals Not for IV administration (causes histamine release and results in profound hypotension)	5 mg/kg SC, IM, q2h	3-5 mg/kg SC, IM, q2h	Painful on injection Derived from atropine; therefore, in contrast to other opioids, is spasmolytic agent on smooth muscle; might be useful for the gut
Morphine	Vomiting common Useful for severe acute pain, can be given by slow IV injection to effect	0.1-0.5 mg/kg SC, IM, IV, 0.1 mg/kg/h by constant rate infusion	0.1-0.2 mg/kg SC, IM, IV	Stimulation of sphincter of Oddi reported in humans but of dubious relevance for dogs and cats
Methadone	Little nausea or vomiting, so more useful than morphine	0.2-0.4 mg/kg SC, IM, q4-6h or as required	0.2 mg/kg SC, IM, q4-6h or as required	Can produce dysphoria May get increased duration of action with repeated doses
Hydromorphone		0.05 mg/kg IV q4h; 0.1-0.4 mg/kg IM	0.1 mg/kg IM q7h	Can produce dysphoria
Fentanyl patch	Very useful, but take great care if sending home with patch	2-4 µg/kg/h patch	25 µg/h patch with half exposed	24-hour onset and 72-hour duration in dogs; 7-hour onset and 72-hour duration in cats

Continued

TABLE 37.4

Analgesics Used for Acute Pancreatitis—cont'd

ANALGESIC	INDICATIONS AND CAUTIONS	DOSAGE AND ROUTE		COMMENTS
		DOGS	CATS	
Tramadol	Author has no personal experience with this drug in acute pancreatitis but may be useful drug for home use orally for mild to moderate pain	Oral—2-5 mg/kg q8-12h	Oral—2-4 mg/kg q8-12h	Tramadol also decreases cardiac contractility; should not be used in acute phase when myocardial depressant factor may be released Published studies on pharmacokinetics in small animals suggest that should be more effective in cats than dogs due to rapid metabolism in dogs to inactive metabolites. Dysphoria more likely in cats
Ketamine infusion	Severe refractory pain in hospitalized patient	2 µg/kg/min	Same as for dogs	Useful as adjunct, probably not suitable as sole analgesic; can produce dysphoria at higher infusion rates
Lidocaine infusion	Excellent analgesic for hospitalized patients	Bolus of 1 mg/kg IV followed by 20-µg/kg/min infusion	0.1 mg/kg/h	Use with caution in cats because of lidocaine toxicity
Acetaminophen (Paracetamol)	Most widely used NSAID for human pancreatitis; often neglected in dogs, but useful because it does not have same deleterious effects on GI tract and kidneys as other nonsteroidals	10 mg/kg PO, IV, q12h	**Do not use**—toxic in cats	Should not be used if significant concurrent liver disease
Carprofen and other nonsteroidal antiinflammatory drugs (NSAIDs)	Mainly for home use; used with great care because of potential gut and renal side effects in pancreatitis; not for use in acute disease or in presence of concurrent hyperadrenocorticism or steroid treatment	Carprofen—4 mg/kg SC, IV, PO, q24h; maintain on 2 mg/kg q12h	Carprofen—2 mg/kg SC, IV, PO; maintain on 2 mg/kg	Underestimated efficacy COX 1:2 inhibition ratio of 65

COX, Cyclooxygenase; *CRI,* constant rate infusion; *GI,* gastrointestinal.

Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided, if possible, because of the increased risk of gastroduodenal ulceration in patients with pancreatitis and the potential of some NSAIDs to precipitate renal failure in animals with hypotension and/or shock. In humans, acute pancreatitis has been associated with the use of NSAIDs. Cyclooxygenase-2 (COX-2) inhibitors have a lower risk ratio than the conventional NSAIDs in this respect, as does acetaminophen if used carefully (see Table 37.4). Alternative analgesics that could be considered in severe cases include a low-dose IV ketamine infusion, which has the advantage of minimal effect on gastrointestinal motility (Fass et al.,

1995), or IV lidocaine. Details of analgesia are given in Table 37.4.

Providing analgesia that can be dispensed for the client to take home for patients with milder or resolving disease can be a challenge. The pain should not be underestimated in these patients. However, it is difficult to find effective and safe analgesia that can be dispensed for use at home. Administration of opioids during visits to the clinic is prudent, and one of the less ulcerogenic NSAIDs or acetaminophen could be used cautiously at home. Cats can be effectively dosed with buprenorphine transmucosally (Robertson et al., 2003), allowing simple home medication, but the oral route requires much larger doses in dogs (Abbo et al., 2008) (see Table 37.4). Anecdotally, tramadol has been found to be helpful for some dogs and cats, but its efficacy is variable. Feeding a low-fat diet helps reduce postprandial pain in humans and anecdotally helps some dogs. However, administering pancreatic enzymes in the food does not seem to reduce pain in dogs, and there is little evidence to support their use for pain relief in dogs or cats.

Nutrition

It is very important to consider appropriate nutritional management of the patient with pancreatitis. Complete pancreatic rest by starvation, avoiding anything by mouth (including water or barium), has traditionally been advised for patients with acute pancreatitis. Initially, it was believed that early enteral nutrition was contraindicated because it was likely to result in cholecystokinin and secretin release, with the consequent release of pancreatic enzymes and worsening of pancreatitis and associated pain. TPN seemed a more logical route early in the disease process, with jejunal tube feeding later in the disease aiming to bypass the areas of pancreatic enzyme stimulation. However, recent studies in humans and also experimental models in dogs have strongly supported early enteral nutrition over TPN; early enteral nutrition in humans with severe acute pancreatitis has been found to reduce the length of hospital stay and decrease mortality.

Current recommendations for feeding veterinary patients with acute pancreatitis are outlined in Box 37.2. It is no longer appropriate or acceptable to starve the patient for a

BOX 37.2

Best Practice for Feeding Patients With Acute Pancreatitis

Recent studies and meta-analyses of studies of nutrition in human acute pancreatitis have led to changes in advice for best-practice feeding in these cases (Al-Omran et al., 2010; Quan et al., 2011). Note that early enteral nutrition is particularly indicated for severe disease, which is perhaps unexpected and counter to recent practice in dogs.

When to Feed?

- Early enteral nutrition reduces mortality and hospitalization time in humans with severe acute pancreatitis and is supported by experimental studies in dogs and studies in canine parvovirus enteritis (Mohr et al., 2003). Start enteral nutrition within 24 to 48 hours, once the animal is rehydrated.
- In mild acute pancreatitis in humans, current best practice is to withhold food in many patients for a little longer, and this is also recommended in dogs to reduce pain and vomiting. Fluids, electrolytes, and analgesics are delivered for 2 to 5 days while the patient is fasted, and then a diet rich in carbohydrate and moderate in fat and protein is initiated with discharge on a normal diet within 4 to 7 days.
- In cats, current anecdotal recommendations are to feed immediately in mild, moderate, and severe pancreatitis because of the high risk of hepatic lipidosis.

How to Feed?

- Multiple studies show better outcomes with enteral compared with parenteral nutrition in humans and experimental dogs due to maintenance of gut wall barrier and reduced bacterial translocation, so enteral is preferred.
- Severe, acute cases will likely need tube feeding. Nasoesophageal tubes are best in the acute stages to avoid the risk of general anesthetic in a dog or cat with multiorgan failure. Longer term, most animals will eat voluntarily, but if necessary, an esophageal or gastrostomy feeding tube can be placed (see Chapter 35 for more details). Recent studies support prepyloric feeding as safe in humans and dogs—jejunostomy tube placement is not necessary (Mansfield et al., 2011).

What to Feed?

- Studies show that high dietary fat increases postprandial pain but does not worsen the pancreatitis. Dogs and cats with severe, acute pancreatitis can be fed any appropriate diet provided they are receiving sufficient analgesia. Tube feeding may require a high-fat convalescence-type diet down a tube, such as Hills a/d diet or Royal Canin convalescence support. The new Royal Canin GI low-fat liquid diet would be particularly appropriate.
- Low-fat diets are indicated in milder pancreatitis in dogs and for recovery at home, to reduce postprandial pain.
- There is no convincing evidence for addition of immune-modulating ingredients such as glutamine or omega-3 fatty acids. Probiotics are best avoided in acute disease (one study in humans showed an increase in mortality when probiotics were used in severe acute pancreatitis [Besselink et al. 2008]).
- Addition of pancreatic enzymes during the acute phase is wise, as they will not be secreted down the duct.

long period while awaiting the resolution of disease. Increasing evidence is accumulating in human medicine about the importance of early enteral nutrition in patients with pancreatitis; the more severe the pancreatitis, the earlier nutrition support should be instituted. Furthermore, recent studies suggest that prepyloric (e.g., nasoesophageal or gastrostomy tube) feeding may be as safe as jejunal feeding. There is little evidence that immunomodulating nutrients are of benefit, and data on probiotics in pancreatitis are conflicting, with one study showing increased mortality in humans (Besselink et al., 2008), so these are best avoided. There have been no studies evaluating the efficacy of early or late enteral or parenteral nutrition in naturally occurring pancreatitis in dogs or cats. Therefore the advice currently given is based on anecdotal evidence, extrapolation from humans, and experimental studies in dogs. However, a recent pilot study comparing early enteral nutrition via esophagostomy tube with parenteral nutrition in 10 dogs with severe acute pancreatitis found that prepyloric tube feeding of a low-fat canine diet, with added pancreatic enzymes and medium-chain triglycerides, was well tolerated by dogs with acute pancreatitis. The dogs receiving enteral nutrition did not show obvious postprandial pain, and a significantly greater number of dogs in the parenteral group showed vomiting and regurgitation compared with those in the enteral group (Mansfield et al., 2011).

Starvation is also contraindicated in cats with acute pancreatitis because of the high risk of concurrent hepatic lipidosis. Current advice is therefore to institute some form of enteral feeding, whenever possible, within 48 hours in dogs and cats. The more severe the disease, the more important it is to feed early. In severe cases this is best achieved with nasoesophageal tube feeding by slow continuous infusion of a critical care diet, although frequent small-volume feeds are also well tolerated by many patients. Anesthesia to place an esophagostomy or gastrostomy tube is best avoided in the acute stages of pancreatitis but is indicated for longer-term feeding, if necessary, in a more stable patient. High-fat critical-care diets are potentially associated with increased pain but are tolerated in hospitalized animals with adequate analgesia. Once the animal is eating voluntarily, it can be transitioned on to a lower-fat diet for recovery. A good initial choice is baby rice mixed with water, followed by a low-fat proprietary veterinary diet (e.g., Eukanuba Intestinal Formula, Mars Petcare; Hill's i/d Low Fat, Hill's Pet Nutrition, Topeka, KN; Royal Canin Digestive Low Fat, Royal Canin USA, St. Charles, MO; Purina EN Gastroenteric Canine Formula, Nestlé SA, Vevey, Switzerland) (Fig. 37.6). It may not even be necessary to use a low-fat diet. There is no evidence that standard diets increase the severity of disease in patients with acute pancreatitis, so a liquid critical care diet should also be tolerated if given in small amounts and often. However, there is evidence in humans that higher-fat diets increase pain and prolong hospitalization times for this reason, which also appears to be anecdotally true in dogs. Addition of pancreatic enzymes to the diet is wise in the very acute phases of the disease when the pancreas is not secreting enzymes down the duct. Concurrent antiemetics are also essential to allow effective feeding in many cases (see next section). In patients for which enteral nutrition is not possible or when only a small percentage of the daily caloric requirements can be given enterally, some form of supplemental parenteral nutrition should be considered. This is administered most practically as peripheral parenteral nutrition (Chandler et al., 2000). However, it is very clear that recovery is improved if at least some of the daily calorie intake can be given enterally.

Antiemetics

Antiemetics are often necessary to manage acute vomiting in dogs and cats with pancreatitis. The neurokinin (NK1) receptor antagonist maropitant has central and peripheral antiemetic effects, and seems to be the most effective antiemetic in dogs and cats with pancreatitis. Maropitant is

FIG 37.6
Baby rice is a good first choice for feeding dogs with moderate acute pancreatitis because it contains no fat and protein. It comes as a finely ground rice powder **(A)** that can then be mixed with water and, if desired, a gravy substitute such as Bovril **(B)** to enhance the flavor for feeding. Dogs with severe acute pancreatitis should be tube fed a critical-care diet (see text and Box 37.2).

available as Cerenia (Zoetis, Madison, NJ) in an injectable solution (10 mg/mL) or as tablets (16, 24, 60, and 160 mg). The dose of injection is 1 mg/kg (1 mL/10 kg body weight q24h for up to 5 days). The dose of the tablets is 2 mg/kg q24h for up to 5 days. Maropitant also has potential analgesic properties because substance P, which acts on the NK1 receptor, is involved in pancreatic pain, but no clinical studies have demonstrated its efficacy. It would be indicated as part of multimodal analgesia in animals with acute pancreatitis and would not be sufficient alone.

Metoclopramide has been used successfully in dogs with pancreatitis (0.5–1 mg/kg, administered intramuscularly, subcutaneously, or orally [PO] q8h, or 1–2 mg/kg, administered intravenously over 24 hours as a slow infusion), but its effect on stimulating gastric motility may increase pain and pancreatic enzyme release in some animals. It is also of limited efficacy in cats. Butorphanol, used as an analgesic in animals with pancreatitis causing mild to moderate pain, also has antiemetic properties. A phenothiazine antiemetic such as chlorpromazine may be more effective for some patients, but phenothiazines have sedative and hypotensive effects, which may be particularly marked if they are used together with opioid analgesia, so care should be taken in these cases. 5-HT_3 receptor antagonists such as ondansetron are useful for other types of vomiting in dogs (e.g., chemotherapy-induced emesis) but are best avoided in pancreatitis because they have occasionally been reported to trigger pancreatitis in humans.

Gastroprotectants

Patients with acute pancreatitis have an increased risk of gastroduodenal ulceration, probably caused by local peritonitis. They should be monitored carefully for evidence of melena or hematemesis and treated as necessary with sucralfate and acid secretory inhibitors (e.g., H_2 blockers such as cimetidine, famotidine, ranitidine, or nizatidine, or the proton pump inhibitor omeprazole). Cimetidine should be avoided in animals with concurrent liver disease because of its effect on the cytochrome P-450 system. Ranitidine can be used instead in these animals, but its additional gastric prokinetic effect can cause vomiting in some individuals; it should be discontinued if this occurs. Famotidine is preferable because it does not have these prokinetic effects.

Antibiotics

Infectious complications are reportedly rare in dogs and cats with pancreatitis, but when they occur, they can be serious; the efficacy of antibiotic therapy in preventing such complications remains contentious in humans. Nonetheless, most veterinary experts advise the use of broad-spectrum antibiotics prophylactically in dogs and cats with severe acute pancreatitis. IV potentiated amoxicillin is most often used. Fluoroquinolones penetrate the pancreas well, but responsible antibiotic use indicates that these should not be used as first-line antibiotic treatment unless there is a specific indication. Animals at the milder end of the disease spectrum do not require antibiotic therapy.

Treatment of biliary tract obstruction associated with pancreatitis

Most cases of extrahepatic biliary obstruction secondary to acute-on-chronic pancreatitis resolve with conservative management; surgical or needle decompression of the gallbladder and stenting of the bile duct are usually unnecessary in dogs and cats. In humans it has now been demonstrated that there is no advantage to surgical intervention in most patients and no difference in the severity and chronicity of secondary liver disease between those treated medically and those treated surgically, provided that there is no neoplasia and the jaundice resolves within a month (Abdallah et al., 2007). No such study has been undertaken in small animals, so treatment advice is empiric; if the feces remain colored (not white or acholic, which implies complete biliary obstruction) and the jaundice gradually resolves over a week to 10 days, then surgical intervention is not indicated and conservative management with antioxidants and ursodeoxycholic acid is advised (see Chapters 35 and 36).

CHRONIC PANCREATITIS

Etiology and Pathogenesis

Chronic pancreatitis is defined as "a continuing inflammatory disease characterized by the destruction of pancreatic parenchyma leading to progressive or permanent impairment of exocrine or endocrine function, or both" (Etemad et al., 2001). The gold standard for diagnosis is histology (see Fig. 37.2), but this is rarely indicated or performed in dogs or cats. Noninvasive diagnosis is difficult with the currently available diagnostic imaging, and clinicopathologic testing has a lower sensitivity than for acute disease.

Chronic pancreatitis has been considered a rare and not particularly important disease in dogs, whereas it is recognized as the most common form of pancreatitis in cats. However, the early literature published on canine pancreatic disease in the 1960s and 1970s recognized it as a common disease of clinical significance. It was noted that a high proportion of cases of EPI in dogs were caused by chronic pancreatitis, and it might be responsible for 30% of cases of DM or more. More recent pathologic and clinical studies in both dogs (Bostrom et al., 2013; Newman et al., 2004; Watson et al., 2007, 2011) and cats (De Cock et al., 2007) have reconfirmed it as a common and clinically relevant disease in dogs and cats. It is likely to cause intermittent and/or ongoing recurrent gastrointestinal signs and epigastric pain in many dogs and cats, but it is frequently underrecognized because of the difficulty of obtaining a noninvasive diagnosis. In dogs the postmortem prevalence of chronic pancreatitis is up to 34%, particularly in susceptible breeds, and even in studies of fatal acute pancreatitis, acute-on-chronic disease accounts for 40% of cases. In cats an even higher postmortem prevalence of chronic pancreatitis of 60% has been reported. It must be noted that postmortem studies tend to overestimate the prevalence of chronic diseases, which leave permanent

architectural changes in the organ, whereas the prevalence of acute, totally reversible diseases will be underestimated unless the animal dies during the episode. Nevertheless, it is clear that there are many more cases of chronic pancreatitis in veterinary practice than currently recognized, and a number of these are clinically relevant.

Idiopathic chronic pancreatitis

As in acute pancreatitis, the cause of chronic pancreatitis in dogs is usually unknown. Any age or breed of dog can be affected, but in Britain the most typical is a middle-aged to old dog, particularly a Cavalier King Charles Spaniel, Cocker Spaniel, Collie, or Boxer (Watson et al., 2007, 2010; Fig. 37.7). One recent study in the United States suggested that breeds defined by the American Kennel Club as toy and nonsporting breeds have a higher prevalence of chronic pancreatitis (Bostrom et al., 2013). An independent large study of EPI in Britain found an increased prevalence in older Cavalier King Charles Spaniels, supporting a breed association. Other parts of the world have also reported a high prevalence in Arctic-type breeds such as Siberian Huskies. There is likely to be some overlap with acute disease, although some cases will have a separate etiology. In humans, both genetic and environmental factors determine whether recurrent acute pancreatitis becomes more chronic with development of fibrosis. One environmental factor predisposing to fibrosis is smoking, which may also be relevant in dogs that can be passive smokers, but no studies have yet investigated this. Some cases are chronic from the outset, with an initial mononuclear infiltrate. Genetic causes are likely to be important in dogs, which explains the high risk in certain breeds. No particular breed prevalence has been reported for cats with chronic pancreatitis; domestic shorthairs are most commonly affected.

FIG 37.7
Eight-year-old neutered male English Cocker Spaniel with chronic pancreatitis.

Autoimmune chronic pancreatitis

The particular form of chronic pancreatitis recognized in English Cocker Spaniels in Britain is thought to be an immune-mediated disorder (Watson et al., 2011; see Fig. 37.7). As in human autoimmune pancreatitis, it typically affects middle-aged to older dogs, with a higher prevalence in males, and at least 50% of affected dogs subsequently develop DM, EPI, or both. Dogs also often have another concurrent autoimmune disease, particularly keratoconjunctivitis sicca and glomerulonephritis. There may also be an association with anal sacculitis and increased risk of anal sac carcinoma. There is often a mass-like lesion on ultrasonography (see Fig. 37.5, *B*). Biopsies show a typical perilobular, diffuse, fibrotic, and lymphocytic disease centered on perilobular ducts and vessels, with loss of large ducts. Immunohistochemistry shows a preponderance of duct- and vein-centered CD3+ lymphocytes (i.e., T cells). The disease in humans is believed to be a duct-centered immune reaction. Recent work has identified a strong association with plasma cells that secrete one subgroup of immunoglobulin G, IgG4. The disease in humans has been redefined as multisystemic because of the frequent involvement of other organs. It is now defined as IgG4-related disease (Bledsoe et al., 2018), and concurrent keratoconjunctivitis sicca, sialoadenitis, biliary tract disease, and glomerulonephritis are common. Early work in English Cocker Spaniels also shows IgG4-positive plasma cells in the pancreas and kidney (Watson et al., 2012). The disease in humans responds well to steroid therapy, including a reduction in insulin requirements in some diabetics. This is clearly differentiated from the proposed autoimmunity in young German Shepherd Dogs with pancreatic acinar atrophy (PAA), which is acinar-centered and does not result in DM (see later). There are not yet any controlled trials evaluating the use of immunosuppressive drugs in English Cocker Spaniels with chronic pancreatitis, but there is now enough circumstantial evidence to justify their use in this particular breed, and the author has had anecdotal success with both prednisolone and cyclosporine therapy in affected dogs. The decision to start immunosuppressive therapy is based on clinical severity including the presence of recurrent bouts of pancreatitis and/or renal involvement with marked proteinuria nonresponsive to conventional therapies. As in humans, less severely affected cases can be treated symptomatically and with "watchful waiting" (Bledsoe et al., 2018). However, the clinician should note that many cases of chronic pancreatitis in dogs are not autoimmune; most terriers in Britain, for example, have a different histopathologic and clinical picture of disease that does not appear to be autoimmune. Confirmation of autoimmune disease requires histologic confirmation, which is rarely available. In the absence of pancreatic histopathology, presence of autoimmune disease in other organs (for example, keratoconjunctivitis sicca and glomerulonephritis) is highly suggestive and justifies the use of immunosuppressives. The use of immunosuppressives in dogs that are not Cocker Spaniels with isolated chronic pancreatitis is not recommended.

Clinical Features

Dogs with chronic pancreatitis, regardless of the cause, usually present with mild intermittent gastrointestinal signs. Typically, they have bouts of anorexia, occasional vomiting, mild hematochezia, and obvious postprandial pain, which often go on for months to years before a veterinarian is consulted. The trigger for finally seeking veterinary attention is often an acute-on-chronic bout or the development of DM or EPI. The main differential diagnoses in the low-grade cases are inflammatory bowel disease and primary gastrointestinal motility disorders. Dogs may become more playful and less picky with their food when they are switched to a low-fat diet, which suggests that they previously had postprandial pain. Chronic epigastric pain is a hallmark of the human disease and is sometimes severe enough to lead to opiate addiction or surgery, so it should not be overlooked or underestimated in small animal patients. In more severe, acute-on-chronic cases, the dogs are clinically indistinguishable from those with classic acute pancreatitis (see earlier), with severe vomiting, dehydration, shock, and potential MOF. The first clinically severe bout tends to come at the end of a long subclinical phase (often years) of quietly progressive and extensive pancreatic destruction in dogs. It is important for clinicians to be aware of this because these dogs are at much higher risk for developing exocrine and/or endocrine dysfunction than those with acute pancreatitis; in addition, they usually already have protein-calorie malnutrition at presentation, which makes their management even more challenging. It is also relatively common for dogs with chronic pancreatitis to present first with signs of DM and a concurrent acute-on-chronic bout of pancreatitis resulting in a ketoacidotic crisis. In some dogs there are no obvious clinical signs until the development of EPI, DM, or both. The development of EPI in a middle-aged to older dog of a breed not typical for PAA has to increase the index of suspicion for underlying chronic pancreatitis. The development of EPI or DM in a dog or cat with chronic pancreatitis requires the loss of approximately 90% of exocrine or endocrine tissue function, respectively, which implies considerable tissue destruction and end-stage disease.

In cats the clinical signs of chronic pancreatitis are usually mild and nonspecific. This is not surprising considering that cats display mild clinical signs, even in association with acute necrotizing pancreatitis. One study showed that the clinical signs of histologically confirmed chronic nonsuppurative pancreatitis in cats were indistinguishable from those of acute necrotizing pancreatitis (Ferreri et al., 2003). However, chronic pancreatitis in cats is significantly more often associated with concurrent disease than acute pancreatitis, particularly inflammatory bowel disease, cholangiohepatitis, hepatic lipidosis, and/or renal disease. The clinical signs of these concurrent diseases may predominate, further confusing diagnosis. Nevertheless, some cats will eventually develop end-stage disease, with resultant EPI and/or DM.

Chronic pancreatitis is the most common cause of extrahepatic biliary obstruction in dogs (see Chapters 33 and 36), and dogs and cats with acute-on-chronic pancreatitis frequently develop jaundice.

Diagnosis

Noninvasive diagnosis

In the absence of a biopsy, which is the gold standard, the clinician must rely on a combination of clinical history, ultrasonography, and clinical pathology. The findings on diagnostic imaging and clinical pathology are similar to those outlined earlier (see "Acute Pancreatitis" and Tables 34.2 and 34.3). However, changes tend to be less marked in dogs and cats with chronic pancreatitis, and the diagnostic sensitivity of all tests is lower. Ultrasonography has a lower sensitivity in cats and dogs with chronic disease because there is less edema than in those with acute disease. A variety of ultrasonographic changes may be seen in patients with chronic pancreatitis, including a normal pancreas, mass lesion, mixed hyperechoic and hypoechoic appearance to the pancreas, and sometimes an appearance resembling that of typical acute pancreatitis, with a hypoechoic pancreas and a bright surrounding mesentery (Watson et al., 2011; see Fig. 37.5). In addition, in patients with chronic disease, adhesions to the gut may be apparent, and the anatomy of the pancreatic and duodenal relationship may be changed by these adhesions. Some patients, particularly English Cocker Spaniels, have large mass-like lesions associated with fibrosis and inflammation; some have tortuous and dilated, irregular ducts; and many patients have completely normal pancreatic ultrasonographic findings in spite of severe disease.

Similarly, clinical pathology can be helpful, but the results may also be normal. Increases in pancreatic enzyme levels are most likely to be seen during an acute-on-chronic bout than during a quiescent phase of disease, similar to the waxing and waning increases in liver enzyme levels in patients with ongoing chronic hepatitis. Again, similar to the situation in hepatic cirrhosis, in end-stage chronic pancreatitis there may not be enough pancreatic tissue left to cause increases in enzyme levels, even in acute flare-ups. On the other hand, occasionally the serum TLI level can temporarily increase into or above the normal range in dogs with EPI as a result of end-stage chronic pancreatitis, confusing the diagnosis of EPI in these dogs. cPLI appears to have the highest sensitivity for the diagnosis of canine chronic pancreatitis, but even this has a lower sensitivity than in acute disease. The diagnostic sensitivity of feline PLI for chronic pancreatitis in cats is unknown.

It is important to measure serum vitamin B_{12} concentrations in dogs and cats with chronic pancreatitis. The gradual development of EPI, often combined with concurrent ileal disease, particularly in cats, predisposes to cobalamin deficiency (see later, "Exocrine Pancreatic Insufficiency"). If the serum vitamin B_{12} concentration is low, cobalamin should be supplemented parenterally (0.02 mg/kg, administered intramuscularly or subcutaneously every 2 weeks in dogs and cats until the serum concentration is normalized). Oral

cobalamin may also be effective: see section on treatment of exocrine pancreatic insufficiency for doses.

Biopsy

The diagnosis of chronic pancreatitis can be difficult in dogs and cats, and these difficulties in diagnosis likely result in underrecognition of the disease. Establishing a definitive diagnosis relies on obtaining a pancreatic biopsy. However, this will not be indicated in most cases until there is an effective treatment, because a biopsy is a relatively invasive procedure; the results do not alter treatment or outcome, except perhaps in English Cocker Spaniels. However, with the potential for more specific therapies, routine biopsy may be indicated in the future. In humans the preferred method is needle biopsy via transendoscopic ultrasonographic guidance. Transendoscopic ultrasonography is expensive and of limited availability in veterinary medicine, so in dogs and cats surgical or laparoscopic biopsies remain the most applicable. Cytology of ultrasonography-guided transcutaneous FNA of the pancreas may help differentiate neoplasia or dysplasia from inflammation, but veterinary experience in this area is limited. If the clinician is performing a laparotomy to obtain other biopsies, it makes perfect sense to obtain a pancreatic biopsy at that time as well. Pancreatitis is not a risk, provided the pancreas is handled gently and the blood supply is not disrupted. However, the biopsy should be small and from the tip of a lobe; this might therefore miss the area of disease, which is usually patchy, particularly early on, and can also be centered on large ducts. Unfortunately, even biopsy has its limitations.

Treatment and Prognosis

Dogs and cats with chronic intermittent pancreatitis may have intermittent bouts of mild gastrointestinal signs and anorexia, and often the owner's primary concern is that the pet has missed a meal. These animals can be managed at home, as long as anorexia is not long-lasting, and the owner should be reassured that a short period of self-induced starvation is not harmful.

As for patients with acute pancreatitis, treatment is largely symptomatic. Dogs and cats with acute flare-ups require the same intensive treatment as cats and dogs with classic acute pancreatitis and have the same risk of mortality (see earlier). The difference from isolated acute pancreatitis is that if the animal recovers from the acute bout, it is likely to remain with considerable exocrine and/or endocrine functional impairment. In the milder cases, symptomatic treatment can make a real difference in the animal's quality of life. Changing to a low-fat diet (e.g., Hill's i/d Low Fat, Royal Canin Digestive Low Fat, or Eukanuba Intestinal) may often reduce postprandial pain and acute flare-ups. Owners often underestimate the effects of fatty treats, which can precipitate a recurrence in susceptible individuals. Some animals need analgesia, intermittently or continuously (see "Acute Pancreatitis" and Table 37.4). According to anecdotal reports, short courses of metronidazole (10 mg/kg PO q12h) seem to help some patients, particularly Cavalier King Charles Spaniels after acute bouts, presumably because they develop secondary bacterial overgrowth as a result of a stagnant loop phenomenon in the adjacent duodenum. The serum vitamin B_{12} concentration should be measured regularly, and cobalamin should be supplemented parenterally as necessary (0.02 mg/kg IM every 24 weeks until serum concentration normalizes). Oral cobalamin may also be effective: see section on treatment of exocrine pancreatic insufficiency for doses. The treatment of suspected autoimmune pancreatitis in English Cocker Spaniels is detailed in an earlier section.

The treatment of extrahepatic biliary tract obstruction associated with acute-on-chronic disease should be as given in the acute pancreatitis section, and most patients can be managed medically. In patients with end-stage disease, exocrine and/or endocrine deficiency may develop. Dogs and cats with EPI and/or DM are managed with the administration of enzymes (see later) and insulin as necessary in the usual way (see Chapter 49). Most do surprisingly well over the long term.

EXOCRINE PANCREATIC INSUFFICIENCY

EPI is a functional diagnosis that results from a lack of pancreatic enzymes. As such, unlike pancreatitis, it is diagnosed on the basis of clinical signs and pancreatic function test results and not primarily by the results of pancreatic histopathology. However, finding a marked reduction in pancreatic acinar mass on histology is supportive of a diagnosis of EPI. The pancreas is the only significant source of lipase, so fat maldigestion with fatty feces (steatorrhea) and weight loss are the predominant signs of EPI.

Pathogenesis

PAA is believed to be the predominant cause of EPI in dogs, but studies have shown that end-stage chronic pancreatitis is also important (Fig. 37.8; Batchelor et al., 2007a; Watson et al., 2010). PAA has only been definitively reported once in cats (Thompson et al., 2009); end-stage pancreatitis is believed to be the most common cause of feline EPI (Fig. 37.9), although reports in cats as young as 3 months of age suggest other congenital or acquired causes in this species (Xenoulis et al., 2016). The raccoon pancreatic fluke *Eurytrema procyonis* has also been reported to cause end-stage fibrosis and EPI in cats in the eastern United States. The development of clinical EPI requires approximately a 90% reduction in lipase production and thus extensive loss of pancreatic acini. It is therefore extremely unlikely to occur after a single severe bout of pancreatitis but tends to result from chronic ongoing disease. However, the chronic disease may be largely subclinical or only present as occasional clinical acute-on-chronic episodes, so the degree of underlying pancreatic damage may be underestimated.

PAA is particularly recognized in young German Shepherd Dogs (see Fig. 37.8, *A*), in which an autosomal mode of inheritance has been suggested, although a recent study refutes this and suggests that the inheritance is more complex (Westermarck et al., 2010). PAA has also been described in Rough Collies, suspected in English Setters, and sporadically

FIG 37.8
(A) Physical appearance of a 2-year-old male German Shepherd Dog with exocrine pancreatic insufficiency (EPI). **(B)** An 11-year-old neutered female English Springer Spaniel with EPI caused by end-stage chronic pancreatitis. This dog also had diabetes mellitus (DM) but was still losing weight in spite of good control of the DM. **(C)** EPI had not initially been suspected, but once it was diagnosed and treated with enzyme supplements, the dog returned to normal weight and coat condition within 6 months. (**A,** Courtesy Dr. William E. Hornbuckle, Cornell University, College of Veterinary Medicine, Ithaca, NY; **B** from Watson PJ: Exocrine pancreatic insufficiency as an end stage of pancreatitis in four dogs, *J Small Anim Pract* 44:306, 2003.)

reported in other breeds. A large study of EPI in Britain reported that young Chow Chows were overrepresented (Batchelor et al., 2007a). The pathogenesis was unknown, but the juvenile onset suggested PAA or perhaps a congenital defect in this breed.

Histologic studies in German Shepherd Dogs suggest that PAA is an autoimmune disease directed against the acini (Wiberg et al., 2000). Therefore the islets are spared, and dogs with PAA are not typically diabetic. However, affected dogs do not respond to immunosuppressive therapy. Most dogs develop the disease in young adulthood, but some German Shepherd Dogs remain subclinical for a prolonged period and present only late in life.

There has been one published study of EPI in young Greyhounds in the United States (Brenner et al., 2009). These dogs differ from the German Shepherd Dogs in that they also have endocrine tissue loss and DM, and some dogs are affected at a very young age (as young as 4 weeks). The cause of the Greyhound disease is unknown.

In contrast, many dogs with end-stage chronic pancreatitis also develop DM before or after EPI as a result of concurrent islet cell destruction (Watson, 2003; Watson et al., 2010). The situation is similar in cats with end-stage chronic pancreatitis. There is no breed relationship in cats, but dogs with EPI as a result of end-stage chronic pancreatitis tend to be middle-aged to older medium- or small-breed dogs, particularly Cavalier King Charles Spaniels, English Cocker Spaniels, and Collies (see Fig. 37.7). Interestingly, although Boxers in Britain were reported to have a high prevalence of chronic pancreatitis in one study, they rarely develop EPI and have also been reported to be significantly underrepresented among dogs with DM. This suggests that, in this breed, their chronic pancreatitis does not progress to end-stage disease. Underrepresented breeds in a large study of EPI were Golden

FIG 37.9
Middle-aged Persian cat with end-stage chronic pancreatitis and exocrine pancreatic insufficiency. Note matting of the coat with feces and poor body condition.

Retrievers, Labrador Retrievers, Rottweilers, and Weimaraners (Batchelor et al., 2007a). Finding compatible clinical signs in these breeds should first trigger a search for other possible causes, such as chronic infection or inflammatory bowel disease.

Cats with EPI are typically middle aged, with a median age of 7.7 years reported in the largest published study (range 3 months to 18.8 years) (Xenoulis et al., 2016). Domestic short-haired cats are most commonly affected, but it has also been reported in a variety of pedigree cats.

Other causes of EPI in dogs and cats are pancreatic tumors, hyperacidity of the duodenum inactivating lipase, and isolated enzyme deficiency, particularly lipase. These are all rare causes. Patients with pancreatic tumors usually present for other reasons, but tumors can result in EPI caused by a combination of compression of pancreatic ducts by the mass, destruction of acinar tissue, and associated pancreatitis.

Early studies suggested that up to 70% of dogs with EPI have concurrent small intestinal bacterial overgrowth (SIBO). Although SIBO as a definition has been replaced now with the term *antibiotic-responsive enteropathy*, the concept of a small intestinal dysbiosis due to unabsorbed nutrients in EPI remains. This may contribute to clinical signs and should be considered when treating an affected dog. Bacteria deconjugate bile salts, thus decreasing fat emulsification and therefore fat digestion. Bacteria also break down the undigested fat to hydroxy fatty acids. These and deconjugated bile salts irritate the colonic mucosa and may cause large intestinal diarrhea by stimulating secretion. Dogs with EPI therefore tend to present with signs of both small and large bowel diarrhea.

A high proportion of dogs, particularly those with low body condition scores, also have reduced duodenal enzyme activity, which may be caused by the effects of malnutrition on the gut and possibly the loss of the trophic influence of pancreatic secretions. Cobalamin deficiency is common in dogs and cats with EPI and seems to be a negative prognostic indicator in dogs if untreated (Batchelor et al., 2007b). Cobalamin is absorbed from the distal ileum via a carrier-mediated process that requires it to bind to IF. The latter is produced entirely by the pancreas in cats and mainly by the pancreas in dogs, although the canine stomach can also produce a small amount. Therefore most cats with EPI are expected to be vitamin B_{12}–deficient, whereas most but not all of dogs with EPI have hypocobalaminemia. In one large study of dogs with EPI, 82% of dogs had low serum cobalamin concentrations (Batchelor et al., 2007b). In the largest study of EPI in cats, 77% of cases had serum cobalamin below the reference range, and serum feline TLI concentrations were significantly lower in the cats with low cobalamin, suggesting more severe and chronic disease than in the cats with normal concentrations (Xenoulis et al., 2016). In cats with end-stage pancreatitis, the hypocobalaminemia is compounded by the high prevalence of concurrent inflammatory bowel disease, which often decreases the ileal absorption of vitamin B_{12}. Cobalamin deficiency causes villous atrophy and reduced gastrointestinal function, weight loss, and diarrhea in cats; therefore it is important not only to document hypocobalaminemia but also to treat it as discussed in the treatment section below.

Clinical Features

Most dogs and cats with EPI present because of chronic diarrhea and emaciation in conjunction with a ravenous appetite (see Fig. 37.8). The diarrhea tends to be fatty (steatorrhea) because of prominent fat maldigestion but is variable from day to day and among individuals. Sometimes diarrhea is not a prominent feature because digestion is interrupted so early in the process that the osmotic effect of molecules is relatively small. Affected dogs and cats also often have chronic seborrheic skin disease resulting from deficiency of essential fatty acids and cachexia, and some patients present to a dermatology clinic for this reason. If EPI is caused by chronic pancreatitis, the diagnosis may be complicated by concurrent ongoing pancreatitis that may cause intermittent anorexia and vomiting. Animals with end-stage chronic pancreatitis may also develop DM before or months to years after the development of EPI.

Concurrent diseases are common in dogs with EPI, related or unrelated to the pancreatic deficiency. In one study in dogs, concurrent gastrointestinal, skeletal, and skin conditions were common (Batchelor et al., 2007b). Cats with pancreatitis often have concurrent cholangitis and/or inflammatory bowel disease and some also have hepatic lipidosis; it is often difficult to differentiate the clinical signs of these conditions because they are so similar.

Diagnosis

ROUTINE CLINICAL PATHOLOGY

CBC and serum biochemistry profile results are often normal in dogs and cats with EPI. In very cachectic animals there may be subtle nonspecific changes consistent with malnutrition, negative nitrogen balance, and breakdown of body muscle, such as low albumin and globulin concentrations, mildly increased liver enzyme levels, low cholesterol and triglyceride concentrations, and lymphopenia.

Finding marked hypoproteinemia or more severe changes on the CBC and biochemistry profiles in an animal with EPI should trigger a search for another concurrent disease. Cats and dogs with end-stage pancreatitis may present with more severe secondary clinicopathologic changes (see earlier). A high percentage of these patients with end-stage pancreatitis (up to 50%) also have concurrent DM, so they have clinicopathologic changes typical of DM (see Chapter 49).

PANCREATIC ENZYMES

The diagnosis of EPI in dogs and cats relies on demonstrating reduced pancreatic enzyme output. The most sensitive and specific way of doing this is by measuring reduced circulating enzyme activity.

Measurement of decreased TLI in the blood has a high sensitivity and specificity for the diagnosis of EPI in dogs and cats, and is currently the single test of choice for diagnosis in small animals. It is important to measure it on a fasting sample because the release of pancreatic enzymes associated with feeding can raise the activity in the serum. It is not necessary to stop exogenous pancreatic enzyme supplementation before measuring TLI, because exogenous enzymes should not be absorbed from the gut into the circulation; even if they are, the test is an immunoassay that does not cross-react with the trypsin or trypsinogen of other species in the supplement. However, there are some problems in interpreting the results, as shown in Box 37.3.

Fecal tests for EPI are rarely used because of their low sensitivity and specificity compared with serum tests. Measurement of fecal elastase may have some usefulness in dogs with EPI as a result of chronic pancreatitis or duct blockage, in which TLI results may be misleading. More details are found in Chapter 34.

BOX 37.3

Interpretation of Trypsin-Like Immunoreactivity (TLI) Results in the Diagnosis of Canine Exocrine Pancreatic Insufficiency

- A low serum TLI level (<2.5 µg/L in dogs) in a dog with compatible clinical signs, particularly in a high-risk breed, is diagnostic of EPI.
  - A repeat blood sample to confirm diagnosis in a few weeks to months is recommended in cats and in older dogs that are not German Shepherd Dogs. Occasionally, a single TLI level may be low in a dog with pancreatitis as a result of a temporary reduction in enzyme production.
- A low serum TLI level (<2.5 µg/L in dogs) with no compatible clinical signs (i.e., no weight loss or diarrhea) is not diagnostic of EPI but should be repeated.
  - A dog with a persistently low TLI level but no steatorrhea or weight loss should be considered to have subclinical EPI and should not be treated but monitored for any evidence of clinical disease. A TLI stimulation test may provide more information about the status of the animal but is rarely performed (Wiberg et al., 1999). Subclinical EPI has been reported in a small number of German Shepherd Dogs with PAA (Wiberg et al., 1999) but has not yet been reported in cats. It is uncommon.
- A TLI level in the gray area (2.5–5.0 µg/L in dogs) is not diagnostic of EPI and should be repeated in a few weeks to months.
  - In some dogs (45% in one study: Wiberg et al., 1999), the TLI level will return to the normal range. In other dogs (about 10%), the TLI level will decrease to the level diagnostic of EPI and in some it may remain in the gray area.
  - In an older dog that is not a German Shepherd Dog, TLI levels may fluctuate, as described below, and samples should be repeated when there is no clinically acute flare-up.
- A normal TLI level in a German Shepherd Dog rules out EPI resulting from PAA, and a search should be made for another cause of the presenting clinical signs.
- A single normal or high TLI level in an older, non–German Shepherd Dog with suspicious clinical signs does not rule out EPI. TLI levels can transiently and intermittently increase into or above the normal range in dogs with EPI secondary to chronic end-stage pancreatitis if it is measured during a bout of inflammation. This is understandable because EPI reduces the TLI level but pancreatitis elevates it, so the two conditions occurring concurrently interfere with interpretation of the test result. This is likely to be true in cats as well, although it has not been well documented. Therefore in any animal with suspected EPI secondary to chronic pancreatitis, TLI level measurements should be repeated, preferably when the animal is showing no clinical signs of pancreatitis. Alternatively, a test for enzyme activity in the gut such as a fecal elastase test could be used in these animals. If clinical signs are suggestive of EPI in a dog or cat with chronic pancreatitis, a trial of enzyme supplementation is indicated even with a normal TLI.

EPI, Exocrine pancreatic insufficiency; *PAA,* pancreatic acinar atrophy.

OTHER DIAGNOSTIC TESTS

It is also advisable to measure the serum cobalamin concentration in animals with EPI because it is often decreased because of a deficiency of pancreatic IF, as noted earlier. If the serum vitamin B_{12} concentration is low, it should be supplemented either parenterally or enterally as detailed in the treatment section.

Serum folate concentrations are high in about one-third of dogs with EPI. This may indicate dysbiosis or SIBO, although the sensitivity and specificity of high serum folate concentration for the diagnosis of SIBO are poor. The definition and diagnosis of SIBO is problematic; if a newly diagnosed dog with EPI fails to respond to enzyme and cobalamin supplementation and other comorbidities have been ruled out, a trial antibiotic therapy for putative SIBO would be indicated. The importance of SIBO and the role of antibiotic treatment in cats with EPI are unknown. Occasionally, in dogs and cats with EPI, the serum folate concentration may be low; this can suggest dietary deficiency or concurrent inflammatory or infiltrative disease in the jejunum, or potentially metabolism by bacteria, which is also reported. Unlike cobalamin, there is no clear evidence that folate should be supplemented in dogs when its level is low.

Dogs with EPI have reduced gut immunity and are thus likely to be more susceptible to GI pathogens. A fecal culture would be indicated in any dog failing to respond to standard therapy, particularly if it had a history of being fed raw diet or raw pancreas.

Treatment

DRUGS

All dogs and cats with clinical EPI require enzyme supplementation for the rest of their lives. In most cases, this is provided as a powder or in the form of a capsule, which is opened and then sprinkled on the food. A recent study confirmed the efficacy of one enteric-coated canine enzyme preparation (Mas et al., 2012). Fresh raw pancreas, which can be frozen in aliquots, may be used as an alternative and can be effective, but there is also the potential for acquiring gastrointestinal infections (e.g., *Salmonella* and *Campylobacter* spp.). The dose of enzymes is initially as recommended by the manufacturer and then titrated to the individual. A large proportion of enzyme activity is lost in the acid pH of the stomach (up to 83% of lipase activity and 65% of trypsin activity). To overcome this, the dosage of enzymes given is increased or an H_2 blocker is administered concurrently to increase the gastric pH. Preincubating enzymes with the food is not indicated because they require the alkaline environment of the small intestine to work properly. Reports suggest that the dosage of enzyme replacement may be reduced over the long term between 6% and 58% but not stopped completely, perhaps because of resolution of the secondary bacterial overgrowth and the effects of chronic malnutrition and cobalamin deficiency on enterocytes and brush border enzymes.

As noted, dogs and cats with hypocobalaminemia require vitamin B_{12} supplementation. This may be by parenteral injections (0.02 mg/kg IM every 2–4 weeks until the serum concentration normalizes) or orally. Recent studies have demonstrated the efficacy of oral cobalamin even in dogs and cats with EPI and a lack of IF (Toresson et al., 2017; 2018). Cyanocobalamin tablets are given at a dose of 0.25 mg once a day for cats and dogs 1 to 10 kg; 0.5 mg once a day for dogs of body weight of >10 to 20 kg; and 1 mg once a day for dogs body weight >20 kg. Efficacy of treatment is monitored with regular measurement of serum cobalamin concentration.

Dogs and cats with EPI failing to respond to standard therapy should also have a fecal culture as previously described and any pathogens treated. Concurrent SIBO may also be suspected in these cases and may respond to courses of appropriate antibiotics (e.g., oxytetracycline, tylosin, metronidazole). It is advisable to administer antibiotics in affected dogs only as necessary if they fail to respond to enzyme and cobalamin therapy.

It is relatively common for German Shepherd Dogs with PAA to have concurrent inflammatory bowel disease, and this must also be addressed. Animals with EPI as a result of chronic pancreatitis may require insulin therapy for concurrent DM and other treatment for acute flare-ups, including analgesics (see earlier).

DIET

Disruption of fat digestion is the most important feature of EPI. A low-fat food has therefore been traditionally recommended, but it may not contain enough calories to feed a large-breed dog (e.g., German Shepherd Dog) effectively. Fat usually contributes a significant proportion of daily energy intake because it is more energy-dense than carbohydrates. In large-breed dogs with EPI and cachexia, weight gain may be difficult to achieve with a low-fat diet. There is no convincing evidence in the literature that long-term feeding of a low-fat diet improves outcome in dogs with PAA, although there is some evidence that it may result in faster resolution of clinical signs. However, high-fat diets, such as proprietary renal diets, should obviously be avoided. We therefore recommend that dogs with PAA be fed a normal to moderately fat-restricted, highly digestible diet, with reasonable calorie density. The diet should also be low in fiber because fiber impairs the activity of pancreatic enzymes, and soluble fiber may actually absorb pancreatic enzymes. Fiber may also reduce small intestinal absorption and activity of brush border enzymes. The proprietary veterinary diets marketed for gastrointestinal disease in dogs (e.g., Hill's i/d, Royal Canin Gastrointestinal diet, Eukanuba Intestinal or Dermatosis FP) fulfill these requirements and are recommended, at least for initial stabilization. In the long term, after the gut wall recovers, these dogs can be maintained on a normal fat level in most cases and can often return to their normal diet. In some individuals with PAA, extra calories can be added to the diet between meals in the form of medium-chain

triglycerides, such as coconut oil. They should not be used in cats and should not be given in overly high doses in dogs because of the risk of osmotic diarrhea. The recommended daily amount is ¼ to 4 teaspoons in dogs in divided doses. Medium-chain triglycerides also cannot carry fat-soluble vitamins, may cause vomiting in some dogs, and are contraindicated in dogs with liver disease because they may worsen encephalopathy.

In dogs with EPI as a result of chronic pancreatitis, dietary advice is slightly different. Many of these dogs benefit from long-term feeding of a low-fat diet, which seems to reduce postprandial pain and acute flare-ups of disease (Hill's i/d Low Fat, Royal Canin Digestive Low Fat, or Eukanuba Intestinal). Therefore proprietary low-fat diets would be preferred for these patients. The use of medium-chain triglycerides is not recommended for dogs with chronic pancreatitis, but fortunately these are often small-breed dogs with less cachexia than German Shepherd Dogs with PAA.

It is best to feed two or more meals a day, each with enzymes added. Owners often do not realize the importance of adding enzymes to all the meals, so this should be stressed and the dog should not be allowed to scavenge. This is often difficult because they are polyphagic, but scavenging, especially of fatty foods, causes recurrence of diarrhea and sets back recovery.

Cats with EPI are often best managed on a hypoallergenic intestinal type diet (e.g., Hill's d/d, Eukanuba Dermatosis LB, Royal Canin limited ingredient diets) because there is a high incidence of concurrent inflammatory bowel disease in cats. If they are also diabetic, most cases should still be fed an intestinal diet because proprietary feline diabetes diets (e.g., Hill's m/d, Royal Canin diabetic diet, Purina DM) are anecdotally associated with postprandial pain in cats with underlying chronic pancreatitis. The feline diabetic diets are most indicated in insulin resistant (type 2) diabetes in cats and not end-stage chronic pancreatitis.

Prognosis

The prognosis for EPI is good because the disease can be successfully treated in most dogs. However, a surprising number of dogs (19% in one study) are euthanized within the first year of treatment because of poor response to therapy (Batchelor et al., 2007b). The same study showed that the median survival time of dogs that responded to treatment was very good (>5 years). This underlines the importance of scheduling regular follow-up appointments, particularly in the initial stages of therapy, to evaluate progress and change management as necessary, and to address all concurrent morbidities as described in the previous treatment section. Prognosis for dogs and cats with EPI as a result of end-stage chronic pancreatitis is surprisingly good in most cases, even if it is complicated by concurrent DM, with survival times of several years in most cases.

EXOCRINE PANCREATIC NEOPLASIA

Neoplasms of the exocrine pancreas are uncommon in cats and dogs. Pancreatic adenocarcinomas have a very aggressive biologic behavior and have usually disseminated widely by the time of diagnosis. They are often subclinical until they have metastasized but can result in single or repeat bouts of pancreatitis and/or EPI. Some pancreatic tumors have been associated with paraneoplastic syndromes such as sterile panniculitis in dogs, alopecia with shiny skin in cats, and hypercalcemia. Chronic pancreatitis is a risk factor for the development of pancreatic adenocarcinomas in humans; this may also be true in dogs because the published reports of these tumors in dogs show a predominance of Cocker and Cavalier King Charles Spaniels.

Pancreatic adenomas are rare in small animals but have been reported in cats. Nodular hyperplasia of the exocrine pancreas is also common in older dogs and cats. This usually presents as multiple small masses, whereas pancreatic tumors are usually single, but histopathology or cytology is necessary to definitively differentiate hyperplasia from neoplasia. Dogs and cats with acute and chronic pancreatitis sometimes present with a large pancreatic mass as a result of fat necrosis and/or associated fibrosis, and it is important not to confuse these with neoplasia. Again, histopathology is required to differentiate these conditions. Ultrasonography-guided FNA cytology has been suggested as a useful means of differentiating inflammatory and neoplastic lesions of the pancreas (see Chapter 34).

Pancreatic tumors are not associated with any specific clinicopathologic changes and may cause no changes in enzyme levels at all. Alternatively, they can result in recurrent bouts of pancreatitis, with typical associated blood changes, and EPI can develop. In some cases biliary tract obstruction may occur, with associated jaundice and marked elevations in liver enzyme levels. Occasionally, pancreatic tumors have been reported to be associated with marked hyperlipasemia.

The prognosis in dogs and cats with pancreatic adenocarcinoma is very poor. The tumors are extremely aggressive, poorly sensitive to chemotherapy or radiotherapy, and usually have disseminated widely by the time of diagnosis.

Neuroendocrine tumors such as insulinomas and gastrinomas appear to be more common than pancreatic adenocarcinomas in dogs and tend to be seen in different breeds, predominantly large breeds (Watson et al., 2007). These are tumors of the endocrine pancreas that produce clinical signs related to the secretion of hormones and are therefore outside the scope of this chapter.

PANCREATIC ABSCESSES, CYSTS, AND PSEUDOCYSTS

Pancreatic abscesses, cysts, and pseudocysts are uncommonly reported in dogs and cats and are usually a complication or sequelae of pancreatitis. Pancreatic cysts may be congenital (e.g., as part of the polycystic renal disease in Persian cats) or

associated with cystic neoplasia (e.g., cystadenocarcinoma), but the most common are pseudocysts secondary to pancreatitis. A pancreatic pseudocyst is a collection of fluid containing pancreatic enzymes and debris in a nonepithelialized sac. Pseudocysts have been recognized in association with pancreatitis in cats and dogs, although they appear to be rare, and microscopic acinar cysts have been found frequently in feline chronic pancreatitis. Pseudocysts are not associated with any distinct clinicopathologic findings other than those associated with the underlying pancreatitis. Analysis of fluid obtained from a pseudocyst by FNA generally shows a modified transudate. Amylase and lipase levels can be measured in the pseudocyst fluid. In humans the enzyme levels are higher in pseudocysts associated with pancreatitis than in those associated with cystic carcinomas, but the value of this measurement in small animals is unknown. Cytology can differentiate a pseudocyst from a true abscess because a pseudocyst contains amorphous debris, some neutrophils and macrophages, and, rarely, small numbers of reactive fibroblasts, whereas an abscess contains many degenerative neutrophils and variable numbers of pancreatic acinar cells, which may appear very atypical as a result of inflammation.

A true pancreatic abscess is a collection of septic exudate that results from secondary infection of necrotic pancreatic tissue or a pancreatic pseudocyst. They are associated with a poor prognosis but fortunately are rare in dogs and cats.

Treatment of pancreatic pseudocysts can be surgical or medical. Medical treatment by ultrasonography-guided cyst aspiration has had a reasonable success rate. Pancreatic abscesses should be treated surgically with omentalization or open peritoneal drainage. Both carry a high mortality rate, but one study suggested that omentalization may be preferable (Johnson et al., 2006).

Drugs Used for Hepatobiliary and Pancreatic Disorders

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Analgesics		See Table 37.4
Antibacterials		
Amoxicillin, ampicillin	10-20 mg/kg PO, SC, IV, q8-12h, dogs and cats	Broad-spectrum bactericidal and therapeutic levels in liver and bile Biliary tract infections; control of gut bacteria in hepatic encephalopathy; control of systemic infection of gut origin Preferably used on basis of culture and sensitivity

Continued

Drugs Used for Hepatobiliary and Pancreatic Disorders—cont'd

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Cephalexin or cefazolin	10-20 mg/kg PO, SC, IV, q8-12h, dogs and cats	Very similar activity and spectrum to ampicillin—see ampicillin Helpful for patients with penicillin hypersensitivity; <10% show cross-reaction to cephalexin
Enrofloxacin (Baytril)	5 mg/kg SC, IV, PO, IM, q24h, dogs and cats	Bactericidal, particularly against gram-negative organisms; poor efficacy against anaerobes and streptococci; good tissue penetration Biliary tract infections, particularly with gram-negative organisms Also infectious complications of pancreatitis Preferably used on basis of culture and sensitivity and not as first line choice Should not be used in growing dogs (toxic to growing cartilage) Use only with care in cats—risk of retinal damage
Marbofloxacin (Zeniquin)	2 mg/kg SC, PO, IV, q24h, dogs and cats	Use as for enrofloxacin
Metronidazole	10 mg/kg PO or slowly IV, q12h, dogs and cats If significant hepatic functional impairment, reduce to 7.5 mg/kg q12h	Bactericidal particularly effective against anaerobes Often used in combination with ampicillin for biliary tract infections or to control gut bacteria in hepatic encephalopathy
Neomycin	20 mg/kg PO q6-8h or as retention enema, dogs and cats	Particularly used for acute hepatic encephalopathy Systemic absorption and oto- and nephrotoxicity can occur if there is concurrent GI ulceration, particularly in cats
Potentiated sulfonamides, (e.g., trimethoprim-sulfamethoxazole)	15 mg/kg of combined ingredients (trimethoprim + sulfonamide) PO q12h	Bactericidal, broad-spectrum, and probably drug of choice with infectious complications of pancreatitis Should not be used in liver disease if possible because hepatotoxic in susceptible individuals Should not be used in Doberman Pinschers because of reduced hepatic clearance Occasional adverse effects with concurrent immune-mediated diseases
Antiemetics		
Chlorpromazine	0.2-0.4 mg/kg SC q8h, dogs and cats	Indicated for vomiting associated with pancreatitis and some cases of hepatitis, but only if other antiemetics tried and ineffective because it is a phenothiazine sedative Effective antiemetic but also sedative, so ensure adequate hydration and avoid or use very low dose with encephalopathy and cardiovascular compromise
Metoclopramide	0.2-0.5 mg/kg PO, SC, q8h, or 1-2 mg/kg IV q24h as constant rate infusion	Indicated for vomiting associated with liver disease and some cases of pancreatitis; however, peripheral prokinetic effect may increase pain in pancreatitis Neurologic adverse effects occasionally seen Avoid in encephalopathy

Drugs Used for Hepatobiliary and Pancreatic Disorders—cont'd

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Maropitant (Cerenia)	Dogs > 8 wk—1 mg/kg SC q24h for up to 5 days, or 2 mg/kg orally q24h for up to 5 days Cats > 16 wk—1 mg/kg SC q24h for up to 5 days; not currently licensed for oral use in cats	Centrally acting antiemetic (NK1 receptor antagonist) Antiemetic of choice in canine pancreatitis, no obvious prokinetic effect Use with care in liver disease because metabolized in the liver, so do not use if significant liver dysfunction Not licensed for oral use cats
Ondansetron (Zofran)	Cats and dogs—0.5 mg/kg IV loading dose followed by 0.5 mg/kg/h infusion q6h or 0.5-1 mg/kg PO q12-24h	Refractory vomiting; may be contraindicated in pancreatitis because it has been reported to trigger vomiting in humans
Antiencephalopathic		
Lactulose	5-15 mL PO q8h (dogs) 0.25-1 mL PO q8h (cats) Can also be given as retention enema in acute encephalopathy	Hepatic encephalopathy with acquired or congenital portosystemic shunts Overdose produces diarrhea Titrate to effect (two or three soft bowel movements/day)
Antibiotics (e.g., ampicillin, metronidazole, neomycin)	See antibacterial section	
Propofol	Constant rate infusion; rate calculated by giving initial bolus to effect (usually ≈1 mg/kg) and timing duration of action; usually ≈0.1-0.2 mg/kg/min	Drug of choice for seizures because of liver disease, hepatic encephalopathy Should not be used in pancreatitis because it is a lipid vehicle
Phenobarbital	5-10 mg/kg PO q24h preoperatively followed by 3-5 mg/kg q12h postoperatively for 3 wk	Can be used prophylactically before and immediately after surgery to reduce risk of postoperative seizures after ligation of PSS, but anecdotal evidence of effectiveness
Levetiracetam (Keppra)	Dogs—20 mg/kg PO q8 for minimum of 24 hours before surgery for portosystemic shunt. Doses of 30 or 60 mg/kg IV have been reported in status epilepticus in dogs	Efficacy for preventing hepatic encephalopathy only reported with pretreatment before surgery for portosystemic shunts Drug appears most effective short term Efficacy of longer term oral treatment not demonstrated
Antiinflammatory-Antifibrotic		
(Note spironolactone also has putative antifibrotic effect—see diuretic section)		
Prednisolone (prednisone)	Antiinflammatory dose—0.5 mg/kg PO q24h Immunosuppressive dose—1-2 mg/kg PO q24h Taper at 0.5 mg/kg PO q24h or q48h	Antiinflammatory or immunosuppressive doses in lymphocytic cholangitis in cats; immunosuppressive doses in suspected autoimmune chronic hepatitis in dogs (see text), and in suspected immune-mediated pancreatitis in English Cocker Spaniels (see text) Avoid in suppurative cholangitis Avoid in portal hypertension or animals with ascites (potential GI ulceration) Avoid use of dexamethasone—very ulcerogenic

Drugs Used for Hepatobiliary and Pancreatic Disorders—cont'd

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Antioxidants		
S-adenosylmethionine (SAM-e) (Denosyl)	Dogs—20 mg/kg (or more) PO q24h Cats—20 mg/kg or 200-400 mg total daily	Indicated for any liver disease, but particularly hepatic lipidosis in cats and toxic hepatitis and diseases causing biliary stasis in dogs and cats Tablets must be given whole on empty stomach for effective absorption
Sylmarin (silymarin, silibin)	50-200 mg/kg PO q24h, for dogs	Antioxidant derived from milk thistle Likely safe, but efficacy unknown as very limited studies on which to base dose advice for dogs; studies were in toxic hepatitis
Vitamin E (tocopherol)	400 IU/day for medium-sized dogs (titrate accordingly for other sizes); 5-25 IU/kg PO daily, dogs and cats	Indications as for SAM-e but including any chronic hepatitis in dogs
Zinc (see copper-chelating agents) and ursodeoxycholic acid (see choleretic); also has antioxidant activities		
Antidotes		
N-acetylcysteine	Cats and dogs—140 mg/kg IV or PO as loading dose; then continued at 70 mg/kg q6h for total of seven treatments or for up to 5 days	Antidote for acetaminophen toxicity that binds toxic metabolite and increases glucuronidation process Can cause nausea and vomiting when given orally Foul taste makes oral dosing difficult without nasogastric tube
Cimetidine	Dogs—5-10 mg/kg IV, IM, PO, q6-8h Cats—2.5-5 mg/kg IV, IM, PO, q8-12h	Slows oxidative hepatic drug metabolism by binding to microsomal cytochrome P-450, so useful additional antidote for acetaminophen toxicity in dogs and cats
Antioxidants (e.g., S-adenosylmethionine) and vitamins E and C also supportive for oxidant toxins such as acetaminophen	See sections on antioxidants and vitamins	
Antiulcer Treatment		
Ranitidine (Zantac)	2 mg/kg PO or slowly IV q12h, dogs and cats	Acid secretory inhibitor of choice in liver disease May not be necessary if gastric pH is high Cimetidine should be avoided because of action on cytochrome P-450 enzymes, except as antidote (see earlier)
Sucralfate (Carafate)	Dogs—1 g/30 kg PO q6h Cats—250 mg/cat PO q8-12h	Gastric ulceration associated with liver or pancreatic disease
Copper-Chelating Agents		
Penicillamine	Dogs only—10-15 mg/kg PO q12h	Copper chelator of choice for copper storage disease; takes months to remove copper from liver Give on an empty stomach; vomiting common Immune-mediated, renal, and skin disease possible

Drugs Used for Hepatobiliary and Pancreatic Disorders—cont'd

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
2,3,2-tetramine tetrahydrochloride (2,3,2–T) and 2,2,2-tetramine tetrahydrochloride	Dogs only—10-15 mg/kg PO q12h	Copper chelator for copper storage disease in dogs More rapid effect than penicillamine so may be more useful in acute disease 2,3,2-Tetramine produces greater copper loss but not available as a drug Isolated case reports of their use in dogs but no extensive trials Toxicity data unclear except that prolonged use may lead to clinical signs resulting from low copper levels
Zinc acetate or sulfate	1-20 mg/kg/day of elemental zinc for dogs 7 mg/kg/day of elemental zinc for cats	Indicated in copper storage disease to reduce copper absorption Also antioxidant, antifibrotic, increases ammonia detoxification, so may be helpful in any chronic hepatitis or hepatic encephalopathy Monitor blood levels every 1-2 wk and keep below 200-300 µg/dL to avoid toxicity (iron deficiency and hemolysis) Main side effect is vomiting—give 1 hour before food to minimize this
Choleretic		
Ursodeoxycholic acid (Ursodiol)	4-15 mg/kg/day split into two doses 12 hours apart (dogs); 15 mg/kg PO once daily (cats)	Choleretic, also moderates bile acid pool to be less toxic Antiinflammatory, antioxidant Indicated for conditions associated with biliary stasis but without complete bile duct obstruction Contraindicated with obstruction in case of gallbladder rupture
Diuretic		
Spironolactone	2-4 mg/kg day PO in two or three divided doses, dogs and cats	Diuretic of choice in ascites of liver disease (see Chapter 39) Gradual onset of action over 2-3 days May be combined with furosemide for more marked diuresis
Furosemide	2 mg/kg PO q8-12h, dogs and cats	Use as additional diuretic if necessary in ascites of liver disease Always use concurrent spironolactone to avoid compensatory increase aldosterone action with further water retention and hypokalemia
Treatment Modalities for Coagulopathies		
Fresh-frozen plasma	Dogs and cats—starting dose of 10 mL/kg; dose of plasma titrated based on results of OSPT and APTT	Replenish depleted clotting factors in severe acute or chronic liver disease, particularly if prolonged OSPT and/or APTT and no response to vitamin K treatment alone
Vitamin K_1 (phytomenadione) (Konakion)	0.5-2 mg/kg, SC or IM, 12 hours before biopsy and then q12h for 3 days, mainly in cats	Treatment of coagulopathy associated with liver disease, particularly if concurrent biliary stasis and/or gut disease reducing vitamin K absorption Treatment of coagulopathy before liver biopsy, particularly in cats. No evidence of efficacy in dogs

Drugs Used for Hepatobiliary and Pancreatic Disorders—cont'd

DRUG NAME (TRADE NAME)	DOSAGE	INDICATIONS AND COMMENTS
Vitamins		
Vitamin B_{12} (cyanocobalamin)	Dogs and cats—0.02 mg/kg IM, SC every 2-4 wk until serum concentration normalizes or oral doing cyanocobalamin tablets: 0.25 mg once a day cats and dogs 1-10 kg; 0.5 mg once a day dogs >10-20; 1 mg once a day dogs body weight >20 kg.	Treatment of vitamin B_{12} deficiency, particularly associated with EPI and lack of pancreatic intrinsic factor
Vitamin K_1 (phytomenadione)	See treatment of coagulopathy section	
Vitamin E	See antioxidant section	
Vitamin C (ascorbic acid)	Cats and dogs oxidant toxins—30-40 mg/kg SC q6h for seven treatments	Indicated only as supportive treatment for oxidant toxins affecting the liver (e.g., acetaminophen) Not indicated in other cases of hepatitis or copper storage disease because increases absorption and hepatic buildup of metals

APPT, Activated partial thromboplastin time; *EPI,* exocrine pancreatic insufficiency; *GI,* gastrointestinal; *IM,* intramuscular; *IV,* intravenous; *NK1,* neurokinin 1; *OSPT,* one-stage prothrombin time; *PO,* by mouth; *PSS,* portosystemic shunt; *SC,* subcutaneous.

PART FIVE ▪ Urinary Tract Disorders

Stephen P. DiBartola and Jodi L. Westropp

CHAPTER 38

Clinical Manifestations of Urinary Disorders

Azotemia refers to an increased concentration of nonprotein nitrogenous compounds in blood, usually urea and creatinine. Prerenal azotemia is a consequence of decreased renal perfusion (e.g., severe dehydration, heart failure); postrenal azotemia results from interference with excretion of urine from the body (e.g., obstruction, uroabdomen). Primary renal azotemia is caused by parenchymal renal disease. The term *renal failure* refers to the clinical syndrome that occurs when the kidneys are no longer able to maintain their regulatory, excretory, and endocrine functions, resulting in retention of nitrogenous solutes and derangements of fluid, electrolyte, and acid–base balance. Renal failure occurs when 75% of more of the nephron population is nonfunctional. Uremia refers to the constellation of clinical signs and biochemical abnormalities associated with a critical loss of functional nephrons. It includes the extrarenal manifestations of renal failure (e.g., uremic gastroenteritis, hyperparathyroidism). The term *renal disease* refers to the presence of morphologic or functional lesions in one or both kidneys, regardless of extent.

CLINICAL APPROACH

Try to answer the following questions:

1. Is renal disease present?
2. Is the disease glomerular, tubular, interstitial, or a combination?
3. What is the extent of the renal disease?
4. Is the disease acute or chronic? Reversible or irreversible? Progressive or nonprogressive?
5. What is the current status of the patient's renal function?
6. Can the disease be treated?
7. Which nonurinary complicating factors are present and require treatment (e.g., infection, electrolyte and acid–base disturbances, hypertension, dehydration, obstruction)?
8. What is the prognosis?

The diagnosis of renal disease begins with a careful evaluation of the history and physical examination findings.

History

Take a complete history, including signalment (age, breed, sex, presenting complaint, husbandry, and review of body systems). The history of the presenting complaint should include information about onset (acute or gradual), progression (improving, unchanging, or worsening), and response to previous therapy. Information about husbandry includes the animal's immediate environment (indoor or outdoor), use (pet, breeding, show, or working animal), geographic origin and travel history, exposure to other animals, vaccination status, diet, and information about previous trauma, illness, or surgery.

Questions relating to the urinary tract include those about changes in water intake and the frequency and volume of urination. Ask about pollakiuria, dysuria, or hematuria. Be careful to distinguish dysuria and pollakiuria from polyuria and to differentiate polyuria from urinary incontinence. The distinction between pollakiuria and polyuria is important because polyuria may be a sign of upper urinary tract disease, whereas pollakiuria and dysuria usually are indicative of lower urinary tract disease. Nocturia may be an early sign of polyuria but can also occur as a result of dysuria. Polydipsia usually is more readily detected by owners than is polyuria. Describe amounts in quantitative terms familiar to the owner, such as cups (≈250 mL/cup) or quarts (≈1 L/quart). Question the owner about exposure of the animal to potential nephrotoxins such as ethylene glycol in antifreeze, chicken jerky treats (dogs), Easter lilies (cats only), aminoglycosides, and nonsteroidal antiinflammatory drugs.

Physical Examination

Perform a complete physical examination, including fundic and rectal examinations. Pay close attention to hydration status and to the presence of ascites or subcutaneous edema

that may accompany nephrotic syndrome (e.g., glomerular disease). Examine the oral cavity for ulcers, tongue tip necrosis, and pallor of the mucous membranes. Note retinal edema, detachment, hemorrhage, or vascular tortuosity during the fundic examination. Occasionally severe hypertension secondary to renal disease will result in acute onset of blindness caused by retinal detachment. Young growing animals with renal failure may develop marked fibrous osteodystrophy characterized by enlargement and deformity of the maxilla and mandible (so-called rubber jaw), but this is rare in older dogs with renal failure.

Both kidneys can be palpated in most cats and the left kidney in some dogs. Kidneys should be evaluated for size, shape, consistency, pain, and location. Unless empty, the bladder can be palpated in most dogs and cats. The bladder should be evaluated for degree of distention, pain, wall thickness, and presence of intramural (e.g., tumors) or intraluminal (e.g., calculi, clots) masses. In the absence of obstruction, a distended bladder in a dehydrated animal suggests abnormal renal function or the administration of drugs that impair urinary concentrating ability (e.g., glucocorticoids, diuretics). Evaluate the prostate gland and pelvic urethra during the rectal examination. Exteriorize and examine the penis, and palpate the testes. Perform a vaginal examination to evaluate for abnormal discharge, masses, and appearance of the urethral orifice.

PRESENTING PROBLEMS

HEMATURIA

Hematuria can be caused by any disease that compromises the urogenital mucosa and results in bleeding. Thus it may be associated with diseases of the urinary tract (i.e., kidneys, ureters, bladder, urethra) or genital tract (i.e., prostate, penis, prepuce, uterus, vagina, vestibule). Hematuria may be classified as macroscopic (i.e., visible to the naked eye) or microscopic (i.e., identified only as increased numbers of red blood cells in the urine sediment). Macroscopic hematuria results in a red, pink, or brown coloration of the urine. Centrifugation of the urine sample readily allows differentiation of pigmenturia (e.g., hemoglobinuria, myoglobinuria) from hematuria (i.e., a pellet of red cells with clear yellow supernatant; Fig. 38.1). Disorders associated with hematuria include urinary tract infection, neoplasia, urolithiasis, trauma, coagulopathies, vascular anomalies (e.g., renal telangiectasia in Welsh Corgi dogs), and idiopathic renal hematuria (Box 38.1). Cystocentesis is commonly associated with microscopic hematuria, and a voided sample should always be obtained to evaluate for this possibility when abnormal numbers of red blood cells (e.g., >three/high-power field) are observed in the sediment of a urine sample collected by cystocentesis. Occasionally microscopic hematuria caused by cystocentesis is interpreted as evidence of ongoing feline

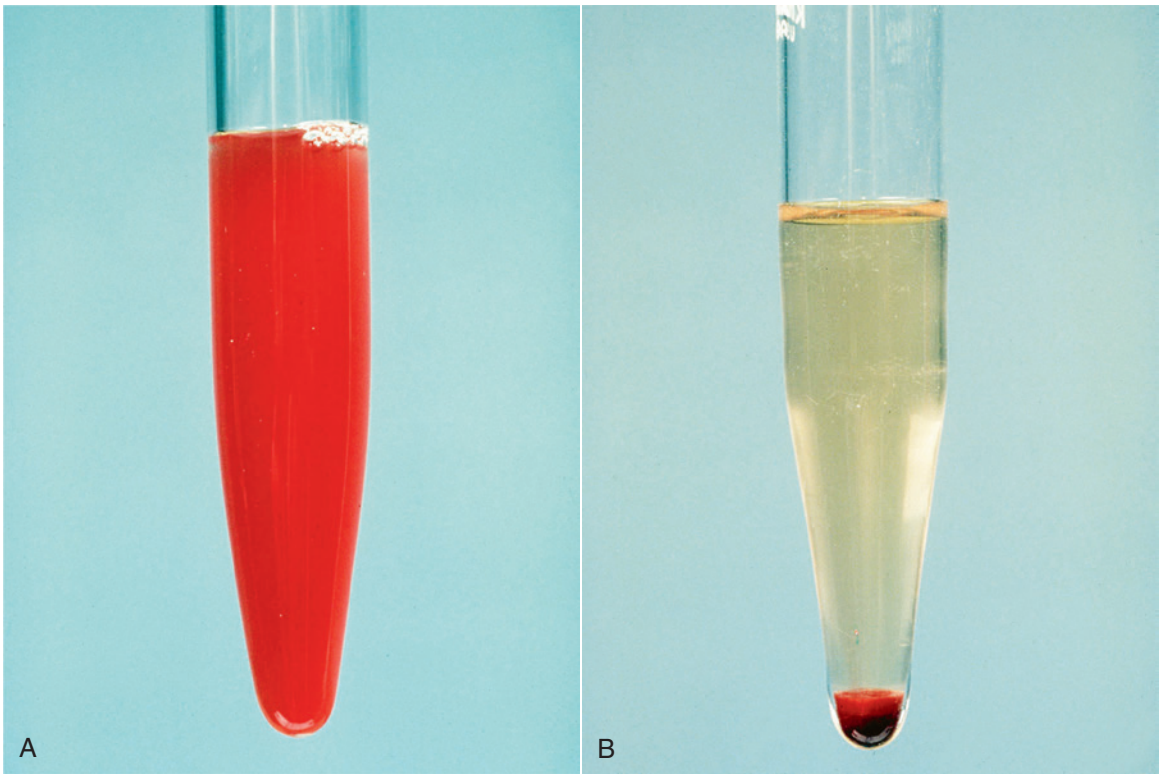

FIG 38.1
(A) Unspun urine sample from a dog with hematuria. Without centrifugation, one cannot differentiate pigmenturia (e.g., hemoglobinuria) from hematuria (i.e., red cells). **(B)** Red blood cell pellet after centrifugation of a urine sample from a dog with hematuria.

BOX 38.1

Causes of Hematuria

Urinary Tract Origin (Kidneys, Ureters, Bladder, Urethra)

- Trauma
  - Traumatic collection (e.g., catheterization, cystocentesis)
  - Renal biopsy
  - Blunt trauma (e.g., automobile accident)
- Urolithiasis
- Neoplasia
- Inflammatory disease
  - Urinary tract infection
  - Feline idiopathic cystitis, urethritis (idiopathic feline lower urinary tract disease)
  - Chemically induced inflammation (e.g., cyclophosphamide-induced cystitis)
  - Polypoid cystitis
  - Proliferative urethritis (granulomatous urethritis)
- Parasites
  - Dioctophyma renale
  - Capillaria plica
- Coagulopathy
  - Intoxication by vitamin K antagonists
  - Coagulation factor deficiencies
  - Disseminated intravascular coagulation
  - Thrombocytopenia
- Renal infarction
- Renal pelvic hematoma
- Vascular malformation
  - Renal telangiectasia (Welsh Corgi)
  - Idiopathic renal hematuria
- Polycystic kidney disease

Genital Tract Contamination (E.G., Prostate, Prepuce, Vagina)

- Estrus
- Subinvolution of placental sites
- Inflammatory, neoplastic, and traumatic lesions of the genital tract

idiopathic cystitis in a cat with a previous history of the disease. This erroneous conclusion (and ongoing diagnostic evaluation) can sometimes be avoided by simply comparing the results of a voided urine sample with those observed in the sample obtained by cystocentesis.

During the history, it is crucial to determine whether dysuria (see later) is associated with hematuria. If present, signs of dysuria (e.g., pollakiuria, stranguria) suggest involvement of the lower urinary tract (i.e., bladder, urethra), whereas painless hematuria suggests upper urinary tract involvement. If hematuria is present, ask the owner about its timing. Blood at the beginning of urination may indicate a disease process in the urethra or genital tract. Blood at the end of urination or throughout urination may signify a problem in the bladder or upper urinary tract (kidneys or ureters). Hematuria is more common in dogs with urinary bladder neoplasia than in dogs with renal neoplasia. Often, dogs with renal neoplasia present with nonspecific signs, such as weight loss and poor appetite. When hematuria is associated with coagulopathies, other signs such as epistaxis, melena, bruising, and prolonged bleeding from venipuncture sites are also likely to be present.

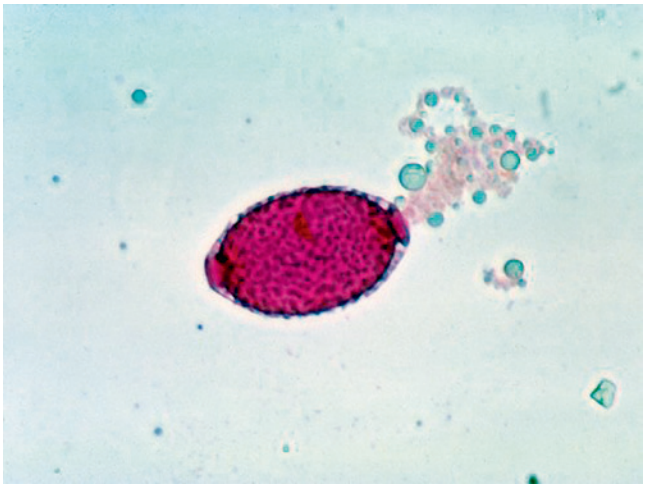

FIG 38.2
Capillaria plica ovum in the urine sediment of a cat (100×).

The first step in the diagnostic evaluation of an animal with hematuria is assessment of a properly collected urine sample by urinalysis and urine culture to rule out bacterial urinary tract infection. The presence of increased numbers of white blood cells in the urine sediment (i.e., pyuria) indicates an inflammatory process and increases the suspicion of bacterial urinary tract infection. Identification of hematuria in a voided urine sample but not in a sample collected by cystocentesis suggests the urethra or genital tract as the source of bleeding. Abnormal transitional epithelial cells observed in urine sediment stained with Wright-Giemsa increases the suspicion of transitional cell carcinoma. However, this diagnosis should always be based on histopathologic findings in tissue biopsy samples collected during urethrocystoscopy or by a catheter-assisted (aspiration) approach because irritation and inflammation can result in dysplastic changes in epithelial cells observed on routine cytologic evaluation. Anemia associated with blood loss is uncommon in patients with hematuria and is mainly seen in dogs with benign renal hematuria (see later). Hematuria is not a common presentation for patients with coagulopathies, but if the cause of hematuria remains obscure after routine clinical diagnostic evaluation, which includes urinalysis, complete blood count, serum biochemical profile, and diagnostic imaging studies, coagulation tests and a platelet count may be indicated. Ova are observed in the urine sediment of animals with urinary tract parasites (Fig. 38.2). Plain abdominal radiographs are useful to identify radiopaque calculi (e.g., struvite, oxalate). A double-contrast cystogram, positive contrast urethrogram, or excretory urogram may be necessary to identify radiolucent calculi and investigate

other potential causes of hematuria (e.g., blood clots in the kidney or bladder). Abdominal ultrasonography is useful to identify soft tissue lesions such as neoplasia and polypoid cystitis.

Idiopathic Renal Hematuria

The urinary bleeding in this disorder originates in the kidney, but its cause is obscure. Renal hemorrhage usually is unilateral, but occasionally it may be bilateral. Large-breed dogs (e.g., Weimaraners, Boxers, Labrador Retrievers) of both sexes often are affected. Most are younger than 5 years at presentation, and approximately one-third of reported cases have been in immature dogs (<1 year).

The owner typically reports severe macroscopic hematuria that does not appear to cause any discomfort to the dog (i.e., no dysuria), and hematuria typically occurs throughout urination. Blood clots also may be observed in the urine. Bleeding may occur for days or weeks and then disappear for months, only to return at a later time. There is no history of trauma, and no abnormalities are detected on physical examination.

The regenerative anemia may be acute (e.g., macrocytosis, polychromasia, reticulocytosis) or chronic, with evidence of iron deficiency (e.g., microcytosis, hypochromasia). Serum creatinine and blood urea nitrogen (BUN) concentrations are normal, urine specific gravity (USG) shows moderately concentrated urine, coagulation tests and platelet count are normal, and urine culture is negative. Hydronephrosis and hydroureter, caused by obstructive blood clots, may be observed on the affected side by diagnostic imaging studies. Filling defects caused by blood clots also sometimes can be observed in the bladder. In female dogs, cystoscopy allows identification of the affected side by observation of normal urine flowing from one ureteral opening as compared with blood coming from the contralateral ureteral opening (Fig. 38.3 and Video 38.1).

Nephrectomy should be considered if bleeding is documented to be unilateral and has been intractable, with the development of severe anemia. Nephrectomy resolves hematuria in dogs with unilateral renal hemorrhage, but some dogs have been reported to develop hemorrhage from the contralateral kidney at some point after nephrectomy. Thus the decision to perform nephrectomy should be weighed carefully. Some affected dogs have intermittent periods of hemorrhage interspersed with long asymptomatic time periods. If there is no anemia or anemia is mild, then observation of the patient over time with monitoring of hematocrit may be preferable to nephrectomy. Recently, endoscopically guided sclerotherapy using solutions containing povidone iodine, silver nitrate, or both has been used as a renal-sparing technique to successfully control renal hemorrhage in dogs with idiopathic renal hematuria.

DYSURIA

Dysuria refers to painful or difficult urination and typically is manifested as pollakiuria (excessively frequent passage of small volumes of urine) and stranguria (straining to urinate because of spasm of the bladder and urethra). It usually is associated with disorders of the lower urinary tract, especially cystitis, urethritis, cystic calculi, bladder neoplasia, and obstruction of the urethra by calculi or neoplasia (Box 38.2). Dysuria can also be associated with neoplastic and inflammatory diseases of the genital tract (e.g., prostate gland, vagina). Frequent licking at the genital area often is observed in dogs and cats with dysuric disorders. Dogs with perineal hernias will sometimes present for dysuria.

During history taking, it is important to clarify what the owner actually is observing. Many owners cannot readily differentiate a dog or cat that is straining to urinate from one that is straining to defecate. Thus owners sometimes believe that their animal is constipated when in fact it is straining to urinate. Also, sometimes owners report that their dog is

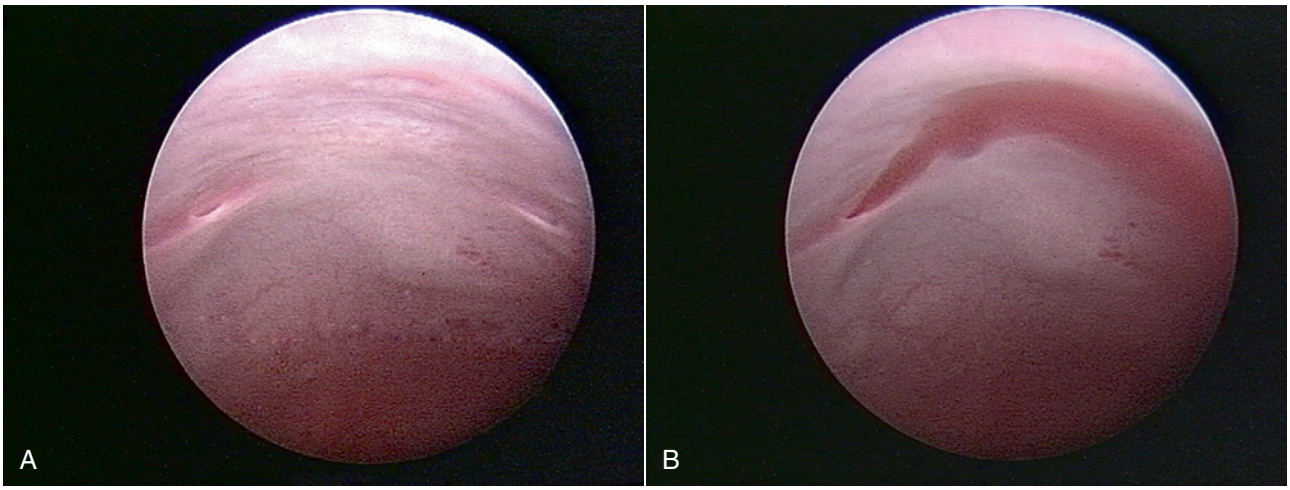

FIG 38.3
(A) Normal ureteral openings in the trigone region of the bladder of a normal dog on cystoscopy. **(B)** Blood coming from a ureteral opening in the trigone region of the bladder in a dog with idiopathic hematuria.

BOX 38.2

Causes of Dysuria

- Inflammatory disease
  - Urinary tract infection
  - Feline idiopathic cystitis, urethritis (idiopathic feline lower urinary tract disease)
  - Chemically induced inflammation (e.g., cyclophosphamide-induced cystitis)
  - Polypoid cystitis
  - Proliferative urethritis (granulomatous urethritis)
- Urolithiasis
  - Cystic calculi
  - Urethral calculi
- Neoplasia
  - Transitional cell carcinoma of bladder or urethra
  - Prostatic neoplasia
  - Vaginal neoplasia
- Trauma
  - Bladder or urethral rupture
  - Urethral stricture (previous trauma or surgery)
- Neurogenic disorder
  - Reflex dyssynergia
- Other
  - Perineal hernia

incontinent because they find urine in inappropriate locations in the house. Although incontinent dogs often leave wet spots where they have been lying down, dogs with polyuria and polydipsia (PU-PD) urinate voluntarily but in inappropriate locations and at inappropriate times because they are not allowed outside frequently enough to accommodate their large volume of urine production. A careful history is therefore very important for understanding the problem.

Dogs and cats with dysuria assume the normal posture for urination but spend an inordinate amount of time attempting to urinate, often passing only small volumes of urine. They shift position, get up, move to another location, and posture repeatedly. Even with an empty bladder, mucosal irritation results in repeated unsuccessful attempts to urinate. Cats with urethral obstruction sometimes adopt a distressed yowling vocalization during attempts to urinate. It is important in this clinical situation to evaluate the animal for the presence of urethral obstruction. Complete urethral obstruction is readily identified during abdominal palpation by the presence of a large, turgid, painful bladder, whereas a small, painful bladder suggests cystitis without obstruction. Caution should be taken to avoid excessive pressure when palpating a bladder that is suspected to be obstructed.

Observing the animal urinate can be valuable for identifying the problem as dysuria. Attempting to pass a urinary catheter allows the clinician to determine quickly whether the urethra is patent or obstructed. Masses and calculi are most easily detected by palpation when the bladder is empty or only partially full. The presence of many small cystic calculi generates a crepitant sensation on palpation, whereas a single large calculus can be difficult to differentiate from a tumor or large blood clot. Rectal palpation should be performed in all dysuric patients, both male and female. Not only is rectal examination important to evaluate the prostate gland in males, but it allows the identification of urethral tumors and proliferative urethritis in female dogs. The perineum should be inspected for perineal hernia, and the penis should be extruded completely to look for lesions such as transmissible venereal tumor in male dogs.

POLYURIA AND POLYDIPSIA

Normal water intake in dogs may be as high as 60 to 90 mL/kg/day; maximal normal water intake in cats is 45 mL/kg/day. Polyuria and polydipsia typically are reported simultaneously and, with the exception of dogs with psychogenic polydipsia (PPD; see later), polydipsia usually occurs in response to polyuria. The presence of polydipsia can be documented by having the owner measure the animal's water intake at home, but this is more practical in dogs than in cats. Normal water intake is more variable than urine output because of variation in several factors, including ambient temperature and respiratory evaporative loss of water, exercise level, water content of food, fecal water content, age, and physiologic state (e.g., pregnancy, lactation). Normal urine production in dogs and cats is 26 to 44 mL/kg/day.

Polyuria and polydipsia can be caused by several disorders, notably diseases of the kidney and endocrine system. In many cases, the pathophysiology of PU-PD is multifactorial (Table 38.1). The history should always include information about drugs that the animal may have been given that could contribute to PU-PD, especially corticosteroids (administered by any route, including topically) and diuretics. Pollakiuria must be differentiated from polyuria because some owners erroneously conclude that because an animal is urinating more frequently, it must be producing more urine. Animals with polyuria may have increased frequency of urination, but each urination consists of a large volume and there is no evidence of stranguria. Nocturia often accompanies polyuria and sometimes is the first sign detected by the dog's owner.

Routine urinalysis, including determination of the USG, is the logical starting point for the diagnostic evaluation of an animal with PU-PD. The USG of dogs can vary widely throughout the day, but the highest USG (usually >1.035–1.040) typically is found in the morning, before the dog eats and drinks. USG varies less throughout the day in cats, and cats typically have moderately concentrated urine when eating dry food (usually ≥1.035). USG values of 1.050 to 1.076 and 1.047 to 1.087 occur in normal dogs and cats, respectively, deprived of water until signs of dehydration have developed. Generally, a USG of 1.040 or higher is expected in sick dogs or cats that are dehydrated. Finding a relatively high USG (>1.025) would cast doubt about the accuracy of the history in an animal presented for evaluation of PU-PD. If the USG at presentation is in the hyposthenuric (<1.007) or isosthenuric (1.007–1.014) range, a minimum database of a complete blood count, serum biochemistry

profile, and serum thyroxine concentration (in cats) should be obtained. Often this information will shed light on the cause of the PU-PD. USG tends to be lowest (i.e., 1.001–1.007) in conditions such as PPD, central diabetes insipidus, and nephrogenic diabetes insipidus. If the USG is higher than 1.014 and the animal seems otherwise healthy, it is reasonable to have the owner quantify water consumption at home before proceeding with the diagnostic evaluation. The water deprivation test (see Chapter 42) should be considered in animals that have normal blood test results after the initial diagnostic evaluation of PU-PD. If the USG is in the isosthenuric range and the cause of the PU-PD is not apparent, abdominal ultrasonography to evaluate renal architecture is indicated. Measurement of serum symmetric dimethylarginine (SDMA) concentration or estimation of glomerular filtration rate by endogenous creatinine clearance or iohexol clearance also is valuable to eliminate nonazotemic chronic renal disease (i.e., <75% loss of renal mass) as a contributing factor (see Chapter 42).

Psychogenic Polydipsia

PPD is an uncommon disorder that usually occurs in large-breed dogs (e.g., German Shepherds, Doberman Pinschers). It is rare to nonexistent in cats. Owners of affected dogs may report that the dog has a nervous disposition or experienced some stressful event before the onset of polydipsia. In some cases, the owner has unknowingly reinforced the water drinking behavior in some way. Some dogs with PPD dramatically decrease their water consumption during hospitalization, which facilitates diagnosis. Dogs with PPD typically

have extremely hyposthenuric urine (i.e., USG = 1.001–1.003). Although not consistently present, mild hyponatremia in a dog with marked hyposthenuria is suggestive of PPD. Dogs with PPD of recent onset often have a normal response to abrupt water deprivation testing, but those with long-standing PPD develop renal medullary washout of solute because the release of vasopressin from the pituitary gland is suppressed by plasma hypo-osmolality. Vasopressin normally facilitates urea reabsorption in the inner medulla of the kidney and helps maintain medullary hypertonicity. Gradual water deprivation testing allows time for restoration of the renal medullary solute gradient and is the preferred diagnostic test in dogs with PPD. Treatment of PPD is accomplished by gradual water restriction into the normal range over several days.

RENOMEGALY

Renomegaly refers to enlargement of the kidney. It may be unilateral or bilateral, and bilateral enlargement may be symmetric or asymmetric. Renomegaly may be acute or chronic in onset. In most animals with renomegaly, onset is insidious. Acute renomegaly is uncommon and when it occurs (e.g., acute obstruction of a kidney by a nephrolith), the presentation is that of acute abdomen (i.e., abdominal pain, reluctance to move, vomiting). Chronic renomegaly typically is moderate or severe but occasionally can be mild. For example, mild enlargement may occur in some dogs with renal amyloidosis and in some cases of acute renal failure (e.g., leptospirosis) because of renal swelling. The renal capsule, however, limits the extent of acute swelling that can occur. Unilateral renal enlargement can occur because of compensatory hypertrophy in animals with a solitary kidney or with severe end-stage disease in the contralateral kidney.

Normally, feline kidneys are 3.5 to 4.5 cm in length and can be readily palpated in cooperative cats. The size of canine kidneys varies according to body size, and generally kidneys are more difficult to palpate in dogs than in cats. Occasionally the left kidney can be palpated in a cooperative dog. Renal length and volume in dogs is correlated with body weight. For example, dogs up to about 15 kg in weight are expected to have kidneys 3 to 5.5 cm in length, whereas dogs in the 30- to 45-kg range are expected to have kidneys 7 to 8 cm in length. A rule of thumb that has been used for many years is based on the ratio of the length of the kidney as observed on plain abdominal radiographs to the length of the second lumbar vertebra (L2). On plain abdominal radiographs, this ratio is 2.5-3.0-to-1 in cats and 2.5-3.5-to-1 in dogs.

Disorders that cause renomegaly include polycystic kidney disease, neoplasia, and obstruction. Renomegaly can occur in dogs and cats, but it is more common in cats. Polycystic kidney disease is inherited as an autosomal dominant trait in Bull Terriers and Persian cats (autosomal dominant polycystic kidney disease [ADPKD]). It is caused by a mutation in exon 29 of the polycystin-1 gene in Persian cats, and prevalence in the breed approaches 30%. Many young Persian cats with ADPKD are asymptomatic, and renomegaly is recognized as an incidental finding. The kidneys of cats with ADPKD become progressively enlarged and irregular over time as the cysts increase in number and size. Renal failure usually does not develop until 7 or 8 years of age. Currently, ultrasonography is the clinical test of choice for identifying ADPKD in affected cats. In one study, renal ultrasonography had a sensitivity of 75% when performed at 4 months of age and a sensitivity of 91% when performed at 9 months of age for the diagnosis of ADPKD. Primary and metastatic renal tumors can cause renomegaly, and lymphosarcoma often is responsible, especially in cats. Renal lymphoma is usually bilateral in cats and often is associated with the alimentary form of the disease. Occasionally renal involvement may be extensive enough to cause renal failure. The diagnosis of renal lymphosarcoma often can be made by cytologic evaluation of a fine-needle aspirate of the kidney that identifies a monomorphic population of immature lymphocytes. Renal obstruction by a nephrolith or ureterolith, or inadvertent ligation of a ureter during ovariohysterectomy, can result in hydronephrosis and renomegaly. Uncommonly, ureteral fibrosis, secondary to previous ureterolith removal or idiopathic in nature, can result in hydronephrosis. Blunt abdominal trauma can cause subcapsular hemorrhage and renomegaly, but the renal capsule usually limits the extent of enlargement. Bacterial infection can result in a renal abscess or pyonephrosis. The noneffusive form of feline infectious peritonitis often affects the kidneys, liver, mesenteric lymph nodes, central nervous system, and eyes. Renal involvement occurs in many affected cats, and they may have enlarged, irregular kidneys on abdominal palpation.

Perinephric Pseudocysts

Although not a renal disease, perinephric pseudocysts can easily be confused with renomegaly on routine abdominal palpation. Perinephric pseudocysts are fluid-filled fibrous sacs that surround the kidney but are not lined by epithelium—hence the term *pseudocyst.* They are idiopathic in origin but often occur in association with chronic kidney disease (CKD) in older (>10 years) cats of both sexes and any breed. Most cats with perinephric pseudocysts have at least mild CKD. Occasionally small kidneys and CKD are diagnosed before the development of perinephric pseudocysts. The presenting complaints may be related to underlying CKD (e.g., PU-PD, anorexia, and weight loss), but usually abdominal distention is the only abnormality detected by the owner. Perinephric pseudocysts may be unilateral or bilateral. Renal ultrasonography is the diagnostic test of choice and demonstrates an accumulation of anechoic fluid between the capsule and renal parenchyma of one or both kidneys (Fig. 38.4). Definitive treatment involves surgical resection of the pseudocyst capsule. The kidney should not be removed in cats with unilateral perinephric pseudocysts because progression of renal disease in the remnant kidney can be accelerated dramatically, and renal failure may worsen rapidly (Fig. 38.5). Recently, a laparoscopic approach has been used for fenestration or subtotal resection of perinephric pseudocyst capsules. Ultimately, the prognosis of

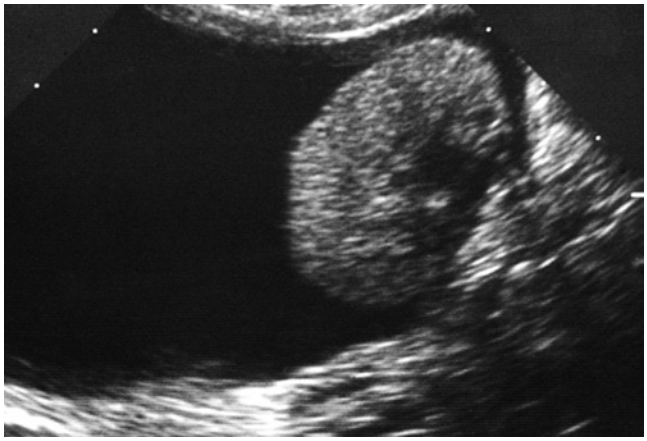

FIG 38.4
Ultrasonographic appearance of a perinephric pseudocyst in a cat. *Left,* Anechoic fluid within the cyst *(black area). Right,* The echogenic structure represents the kidney itself.

cats with perinephric pseudocysts is related primarily to the extent of underlying CKD at the time of diagnosis. Rarely, a perinephric pseudocyst can occur in conjunction with transitional cell carcinoma.

CHAPTER 39

Diagnostic Tests for the Urinary System

GLOMERULAR FUNCTION

Evaluation of glomerular function is an essential part of the diagnostic approach to patients with suspected renal disease because the glomerular filtration rate (GFR) is directly related to functional renal mass. Serum creatinine (SCr) and blood urea nitrogen (BUN) concentrations are commonly used screening tests; symmetric dimethylarginine (SDMA) and creatinine clearance are useful for patients with suspected renal disease who have normal BUN and SCr. Plasma clearance of radioisotopes and renal scintigraphy are advanced techniques that may be used to determine GFR and obtain information about individual kidney function but do not require urine collection. Iohexol clearance provides an estimate of the GFR without the need of urine samples, radioisotopes, or specialized equipment. Evaluation of urinary protein excretion allows for the assessment of the patient for glomerular disease (e.g., glomerulonephritis, glomerular amyloidosis).

BLOOD UREA NITROGEN

Urea is synthesized in the liver via the ornithine cycle from ammonia derived from amino acid catabolism. Amino acids used in the production of urea arise from the catabolism of exogenous (i.e., dietary) and endogenous proteins. Renal excretion of urea occurs by glomerular filtration, and BUN concentrations are inversely proportional to the GFR. Urea is subject to passive reabsorption in the tubules, which occurs to a greater extent at slower tubular flow rates during dehydration and volume depletion. Thus urea clearance is not a reliable estimate of the GFR and, in the face of volume depletion, decreased urea clearance may occur without a decrease in GFR.

The production and excretion of urea do not proceed at a constant rate. Urea production and excretion increase after a high-protein meal, and an 8- to 12-hour fast is recommended before measuring BUN concentrations to avoid the effect of feeding on urea production. Gastrointestinal bleeding can increase BUN concentrations because blood represents an endogenous protein load. Clinical conditions characterized by increased catabolism (e.g., starvation, infection, fever) also can increase BUN concentrations slightly. Some drugs may increase BUN concentrations by increasing tissue catabolism (e.g., glucocorticoids, azathioprine) or decreasing protein synthesis (e.g., tetracyclines), but these effects are usually minimal. Conversely, BUN concentrations can be decreased by low-protein diets, anabolic steroids, severe hepatic insufficiency, or portosystemic shunting. These nonrenal variables limit the usefulness of BUN as an indicator of the GFR. Normal BUN concentrations are 8 to 25 mg/dL in the dog and 15 to 35 mg/dL in the cat. Reagent test strips (Azostix, Bayer, Elkhart, Ind) can be used to estimate BUN levels in whole blood samples from dogs and cats, with relatively high sensitivity and specificity.

SERUM CREATININE

Creatinine is a nonenzymatic breakdown product of phosphocreatine in muscle; the daily production of creatinine in the body is determined largely by the muscle mass of the individual. Young animals have lower serum concentrations, whereas males and well-muscled individuals have higher concentrations. SCr concentration is not affected appreciably by diet. Creatinine is not metabolized and is excreted by the kidneys almost entirely by glomerular filtration. Its rate of excretion is relatively constant in the steady state, and SCr varies inversely with the GFR. Thus determination of creatinine clearance provides an estimate of the GFR.

Creatinine is measured by the alkaline picrate reaction, which is not entirely specific for creatinine and measures another group of substances collectively known as noncreatinine chromagens. These substances are found in plasma, in which they may constitute up to 50% of the measured creatinine at normal serum concentrations but normally do not appear in urine. As SCr increases because of the progression of renal disease and decreasing GFR, the amount of noncreatinine chromagens is unchanged and contributes progressively less to the total measured SCr. Normal SCr in the dog and cat are 0.3 to 1.3 mg/dL and 0.8 to 1.8 mg/dL, respectively. Greyhounds have slightly higher SCr than non-Greyhounds; this difference is attributable to increased muscle mass and not to any decrease in the GFR. Relatively wide reference intervals and assay imprecision can result in

considerable interassay variation in SCr concentration measurements. As a consequence, comparing an individual animal's fasting SCr concentration to previous results from the same animal over time (so-called trending) rather than to a laboratory reference range can improve the clinician's ability to identify progressive kidney disease and establish a prognosis.

The relationship of BUN or SCr to the GFR is a rectangular hyperbola. The slope of the curve is small when the GFR is mildly or moderately decreased but large when the GFR is severely decreased (Fig. 39.1). Thus large changes in the GFR early in the course of renal disease cause small increases in BUN or SCr, which may be difficult to appreciate clinically, whereas small changes in the GFR in advanced renal disease cause large changes in the BUN or SCr. The inverse relationship between SCr and the GFR is valid only in the steady state.

When nonrenal variables have been eliminated from consideration, an increase in BUN or SCr above normal implies that at least 75% of the nephrons are not functioning (see Fig. 39.1). Neither the cause nor the reversibility of this malfunction can be predicted from the magnitude of the BUN or SCr. The magnitude of the BUN or SCr cannot be used to predict whether azotemia is prerenal, primary renal, or postrenal in origin and cannot be used to distinguish between acute and chronic, reversible and irreversible, or progressive and nonprogressive processes. The BUN-to-creatinine ratio in prerenal and postrenal azotemia may be increased as a result of increased tubular reabsorption of urea at lower tubular flow rates or easier absorption of urea than creatinine across the peritoneal membranes in animals with uroabdomen. A decrease in the BUN-to-creatinine ratio often follows fluid therapy and reflects decreased tubular reabsorption of urea rather than an increased GFR.

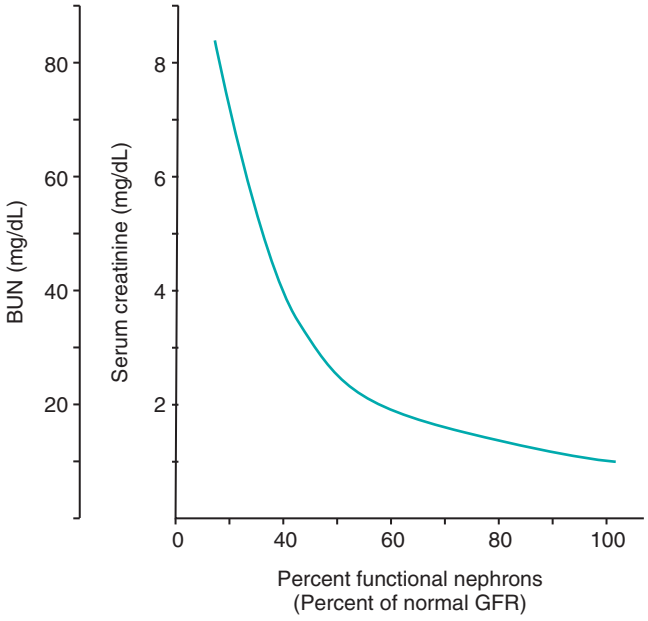

FIG 39.1
Relationship of blood urea nitrogen (BUN) or SCr to percentage of functional nephrons. *GFR,* Glomerular filtration rate.

SYMMETRIC DIMETHYLARGININE

SDMA is a low-molecular-weight (113 Da) by-product of posttranslational methylation of arginine residues in proteins. More than 90% of SDMA is removed from the body by filtration in the kidneys, and therefore its serum concentration can be used as an indicator of GFR. The serum concentration of SDMA is highly correlated with inulin clearance (the gold standard for GFR determination) as well as with SCr in humans, dogs, and cats. Its serum concentration increased above the upper limit of the reference range when GFR decreased by 40% from median normal GFR in cats with chronic kidney disease (CKD). In this study, it had 100% sensitivity, 100% negative predictive value, 91% specificity, and 86% positive predictive value. In longitudinal studies of animals with CKD, it increased a median of 17 months before SCr in cats and mean of almost 10 months before SCr in dogs. It is not highly protein-bound, is produced at a relatively constant rate in the body, and is not affected by nonrenal factors. Especially important, and unlike SCr, SDMA is not affected by lean body mass and thus is a more reliable indicator of GFR in animals with decreased muscle mass, in which SCr can be falsely low. Normal serum SDMA concentrations are < 14 μg/dL in adult dogs and cats and < 16 μg/dL in puppies and kittens.

CYSTATIN C

Cystatin C is a small polypeptide protease inhibitor that is freely filtered by the glomeruli and meets many of the criteria for an endogenous marker of GFR. Serum cystatin C concentration in cats is not affected by age, breed, or sex, and food does not have to be withheld before testing. In dogs, plasma cystatin C concentration may be affected by age and body weight, and it decreases markedly 1 hour after feeding, only returning to normal 12 hours later. In some studies, serum cystatin C concentrations could not reliably differentiate dogs and cats with low, borderline, or normal GFR. In one study, serum cystatin C concentrations were not different between hyperthyroid cats that became azotemic after treatment and those that remained non-azotemic, did not increase with establishment of euthyroidism, and could not differentiate nonhyperthyroid CKD cats from healthy geriatric cats. Based on the results of these studies, serum cystatin C concentration does not appear to be a clinically useful indicator of GFR in dogs and cats.

FIBROBLAST GROWTH FACTOR-23

Fibroblast growth factor-23 (FGF-23) is a phosphate regulatory hormone (i.e., a phosphatonin) produced by osteocytes and osteoblasts in response to hyperphosphatemia and increased serum calcitriol concentration. It inhibits 1-α-hydroxylase in the kidney (thus decreasing calcitriol production), downregulates sodium-phosphate co-transport in the proximal tubules (thus increasing urinary phosphate excretion), and decreases parathyroid hormone secretion by

the parathyroid glands. Its concentration has been shown to increase from baseline in cats that developed azotemia over a 1-year time period as compared with cats that remained non-azotemic, and survival of cats with CKD has been negatively correlated with serum FGF-23 concentrations. Serum FGF-23 concentration decreases from baseline in cats with stable azotemic CKD fed a decreased protein diet.

N-ACETYL-β-D-GLUCOSAMINIDASE AND γ-GLUTAMYL TRANSFERASE

N-acetyl-β-D-glucosaminidase (NAG) is located in the cytoplasm (in lysosomes) and γ-glutamyl transferase (GGT) in the luminal brush border of proximal tubular cells. Their large molecular size precludes glomerular filtration, and increased urinary concentration of these enzymes indicates tubular cell injury. Their clinical utility lies in the early detection of renal tubular injury in patients with acute kidney injury (AKI). For example, twofold to threefold increases in urinary NAG-to-creatinine or GGT-to-creatinine ratios have been observed in models of aminoglycoside nephrotoxicity. Pyelonephritis can result in increased urinary NAG-to-creatinine ratio, but it does not seem to be affected by lower urinary tract infection. Thus additional studies are warranted to determine if urinary NAG-to-creatinine ratio can help differentiate upper from lower urinary tract infection.

KIDNEY INJURY MOLECULE-1

Kidney injury molecule-1 (KIM-1) is a transmembrane protein expressed on the luminal surface of proximal tubular cells that is thought to function in cell-to-cell or cell-to-matrix adhesion. It is expressed at low to nondetectable levels in the normal kidney, but it is markedly upregulated 24 to 48 hours after ischemic or toxic injury to the proximal tubules and shed in urine. KIM-1 likely plays a role in tubular repair because tubular cells that survive ischemic damage express KIM-1 and develop a phagocytic phenotype that allows them to internalize apoptotic cells and clear tubular debris. In cats, it was not detected in normal renal tissue but was identified in the kidneys and urine of cats with kidney injury.

NEUTROPHIL GELATINASE-ASSOCIATED LIPOCALIN

Neutrophil gelatinase-associated lipocalin (NGAL) is a small glycoprotein expressed on neutrophils as well as many types of epithelial cells including renal proximal epithelial cells, the loop of Henle, and collecting ducts. Its siderophore-chelating properties allow it to interfere with iron accumulation by bacteria. NGAL is upregulated in response to inflammatory signals that occur with proximal tubular cell injury. It is not kidney-specific, however, and also can be increased in the urine of dogs with pyuria caused by lower urinary tract infection. A canine-specific NGAL ELISA has been validated in dogs, and serum and urine NGAL concentrations as well as urine NGAL-to-creatinine ratios (UNCR) have been reported in normal dogs and those with AKI, CKD, and lower urinary tract disorders. NGAL seems to be a sensitive and specific biomarker for AKI, and the urine NGAL-to-creatinine ratio may facilitate early detection of AKI in high-risk clinical situations such as renal ischemia associated with general anesthesia, heatstroke, and nephrotoxin exposure. The UNCR recently was evaluated in healthy dogs and those with non-azotemic (IRIS stage I) and azotemic (IRIS stage II-V) AKI, CKD, and lower urinary tract disorders. Dogs with non-azotemic and azotemic AKI had the highest UNCR, followed by those with CKD and lower urinary tract disorders. Among the dogs with AKI, there was no significant difference between survivors and nonsurvivors.

CREATININE CLEARANCE

The renal clearance of a substance is the volume (V) of plasma (P) that would have to be filtered by the glomeruli per minute to account for the amount of that substance appearing in the urine per minute. The renal clearance of a substance that is neither reabsorbed nor secreted by the tubules is equal to the GFR. For such a substance in a steady state, the amount filtered equals the amount excreted, so the $GFR \times P_x = U_x \times V$. Dividing both sides of the equation by P_x gives the familiar clearance formula (U_xV/P_x), which in this case is equal to the GFR.

Creatinine is produced endogenously and excreted by the body largely by glomerular filtration. Its clearance can be used to estimate the GFR in the steady state. Numerous studies in the dog and cat have shown that endogenous creatinine clearance in these species is 2 to 5 mL/min/kg. Values for glomerular function tests in the dog and cat are presented in Table 39.1.

In chronic progressive renal disease, the urinary concentrating ability is impaired after two-thirds of the nephron population has become nonfunctional, whereas azotemia typically does not develop until 75% of the nephrons have become nonfunctional. Thus the main reason to determine endogenous creatinine clearance is the clinical suspicion of renal disease in a patient with polyuria and polydipsia but normal BUN and SCr. The only requirements for the determination of endogenous creatinine clearance are an accurately timed collection of urine (preferably, 12 or 24 hours) and determination of the patient's body weight and serum and urine creatinine concentrations. Failure to collect all urine produced will erroneously decrease the calculated clearance value.

To eliminate inaccuracy caused by noncreatinine chromagens, some investigators have advocated the use of exogenous creatinine clearance. In this procedure, creatinine is administered subcutaneously or intravenously to increase the SCr approximately 10-fold and decrease the relative effect of noncreatinine chromagens. Exogenous creatinine clearance exceeds endogenous creatinine clearance and closely approximates inulin clearance in the dog. The creatinine-to-inulin clearance ratio is not affected by sex, dietary protein, or duration of time after renal ablation. Endogenous creatinine clearance is a reliable estimate of the GFR only when methodology specific for creatinine is used.

TABLE 39.1

Normal Values for Tests of Renal Function in Dogs and Cats

TEST	DOG	CAT
Blood urea nitrogen concentration (mg/dL)	8-25	15-35
Serum creatinine concentration (mg/dL)	0.3-1.3	0.8-1.8
Serum symmetric dimethylarginine (µg/dL)	<14	<14
Serum cystatin C concentration (mg/dL)	0.5-1.5	0.5-1.5
Plasma fibroblast growth factor-23 (pg/mL)	211-499	56-700
Endogenous creatinine clearance (mL/min/kg)	2-5	2-5
Exogenous creatinine clearance (mL/min/kg)	3-5	2-4
Iohexol clearance (mL/min/kg)	1.7-4.1	1.3-4.2
24-hour urine protein excretion (mg/kg/day)	<20	<20
U_{Pr}/U_{Cr}	<0.5	<0.4
Urine NGAL-to-creatinine ratio (pg/mg)	40-3660	NA

In cats, exogenous creatinine clearance may be slightly lower than inulin clearance.

SINGLE-INJECTION METHODS FOR ESTIMATION OF GLOMERULAR FILTRATION RATE

Single-injection plasma clearance methods using inulin, iohexol, or creatinine have been used in dogs and cats with normal or decreased renal mass to estimate the GFR. Using these methods, the plasma clearance of a substance that is not bound to plasma proteins and is excreted only by the GFR (e.g., inulin, iohexol, creatinine) is calculated as the quotient of the administered dose divided by the area under the plasma concentration versus time curve. This technique has the advantage of not requiring collection of urine, but its accuracy depends on the pharmacokinetic model used to calculate the area under the curve and timing and number of samples used to make the calculation.

IOHEXOL CLEARANCE

Iohexol is an iodinated, water-soluble, nonionic, low-osmolar contrast agent that can be used to estimate the GFR in humans and domestic animals. It is nontoxic, confined to the extracellular space, not metabolized, experiences negligible binding to plasma proteins, and almost 100% of an injected dose can be recovered in the urine within 24 hours of injection.

Determination of iohexol clearance allows estimation of the GFR with a limited number of plasma samples and without the need for urine collection. Other advantages include the stability of iodine in plasma, which allows samples to be shipped to remote laboratories, no radioactivity, relatively easy measurement, and wide availability. Iohexol has not been reported to be toxic in dogs and cats, and the only disadvantage is the relatively large injection volume required in large dogs when the usual dosage of 300 mg iodine/kg body weight is used.

The clearance of iohexol is calculated as the dose administered divided by the area under the plasma disappearance curve. The elimination of iohexol can be described by a two-compartment model with initial disappearance from plasma (30–60 minutes) followed by disappearance from interstitial fluid (6–8 hours). For clinical use, a two-sample method with plasma samples collected at 5 and 120 minutes in dogs and at 20 and 180 minutes in cats can be used.

Normal values for iohexol clearance vary, depending on the pharmacokinetic model used to calculate clearance and laboratory method used to measure iohexol in plasma. Results should be normalized to body weight or body surface area. Normal values are 1.7 to 4.1 mL/min/kg or 44 to 96 mL/min/m^2 in dogs and 1.3 to 4.2 mL/min/kg or 22 to 65 mL/min/m^2 in cats.

RADIOISOTOPES

Radioisotopes (e.g., ^{125}I- or ^{131}I-iothalamate, ^{51}Cr-ethylenediaminetetraacetic acid [EDTA], ^{99m}Tc-diethylenetriaminepentaacetic acid [DTPA]) also have been used to estimate the GFR in dogs and cats using plasma clearance and dynamic renal scintigraphy. The plasma clearance approach has the same advantages and limitations as described for iohexol or exogenously administered creatinine, but procedures using radioisotopes require technical expertise and equipment available primarily at referral institutions. The percentage of an injected dose of ^{99m}Tc-DTPA extracted by the kidneys over a finite time period correlates well with inulin clearance, the gold standard for estimation of the GFR. A major advantage of dynamic renal scintigraphy is that it provides information about individual kidney function, but this method correlates less well with inulin clearance than does the plasma clearance method in dogs with renal disease.

URINE PROTEIN-TO-CREATININE RATIO

In animals with persistent proteinuria on routine urinalysis, the severity of proteinuria may be assessed by measuring 24-hour urine protein excretion or determining a urine protein–to–urine creatinine ratio (U_{Pr}/U_{Cr}) on a spot urine sample. Normal values for 24-hour urine protein excretion in dogs and cats are less than 20 mg/kg/day. Dogs with primary glomerular disease (e.g., glomerulonephritis, glomerular amyloidosis) often have markedly increased 24-hour urine protein excretion, and those with amyloidosis generally have the highest 24-hour urine protein excretion. Determination of U_{Pr}/U_{Cr} eliminates the necessity of a 24-hour

urine collection, and the U_{Pr}/U_{Cr} has been shown to be highly correlated with 24-hour urine protein excretion in dogs and cats. Its utility lies in the fact that whereas both urine creatinine and protein concentrations are affected by total urine solute concentration, their ratio is not. According to International Renal Interest Society (IRIS) guidelines, dogs with $U_{Pr}/U_{Cr} < 0.2$ are considered nonproteinuric, those with U_{Pr}/U_{Cr} 0.2–0.5 are considered borderline proteinuric, and those with $U_{Pr}/U_{Cr} > 0.5$ are considered proteinuric. In cats the guidelines are < 0.2 (nonproteinuric), 0.2–0.4 (borderline proteinuric) and > 0.4 (proteinuric).

In general, U_{Pr}/U_{Cr} results are not affected by differences in sex, method of urine collection, fasted versus fed states, or by time of day of collection. Urine samples collected at home may have somewhat lower U_{Pr}/U_{Cr} than samples collected in the hospital. The U_{Pr}/U_{Cr} should be determined within 2 to 4 hours of sample collection because values may increase after 12 hours at room temperature. Pyuria and marked blood contamination of urine samples have the potential to affect the U_{Pr}/U_{Cr}. Consequently, the urine protein concentration should be evaluated in conjunction with urinary sediment findings, and ideally the U_{Pr}/U_{Cr} should be evaluated only if the patient does not have pyuria. In a recent study, 25% of apparently healthy geriatric dogs had U_{Pr}/U_{Cr} results in the borderline proteinuric or proteinuric range as defined by IRIS guidelines. A high degree of overlap is found between dogs with glomerulonephritis and those with amyloidosis with regard to their 24-hour urine protein excretion and U_{Pr}/U_{Cr}. Thus renal biopsy remains the only reliable way to differentiate these two diseases. Values for 24-hour urine protein excretion and U_{Pr}/U_{Cr} are presented in Table 39.1.

MICROALBUMINURIA

In humans, microalbuminuria is defined as excretion of 30 to 300 mg/day of albumin in urine, and its presence may be an early indicator of vascular endothelial damage. Microalbuminuria is an established risk factor for progression of renal disease in human patients with diabetes mellitus and may be predictive of progressive renal disease in those with essential hypertension. Microalbuminuria in dogs and cats has been defined as a urine albumin concentration of 1 to 30 mg/dL, and urine albumin concentrations in this range can be detected by antigen capture enzyme-linked immunoassay. Microalbuminuria can be detected in 15% to 20% of otherwise healthy dogs and cats, and its prevalence increases with increasing age (e.g., approximately 7% in dogs < 3 years but 49% in dogs ≥ 12 years). Its prevalence in a hospital population of dogs was 36%. The effect of pyuria on microalbuminuria is variable. Many urine samples of dogs with pyuria have a negligible urine albumin concentration (<1 mg/dL) and a normal U_{Pr}/U_{Cr} ratio (<0.4). The addition of blood to canine urine samples does not result in a urine albumin concentration more than 1 mg/dL until the urine is grossly pink or red and more than 250 red blood cells (RBCs)/high-power field (hpf) are observed in the urine sediment. U_{Pr}/U_{Cr} ratios generally do not exceed 0.4 with the addition of RBCs to canine urine. Semiquantitative tests for microalbuminuria have relatively high specificity (92% in dogs, 82% in cats) but low sensitivity (37% in dogs, 43% in cats) for differentiating healthy animals from those with systemic diseases. It remains to be determined whether seemingly normal dogs and cats with microalbuminuria are at increased risk for the development of progressive renal disease. Sequential monitoring of animals with documented microalbuminuria probably is warranted until its prognostic value in otherwise normal animals can be determined.

BLADDER TUMOR ANTIGEN TEST

The first-generation bladder tumor antigen (BTA) test is a qualitative latex agglutination dip strip test run on voided urine that detects a glycoprotein antigen complex associated with bladder neoplasia. The BTA test has high sensitivity but low specificity for the detection of transitional cell carcinoma in dogs. False positives occur in urine samples with marked proteinuria or glucosuria and in those with pyuria or hematuria. The high sensitivity of the test and its less reliable performance in the presence of pyuria and hematuria suggest that its most appropriate use would be as a routine screening test to rule out transitional cell carcinoma in geriatric dogs. Second- and third-generation BTA and other tests that use monoclonal antibodies against human bladder tumor antigens give false-negative results in dogs and should not be used.

TUBULAR FUNCTION

The kidney is an organ of water conservation. Depending on the needs of the animal, the kidney can produce urine that is highly concentrated or very dilute. Normal urinary concentrating ability is dependent on the ability of hypothalamic osmoreceptors to respond to changes in plasma osmolality, release of antidiuretic hormone (ADH) from the neurohypophysis, and response of the distal nephron to ADH. In addition, medullary hypertonicity must be generated and maintained by the countercurrent multiplier and exchanger systems of the kidney, and an adequate number of functional nephrons must be present to generate the appropriate response to ADH. Laboratory tests of tubular function are summarized in Table 39.2.

URINE SPECIFIC GRAVITY AND OSMOLALITY

Total urine solute concentration is measured by urine specific gravity (USG) or urine osmolality (U_{Osm}). Urine osmolality depends only on the number of osmotically active particles, regardless of their size. USG is defined as the weight of a solution compared with an equal volume of distilled water. It is dependent on the number and molecular weight of the solute particles but has the advantage of requiring only simple, inexpensive equipment for measurement.

Normally, urine is composed of solutes of relatively low molecular weight (e.g., urea, electrolytes), and a roughly

TABLE 39.2

Normal Values for Tests of Renal Tubular Function in Dogs and Cats

TEST	DOG	CAT
Random urine specific gravity	1.001-1.070	1.001-1.080
Urine specific gravity after 5% dehydration	1.050-1.076	1.047-1.087
Urine osmolality after 5% dehydration (mOsm/kg)	1787-2791	1581-2984
Urine-to-plasma osmolality ratio after 5% dehydration	5.7 : 1-8.9 : 1	Not available
Fractional Electrolyte Excretion (%)		
Sodium	<1	<1
Potassium	<20	<24
Chloride	<1	<1.3
Phosphate	<39	<73

linear relationship exists between urine osmolality and specific gravity. The range of urine osmolality corresponding to a given USG value, however, may be relatively wide. If the urine contains appreciable amounts of larger molecular weight solutes, such as glucose, mannitol, or radiographic contrast agents, these substances will have a proportionally greater effect on specific gravity than on osmolality.

The term *isosthenuria* (USG, 1.007–1.015; U_{Osm}, 300 mOsm/kg) refers to urine of the same total solute concentration as unaltered glomerular filtrate. The term *hyposthenuria* refers to urine of a lower total solute concentration than glomerular filtrate (USG < 1.007, U_{Osm} < 300 mOsm/kg). Although rarely used clinically, the term *hypersthenuria* (baruria) refers to urine of a higher total solute concentration than glomerular filtrate (USG > 1.015, U_{Osm} > 300 mOsm/kg). The normal range of total urine solute concentration for dogs and cats is wide (USG, 1.001–1.080). Samples obtained in the morning have higher USG values than those obtained in the evening, and urine concentration decreases with age, but there is no effect of sex on USG. Normal young puppies have a lower USG than do older dogs.

WATER DEPRIVATION TEST

The water deprivation test is a useful test of tubular function and is indicated for the evaluation of animals with confirmed polydipsia and polyuria, the cause of which remains undetermined after initial diagnostic evaluation. It usually is performed in animals with hyposthenuria (USG < 1.007) suspected to have central or nephrogenic diabetes insipidus or psychogenic polydipsia. An animal that is dehydrated but has dilute urine has already failed the test and should not be subjected to water deprivation. In such an animal, failure to concentrate urine likely is caused by structural damage, renal dysfunction, or administration of drugs that interfere with urinary concentrating ability (e.g., glucocorticoids, diuretics). The water deprivation test also is contraindicated in animals that are azotemic. It should be performed with extreme caution in animals with severe polyuria because they may rapidly become dehydrated during water deprivation if they have a defective urinary concentrating ability.

At the beginning of the water deprivation test, the bladder must be emptied and baseline data collected—body weight, hematocrit, plasma proteins, skin turgor, serum osmolality, urine osmolality, and USG. Water is then withheld and these parameters monitored every 2 to 4 hours. Urine and serum osmolalities are the best tests to follow, but osmolality results are often not immediately available to the clinician. Thus USG and body weight assume the greatest importance for decision making during performance of the test. An increase in the total plasma protein concentration is a relatively reliable indicator of progressive dehydration, but increases in hematocrit and changes in skin turgor are not reliable. SCr and BUN concentrations should not increase during a properly conducted water deprivation test.

Maximal stimulation of ADH release will be present after loss of 5% of body weight. The test is concluded when the patient demonstrates adequate concentrating ability or becomes dehydrated, as evidenced by loss of 5% or more of its original body weight. Use the same scale each time when weighing the animal, and empty the bladder at each evaluation.

The time required for dehydration to develop during water deprivation varies. Dehydration usually becomes evident within 48 hours in normal dogs and cats but, rarely, a longer period of time may be required. Dogs with diabetes insipidus and psychogenic polydipsia usually become dehydrated after a much shorter period of water deprivation (<12 hours). By the time dehydration is evident, USG usually exceeds 1.045 in normal dogs and cats. Failure to achieve maximal urinary solute concentration does not localize the level of the malfunction, and a structural or functional defect may be present anywhere along the hypothalamic-pituitary-renal axis. Furthermore, animals with medullary solute washout may have impaired concentrating ability, regardless of the underlying cause of polyuria and polydipsia.

If there has been less than a 5% increase in urine osmolality or less than a 10% change in USG for three consecutive determinations, or if the animal has lost 5% or more of its original weight, 0.2 to 0.4 U/kg aqueous vasopressin (Pitressin), up to a total dose of 5 U, or 5 µg desmopressin (DDAVP) may be given subcutaneously and parameters of urinary concentrating ability monitored 2 to 4 hours after ADH injection. Any additional increase in urine osmolality after the administration of ADH should not exceed 5% to 10% in normal dogs and cats.

GRADUAL WATER DEPRIVATION

Gradual water deprivation can be used to eliminate diagnostic confusion caused by medullary solute washout. The owner can be instructed to restrict water consumption to 60 mL/lb/day 72 hours before, 45 mL/lb/day 48 hours before, and 30 mL/lb/day 24 hours before the scheduled water deprivation test. In dogs with psychogenic polydipsia, this will promote the endogenous release of ADH, increased permeability of the inner medullary collecting ducts to urea, and restoration of the normal gradient of medullary hypertonicity. An alternate approach is to instruct the owner to decrease water consumption by approximately 10%/day over a 3- to 5-day period (but not < 30 mL/lb/day). Gradual water deprivation should only be used in animals that are otherwise healthy on initial clinical evaluation, and the owner should provide dry food ad lib and weigh the dog daily to monitor for loss of body weight. During the period of gradual water restriction, the water provided each day should be divided into several aliquots that can be given to the dog throughout the 24-hour time period to prevent the dog from drinking all of its daily allotment at once.

FRACTIONAL CLEARANCE OF ELECTROLYTES

The extent to which electrolytes appear in the urine is the net result of tubular reabsorption and secretion. The fractional clearance of electrolytes (FC_x) can be used to evaluate tubular function. Fractional clearance is defined as the ratio of the clearance of the electrolyte in question (U_xV/P_x) to that of creatinine ($U_{Cr}V/P_{Cr}$):

$$FC_x = (U_xV/P_x)/(U_{Cr}V/P_{Cr}) = (U_xP_{Cr})/(U_{Cr}P_x)$$

This ratio usually is multiplied by 100 and the fractional clearance value expressed as a percentage. The advantage of this measurement is that a timed urine collection is not necessary. In normal animals, the fractional clearances of all electrolytes are much less than 1.0 (100%), implying net conservation, but values are higher for potassium and phosphorus than for sodium and chloride. Unfortunately, fractional excretion values calculated from so-called spot urine samples are highly variable and do not correlate well with values calculated using 72-hour urine samples.

The fractional clearance of sodium may be useful in the differentiation of prerenal and primary renal azotemia. In animals with prerenal azotemia and volume depletion, sodium conservation should be avid and the fractional clearance of sodium very low (<1%). On the other hand, in animals with azotemia caused by primary parenchymal renal disease, the fractional clearance of sodium will be higher than normal (>1%). Normal values for urinary fractional clearance of electrolytes are summarized in Table 39.2.

URINALYSIS

Urine for urinalysis may be collected by voiding (midstream sample), catheterization, or cystocentesis. Cystocentesis is preferred because it prevents contamination of the sample by the urethra or genital tract, it is simple to perform when the bladder is palpable, there is negligible risk of introducing infection, and it is well tolerated by both dogs and cats. In animals presented for the evaluation of hematuria, however, it may be helpful first to evaluate a sample collected by voiding because other methods of urine collection may add RBCs to the sample as a result of trauma.

When performing the urinalysis, fresh urine should be examined whenever possible. Refrigerated urine should be warmed to room temperature before performing the urinalysis. Note how the sample was collected because this may influence interpretation. Urinalysis is divided into three parts—physical properties, chemical properties, and sediment evaluation.

PHYSICAL PROPERTIES OF URINE

Appearance

Normal urine is yellow because of the presence of urochrome pigment. Very concentrated urine may be deep amber in color, whereas very dilute urine may be almost colorless. A red or reddish-brown color usually is caused by RBCs, hemoglobin, or myoglobin, whereas a yellow-brown to yellow-green color may be caused by bilirubin; urine containing bilirubin appears concentrated. Normal urine usually is clear. Cloudy urine often contains increased cellular elements, crystals, or mucus. The most common abnormal odor is ammoniacal and is caused by the release of ammonia by urease-producing bacteria.

Specific Gravity

USG is a reflection of the total solute concentration of urine, and the amount of any substance in urine must be interpreted in light of the specific gravity. For example, 4+ protein in 1.010 urine represents more severe proteinuria than 4+ protein in 1.045 urine. Refractometry is the best technique for estimation of USG in general practice. Dip strip methods to estimate USG are unreliable in dogs and should not be used. USG should be determined before any treatment because fluids, diuretics, or glucocorticoids may alter the specific gravity.

CHEMICAL PROPERTIES OF URINE

pH

Urine pH varies with diet and acid–base balance. Normal urine pH of dogs and cats is 5.0 to 7.5. Causes of acidic urine pH include meat protein–based diet, administration of acidifying agents, metabolic acidosis, respiratory acidosis, paradoxic aciduria in metabolic alkalosis, and protein catabolic states. Causes of alkaline urine pH include urinary tract infection (UTI) by urease-positive bacteria, plant protein-based diet, urine allowed to stand exposed to air at room temperature, postprandial alkaline tide, administration of alkalinizing agents, metabolic alkalosis, respiratory alkalosis, and distal renal tubular acidosis. Dip strip methods to

estimate urine pH show moderate to poor agreement with pH meters, and the latter should be used when accurate pH measurements are necessary.

Protein

Randomly obtained urine samples from normal dogs contain small amounts of protein (up to 50 mg/dL). Commonly used dip strip methods for protein determination are much more sensitive to albumin than to globulin. For the evaluation of proteinuria, it is critical to localize the origin of the protein loss by history, physical examination, and critical evaluation of the urine sediment. Persistent, moderate to heavy proteinuria in the absence of urine sediment abnormalities is highly suggestive of glomerular disease (e.g., glomerulonephritis, glomerular amyloidosis). If the sediment is active and proteinuria is mild to moderate, consider inflammatory renal disease or disease of the lower urinary or genital tract.

Glucose

Glucose in the glomerular filtrate is almost completely resorbed in the proximal tubules and is not normally present in the urine of dogs and cats. Glucose will appear in the urine (glucosuria) if the blood glucose concentration exceeds the renal threshold (approximately 180 mg/dL in the dog and 300 mg/dL in the cat). Most dip strip kits are a colorimetric test based on an enzymatic reaction (glucose oxidase) specific for glucose. Causes of glucosuria include diabetes mellitus, stress or excitement in cats, administration of glucose-containing fluids, and renal tubular diseases, such as primary renal glucosuria and Fanconi syndrome. Glucosuria also may be observed occasionally in dogs and cats with chronic renal disease, with tubular injury caused by nephrotoxins, and in some dogs with familial renal disease.

Ketones

β-hydroxybutyrate, acetoacetate, and acetone are ketones, the products of exaggerated and incomplete oxidation of fatty acids. They are not normally present in the urine of dogs and cats. The nitroprusside reagent present in dip strip tests reacts with acetone and acetoacetate, but is much more reactive with acetoacetate. It does not react with β-hydroxybutyrate. Causes of ketonuria include diabetic ketoacidosis, starvation or prolonged fasting, glycogen storage disease, low-carbohydrate diet, persistent fever, and persistent hypoglycemia. Ketonuria occurs more readily in young animals and, of the causes listed, diabetic ketoacidosis is the most important cause in adult dogs and cats.

Occult Blood

Dip strip tests for blood are very sensitive but do not differentiate among erythrocytes, hemoglobin, and myoglobin. The test is more sensitive to hemoglobin than to intact erythrocytes; the former causes a diffuse color change, whereas the latter causes spotting of the reagent pad. A positive test must be interpreted in light of the urine sediment findings (i.e., presence or absence of RBCs). Free hemoglobin, secondary to hemolysis, is the most common abnormal pigment found in urine. Potential causes of hemolysis include immune-mediated hemolytic anemia, disseminated intravascular coagulation, postcaval syndrome, splenic torsion, and heat stroke. Myoglobinuria is less common but may occur if severe rhabdomyolysis (e.g., status epilepticus, crushing injury) occurs. For proper interpretation, the occult blood reaction must be considered together with the urine sediment findings (e.g., hematuria). Myoglobinuria can be distinguished from hemoglobinuria by ammonium sulfate precipitation or urine protein electrophoresis.

Bilirubin

Bilirubin is derived from the breakdown of heme by the reticuloendothelial system. It is transported to the liver, where it is conjugated with glucuronide and excreted in the bile. Only direct-reacting or conjugated bilirubin appears in the urine. The canine kidney can degrade hemoglobin to bilirubin, and the renal threshold for bilirubin is low in dogs. Thus in dogs with liver disease, bilirubin may be detected in the urine before its serum concentration is increased. It is relatively common to find small amounts of bilirubin in concentrated urine samples from normal dogs, especially males. Bilirubin is absent from normal feline urine. The causes of bilirubinuria are hemolysis (e.g., immune-mediated hemolytic anemia), liver disease, extrahepatic biliary obstruction, fever, and starvation.

Leukocyte Esterase Reaction

Indoxyl released by esterases from intact or lysed leukocytes reacts with a diazonium salt and is detected as a blue color reaction after oxidation by atmospheric oxygen. This test is specific for pyuria in canine urine samples but has low sensitivity (many false-negative results). In cats the leukocyte esterase test is moderately sensitive but not specific (many false-positive results) for the detection of pyuria.

URINARY SEDIMENT EXAMINATION

Depending on the criteria used for data analysis, as few as 3% or as many as 16% of dogs and cats with normal findings on physical and chemical evaluation of urine may have important urinary sediment abnormalities (e.g., pyuria, bacteriuria, microscopic hematuria). The sediment examination should be performed on fresh urine samples because casts and cellular elements degenerate rapidly at room temperature. Urine should be centrifuged at 1000 to 1500 rpm for 5 minutes and the sediment stained with Sedi-Stain (Becton Dickinson, Franklin Lakes, NJ) or examined unstained, depending on individual preference. When evaluating the urine sediment, keep the method of urine collection in mind because it will influence interpretation, and keep the USG in mind because it will influence the relative numbers of formed elements. The number of casts is recorded per low-power field (lpf) whereas numbers of RBCs, white blood cells, and epithelial cells are recorded per high-power field (hpf).

Red Blood Cells

Occasional RBCs are considered normal in the urine sediment. Normal values are: voided sample, 0 to 8/hpf; catheterized sample, 0 to 5/hpf; and, cystocentesis sample, 0 to 3/hpf. Excessive numbers of RBCs in urine is termed *hematuria* (Fig. 39.2) and may be microscopic or macroscopic. The causes of hematuria are summarized in Box 39.1.

White Blood Cells

Occasional white blood cells are considered normal in the urine sediment. Normal values are as follows: voided sample, 0 to 8/hpf; catheterized sample, 0 to 5/hpf; and cystocentesis sample, 0 to 3/hpf. An increased number of white blood cells in the urine sediment is termed *pyuria* (Fig. 39.3) and, in an appropriately collected urine sample, is indicative of inflammation somewhere in the urinary tract. The presence of white blood cells does not help localize the lesion unless white cell casts are present, indicating renal origin. UTI is the most common cause of pyuria, but it also can result from genital tract contamination in voided or catheterized samples (Box 39.2).

Epithelial Cells

Both squamous and transitional epithelial cells may be found in the urine sediment, but they are often of little diagnostic significance. Squamous cells are large polygonal cells with small round nuclei (Fig. 39.4). They are common in voided or catheterized samples because of urethral or vaginal contamination. Occasional squamous cells are normal and increased numbers may be present during estrus.

Transitional epithelial cells are variably sized cells derived from the urothelium from the renal pelvis to the urethra (Fig. 39.5). Although their size generally increases from the renal pelvis to the urethra, the finding of small transitional cells in the urine sediment does not have localizing value. Caudate cells are transitional cells with tapered ends thought to originate from the renal pelvis. Occasional transitional cells are normal, and increased numbers may be present if there is infection, irritation, or neoplasia of the urinary tract.

BOX 39.1

Causes of Hematuria in Dogs and Cats

Urinary tract origin (kidneys, ureters, bladder, urethra)
- Trauma
  - Traumatic collection (e.g., catheter, cystocentesis)
  - Renal biopsy
  - Blunt trauma (e.g., automobile accident)
- Urolithiasis
- Neoplasia (common in dogs with hemangiosarcoma)
- Inflammatory disease
  - Urinary tract infection
  - Idiopathic feline lower urinary tract disease
  - Chemically induced inflammation (e.g., cyclophosphamide-induced cystitis)
- Parasites
  - *Dioctophyma renale*
  - *Capillaria plica*
- Coagulopathy
  - Warfarin intoxication
  - Disseminated intravascular coagulation
  - Thrombocytopenia
- Renal infarction
- Renal pelvic hematoma
- Vascular malformation
  - Renal telangiectasia (Welsh Corgi)
  - Idiopathic renal hematuria

Genital tract contamination (prostate gland, prepuce, vagina)
- Estrus
- Inflammatory, neoplastic, and traumatic lesions of the genital tract

BOX 39.2

Causes of Pyuria in Dogs and Cats

Urinary tract origin (kidneys, ureters, bladder, urethra)
- Infectious
  - Urinary tract infection (e.g., pyelonephritis, cystitis, urethritis)
- Noninfectious
  - Urolithiasis
  - Neoplasia
  - Trauma
  - Chemically induced (e.g., cyclophosphamide)

Genital tract contamination (e.g., prostate gland, prepuce, vagina)

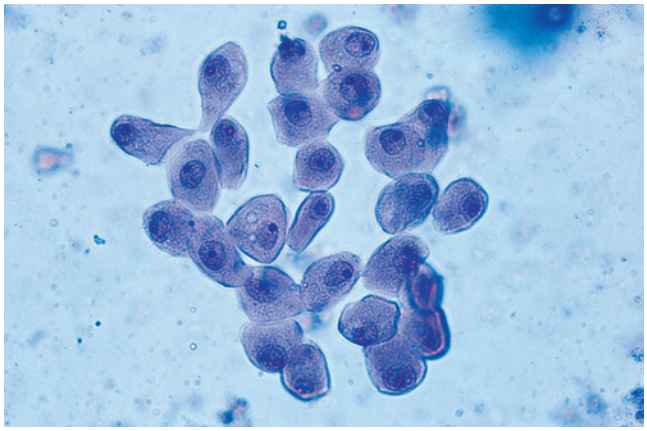

FIG 39.5
Photomicrograph of transitional epithelial cells in urine sediment (Sedi-Stain, ×100).

Renal cells are small epithelial cells from the renal tubules, but their renal origin can only be determined if they are observed in cellular casts. Neoplastic epithelial cells are best identified using conventional blood cell stains (e.g., Wright-Giemsa).

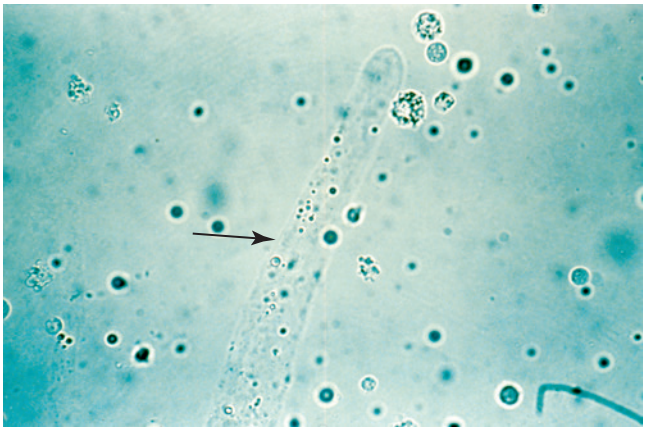

FIG 39.6
Photomicrograph of a hyaline cast in urine sediment *(arrow)* (unstained, ×400).

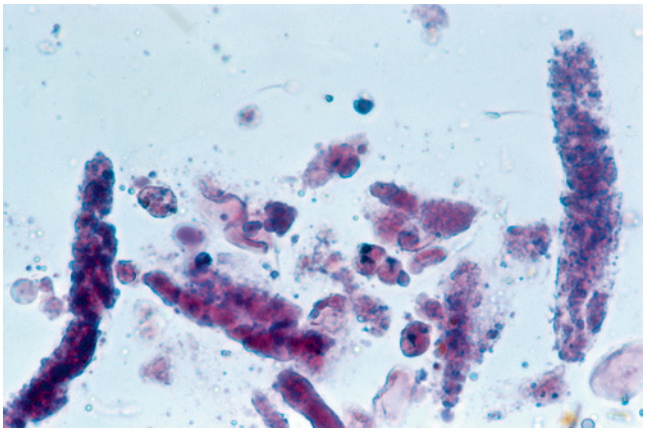

FIG 39.7
Photomicrograph showing coarsely granular casts in urine sediment (Sedi-Stain, ×400).

Casts

Casts are cylindric molds of the renal tubules composed of aggregated proteins or cells. They form in the ascending limb of the loop of Henle and distal tubule because of maximal acidity, highest solute concentration, and lowest flow rate in this area. The presence of casts in the urinary sediment indicates a disease process within the kidney itself and thus is of localizing value. Occasional hyaline and granular casts per low-power field are considered normal. No cellular casts should be observed in sediment from normal urine. Excretion of abnormal numbers of casts in the urine is termed *cylindruria*. The types of casts observed in the urine sediment are hyaline, granular, cellular, and waxy. Hyaline casts (Fig. 39.6) are pure protein precipitates (Tamm-Horsfall mucoprotein and albumin). They are difficult to see and dissolve rapidly in dilute or alkaline urine. Small numbers of hyaline casts may be observed in association with fever or exercise. They are commonly seen in renal diseases associated with proteinuria (e.g., glomerulonephritis, glomerular amyloidosis). Coarse (Fig. 39.7) and fine (Fig. 39.8) granular

FIG 39.8
Photomicrograph showing finely granular cast in urine sediment (Sedi-Stain, ×400).

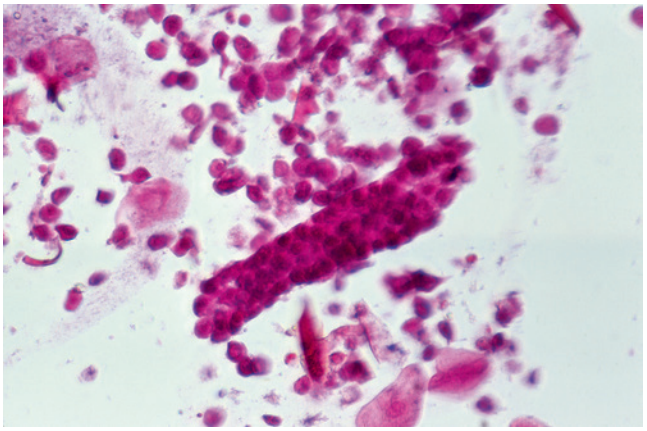

FIG 39.10
Photomicrograph showing an epithelial cell cast in urine sediment (Sedi-Stain, ×400).

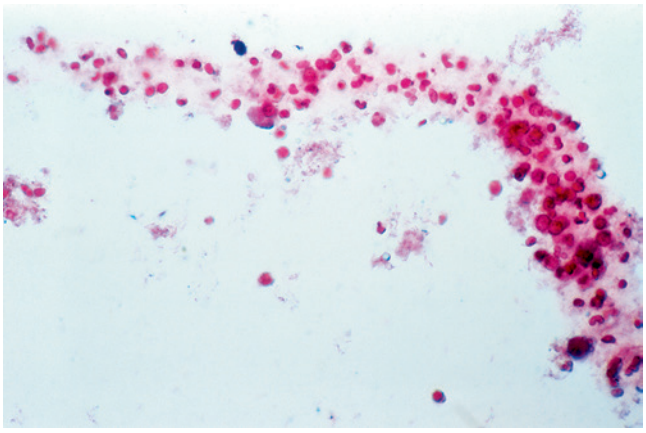

FIG 39.9

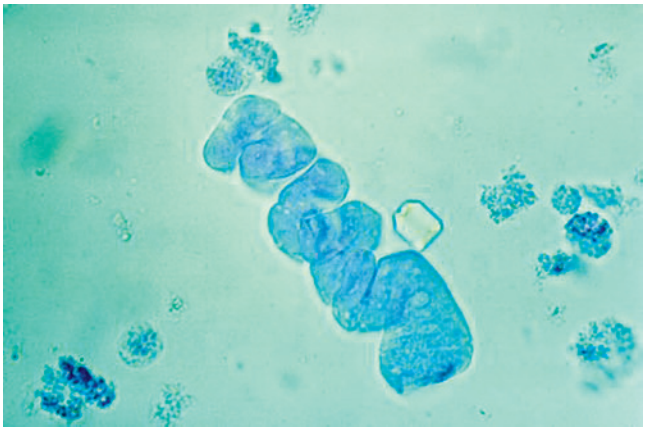

FIG 39.11
Photomicrograph showing a waxy cast in urine sediment (Sedi-Stain, ×400).

casts represent the degeneration of cells in other casts or precipitation of filtered plasma proteins and are suggestive of ischemic or nephrotoxic renal tubular injury. Fatty casts are a type of coarse granular cast containing lipid granules and may be seen in nephrotic syndrome or diabetes mellitus. Cellular casts include white cell or pus casts (suggestive of pyelonephritis; Fig. 39.9), red cell casts (fragile and rarely observed in dogs and cats), and renal epithelial cell casts (suggestive of acute tubular necrosis or pyelonephritis; Fig. 39.10). Waxy casts represent the final stage of degeneration of granular casts, are relatively stable, and suggest intrarenal stasis (Fig. 39.11). They often are very convoluted, with cracks and blunt ends.

Organisms

Normal bladder urine is sterile. The distal urethra and genital tract harbor bacteria, and voided or catheterized urine samples may be contaminated with bacteria from the distal urethra, genital tract, or skin. Contamination from the urethra in voided or catheterized specimens usually does not result in large enough numbers of bacteria to be visualized microscopically in the urine sediment. If allowed to incubate at room temperature, however, these contaminants may proliferate. To be readily apparent microscopically, there must be more than 10^4 rods/mL urine or more than 10^5 cocci/mL urine. Examination of modified Wright-Giemsa–stained urine sediment preparations improves light microscopic identification of bacteriuria. Large numbers of bacteria in urine collected by catheterization or cystocentesis suggest the presence of UTI (Fig. 39.12). Usually, there is accompanying pyuria. Particulate debris in the sediment may be confused with bacteria and cause false positive results. Also, the bottle of stain may be contaminated with bacteria. The microscopic absence of bacteria in the sediment does not rule out urinary tract infection. Yeast and fungal hyphae in the sediment usually are contaminants.

Crystals

The solubility of crystals is dependent on urine pH, temperature, and specific gravity. Crystals commonly are present in

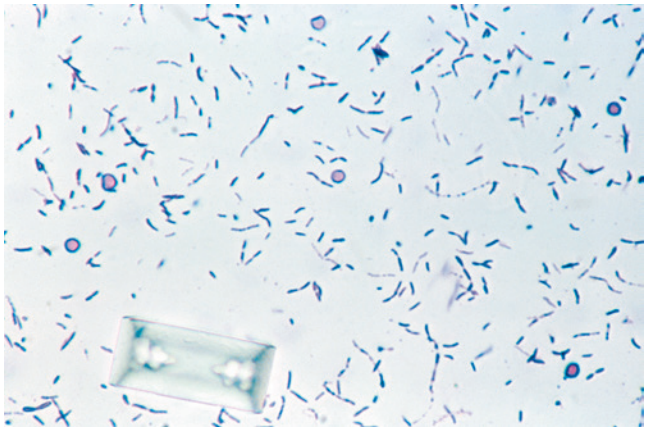

FIG 39.12
Photomicrograph showing numerous rod-shaped bacteria in urine sediment and a single struvite crystal *(lower left)*. Red blood cells also are present (Sedi-Stain, ×400).

TABLE 39.3

Conditions Associated With Crystalluria

CRYSTAL TYPE	ASSOCIATED CONDITIONS
Struvite	Normal Urinary tract infection with urease-positive bacteria Struvite urolithiasis Plant protein-based diet
Calcium oxalate	Normal Ethylene glycol intoxication Oxalate urolithiasis
Ammonium biurate	Breed-related (e.g., Dalmatian, English Bulldog) Urate urolithiasis Liver disease Portosystemic shunt
Cystine	Cystinuria
Bilirubin	Normal in concentrated urine from dogs (especially males); abnormal in feline urine Hemolytic disease Liver disease Posthepatic disease

urine of dogs and cats and often are of little diagnostic significance (Table 39.3). Struvite, amorphous phosphates, and oxalates are examples of crystals that may be found in normal urine samples. Prolonged storage of urine (24 versus 6 hours) and refrigeration can increase the number and size of crystals, especially calcium oxalate, observed in the urine sediment. Uric acid, calcium oxalate, and cystine typically are found in acidic urine, whereas struvite ($MgNH_4PO_4 \cdot 6H_2O$, so-called triple phosphate), calcium phosphate, calcium carbonate, amorphous phosphate, and ammonium biurate

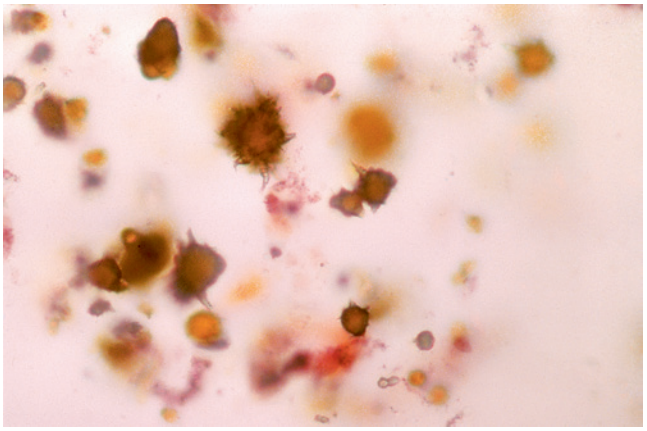

FIG 39.13
Photomicrograph of ammonium biurate crystals in urine sediment (Sedi-Stain, ×400).

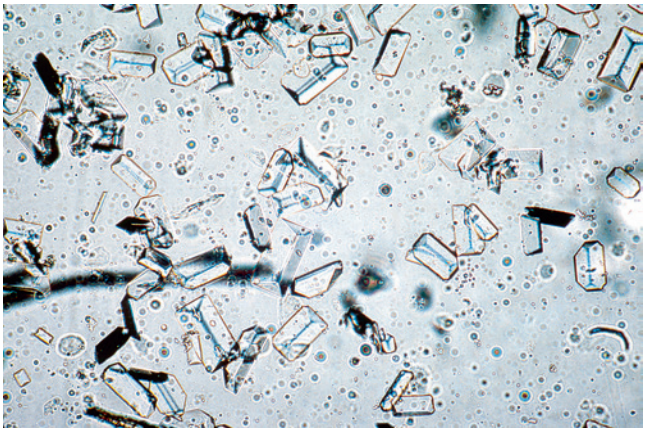

FIG 39.14
Photomicrograph showing numerous struvite crystals in urine sediment (unstained, ×400).

typically are found in alkaline urine. Characteristic crystals also may be found in the urine sediment of animals receiving certain drugs, especially sulfonamides. Bilirubin crystals may be found in concentrated samples of normal dog urine. Urates are commonly observed in the urine of Dalmatians and may be seen in the urine of animals with liver disease or portosystemic shunts (Fig. 39.13). Struvite crystals may be observed in the urine of cats with idiopathic lower urinary tract disease, in dogs and cats with struvite urolithiasis, and in the urine of normal animals (Fig. 39.14). In the presence of oliguric AKI, the presence of calcium oxalate crystals (Fig. 39.15) is highly suggestive of ethylene glycol intoxication. The presence of cystine crystals in urine of dogs and cats is abnormal and suggestive of cystinuria (Fig. 39.16).

Miscellaneous

Sperm are commonly found in urine samples from normal intact male dogs. Rarely, parasite ova of *Dioctophyma renale* or *Capillaria plica* or microfilaria of *Dirofilaria immitis* may be observed in the urine sediment. Refractile lipid droplets

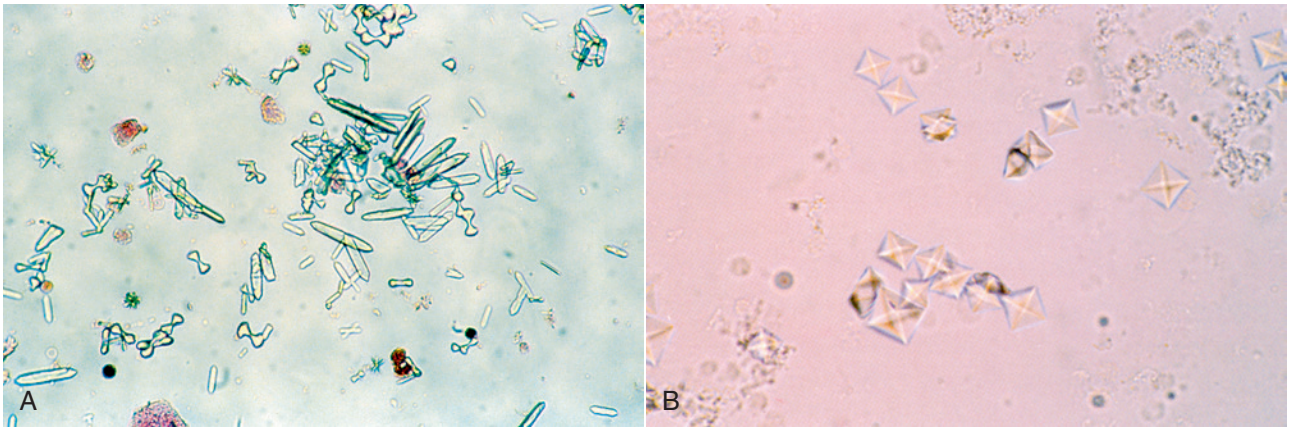

FIG 39.15

Photomicrograph showing cystine crystals in urine sediment (Sedi-Stain, ×400).

may occur in diabetes mellitus or nephrotic syndrome. They also may be observed in cats because of the degeneration of lipid-laden tubular cells.

MICROBIOLOGY

Clinical signs and urinalysis findings provide supportive evidence, but microbiology is required to diagnose UTI conclusively. The kidneys, ureters, bladder, and proximal urethra of normal dogs and cats are sterile, whereas a resident bacterial flora populates the distal urethra, prepuce, and vagina. UTI occurs when bacteria colonize areas of the urinary tract that normally are sterile. Aerobic gram-negative bacteria account for most UTIs in dogs and cats, and the remainder are caused by gram-positive organisms. *Escherichia coli* is the most common organism implicated in UTIs of dogs and cats. Other organisms isolated include *Proteus* spp., coagulase-positive staphylococci, and streptococci. *Pasturella multocida* occasionally is isolated from cats with UTIs. *Enterobacter* spp., *Klebsiella* spp., and *Pseudomonas aeruginosa* are observed less commonly in dogs and rarely in cats.

Results obtained by bacterial culture of urine are dependent on the method of urine collection. Voided urine has the greatest potential for bacterial contamination. Catheterization may inoculate the bladder with bacteria from the distal urethra, but urine collected by cystocentesis should be sterile in normal animals. Quantitative bacterial culture of urine allows determination of the number of bacterial colonies (colony-forming units [cfu]) that grow from 1 mL of urine (cfu/mL). Ideally urine should be submitted for culture within 30 minutes of collection. If this is not possible, the sample may be refrigerated for up to 24 hours without significant loss of bacterial growth.

Bacterial culture of midstream voided urine samples from normal dogs and cats often results in growth of $< 10^3$ to $\geq 10^5$ cfu/mL. Therefore culture of voided urine is not recommended for the evaluation of patients for UTI. If, however, no growth is obtained from a voided urine sample, UTI can be excluded as a diagnosis. Bacterial growth of $\geq 10^5$ cfu/mL may result from culture of urine obtained from catheterization in 20% of normal female dogs. Thus using $\geq 10^5$ cfu/mL as an indicator of UTI in female dogs will result in a substantial number of false-positive results. Also, the procedure of urethral catheterization itself may cause UTI in 20% of normal female dogs. Consequently, the collection of urine by cystocentesis is recommended for establishing a diagnosis of UTI in female dogs. Isolation of bacteria from urine collected by catheterization of male dogs is uncommon, and $\geq 10^4$ cfu/mL is recommended for establishing a diagnosis of UTI in urine samples collected by catheterization from male dogs. In male and female cats, growth of $\geq 10^3$ cfu/mL in samples collected by catheterization is considered compatible with UTI. Urine samples obtained by cystocentesis from normal dogs and cats should yield no growth because this procedure bypasses the normal bacterial flora of the urethra and genital tract. Consequently, results obtained by cystocentesis are the standard against which results obtained

using voided or catheterized samples are compared. Small numbers of organisms from the skin or environment occasionally contaminate samples obtained by cystocentesis, and growth of $< 10^3$ cfu/mL may be considered suggestive of contamination. Isolation of bacteria from urinary tissues obtained during surgery indicates UTI, regardless of number.

DIAGNOSTIC IMAGING

RADIOGRAPHY

Radiography provides precise information about renal size that frequently cannot be obtained from physical examination. To correct for variation in patient size and radiographic magnification, renal size is evaluated in reference to surrounding anatomic landmarks, usually the second lumbar vertebra (L2) on the ventrodorsal view. The left kidney normally is well–visualized in the dog, but the right kidney often cannot be seen as well, especially its cranial pole. In the dog, the left kidney (near vertebrae L2–L5) is located caudal to the right kidney (near vertebrae T13–L3). In the cat, the kidneys lie near vertebra L3, with the right kidney positioned slightly cranial to the left. Renal size in dogs and cats can be assessed radiographically and compared with the length of vertebra L2. On the ventrodorsal view, the kidney-to-L2 ratio is 2.5:1 to 3.5:1 in dogs and 2.4:1 to 3.0:1 in cats.

Excretory urography is performed by taking sequential abdominal radiographs after the intravenous (IV) administration of an iodinated organic compound. The contrast medium is filtered and excreted by the kidneys, and the quality of the study is partially dependent on the patient's GFR. Radiographs should be taken at appropriate intervals after injection (e.g., <1, 5, 20, and 40 minutes) to obtain maximal information about the renal parenchyma and collecting system. Excretory urography is useful for the evaluation of abnormalities in renal size, shape, or location, filling defects in the renal pelvis or ureters, certain congenital defects (e.g., unilateral agenesis), renomegaly, acute pyelonephritis, and rupture of the upper urinary tract. Excretory urography should not be performed in dehydrated patients or in those with known hypersensitivity to contrast media. Although excretory urography normally is a safe procedure, decreases in the GFR may persist for several days after IV administration of contrast agents to normal dogs, and AKI has been reported rarely in dogs after excretory urography.

ULTRASONOGRAPHY

Renal ultrasonography is a noninvasive imaging technique that does not depend on renal function, has no known adverse effects on the patient, and allows characterization of internal renal architecture. The major advantage of ultrasonography is the ability to discriminate among the renal capsule, cortex, medulla, pelvic diverticula, and renal sinus. Normally the kidney is less echogenic than the liver or spleen. Collagen and fat provide highly reflective acoustic interfaces and account for the observation that the renal capsule, diverticula, and sinus are the most echogenic structures in the kidney. The renal medulla normally is less echogenic than the renal cortex because of its higher water content and fewer acoustic interfaces. The hyperechogenicity of the renal cortex relative to the medulla varies among normal cats and has been attributed to variations in the amount of fat present in proximal tubular cells.

Renal length and volume, as determined by ultrasonography, are linearly related to body weight in dogs. In normal cats, renal length as determined by ultrasonography ranges from 3.0 to 4.3 cm. Measurements of renal size determined by excretory urography exceed those obtained by ultrasonography. This difference is caused by osmotic diuresis and radiographic magnification effects during excretory urography and by indistinct renal margins and inaccurate choice of scanning planes during ultrasonography. Ultrasonographic comparison of renal length to aortic luminal diameter (measured just caudal to the origin of the left renal artery in a longitudinal plane) and calculation of the kidney-to-aorta ratio can be used to assess renal size in dogs. Normal values for kidney-to-aorta ratio in dogs range from 5.5:1 to 9.1:1.

Renal ultrasonography is useful for differentiating solid from fluid-filled lesions and for determining the distribution of lesions within the kidney (i.e., focal, multifocal, or diffuse). A pattern of multiple anechoic cavitations is highly suggestive of polycystic kidney disease. Cysts are smooth, sharply demarcated, anechoic lesions that are characterized by "through transmission." The renal pelvis is dilated with anechoic fluid in hydronephrosis, and the kidney is surrounded by an accumulation of anechoic fluid in cats with perinephric pseudocysts. Organized hematomas, abscesses, and necrotic nodules result in a pattern of mixed echogenicity. Focal or diffuse lesions of mixed echogenicity that disrupt normal anatomy often are tumors. Poorly vascular tumors of a homogenous cell type (e.g., lymphoma) may produce hypoechoic lesions that occasionally may be misinterpreted as cysts. Diffuse parenchymal renal diseases characterized by cellular infiltration, with preservation of normal renal architecture (e.g., chronic tubulointerstitial nephritis), may produce diffuse hyperechogenicity, but occasionally are characterized by a normal ultrasonographic appearance. Consequently, normal renal ultrasonography does not eliminate the possibility of renal disease. Ultrasonography is the modality of choice to obtain fine-needle aspirates of renal or perirenal lesions. Ethylene glycol intoxication also causes renal hyperechogenicity. Renal hyperechogenicity in ethylene glycol intoxication is attributed to the deposition of calcium oxalate crystals in the kidneys.

Intrarenal resistance to blood flow may be assessed during duplex Doppler ultrasonography and evaluated by calculation of the resistive index (RI). Normal values for renal RI in normal nonsedated dogs are approximately 0.6. An upper limit of 0.7 has been suggested for RI in normal nonsedated cats. Higher than normal values for RI have been reported in dogs and cats with some renal diseases.

URODYNAMIC TESTING

URETHRAL PRESSURE PROFILE

Urodynamic testing can be useful in animals presented for evaluation of urinary incontinence, especially those refractory to standard treatment. The urethral pressure profile (UPP) evaluates pressure along the length of the urethra. This test is indicated for dogs with refractory urethral sphincter mechanism incompetence (USMI) or for dogs with USMI for which medications may cause potentially serious adverse effects. It usually is unnecessary in dogs that present for uncomplicated urinary incontinence suspected to be caused by USMI. A UPP also can be used to screen dogs with ectopic ureters before surgical or laser correction. The screening might suggest concurrent USMI and provide evidence that medication to treat this condition may be needed after ectopic ureter correction. Finally, UPP can be considered to evaluate dogs and cats with suspected functional urethral outflow tract obstruction.

Procedure

A UPP can be obtained on a male or female dog, and this test can be done on most cats. Urinary tract infections should be treated appropriately before performing urodynamic procedures.

All anesthetics will decrease urethral closure pressure to some extent, but performing this procedure without sedation can be challenging. If chemical restraint is necessary, a bolus of propofol (2–3 mg/kg IV) can be given to facilitate placement of the urinary catheter. Once the animal is sedated, a double- or triple-lumen catheter (of appropriate size) is inserted via the urethra to the level of the bladder trigone. The catheter is slowly withdrawn at a standard rate (0.5–1 mm/sec) while warm sterile water is infused at a rate of 2 mL/min. This procedure generates a pressure curve that can be visualized on the computer screen. From this curve, the maximal urethral closure pressure is determined, which is the maximal urethral pressure minus the resting bladder pressure. The UPP can be obtained in female cats, but catheters of appropriate size for male cats are not commercially available.

CYSTOMETROGRAPHY

Cystometrography (CMG) can be performed to evaluate detrusor function in dogs and cats. This study evaluates the detrusor reflex, bladder filling volume, and compliance. Referral for this procedure generally is indicated for dogs and cats with refractory USMI or those with persistent pollakiuria for which underlying causes, such as bacterial cystitis, urolithiasis, neoplasia, and polypoid cystitis, have been ruled out. CMG also can be used to evaluate dogs and cats with suspected detrusor atony. To perform this procedure, the patient is anesthetized with propofol and a catheter is inserted into the bladder. The catheter is connected to pressure transducers and the bladder is slowly filled with sterile warm water at a constant rate, calculated based on the animal's body size. The volume infused and intravesical pressure are monitored on the computer screen.

Procedure

As for the UPP, all drugs affect the detrusor reflex to some extent. Many drugs (e.g., inhalant anesthetics) can abolish the reflex and, ideally, the CMG should be done without sedation, but usually doing so is not practical. Intravenously administered propofol can be used for this procedure. Once the animal is sedated, a double-lumen urinary catheter is aseptically placed into the urinary bladder of the dog or cat. One of the ports is connected to the pressure transducer on the machine and the other is used for fluid administration. Sterile water is infused at a constant rate. The rate of fluid infusion is very important and should be calculated based on patient size. Pressures are measured as the bladder is filled with water, indicating the degree of compliance of the bladder. Resting bladder pressure, threshold pressure (the pressure at which the detrusor reflex occurs), and threshold volume (the volume at which the detrusor reflex occurs) are recorded. Bladder compliance then can be calculated.

URETHROCYSTOSCOPY

Urethrocystoscopy using a rigid cystoscope allows visual inspection of the mucosal surfaces of the vestibule, vagina, urethra, ureteral orifices, and bladder in female dogs and cats weighing > 3 kg. It is a valuable technique for the diagnosis of several lower urinary tract disorders, including ectopic ureter, urachal remnant, proliferative urethritis, polypoid cystitis, and transitional cell carcinoma of the bladder or urethra. It is the gold standard for the diagnosis of ectopic ureters in dogs and is valuable for identifying the termination sites of ectopic ureters. It allows a presumptive diagnosis of transitional cell carcinoma of the urethra or bladder and permits a biopsy to be performed in a minimally invasive manner. Female dogs with recurrent UTIs can be evaluated for predisposing anatomic abnormalities. The technique also is useful for the diagnosis of idiopathic renal hematuria in dogs and allows identification of the kidney responsible for hemorrhage by observing the discharge of bloody urine from the ureteral orifice on the affected side. Urethrocystoscopy also can be used to treat sphincter mechanism incompetence by submucosal injection of collagen in the urethra, to remove small cystic calculi in female dogs by voiding hydropulsion, and to perform lithotripsy.

RENAL BIOPSY

Renal biopsy allows the clinician to establish a histologic diagnosis and should be considered when the information obtained is likely to alter patient management. Examples of such situations include differentiation of protein-losing glomerular diseases, differentiation of AKI from CKD, determination of the status of tubular basement membranes in AKI,

and establishing the response of the patient to therapy or the progression of previously documented renal disease. Proteinuria is a common indication for renal biopsy in dogs and cats (Video 39.1).

Several techniques for renal biopsy are available; these include blind percutaneous, laparoscopic, keyhole, open, and ultrasonography-guided approaches. The choice of technique is dependent largely on the experience and technical skill of the operator, species to be biopsied, and size of sample required. The blind percutaneous technique works well in cats because their kidneys can be readily palpated and immobilized. Laparoscopy allows direct visualization of the kidney and detection of hemorrhage but requires special equipment and expertise. The keyhole approach occasionally is used in dogs but is useful only if the operator is experienced with the technique. Modifications of the keyhole technique and use of laparoscopy do not necessarily improve the quality of the biopsy specimen obtained or decrease the complication rate. If the operator is relatively inexperienced with renal biopsy or a larger sample is required, wedge biopsy via laparotomy is recommended. Advantages of this procedure include the ability to inspect the kidneys and other abdominal organs visually, choose the specific biopsy site, take an adequately sized sample, and observe the kidney for hemorrhage. Ultrasonography-guided techniques can be performed under sedation, allow specific regions of the kidney to be selected for biopsy, and allow for the evaluation of hemorrhage postbiopsy. Some techniques require general anesthesia to provide adequate patient restraint and analgesia, but needle biopsies of the kidney can be obtained from dogs and cats under ultrasound guidance using sedation. Occasionally, tissue architecture is less important (e.g., renal lymphosarcoma, feline infectious peritonitis), and aspiration of the kidney using a 23- or 25-gauge needle may provide useful material for cytology.

Before renal biopsy, an IV catheter should be placed and clotting ability evaluated (see Chapter 87). The patient's hematocrit and plasma protein concentration should be determined before biopsy but after adequate rehydration with parenteral fluids. Hematocrit and plasma protein concentration then may be monitored after biopsy to detect hemorrhage.

The most commonly used biopsy instruments consist of modifications of the Franklin-modified Vim Silverman needle and Tru-Cut biopsy needle. Spring-loaded biopsy units (e.g., Bard Biopty-Cut, Bard Biopsy Systems, Tempe, AZ) allow for the rapid and efficient retrieval of cores of renal tissue for histopathologic evaluation. Excessive penetration of the kidney with the outer cannula of the Franklin-modified Vim Silverman instrument should be avoided to prevent retrieval of an insufficient amount of renal cortex. Most biopsy needles have an outer cannula that advances 23 to 25 mm, and caution should be taken when directing the angle of the biopsy instrument to avoid the renal hilus and major vessels. Samples containing large amounts of medulla are more likely to contain large vessels and lead to infarction of renal tissue. Therefore it is recommended that the biopsy needle be directed along the long axis of the kidney, solely through cortical tissue. Because of the small size of the feline kidney, it is common to obtain relatively large amounts of medullary tissue, which has been associated with infarction and fibrosis.

After biopsy using the open approach or keyhole technique, the kidney should be digitally compressed for 5 minutes and, after release, the abdomen inspected for hemorrhage. The biopsy sample may be dislodged from the biopsy instrument using a stream of sterile saline from a syringe or, alternatively, the biopsy instrument may be immersed directly in fixative. For routine histopathology, the sample should be fixed in buffered 10% formalin for at least 3 to 4 hours. For immunofluorescence studies, the sample can be preserved in Michel's transport medium. Immunopathology studies also may be performed by a peroxidase-antiperoxidase method using formalin-fixed samples without the need for special preservation of the sample.

After renal biopsy, a brisk fluid diuresis should be initiated to prevent potential clot formation in the renal pelvis. The patient's hematocrit and plasma protein concentration should be monitored at appropriate intervals over the next 12 to 24 hours to detect serious hemorrhage.

The most common complication of renal biopsy is hemorrhage. Subcapsular hemorrhage may occur at the site of biopsy, and some patients experience microscopic hematuria during the first 48 hours after biopsy. Macroscopic hematuria is less common. In one study, severe hemorrhage occurred after renal biopsy in 10% of dogs and 17% of cats, but gross hematuria was uncommon (4% of dogs and 3% of cats). Severe hemorrhage into the peritoneal cavity should be treated aggressively by compression bandage of the abdomen, fresh whole blood transfusion, and exploratory surgery if necessary. Rarely, hydronephrosis may complicate renal biopsy. If the renal pelvis is penetrated by the biopsy needle, bleeding may occur and clot formation can lead to obstruction of the kidney and hydronephrosis. This complication should be considered if progressive renal enlargement is detected after renal biopsy. The risk of this complication is minimized by limiting the biopsy site to the renal cortex and instituting a fluid diuresis afterward.

CHAPTER 40

Glomerular Disease

Glomerular disease is an important cause of chronic kidney disease (CKD) in humans and has been increasingly recognized in veterinary medicine. Destruction of the glomerulus renders the remainder of the nephron nonfunctional, and progressive destruction of glomeruli can lead to decreased glomerular filtration rate, azotemia, and renal failure. Important glomerular diseases of dogs include glomerulonephritis (GN), glomerular amyloidosis, familial glomerular basement membrane (GBM) disorders, and glomerular sclerosis. GN is less common in cats, and amyloidosis in cats affects the renal medulla more severely than the glomeruli.

Marked, persistent proteinuria is the hallmark of primary glomerular disease. The term *nephrotic syndrome* traditionally has been used to describe patients with proteinuria, hypoalbuminemia, hypercholesterolemia, and edema or ascites. Many dogs and cats with glomerular disease, however, do not have clinically detectable ascites at presentation. In one study of dogs with glomerular disease, nephrotic syndrome was not associated with specific histopathologic diagnoses, but dogs with nephrotic syndrome had higher urine protein-to-creatinine (UPC) ratios and shorter survival times than dogs with nonnephrotic glomerular disease. Human patients excreting more than 3.5 g protein/1.73 m^2 body surface area/day (likely equivalent to 2 g/m^2 in dogs) in their urine or with UPC ratios > 2.0 to 3.5 are said to have nephrotic-range proteinuria.

NORMAL STRUCTURE

The glomerulus is a unique vascular structure consisting of a capillary bed between two arterioles (Fig. 40.1). The glomerular capillary wall is a size- and charge-selective barrier. It excludes macromolecules more than 35 Å in radius (serum albumin has a molecular radius of 36 Å) and, for any given size, negatively charged macromolecules experience greater restriction to filtration than neutral macromolecules.

The filtration barrier of the glomerulus consists of three layers, from the vascular space to the urinary space—the capillary endothelium, GBM, and interdigitating foot processes of the podocytes (Fig. 40.2). The fenestrated capillary endothelium is much more permeable to water and crystalloids than are systemic capillaries, and the negatively charged endothelial surface contributes to the charge selectivity of the glomerular barrier. The GBM contains type IV collagen, proteoglycans, laminin, fibronectin, and water. The proteoglycans are large, highly negatively charged molecules consisting of a protein backbone with polysaccharide (glycosaminoglycan) side chains. These proteoglycans are responsible for the charge selectivity of the basement membrane. Type IV collagen in the GBM forms a mesh and contributes to the size selectivity of the glomerular capillary wall. The visceral epithelial cells or podocytes cover the filtration barrier on the urinary side via primary and interdigitating secondary foot processes. The negatively charged cell surface of the podocyte foot processes contributes to their unique morphology and the charge selectivity of the glomerular barrier. The podocytes synthesize the GBM and may phagocytize macromolecules trapped in the filtration barrier.

The mesangial cells of the glomerulus provide structural support for the capillary loops (Fig. 40.3). They produce mesangial matrix, similar to the basement membrane in composition, and may clear filtration residues from the mesangial space by virtue of their phagocytic capacity. Their contractile elements can alter the amount of glomerular surface area available for filtration in response to mediators such as angiotensin II. The mesangium is an early site of deposition of immune complexes and amyloid fibrils, and mesangial cells can contribute to inflammation and progression of CKD by the release of eicosanoids, cytokines, and growth factors and by increased matrix production. Ultimately, these effects can lead to glomerular sclerosis.

The parietal epithelial cells line the urinary side of the glomerular capsule (Bowman's capsule) and are continuous with the visceral epithelial cells at the vascular pole of the glomerulus and with the proximal tubule at the urinary pole (see Fig. 40.1). The juxtaglomerular apparatus, at the vascular pole, consists of specialized smooth muscle cells of the afferent and efferent arterioles containing electron-dense renin granules, and the macula densa, a specialized segment of the distal tubule. The juxtaglomerular apparatus mediates tubuloglomerular feedback.

PATHOGENESIS

Glomerular injury may be immune-mediated or non–immune-mediated. Immune-mediated GN typically is associated with immune complex deposition in the glomeruli. Examples of non–immune-mediated glomerular disease include amyloid fibril deposition and glomerular damage caused by hyperfiltration. Minimal change nephropathy is a glomerular disease associated with loss of negative charge, foot process fusion, and severe proteinuria without immune complex deposition. It has been reported only rarely in dogs and cats.

Immune complex GN is caused by deposition of immunoglobulins or complement or both in the glomerular capillary wall. Immune complexes deposit in the glomerular filter via two different mechanisms (Fig. 40.4). Soluble

circulating immune complexes may become trapped in the glomeruli in conditions of antigen-antibody equivalence or slight antigen excess. Immune complexes also may be formed in situ in response to endogenous glomerular antigens, endogenous nonglomerular antigens, or exogenous antigens deposited or planted in the glomerular filter. Immune complexes may be deposited in subepithelial, subendothelial, or intramembranous locations in the glomerular capillary wall or in the mesangium. Factors affecting the location of these deposits include the size and charge of the complexes as well as the potential removal of complexes by phagocytosis. The location of deposition contributes to the histopathologic findings and severity of glomerular dysfunction.

Immune complexes can be detected in the glomeruli by staining renal tissue sections with fluorescein-labeled antibody against immunoglobulins or complement of the species being studied. This technique requires renal biopsy specimens to be collected and sent to the diagnostic laboratory in special preservative solutions (e.g., Michel's solution). More recently, immunohistochemistry using peroxidase-antiperoxidase methods have been applied to specimens preserved routinely in 10% buffered formalin. Glomerular deposition of preformed immune complexes usually results in a so-called lumpy bumpy or granular discontinuous immunofluorescence pattern on fluorescence microscopy (Fig. 40.5, *A*). In situ formation of immune complexes can occur within glomeruli when circulating antibodies react with endogenous glomerular antigens or planted nonglomerular antigens in the glomerular capillary wall. In this case, a smooth, linear, continuous pattern of immunofluorescence usually results (see Fig. 40.5, *B*). True autoimmune GN (anti-GBM GN) with antibodies against endogenous GBM antigens has not been conclusively identified in dogs and cats.

MECHANISMS OF IMMUNE INJURY

Immune complex deposition in glomeruli may decrease the amount of fixed negative charge and increase the filtration of negatively charged circulating macromolecules (e.g., albumin). Complement activation results in membrane damage and proteinuria, and soluble complement components recruit inflammatory cells. Platelet activation and aggregation may occur because of endothelial damage or antigen–antibody interaction, thus exacerbating glomerular damage by release of a variety of mediators. These mediators cause activation and proliferation of mesangial cells and endothelial cells, vasospasm, and local hypercoagulability. Neutrophils and macrophages localize in the glomeruli in response to soluble mediators, including complement components, platelet activating factor, platelet–derived growth factor, and eicosanoids. Activated neutrophils release reactive oxygen species and proteinases, leading to additional damage. Macrophages produce proteinases, oxidants, eicosanoids, growth factors, cytokines, complement fragments, and coagulation factors. Several infectious and inflammatory diseases have been associated with glomerular deposition or in situ formation of immune complexes in dogs and cats (Box 40.1). Often, however, the antigen source or underlying disease process is not identified and the glomerular disease is referred to as idiopathic.

PROGRESSION

The continued deposition of immune complexes and release of inflammatory mediators eventually leads to glomerular sclerosis. Obstruction of glomerular capillaries may result in ischemia of the tubules and tubulointerstitial disease, which may progress to CKD.

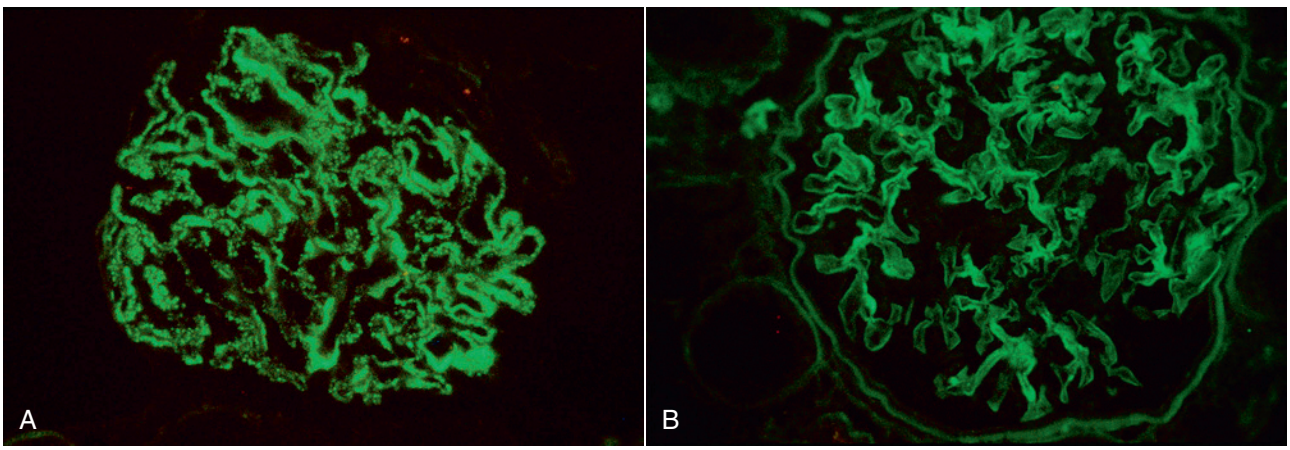

FIG 40.5

BOX 40.1

Causes of Immune-Mediated Glomerulonephritis in Dogs and Cats

Dogs

Infectious diseases
- Dirofilariasis*
- Blastomycosis
- Coccidioidomycosis
- Pyometra*
- Bacterial endocarditis
- Brucellosis
- Pyoderma
- Borreliosis*
  - Membranoproliferative glomerulonephritis (GN) in Bernese Mountain dogs inherited as an autosomal recessive trait has a strong association with seropositivity for *Borrelia burgdorferi*.
- Ehrlichiosis*
- Rocky Mountain spotted fever *(Rickettsia rickettsii)*
- Bartonellosis
- Other chronic bacterial infections
- Leishmaniasis
- Babesiosis
- Hepatozoonosis
- Trypanosomiasis
- Canine adenovirus-1 (infectious canine hepatitis)

Noninfectious inflammatory diseases
- Systemic lupus erythematosus (SLE)
- Immune-mediated polyarthritis
- Chronic inflammatory skin disease
- Pancreatitis

Neoplasia
- Lymphoma
- Mast cell tumor
- Other tumors

Other disease associations
- Exogenous or endogenous (e.g., hyperadrenocorticism) glucocorticoids (dogs treated with glucocorticoids develop proteinuria and glomerular lesions but not deposition of immune complexes).
- Drug reaction (e.g., trimethoprim-sulfonamide, masitinib, and minimal-change nephropathy in a dog).

Familial glomerular disease
- Familial glomerulopathy in soft-coated Wheaten Terriers associated with mutations in NPHS1 and KIRREL2 which encode slit diaphragm proteins nephrin and Neph3/filtrin
- Juvenile glomerulonephropathy in French Mastiff (Bordeaux) dogs
- Autosomal recessive collagen type III glomerulopathy
- Membranoproliferative GN associated with hereditary deficiency of complement component III in Brittany Spaniels
- Autosomal recessive type IV collagen defect in English Cocker Spaniels
- X-linked dominant type IV collagen defect in Samoyeds
- Suspected basement membrane disorders in Doberman Pinschers and Bull Terriers
- Glomerulopathy with increased collagen deposition and glomerular sclerosis in young Newfoundland dogs

Cats

Infectious diseases
- Feline leukemia virus infection
- Feline immunodeficiency virus
- Feline infectious peritonitis
- Chronic progressive polyarthritis (Mycoplasma gatae)
- Other chronic bacterial infections

Noninfectious inflammatory diseases
- Pancreatitis
- Systemic lupus erythematosus

Neoplasia
- Lymphoma
- Mastocytocytosis
- Other tumors

Familial (sibling cats with GN)

Note: Most cases of GN in cats are idiopathic, and many cases of GN in dogs (50% or more) are idiopathic.
*Most common causes of glomerulonephritis in dogs and cats.

Proteinuria itself may promote interstitial inflammation and contribute to tubulointerstitial disease. Increased protein in the glomerular ultrafiltrate is resorbed and degraded by proximal tubular cells. Overload of the lysosomal systems in these cells may lead to cell damage and death. Increased protein reabsorption also leads to upregulation of inflammatory mediators, which contribute to tubulointerstitial inflammation. GN also has the potential to resolve after removal of the causative antigen (e.g., ovariohysterectomy in dogs with pyometra, treatment of heartworm disease).

HISTOPATHOLOGIC LESIONS OF GLOMERULONEPHRITIS

GN is classified morphologically according to the presence of basement membrane thickening, hypercellularity, or both. Disease characterized primarily by basement membrane thickening is called membranous GN, whereas that characterized primarily by increased glomerular cellularity (due to inflammatory cell influx, mesangial cell proliferation, or both) is called proliferative GN. Disease characterized by basement membrane thickening and increased cellularity is called membranoproliferative GN. Disease characterized primarily by fibrosis of the glomeruli is called glomerular sclerosis. The prevalence of immune-complex GN was only 48% in a series of 501 dogs that underwent renal biopsy as part of diagnostic evaluation for suspected glomerular disease. The remaining dogs were diagnosed with primary glomerular sclerosis, amyloidosis, nonimmune complex glomerulopathy or nephropathy, and tubulointerstitial disease

The presence and location of immunoglobulin deposits in the glomerular capillary wall and podocyte foot process

fusion can be detected by electron microscopy. Ultrastructural changes include thickening or splitting of the basement membrane, podocyte foot process fusion, increased cellularity of the mesangial space, and the presence of electron-dense deposits (i.e., immune complexes).

AMYLOIDOSIS

Amyloidosis refers to a diverse group of diseases characterized by extracellular deposition of fibrils formed by polymerization of protein subunits, with a specific biophysical conformation called the β-pleated sheet. This specific biophysical conformation is responsible for the unique optical and tinctorial properties of amyloid deposits as well as their insolubility and resistance to proteolysis in vivo. Amyloid deposits have a homogeneous eosinophilic appearance when stained by hematoxylin and eosin (H&E) and viewed by conventional light microscopy (Fig. 40.6). They demonstrate green birefringence after Congo red staining when viewed under polarized light, and the clinical diagnosis of amyloidosis is based on this finding. Congo red-stained amyloid deposits from patients with reactive (secondary) amyloidosis lose their affinity for Congo red after permanganate oxidation; this feature is useful in the preliminary differentiation of reactive from other types of amyloidosis.

Amyloid syndromes may be classified by distribution of the deposits (systemic or localized) and by the nature of the responsible protein. Localized syndromes usually affect one organ and are uncommon in domestic animals. Examples of localized amyloidosis include pancreatic islet cell amyloid in domestic cats and solitary extramedullary plasmacytomas of the gastrointestinal tract or skin that produce immunoglobulin-associated amyloid. Systemic syndromes affect more than one organ and include reactive, immunoglobulin-associated, and heredofamilial syndromes.

Reactive (secondary) amyloidosis is a systemic syndrome characterized by tissue deposition of amyloid A protein (AA amyloid). Naturally occurring systemic amyloidosis in domestic animals is an example of reactive amyloidosis. Familial amyloid syndromes in the Abyssinian, Siamese, and Oriental Shorthair breeds of cat and in the Shar Pei, Beagle, and English Foxhound breeds of dog are examples of reactive systemic amyloidosis.

Tissue deposits in animals with reactive systemic amyloidosis contain amyloid A protein, which is an amino terminal fragment of an acute-phase reactant called serum amyloid A protein (SAA). Serum amyloid A protein is one of several acute-phase reactants synthesized by the liver in response to tissue injury. The normal serum concentration of SAA is approximately 1 mg/L, but its concentration increases 100- to 500-fold after tissue injury (e.g., inflammation, neoplasia, trauma, infarction). SAA concentration decreases to baseline by 48 hours if the inflammatory stimulus is removed. If inflammation persists, SAA concentration remains increased. Serum amyloid A protein serves as the precursor of amyloid A protein in tissues, and the concentration of SAA is increased in plasma before amyloid deposits are observed in tissues. Chronic inflammation and a prolonged increase in SAA concentration are necessary prerequisites for development of reactive amyloidosis. Despite this, only a small percentage of individuals with chronic inflammatory disease develop reactive amyloidosis. Thus other factors must also be important in development of amyloidosis.

Among domestic animals, reactive amyloidosis is most common in the dog. It is relatively uncommon in other species. Diseases that have been observed in association with reactive systemic amyloidosis in the dog include chronic infectious or noninfectious inflammatory diseases and

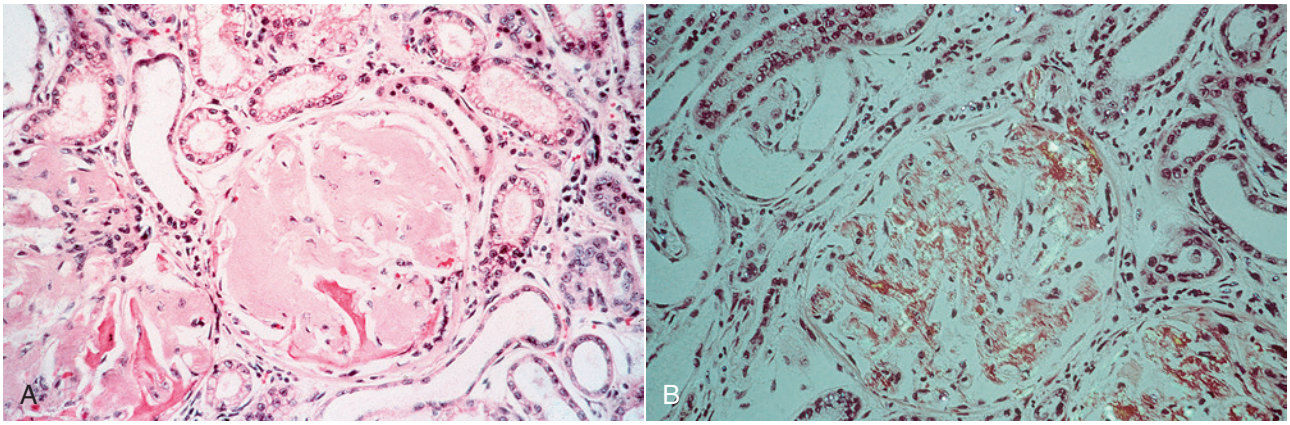

FIG 40.6
Light microscopic appearance of glomerular amyloidosis in a dog. **(A)** Note hypocellularity of the glomerulus caused by deposition of an eosinophilic extracellular material (amyloid; H&E, 400×). **(B)** Congo red stain viewed under polarized light. Note the green birefringence of Congo red-stained amyloid deposits (400×). (**A** from Chew DJ, DiBartola SP, Schenck PA: *Canine and feline nephrology and urology,* ed 2, St Louis, 2011, Elsevier Saunders.)

neoplasms, but there is no discernible associated inflammatory or neoplastic disease in up to 50% of dogs with reactive systemic amyloidosis.

The cause of species differences in the tissue tropisms of reactive amyloid deposits is unknown. In the dog, amyloid AA deposits are most common in the kidney, and clinical signs are caused by renal failure and uremia. The spleen, liver, adrenal glands, and gastrointestinal tract also may be involved, but associated clinical signs are rare. In the cat, there is widespread deposition of amyloid deposits, but clinical signs are due to renal failure and uremia. The Shar Pei dog, Siamese cat, and Oriental Shorthair cat can be exceptions to these general rules. Severe liver deposition of amyloid can cause rupture of the liver and acute hemoabdomen in these breeds. Within the kidney itself, the distribution of amyloid deposits varies among species. For example, amyloidosis is primarily a glomerular disease in the dog, whereas amyloid deposits may have a predominant medullary distribution in the cat.

CLINICAL FINDINGS

Most animals with glomerular disease are middle-aged or older at presentation. There is no sex predilection in dogs, but approximately 75% of cats with GN are males. Any breed can be affected by glomerular disease, but familial forms of membranoproliferative GN have been reported in soft-coated Wheaten Terriers (associated with mutations in the slit diaphragm proteins, nephrin, and Neph3/filtrin), Brittany Spaniels (associated with hereditary deficiency of the third component of complement), and Bernese Mountain dogs (often associated with positive serology for *Borrelia burgdorferi*). Hereditary defects of GBM type IV collagen occur as an autosomal recessive trait in English Cocker Spaniels and as an X-linked dominant trait in male Samoyeds. Basement membrane defects are also suspected to occur in Doberman Pinschers and Bull Terriers. Familial renal amyloidosis occurs in young Abyssinian, Siamese, and Oriental Shorthair cats and in Shar Pei dogs. Familial amyloidosis also has been reported in Beagles and English Foxhounds.

History and Physical Examination Findings

There are several possible clinical presentations of dogs and cats with glomerular disease. Clinical signs may be related to the presence of CKD if more than 75% of the nephron population has become nonfunctional (e.g., anorexia, weight loss, lethargy, polyuria, polydipsia, vomiting). This presentation is common. Signs may be related to an underlying infectious, inflammatory, or neoplastic disease, or proteinuria may be an incidental finding detected during diagnostic evaluation of another medical problem. Clinical signs occasionally may be related to classical nephrotic syndrome (e.g., ascites, subcutaneous edema). Signs may be related to thromboembolism (e.g., sudden onset of dyspnea with pulmonary embolism, sudden onset of paraparesis with iliac, or femoral artery embolism), or sudden blindness may occur because of retinal detachment resulting from systemic hypertension.

Physical examination findings usually are related to the presence of CKD and uremia (e.g., poor body condition, poor hair coat, dehydration, oral ulceration, small irregular kidneys). Other physical examination findings may be related to the presence of underlying infectious, inflammatory, or neoplastic diseases. Affected Shar Pei dogs may have a previous history of so-called Shar Pei fever, episodic joint swelling usually involving the tibiotarsal joints, and high fever that resolves within a few days, regardless of treatment. Some physical examination findings may be related to severe protein loss (e.g., ascites, edema, poor body condition and hair coat). Retinal hemorrhages, vascular tortuosity, and retinal detachment may occur because of systemic hypertension.

Laboratory Findings

A careful search for known associated diseases (see Box 40.1) is a crucial part of the diagnostic evaluation, despite the fact that the glomerular disease ultimately is idiopathic in most cases. Marked persistent proteinuria with inactive urine sediment is the hallmark of glomerular disease. Increased numbers of hyaline casts and occasionally lipid droplets may be observed in the urine sediment of animals with nephrotic range proteinuria. Isosthenuria (urine specific gravity, 1.007-1.015) may be observed if 67% or more of the nephron population has become nonfunctional, and earlier loss of concentrating ability may occur in animals with medullary deposition of amyloid (e.g., Abyssinian cats, Shar Pei dogs).

Glomerulonephritis or amyloidosis can lead to chronic renal failure with the expected biochemical abnormalities (e.g., azotemia, hyperphosphatemia, metabolic acidosis). Hypoalbuminemia occurs in many dogs with glomerular disease (up to 75% of dogs with amyloidosis and 60% of dogs with GN). Hypercholesterolemia occurs in most dogs with glomerular disease (up to 60% of dogs with GN and 90% of dogs with amyloidosis) but tends to be a nonspecific finding in cats with renal disease. Hypercholesterolemia may be caused in part by increased hepatic synthesis of cholesterol-rich lipoproteins secondary to chronic hypoalbuminemia.

The UPC ratio avoids the confounding effect of total urine solute concentration (i.e., specific gravity) on the qualitative assessment of proteinuria. It correlates well with 24-hour urinary protein loss but is much easier to measure—that is, it does not require a 24-hour urine sample. The magnitude of increase in UPC is roughly correlated with the nature of glomerular disease. UPCs are highest in dogs with glomerular amyloidosis (often >10) and lowest in those with interstitial renal disease (usually <10). Animals with GN have very variable UPC (normal to >30). The presence of hematuria or pyuria potentially can make the UPC difficult to interpret; it may cause a false-positive result. Normal UPC is < 0.5 in dogs and < 0.4 in cats. In one study of dogs, results of UPC obtained on three separate urine samples correlated well with a single determination made from a pooled sample of

the three specimens, suggesting a cost-effective alternative to repeated UPC determinations on individual samples. As glomerular disease advances and glomerular filtration rate decreases, less protein is filtered and the UPC may decrease, usually as the azotemia worsens. Such a decrease does not necessarily indicate clinical improvement and is a poor prognostic sign. Proteinuria is mild or absent in animals with renal medullary amyloidosis but without glomerular amyloidosis (e.g., some cats and Shar Pei dogs with amyloidosis).

In addition to being valuable for the diagnosis of glomerular disease, proteinuria also has been recognized as a factor in the progression of CKD. Dogs with CKD and a UPC ratio of 1.0 or higher had a threefold greater risk of uremic crises and death as compared with those with a UPC ratio less than 1.0. In cats with CKD, survival was correlated with UPC ratio; cats with a UPC ratio more than 0.4 had a 4.0 hazard ratio for death or euthanasia as compared with a hazard ratio of 2.9 for cats with a UPC ratio between 0.2 and 0.4. Treatment with angiotensin-converting enzyme inhibitors (ACEi) to decrease proteinuria and slow progression of CKD has become an important management strategy in patients with CKD (see later). The diagnostic approach to proteinuria is summarized in Box 40.2.

Renal biopsy is the only reliable way to differentiate GN from glomerular amyloidosis. A renal cortical biopsy will reliably differentiate GN from glomerular amyloidosis, but medullary tissue is needed to diagnose renal medullary amyloidosis. Light microscopic lesions may be minimal in GN.

BOX 40.2

Clinical Approach to Proteinuria

Localization: Proteinuria in a sample collected by cystocentesis and with an inactive urinary sediment is likely renal in origin.

Persistence: Proteinuria should be repeatable on at least three urine samples obtained at least 2 weeks apart.

Magnitude: The next steps should be determined by the magnitude of the proteinuria.

- Microalbuminuria based on results of enzyme-linked immunosorbent assay (ELISA) (1-30 mg/dL)
  - Monitor for persistence and progression when found in an otherwise healthy older animal.
  - Investigate previously unsuspected systemic disease when found in an older animal.
  - Progressive increases suggest ongoing renal injury and prompt further evaluation.
- Urine protein-to-creatinine (UPC) ratio
  - >0.5 to 1.0 suggests renal (but not necessarily glomerular) proteinuria.
  - >1.0 to 2.0 suggests increased risk for morbidity and mortality in animals with azotemic chronic kidney disease.
  - >2.0 suggests glomerular disease.

From Lees GE et al.: Assessment and management of proteinuria in dogs and cats: 2004 ACVIM Forum Consensus Statement (small animal), *J Vet Intern Med* 19:377, 2005.

Immunopathologic methods using fluorescence microscopy or peroxidase-immunoperoxidase staining and transmission electron microscopy are necessary to accurately diagnose and characterize immune complex GN. If ascitic fluid is available for analysis, evaluation typically indicates a pure transudate with low cell count and low total protein concentration. Measurement of plasma fibrinogen and antithrombin concentrations may identify animals at risk for thromboembolism.

MANAGEMENT OF PATIENTS WITH GLOMERULAR DISEASE

The primary guiding principle for the treatment of dogs and cats with glomerular disease is to identify and treat any underlying predisposing infectious, inflammatory, or neoplastic disease (i.e., remove the offending antigen if possible; Box 40.1). For example, ovariohysterectomy in a dog with pyometra or heartworm treatment in a dog with dirofilariasis can result in resolution of the underlying GN. If CKD is present, it is treated according to the principles outlined in Chapter 41.

Although it may seem logical that supplemental dietary protein would be beneficial in dogs and cats with protein-losing renal disease, doing so merely exacerbates urinary protein loss. On the other hand, feeding a low-protein diet decreases intraglomerular pressure and results in a reduction in proteinuria. In one study, feeding a 14% protein diet (on a dry matter basis) to dogs with X-linked hereditary nephropathy was associated with a mean UPC of 1.8 as compared with a mean UPC of 4.7 in those fed a 35% protein diet. In dogs, supportive treatment of hypertension may include a low-salt diet (<0.3% on a dry matter basis). A low-sodium diet also may enhance the antihypertensive effects of renin-angiotensin-aldosterone system (RAAS) inhibitors. Dietary supplementation with long chain n-3 polyunsaturated fatty acids (PUFA) may suppress glomerular inflammation and coagulation by interfering with production of proinflammatory prostanoids. Renal diets that provide 0.6% n-3 PUFA on a dry matter basis decrease the n-6/n-3 ratio from approximately 50:1 to 5:1. If preferred, the animal's food can be supplemented with 0.25-0.5 g/kg/day of long chain n-3 PUFA using fish oil. Such supplementation increases the requirement for antioxidants (e.g., 1.1 IU vitamin E per g fish oil added to the diet).

Inhibition of the RAAS decreases transcapillary glomerular pressure by decreasing efferent arteriolar resistance, and results in a decrease in proteinuria. Treatment with angiotensin converting enzyme inhibitors (ACEi), angiotensin receptor blockers (ARB), or both has become standard treatment for patients with glomerular disease. Either enalapril or benazepril can be started at dosage of 0.5 mg/kg q24h and gradually increased to 2.0 mg/kg/day divided q12h based on monitoring the patient's UPC. Ideally, the UPC would return to normal (≤ 0.5), but a decrease of 50% from baseline UPC is considered a reasonable partial response. Worsening of

azotemia (i.e., increase in serum creatinine concentration > 30% above baseline) is uncommon when ACEi are used alone. If the patient fails to respond adequately to an ACEi alone, an ARB such as lorsartan or telmisartan can be added to the treatment regimen (Box 40.3). Finally, spironolactone can be added to the treatment regimen if aldosterone escape occurs, but any additional improvement must be weighed against the risk of hyperkalemia or worsening azotemia when these drugs are used in combination. Loop diuretics (e.g., furosemide) may be used in animals with ascites, but caution must be exercised to avoid dehydration and prerenal azotemia.

BOX 40.3

Drugs Used in the Management of Glomerular Disease

Drug	Initial Dosage	Dose Escalation
Ace Inhibitors		
Enalapril	0.5 mg/kg PO q24h	Increase by 0.5 mg/kg/day to a maximum of 2.0 mg/kg/day divided q12h
Benazepril	0.5 mg/kg PO q24h	Increase by 0.5 mg/kg/day to a maximum of 2.0 mg/kg/day divided q12h
Angiotensin Receptor Blockers		
Losartan	0.125 mg/kg/day in azotemic dogs; 0.5 mg/kg/day in nonazotemic dogs	Up to 0.25 mg/kg/day in azotemic dogs; up to 1.0 mg/kg/day in nonazotemic dogs
Telmisartan	1.0 mg/kg/day	Increase by 0.5 mg/kg/day to a maximum of 2.0 mg/kg/day
Aldosterone Receptor Blockers		
Spironolactone	1.0-2.0 mg/kg PO q12h	
Calcium Channel Blockers		
Amlodipine	0.1-0.75 mg/kg q24h	
Loop Diuretics		
Furosemide	1.0 mg/kg q6h to q12h	Incremental increases of 0.5-1.0 mg/kg q6h to q12h up to total of 4.0 mg/kg; or, constant rate infusion of 2-15 µg/kg/min after a loading dose of 2 mg/kg
Antithrombotic Therapy		
Aspirin	1.0-5.0 mg/kg/day	

Adapted from: IRIS Canine GN Study Group Standard Therapy Subgroup, S. Brown, chair, J. Elliott, T. Francey, D. Polzin, S. Vaden: Consensus recommendations for standard therapy of glomerular disease in dogs, *J Vet Int Med* 27:S27, 2013.

The ACEi and ARB have modest effects on systemic blood pressure (i.e., approximately 10%-15% decrease from baseline). Additional antihypertensive treatment is recommended if systolic blood pressure is > 160 mm Hg and diastolic pressure is > 100 mm Hg in a patient with glomerular disease already receiving ACEi and ARB. Typically, the calcium channel blocker amlodipine (0.1-0.2 mg/kg/day) is added to the treatment regimen to manage system blood pressure. In the glomerulus, its effect is primarily on the afferent arteriole and consequently it has little effect on proteinuria. The goal should be to decrease systolic blood pressure to < 150 mm Hg and diastolic pressure to < 95 mm Hg.

Platelet inhibition may decrease intraglomerular coagulation and decrease the risk of thromboembolism. In dogs, an aspirin dosage of 1 to 5 mg/kg PO, q24h, may inhibit platelet cyclooxygenase without preventing the beneficial effects of prostacyclin formation (e.g., vasodilatation, inhibition of platelet aggregation). An aspirin dosage of 5 mg PO, q72h, may be considered in cats.

Immunosuppressive drugs (e.g., corticosteroids, cyclosporine, cyclophosphamide, chlorambucil, azathioprine, mycophenolate, leflunomide) seem like logical candidates for treatment of immune-mediated GN, but no studies in veterinary medicine are available that clearly demonstrate their effectiveness. Corticosteroid administration can cause proteinuria in dogs, and one retrospective study suggested that corticosteroid therapy actually may be detrimental in dogs with idiopathic GN. A controlled trial of cyclosporine treatment (15 mg/kg PO, q24h) in dogs with GN failed to show a beneficial effect. Cyclophosphamide and chlorambucil are alkylating agents that can be considered, but studies in dogs with GN are lacking and adverse effects are a concern, especially with cyclophosphamide. Azathioprine (50 mg/m^2 PO, q24-48h) may be considered for immunosuppression in dogs with idiopathic GN, but only anecdotal evidence of effectiveness is available. Azathioprine is thought to require 2 to 5 weeks of treatment to be fully effective in dogs, and consequently it usually is combined initially with a more rapidly acting immunosuppressive drug. Azathioprine should not be used in cats because they metabolize the drug very slowly and develop bone marrow suppression and severe leukopenia when given dosages similar to those used in dogs; chlorambucil can be used as an alternative in cats. Whether corticosteroids are beneficial for the treatment of cats with GN is unclear. Mycophenolate inhibits purine synthesis and is less toxic than alkylating agents. Its adverse effects are primarily gastrointestinal and reversible upon discontinuation of the drug. Leflunomide inhibits pyrimidine synthesis and can be associated with unexplained hemorrhage and thrombocytopenia at higher dosages. These newer immunosuppressive drugs have potential in the treatment of immune-mediated disease but limited information is available for their use in GN in dogs. The mechanism of action, dosage, and adverse effects of immunosuppressive drugs potentially useful in the treatment of GN are presented in Box 40.4.

BOX 40.4

Immunosuppressive Drugs Potentially Useful in the Management of Glomerular Disease

Immunosuppressive Therapy			
Drug	***Mechanism of Action***	***Dosage***	***Adverse Effects***
Prednisone	Inhibits phospholipase A2, decreases cytokine release, inhibits neutrophil migration, decreases function and numbers of T cells and B cells, induces antiinflammatory phenotype during macrophage differentiation	1.0-2.0 mg/kg/day	Polyuria, polydipsia, polyphagia, pendulous abdomen, panting, worsening of proteinuria, hypercatabolism and muscle loss, increased hypercoagulability, sodium and fluid retention, hypertension, behavioral changes, adrenal suppression
Mycophenolate	Inhibits inosine monophosphate dehydrogenase, rate-limiting step in synthesis of guanosine nucleosides needed for DNA and RNA synthesis	10 mg/kg q12h	GI upset
Cyclosporine	Binds to cyclophilin and inhibits calcineurin essential for transcription of interleukin-2 needed for T-cell activation	5-20 mg/kg q12h	GI upset, gingival hyperplasia
Cyclophosphamide	Alkylating agent that interferes with DNA and RNA synthesis	Pulse therapy of 200-250 mg/M^2 q3wks or continuous therapy of 50 mg/M^2 4 days/wk	GI upset, myelosuppression, hemorrhagic cystitis
Chlorambucil	Alkylating agent that interferes with DNA and RNA synthesis	0.2 mg/kg q24-48h	GI upset, myelosuppression
Azathioprine	Purine analogue that interferes with DNA and RNA synthesis and lymphocyte proliferation	2 mg/kg q24h for 1-2 wks, then 1-2 mg/kg q48h	GI upset, myelosuppression, acute pancreatitis, hepatotoxicity
Leflunomide	Inhibits pyrimidine synthesis leading to decrease in DNA and RNA synthesis and lymphocyte proliferation	2 mg/kg/day	Diarrhea, lethargy, unexplained hemorrhage, thrombocytopenia, increased liver function tests (more common at dosages ≥ 3 mg/kg/day)

Adapted from: IRIS Canine GN Study Group Established Pathology Subgroup, G. Segev, chair, L.D. Cowgill, R. Heiene, M.A. Labado, D.J. Polzin: Consensus recommendations for immunosuppressive treatment of dogs with glomerular disease based on established pathology, *J Vet Int* Med 27:S44, 2013.

Response to treatment of GN is gauged by the change in UPC as well as improvement in serum creatinine and albumin concentrations, if these were abnormal at the start of treatment. The patient should be assessed every 2 weeks during the initial phase of treatment. If the patient is tolerating immunosuppressive therapy without serious adverse effects, it can be continued for 8 to 12 weeks before beginning to taper the patient off treatment. If the response is minimal, increased dosage or alternative drugs can be tried, but if there is no response after 12 to 16 weeks, continued immunosuppressive therapy is unlikely to be worthwhile.

No specific therapy has been shown to be beneficial for the treatment of amyloidosis. Experimentally, dimethyl sulfoxide (DMSO) given during the rapid deposition phase can cause resolution of amyloid deposits and a persistent decrease in SAA concentration, and may improve renal function by decreasing interstitial inflammation and fibrosis. One case report in a dog with amyloidosis showed a beneficial effect (e.g., less proteinuria, improved glomerular filtration rate) of DMSO when used at a dosage of 90 mg/kg/wk administered subcutaneously. Another study of several affected dogs showed no effect of DMSO; the dogs had similar amounts of amyloid in their kidneys at necropsy as in renal biopsies taken before instituting DMSO treatment.

In human patients with systemic AA amyloidosis, amyloid deposits regress and prognosis is most favorable in patients when the SAA concentrations remain low (<10 mg/L). The drug eprodisate, which binds to glycosaminoglycan binding sites on serum amyloid A (SAA) protein and inhibits polymerization and deposition of amyloid fibrils in tissues, may slow the progression of renal disease in some human patients with systemic AA amyloidosis. Recently, tocilizumab (a monoclonal antibody directed against the interleukin-6 receptor) has shown promise in treatment of human patients with AA amyloidosis secondary to inflammatory diseases. It results in markedly decreased SAA concentration and, in some cases, it decreased proteinuria and stabilized renal function. Amyloid deposits in treated patients regressed or remained stable.

Colchicine impairs the release of SAA from hepatocytes by binding to microtubules and preventing its secretion. It prevents the development of amyloidosis in human patients with familial Mediterranean fever (FMF), a genetic disorder characterized by recurrent, self-limiting febrile episodes

associated with serosal inflammation. FMF is caused by mutations in the pyrin gene, which is expressed in neutrophils and normally inhibits inflammation provoked by minor insults. If untreated, most people with FMF develop reactive amyloidosis, nephrotic syndrome, and renal failure in middle age. Colchicine prevents most febrile attacks and prevents development of amyloidosis in this population. Colchicine (0.03 mg/kg/day) may be beneficial in Shar Pei dogs with recurrent fever and joint swelling (so-called Shar Pei fever) that may be at risk for the development of systemic amyloidosis, but no prospective placebo-controlled study is available to support this treatment. Adverse effects of colchicine include gastrointestinal upset and rare development of neutropenia.

COMPLICATIONS

HYPOALBUMINEMIA

The hypoalbuminemia of nephrotic syndrome is only partially explained by the urinary loss of albumin. Hepatic albumin synthesis is increased in nephrotic syndrome but this increase is insufficient for the degree of hypoalbuminemia. Low plasma oncotic pressure is thought to be the primary stimulus for increased hepatic synthesis of albumin in this syndrome. Renal catabolism of albumin is increased in nephrotic syndrome because of increased reabsorption of filtered protein. Although an increase in dietary protein stimulates hepatic albumin synthesis, it does not correct hypoalbuminemia in patients with nephrotic syndrome and only worsens the urinary loss of protein.

SODIUM RETENTION

The underfill hypothesis of edema and ascites formation in the nephrotic syndrome involves activation of the RAAS. Progressive loss of albumin through the glomeruli and inadequate hepatic synthesis of albumin lead to hypoalbuminemia, which in turn leads to decreased oncotic pressure with loss of water and electrolytes from the vascular compartment. Decreased circulating volume leads to decreased renal blood flow and activation of the RAAS with aldosterone release and consequent renal conservation of sodium and water. Attempted restoration of circulating volume is unsuccessful because hypoalbuminemia and decreased oncotic pressure prevent retention of water in the vascular compartment. In addition to the RAAS, nonosmotic stimulation of antidiuretic hormone (ADH) release and increased sympathetic nervous system activity could be invoked by decreased circulating volume and also would promote renal water and sodium retention.

The overfill hypothesis is based on evidence for a primary intrarenal mechanism of sodium retention in nephrotic syndrome. Aldosterone concentrations frequently are normal or even low in affected human patients, and treatment with ACEi does not always prevent sodium retention. Primary intrarenal sodium retention in nephrotic syndrome occurs in the distal nephron and contributes to extracellular fluid volume expansion and edema formation. Recent studies have suggested that upregulation of the electrogenic sodium channel (ENaC) in collecting duct epithelial cells may mediate this sodium retention.

The underfill and overfill hypotheses of sodium retention and edema formation in the nephrotic syndrome can be reconciled by considering the stage of disease. Earlier in the disease process, when the serum albumin concentration and intravascular oncotic pressure are adequate, intrarenal sodium retention may result in expansion of circulating volume and suppression the RAAS (overfill). Later in the disease process, when severe hypoalbuminemia and low circulating volume caused by decreased intravascular oncotic pressure develop, the RAS would be activated, despite the presence of an intrarenal mechanism for sodium retention (underfill).

THROMBOEMBOLISM

The nephrotic syndrome results in a hypercoagulable state. Occasionally, thromboembolic phenomena are responsible for the major presenting signs and overshadow the underlying renal disease, thus complicating the clinical course and delaying the primary diagnosis. Hypercoagulability and thromboembolism associated with the nephrotic syndrome occur secondary to several abnormalities in the coagulation system. Mild thrombocytosis and platelet hypersensitivity occur in association with hypoalbuminemia and result in increased platelet adhesion and aggregation. Plasma arachidonic acid normally is protein-bound, and more arachidonic acid is free to bind to platelets in the presence of hypoalbuminemia. This may result in increased thromboxane production by platelets and platelet hyperaggregability. Hypercholesterolemia also may contribute to platelet hyperaggregability by altering platelet membrane composition or affecting platelet adenylate cyclase response to prostaglandins.

Loss of antithrombin (AT; molecular weight [MW], 65,000) in urine also contributes to hypercoagulability. AT acts in concert with heparin to inhibit serine proteases (clotting factors II, IX, X, XI, and XII) and normally plays a vital role in modulating thrombin and fibrin production. Decreased plasma concentrations of factors IX, XI, and XII occur because of urinary loss of these proteins. Hyperfibrinogenemia and decreased fibrinolysis contribute to hypercoagulability. Decreased fibrinolysis occurs as a result of decreased concentration of plasminogen and increased concentration of α_2-macroglobulin (a plasmin inhibitor). Increased concentration of large-MW coagulation factors (factors II, V, VII, VIII, and X) may lead to a relative increase in coagulation factors as compared with regulatory proteins. This increase may result from increased protein synthesis by the liver as it attempts to correct hypoalbuminemia.

Thromboembolism has been reported to occur in 15% to 25% of dogs with nephrotic syndrome. It is rare but has been reported in cats with glomerular disease. Animals with fibrinogen concentrations more than 300 mg/dL and AT concentrations less than 70% of normal are considered at risk for thromboembolism, and anticoagulant therapy (e.g.,

aspirin) should be considered. In one study, the prevalence of hypercoagulability characterized by thromboelastography was 89% in 76 dogs with protein-losing nephropathy in which the diagnosis was based on the UPC results, but the prevalence of thromboembolism was only 6.6%. Hypercoagulability could not be predicted by the severity of proteinuria, hypertension, hypoalbuminemia, or low AT activity. The pulmonary artery is the most common site for thromboembolism, but emboli also may lodge in the mesenteric, renal, iliac, coronary, and brachial arteries and in the portal vein. Dogs with pulmonary thromboembolism usually are dyspneic and hypoxic, with minimal pulmonary parenchymal radiographic abnormalities. Treatment usually is unsuccessful, and the prognosis in dogs with glomerular disease and pulmonary thromboembolism is grave.

HYPERLIPIDEMIA

Hypercholesterolemia and hyperlipidemia are common in patients with nephrotic syndrome. Decreased plasma oncotic pressure caused by hypoalbuminemia and increased loss of regulatory factors for lipid metabolism in urine cause increased hepatic synthesis of lipoproteins and decreased peripheral catabolism of lipoproteins. Large-MW, cholesterol–rich lipoproteins that are not easily lost through the damaged glomerular capillary wall accumulate, whereas smaller MW proteins such as albumin and AT are lost in the urine. In nephrotic patients, cholesterol and lipid concentrations tend to increase as albumin concentration decreases. Decreased hepatic catabolism of lipoproteins occurs because of abnormal lipoprotein lipase function. Normal lipoprotein lipase function requires heparin sulfate as a cofactor, and concentrations of heparin sulfate frequently are decreased in nephrotic patients. The decrease in heparin sulfate has been linked to increased urinary loss of another glycoprotein, orosomucoid. Diversion of necessary sugar intermediates as the liver replaces the lost orosomucoid causes the decreased production of heparin sulfate. Orosomucoid also has an important role in maintaining normal glomerular permselectivity. Consequently, urinary loss of orosomucoid not only contributes to the hyperlipidemia of the nephrotic syndrome but also exacerbates proteinuria.

HYPERTENSION

Systemic hypertension may occur in dogs and cats with glomerular disease caused by sodium retention, activation of the RAAS, and impaired release of normal renal vasodilator substances. Systemic hypertension has been associated with immune–mediated GN, glomerular sclerosis, and glomerular amyloidosis and may occur in 50% or more of dogs with glomerular disease. Retinal hemorrhage, retinal vascular tortuosity, and retinal detachment may result from systemic hypertension, and blindness may be the presenting complaint in hypertensive dogs and cats with glomerular disease.

Prognosis

Amyloidosis is a progressive disease with a poor prognosis. Affected animals often are in renal failure at the time of presentation and generally live less than 1 year after diagnosis. GN has a variable course, and a poor prognosis should not be given unless there is evidence of progression to CKD. Dogs and cats with GN may experience spontaneous remission, may have a relatively stable clinical course with ongoing proteinuria for several months to years, or may progress to chronic renal failure over months to years.

CHAPTER 41

Acute Kidney Injury and Chronic Kidney Disease

It can be difficult sometimes to determine whether an animal is suffering from acute kidney injury (AKI) or chronic kidney disease (CKD), but differentiation is important because AKI is potentially reversible, whereas CKD is not. Several of the clinical findings that help differentiate AKI from CKD are specific but not sensitive for CKD (i.e., they are useful if present but not if absent). For example, the kidneys are expected to be normal-sized (or occasionally mildly enlarged) in patients with AKI, whereas small irregular kidneys signify CKD. Some animals with CKD, however, can have normal-sized kidneys, and some chronic renal diseases in cats are associated with enlarged kidneys (e.g., renal lymphoma, polycystic kidney disease). A history of previous polyuria (PU) and polydipsia (PD) often (but not always) is present in CKD, whereas this history is absent in AKI. Nonregenerative anemia often (but not always) is detected at presentation in dogs and cats with CKD, whereas anemia is not present initially in AKI. If present, weight loss, poor body condition, and poor hair coat suggest CKD, and these findings are not expected in animals with AKI. However some dogs and cats with CKD are in good body condition. The observation of enlarged parathyroid glands (>4 mm) on ultrasound examination of a dog with kidney disease suggests CKD, whereas a dog with AKI is expected to have normal-sized parathyroid glands (≤4 mm). Hyperkalemia may be observed with the development of oliguria or anuria in AKI or CKD. The clinical differentiation of AKI and CKD is summarized in Table 41.1.

ACUTE KIDNEY INJURY

AKI is a clinical syndrome characterized by abrupt increases in serum creatinine (SCr) and blood urea nitrogen (BUN) concentrations (azotemia). Early recognition of AKI is crucial because it can be reversed in patients with enough surviving nephrons, provided treatment is instituted early. AKI probably occurs more frequently than appreciated and may go undiagnosed or be confused with CKD. Recognizing situations in which AKI is likely to develop and taking appropriate preventive measures is preferable to treating established AKI. The clinicopathologic abnormalities in patients with AKI frequently are more severe than those observed in patients with CKD because most of the compensatory mechanisms that develop in CKD are not present in AKI.

Pathophysiology

Renal ischemia or exposure to nephrotoxins causes tubular injury that ranges from degeneration to necrosis and historically has been referred to as nephrosis or acute tubular necrosis (Fig. 41.1). In some cases, severe excretory failure can occur, despite minimal or no light microscopic lesions. Several factors may contribute to azotemia and oliguria in AKI, including tubular backleak, intraluminal tubular obstruction (e.g., casts, cellular debris, tubular swelling), extraluminal tubular obstruction (e.g., interstitial edema, cellular infiltrates), and primary filtration failure (e.g., afferent arteriolar vasoconstriction, efferent arteriolar vasodilatation, decreased glomerular permeability). Some combination of these pathophysiologic mechanisms likely occurs in clinical patients, depending upon the underlying cause of AKI (Fig. 41.2). Depending on duration and severity, renal ischemia can cause reversible prerenal azotemia or acute tubular necrosis. The renal cortex is richly supplied with adrenergic innervation, which results in vasoconstriction during renal ischemia. Because of a large reserve of blood supply, temporary or mild reductions in renal blood flow (RBF) do not result in tubular necrosis. Deprivation of blood supply, if severe and prolonged, results in decreased cellular energy production and loss of cellular integrity. Tubules with high metabolic activity are at greatest risk of injury during decreased oxygen delivery. The outer medulla is supplied with the lowest amount of oxygen relative to its high metabolic activity, and this region of the kidney is at increased risk for injury during hypoxia. Nonsteroidal antiinflammatory drugs (NSAIDs) can result in renal ischemia by blocking the renal production of vasodilatory prostaglandins that maintain RBF during dehydration. True nephrotoxins exert their deleterious effects directly on the kidney after binding

TABLE 41.1

Clinical Differentiation of Acute Kidney Injury and Chronic Kidney Disease

CLINICAL FEATURE	ACUTE KIDNEY INJURY	CHRONIC KIDNEY DISEASE
Renal size	Normal or mildly enlarged	Small and irregular or normal
Previous history of polyuria and polydipsia	Absent	Present or absent
Nonregenerative anemia	Absent	Present or absent
Weight loss	Absent	Present or absent
Poor body condition	Absent	Present or absent
Poor hair coat	Absent	Present or absent
Ultrasound appearance of parathyroid glands	Normal-sized	Enlarged

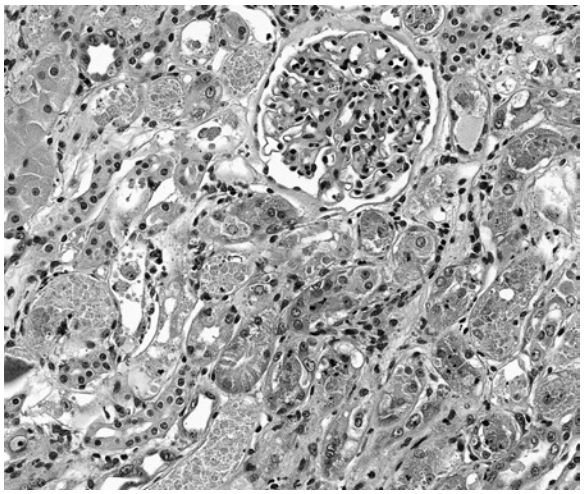

FIG 41.1

BOX 41.1

Some Causes of AKI in Dogs and Cats

Nephrotoxins

- Ethylene glycol
- Aminoglycosides
- Amphotericin B
- Easter lily (cats)
- Grape or raisin toxicity (dogs)
- Hypercalcemia
  - Cholecalciferol rodenticide
  - Calcipotriene (Dovonex)
- Anticancer drugs
  - Cisplatin
- Radiocontrast dyes administered intravenously
- Heavy metals (e.g., thiacetarsamide)
- Tainted food (melamine, cyanuric acid)
- Hydroxyethyl starch (increased risk with 10% solution but not 6%)

Renal Ischemia

- Dehydration
- Trauma
- Anesthesia
- Sepsis
- Heat stroke
- Pigment nephropathy
  - Myoglobinuria
- Shock
- Hemorrhage
- Surgery
- Nonsteroidal antiinflammatory drugs (NSAIDs)

Other

- Leptospirosis—acute tubulointerstitial nephritis
- Borrelia—rapidly progressive glomerulonephritis
- Cutaneous and renal glomerular vasculopathy—renal thrombotic microangiopathy (especially Greyhounds)

Acute Hyperphosphatemia

- Tumor lysis syndrome

to tubular cell membranes. The term *nephrotoxicant* refers to a chemical or drug that can result in renal injury regardless of whether it is caused by direct nephrotoxic injury (e.g., aminoglycosides) or renal ischemia (e.g., NSAIDs). Patients with underlying renal disease may develop AKI more readily than patients with kidneys that were normal before the insult. Concurrent dehydration also may increase the severity of AKI after renal ischemia or exposure to nephrotoxins, in part because dehydration activates renal vasoconstriction, which can contribute to additional ischemic damage. Causes of AKI in dogs and cats are presented in Box 41.1.

AKI passes through three clinical phases (Fig. 41.3). The latent phase represents the time after exposure to a nephrotoxin or renal ischemia before the onset of azotemia. It is associated with an increasing number and severity of renal tubular lesions over time if the renal insult is not removed. The latent phase often is not detected because clinical signs are absent or minimal. Prompt removal of the inciting cause will result in rapid return to normal renal function.

Entry into the maintenance phase signifies that a critical amount of lethal injury has occurred in the renal tubules, and a course of 1 to 3 weeks of AKI is expected before restoration of renal function can occur. Removal of the inciting cause during the maintenance phase will not result in

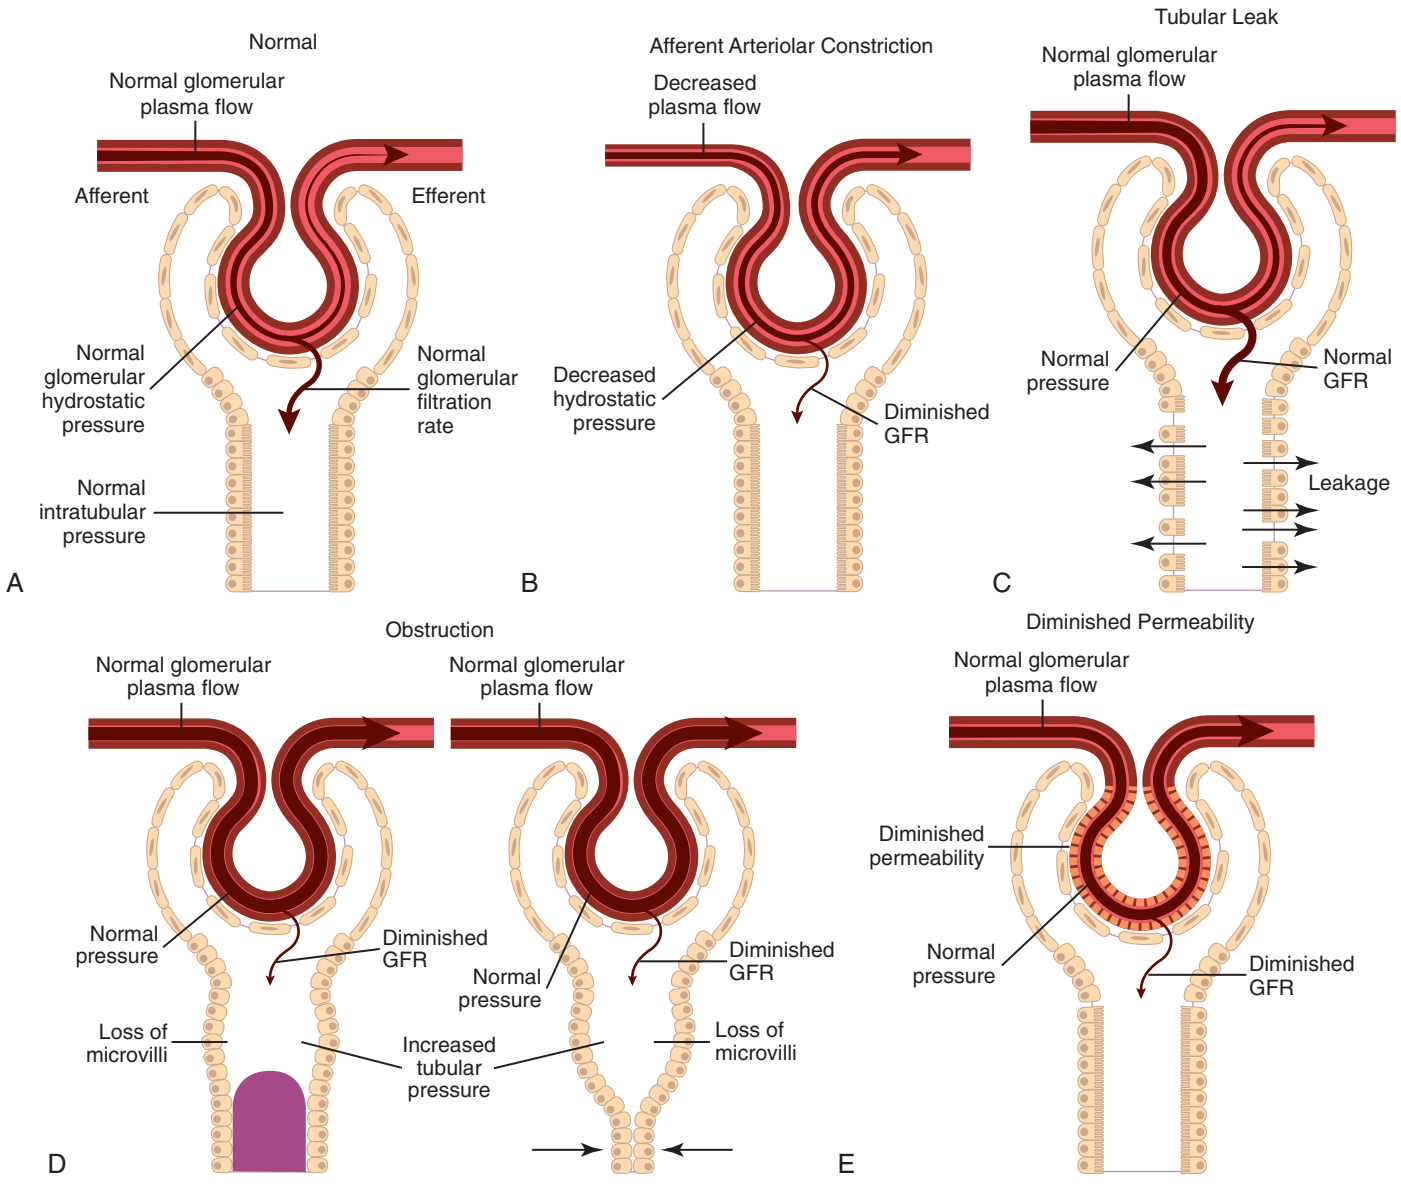

FIG 41.2
Mechanisms contributing to decreased GFR and oliguria in AKI. **(A)** Normal nephron. Glomerular filtration pressure normally is not impeded to any appreciable extent by the normally low intratubular pressure. The healthy renal tubular epithelium prevents tubular fluid from leaking between or across tubular cells. No obstructing material is present within the tubular lumen and the lumen is completely patent. **(B)** Afferent arteriolar vasoconstriction (i.e., vasomotor nephropathy). Glomerular filtration is severely decreased by constriction of the afferent arteriole. Decreased intraglomerular pressure can result in azotemia and decreased urine production. **(C)** Tubular backleak. Filtration pressure may be normal, but filtered fluid leaks back across the damaged tubular epithelium into the interstitium. Some fluid also may accumulate within the damaged tubule. Tubular backleak occurs in patients with more severe tubular injury. Backleak is increased by any concurrent increase in tubular pressure (see **D**). **(D)** Obstruction-increased intratubular pressure. Increased intratubular pressure occurs proximal to the obstructed segment of the nephron. The obstruction can be intraluminal or extraluminal, and the resultant increase in pressure opposes glomerular filtration. The obstructing material can be cellular debris, precipitated proteins, or occasionally crystalline precipitates. Interstitial edema or cellular infiltrates can cause extraluminal obstruction and decrease renal blood flow by compressing interstitial blood vessels. Tubular swelling also can contribute to increased intraluminal pressure. **(E)** Decreased glomerular permeability. In this example, the disease process has decreased the surface area available for glomerular filtration. Decreased glomerular permeability can arise as a consequence of mesangial cell contraction and decreases in the number and diameter of the glomerular fenestrae (pores).

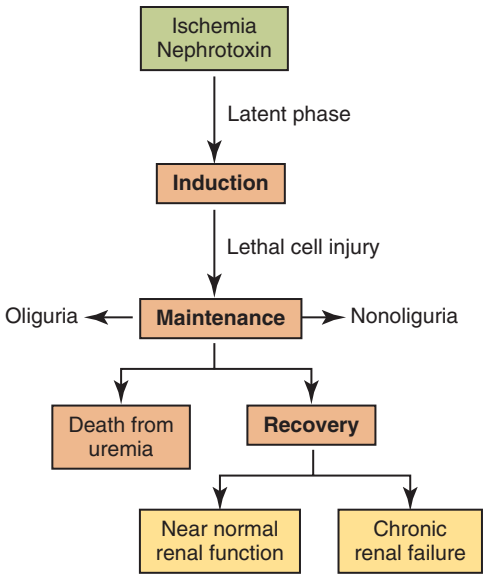

FIG 41.3
Phases of AKI and potential outcomes.

immediate return of normal renal function. Anuria, oliguria, normal urine production, or PU may occur, depending on the specific cause and severity of renal injury. Anuria or marked oliguria occurs in patients with the most severe renal injury (e.g., ethylene glycol, lily toxicity in cats), whereas normal urine production or PU is more likely in those with aminoglycoside nephrotoxicity. Persistently increased SCr characterizes the maintenance phase of AKI, despite correction of all prerenal factors (i.e., restoration of extracellular fluid volume and renal perfusion). With severe renal injury, the patient may not survive the maintenance phase. RBF may be restored by volume expansion during the maintenance phase, but the glomerular filtration rate (GFR) remains very low.

During the recovery phase, BUN and SCr return to normal as GRF and RBF recover, and diuresis ensues in patients that previously were anuric or oliguric. Maximal urinary concentrating ability and urinary acidification may not return to normal, but these limitations are usually not of clinical consequence. BUN and SCr also may not completely normalize, depending on the amount of renal injury sustained. These patients, however, may show sufficient improvement to have a reasonable quality of life as a CKD patient.

Clinical Findings

The clinical findings in AKI are nonspecific and include anorexia, lethargy, vomiting, and diarrhea. These signs are of recent onset, and a longstanding history of PU or PD should not be present. In one study of dogs with AKI, approximately 18% had anuria, 43% had oliguria, 25% had normal urine output, and 14% had PU. Recent trauma, shock, surgery, or general anesthesia suggests the possibility of ischemic AKI. Recent administration of known nephrotoxicants increases the likelihood of nephrotoxic AKI. Physical examination findings in AKI patients tend to be more severe than those observed in animals with prerenal azotemia and include dehydration, uremic breath, and oral ulceration. Mucous membrane pallor, as may be observed in patients with CKD, should not be detected. Fever may be present in animals with AKI caused by nephritis (e.g., dogs with leptospirosis). Overhydration may be present in oligoanuric animals with AKI that have received an excessive amount of fluids intravenously. The kidneys are normal or enlarged and not small and irregular, as may be observed in animals with CKD. Bladder size will vary depending on urine output. If present, bradycardia suggests the need to evaluate the serum potassium concentration.

Clinicopathologic Findings

Anemia should be absent early in the course of AKI, but may develop with repeated blood sampling and ongoing gastrointestinal (GI) blood loss. Total protein concentration may be normal or high, depending on the extent of dehydration. A stress response (e.g., mature neutrophilia, lymphopenia) is common on the complete blood count (CBC). Leukocytosis with left shift and thrombocytopenia may be seen in dogs with acute leptospirosis. The urine specific gravity (USG) typically is in the isosthenuric range (1.007-1.015), regardless of whether the animal is oliguric or nonoliguric. Proteinuria, hematuria, or glucosuria may be observed, and the urine sediment may be active with many casts (e.g., renal tubular cellular casts, coarsely and finely granular casts).

The absence of casts, however, does not exclude a diagnosis of AKI. The presence of oxalate crystals in the urine sediment of an animal with AKI supports a diagnosis of ethylene glycol poisoning. BUN and SCr are high and continue to increase until a plateau is established. It may take days to reach a steady-state SCr after severe acute renal injury, and SCr may continue to increase as additional lethal renal cell injury occurs (i.e., ongoing undetected ischemia or nephrotoxic insult). The magnitude of increase in BUN or SCr is not helpful in the differentiation of AKI from CKD or in the differentiation of prerenal, intrinsic renal, and postrenal azotemia. Rapid increases in BUN, SCr, and serum phosphorus concentrations may occur during AKI. Depending on urine output, serum potassium concentrations may be normal or high, whereas normal or low serum potassium concentrations are expected in polyuric CKD patients. Hyperphosphatemia is present and often severe in AKI patients. Renal secondary hyperparathyroidism maintains phosphorus balance in slowly progressive CKD, a compensatory effect that does not have sufficient time to develop in AKI patients. The serum total calcium concentration usually is normal or low. Blood gas analysis during the maintenance phase usually shows moderate to severe metabolic acidosis. Fractional excretion of sodium is increased in animals with AKI and may be a useful biomarker because it decreases over time in survivors. Recently, other urinary biomarkers such as neutrophil gelatinase-associated lipocalin (NGAL) have been shown to be valuable in the detection and monitoring of patients with AKI (see Chapter 39).

The kidneys are normal-sized or enlarged and of normal shape in patients with AKI. Renal ultrasonography may show increased cortical or medullary echogenicity, but normal ultrasonographic examination findings do not exclude AKI. The kidneys of animals with ethylene glycol intoxication are extremely hyperechoic, and this observation may be helpful diagnostically (Fig. 41.4). Radiographic signs of pulmonary disease (e.g., alveolar pattern, alveolar mineralization) were more common in dogs with AKI than in those with CKD in one study, but these findings did not affect survival. Acute and convalescent serology testing is useful to establish a diagnosis of leptospirosis in dogs with acute nephritis.

Renal biopsy is used to confirm that azotemia is caused by primary renal lesions, to characterize the lesions as acute or chronic, and to establish a prognosis. Renal lesions compatible with AKI include tubular degeneration, tubular necrosis, and intratubular casts. The presence of intact tubular basement membranes with evidence of tubular regeneration is a good prognostic sign, whereas disrupted basement membranes suggest a worse prognosis. Interstitial inflammation is minimal in AKI caused by nephrosis but substantial in AKI caused by nephritis. Lack of fibrosis is supportive of a diagnosis of AKI rather than CKD. Histopathologic changes on light microscopy may be minimal to absent in some animals with AKI. Renal biopsy during a prolonged recovery phase can be helpful to evaluate whether healing is occurring by fibrosis and nephron loss or by tubular regeneration and repopulation of intact basement membranes.

Treatment

The ultimate goal in management of the maintenance phase of AKI is to provide adequate supportive care and time for healing to occur. Prevention of additional renal injury is an important treatment goal; this requires conscientious fluid therapy to provide optimal renal perfusion while at the same time avoiding overhydration. It may take as long as 3 weeks of supportive care to determine whether adequate renal function is likely to return. The severity of residual azotemia will determine whether the animal can be managed successfully as a CKD patient.

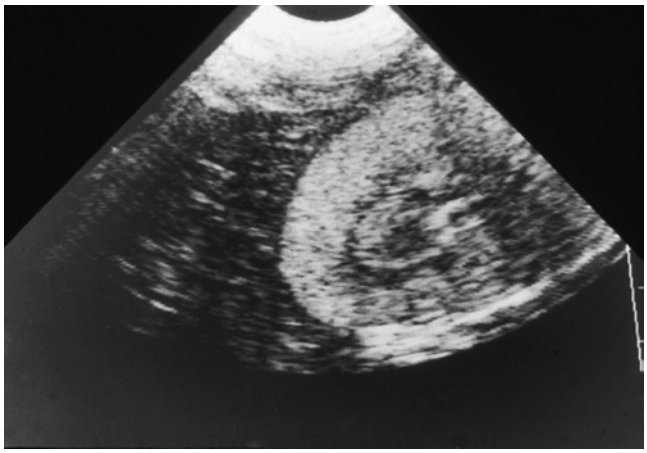

FIG 41.4
Ultrasound appearance of kidney of a dog with ethylene glycol poisoning. Note the extremely hyperechoic renal cortex.

Initially, the most life-threatening disturbances should be identified and corrected while searching for the underlying cause of AKI. Administration of nephrotoxic drugs should be discontinued and no nephrotoxic drugs should be prescribed. Because of the loss of renal autoregulation, AKI patients cannot protect themselves against ongoing episodes of decreased renal perfusion, so general anesthesia and surgery should be avoided.

An indwelling intravenous catheter should be placed to administer fluids and medications. A jugular catheter is preferred so that central venous pressure (CVP) can be monitored. Fluid administration should be decreased or discontinued temporarily if the CVP exceeds 13 cm H_2O or increases rapidly by 2 cm H_2O or more in any 10-minute period. A volume challenge of 20 mL/kg can be administered over 10 minutes to assess the likelihood of impending volume overload. Central venous pressure should not increase by more than 2 cm H_2O if the heart is normal. Dehydration should be corrected rapidly, ideally within 6 to 8 hours to prevent additional renal injury as a result of ongoing ischemia. Once dehydration has been corrected, additional fluids are given to match sensible (i.e., measured urine volume), insensible (i.e., GI and respiratory losses of approximately 20 mL/kg/day), and ongoing contemporary fluid losses (estimated losses from vomiting and diarrhea). An indwelling urinary catheter is needed to monitor urine output and facilitate fluid therapy in the initial 24 to 48 hours. The presence of oliguria necessitates meticulous attention to fluid therapy to prevent overhydration. Weighing the patient twice daily on the same scale will provide useful information about fluid balance. Normal urine output is 1 to 2 mL/kg/h, and a urine output of 2 to 5 mL/kg/h is expected in normal dogs and cats receiving adequate fluid volume expansion. Urine output less than 2 mL/kg/h in an adequately hydrated animal receiving fluid therapy is considered relative oliguria.

Normal saline (0.9% NaCl) usually is the initial fluid of choice for rehydration because of its sodium content (154 mEq/L) and lack of potassium. When rehydration has been accomplished, hypotonic fluids (0.45% sodium chloride in 2.5% dextrose) can be provided for maintenance needs to prevent hypernatremia.

Potassium supplementation, if required, must be adjusted carefully based on serial determinations of serum potassium concentration. Serum potassium concentration will vary depending on urine output, renal excretory function, severity of metabolic acidosis, and oral intake.

Treatment of hyperkalemia may be necessary in oligoanuric patients. Electrocardiography can be useful for detecting the physiologic effects of hyperkalemia, including bradycardia, prolongation of the P-R interval, widening of the QRS complexes, blunting or absence of P waves (atrial standstill), and tenting of T waves. Electrocardiographic

abnormalities usually occur when the serum potassium concentration exceeds 8 mEq/L. Serum potassium concentrations of 8 to 10 mEq/L are considered dangerous for cardiac function, and concentrations of 10 mEq/L or higher are life-threatening. If electrocardiographic changes associated with hyperkalemia are present, treatment should be instituted immediately. Sodium bicarbonate (0.5-1.0 mEq/kg IV) usually is infused first, especially if metabolic acidosis is present. Alternatively, infusion of 20% to 30% hypertonic glucose can stimulate endogenous insulin release and translocation of potassium into cells. Glucose infusion may be selected over sodium bicarbonate when the total or ionized calcium concentration is low, seizures have occurred, or metabolic alkalosis is present. Administration of insulin in combination with hypertonic glucose infusion is controversial. A 10% calcium gluconate solution (0.5-1.0 mL/kg) can be infused to counteract the effects of potassium on the heart, but this approach does not lower the serum potassium concentration. Calcium salts may be beneficial in patients with hypocalcemia, but they also may promote soft tissue mineralization in the presence of hyperphosphatemia. The electrocardiogram (ECG) should become normal within minutes of these treatments, but they only provide temporary relief from the effects of hyperkalemia. Maximizing renal excretory function and maintaining serum pH and bicarbonate concentration in the normal range will promote normalization of the serum potassium concentration. Chronic hyperkalemia may be treated with an ion exchange resin (sodium polystyrene sulfate, 2 g/kg, divided into three doses/day and administered orally or as a retention enema) or may require dialysis.

Metabolic acidosis may be severe and require treatment during the maintenance phase of AKI. If blood gas analysis is not available, total CO_2 concentration (<15 mEq/L) can be used to identify metabolic acidosis. Alkali therapy should be provided if the total CO_2 is less than 15 mEq/L. To correct metabolic acidosis, sodium bicarbonate (1-3 mEq/kg) can be added to maintenance fluids that do not contain calcium (e.g., 0.9% NaCl). Hypernatremia, hyperosmolality, metabolic alkalosis, and ionized hypocalcemia are potential complications of alkali therapy.

Hyperphosphatemia may be severe during the maintenance phase of AKI and may contribute to a worsening of renal lesions and excretory function by several mechanisms, including renal mineralization, direct nephrotoxicity, and vasoconstriction. Hyperphosphatemia also contributes to metabolic acidosis and ionized hypocalcemia. Intestinal phosphate binders may lower serum phosphorus concentration to some degree, even in anorexic patients, by binding with phosphorus in GI secretions. Aluminum hydroxide and aluminum carbonate can be used at a dosage of 30 to 90 mg/kg/day. The dosage should be modified based on serial measurements of the serum phosphorus concentration. Excessive administration of aluminum-containing phosphate binders may result in aluminum toxicity, which is manifested as dementia that may be difficult to distinguish from the effects of uremia.

It is easier to manage nonoliguric patients because hyperkalemia and overhydration are less likely to develop and the severity of nitrogenous waste product retention may be less. Therefore diuretics often are administered in an attempt to convert oliguria to nonoliguria after rehydration. Patients that remain oliguric despite diuretic therapy have a poor prognosis because of limited access to dialysis in veterinary practice. Usually, conversion to nonoliguria occurs without a detectable increase in GFR, as typified by an increase in urine volume with no concomitant decrease in the BUN and SCr. To prevent dehydration and additional renal injury, it is important to replace excessive urinary fluid losses in patients that respond dramatically with increased urine volume after diuretic administration.

Osmotic diuretics are freely filtered, low-molecular-weight substances that undergo little or no tubular reabsorption. The increased osmolality of the glomerular ultrafiltrate obligates water excretion. Mannitol can be administered intravenously at a dosage of 0.25 to 0.50 g/kg and repeated once if no increase in urine volume is observed within 30 to 60 minutes. A total daily dose of 2 g/kg should not be exceeded. The effects of mannitol exceed those observed with isotonic volume expansion (e.g., 0.9% NaCl) and are more potent than those achieved with hypertonic dextrose. Adverse effects include volume overload and hyperosmolality.

Loop diuretics (e.g., furosemide) are probably the diuretics most widely used in AKI patients. Furosemide may be administered intravenously at a dosage of 1 to 2 mg/kg IV followed by an infusion of 1 mg/kg/h for up to 6 hours in an attempt to convert oliguria to nonoliguria. If urine output increases, a constant rate infusion of 0.1 mg/kg/h of furosemide may be administered or intermittent doses may be given as necessary to maintain urine output. If urine output does not increase, furosemide should be discontinued and dopamine or fenoldopam considered. Furosemide may potentiate aminoglycoside toxicity, and its use in this setting is contraindicated.

Dopaminergic receptors are found in renal cortical vasculature and renal tubules. Cats originally were thought to lack dopaminergic receptors in their renal vasculature but recent reports have documented their presence. Dopamine increases RBF and occasionally GFR in normal animals at low dosages (<10 μg/kg/min). Higher dosages cause vasoconstriction, which reduces GFR and RBF. Dopamine contributes to natriuresis by blocking sodium reabsorption in the proximal tubules. Renal dose dopamine usually is defined as 2 to 5 μg/kg/min. The use of renal dose dopamine has never been documented in human or veterinary medicine to be superior to supportive care, and IV administration requires an infusion pump to deliver the calculated dose accurately. The use of furosemide and dopamine together has resulted in conversion from oliguria to nonoliguria in experimental dogs with severe nephrotoxicity, and this combination may be tried when other treatments have failed.

Fenoldopam is a dopamine-1 receptor agonist that causes peripheral vasodilatation, increased RBF, and diuresis. When

administered to normal dogs at an infusion rate of 0.8 µg/kg/min, it significantly increased GFR and fractional excretion of sodium. In a study of dogs and cats with AKI, however, no significant differences in BUN or SCr, length of hospital stay, and survival were found between animals treated with fenoldopam and those not treated with the drug.

Dialysis may be the only way for a dog or cat with AKI to survive the metabolic consequences of advanced uremia, especially in the presence of oliguria or anuria. Hemodialysis removes uremic waste products and retained water very efficiently but is technically demanding, very expensive, and available for dogs and cats only at a limited number of treatment facilities. Even with intermittent hemodialysis, overall survival at time of discharge was only 53% for dogs and 50% for cats with AKI in one study. Peritoneal dialysis requires less technical expertise, is less expensive, and is more widely available than hemodialysis. Historically, dialysis has been attempted mainly late in the clinical course of dogs and cats with AKI when fluid, acid-base and electrolyte abnormalities, and azotemia are advanced. Early institution of dialysis in severe AKI may provide greater opportunity for survival and recovery

Prognosis

Oliguria or anuria that persists or develops during treatment is associated with a poor prognosis. The most common causes for death or euthanasia during initial management of AKI in the maintenance phase are hyperkalemia, metabolic acidosis, or severe azotemia. Overhydration with resultant pulmonary edema as a consequence of aggressive fluid therapy is another important cause of death or euthanasia. The underlying cause of AKI also affects prognosis because some causes of AKI are worse (e.g., ethylene glycol intoxication) than others (e.g., leptospirosis). Aminoglycoside nephrotoxicity and NSAID-induced AKI also often are associated with a poor prognosis. Other organ system disease or failure also worsens the prognosis (e.g., heart failure, diabetes mellitus, liver disease, pancreatitis, disseminated intravascular coagulation, neoplasia, sepsis). AKI patients require intensive care and major surveillance, so the level of medical care available also affects prognosis. Overall, death or euthanasia can be expected in approximately 50% of dogs and cats with AKI. Of those that survive, approximately half can be expected to develop CKD and the other half to become clinically normal, based on the SCr.

CHRONIC KIDNEY DISEASE

CKD culminates in renal failure when compensatory mechanisms are no longer able to maintain the normal excretory, regulatory, and endocrine functions of the kidneys. The resultant retention of nitrogenous solutes, derangements of fluid, electrolyte, and acid-base balance, and failure of hormone production constitute the syndrome of CKD. A diagnosis of CKD is made when these abnormalities have been present for 3 months or longer. Causes of CKD in dogs and cats are listed in Box 41.2 and familial diseases of dogs and cats are listed in Box 41.3.

Staging

The term *chronic kidney disease* is used by the National Kidney Foundation to refer to human patients with five stages of renal disease. Patients in stage 5 CKD have a GFR less than 17% of normal (<15 mL/min/1.73 m^2), are azotemic, and are classified as being in chronic renal failure. Those in stage 4 CKD have a GFR 17% to 32% of normal (15-29 mL/min/1.73 m^2), and might also be azotemic and in chronic renal failure. CKD in dogs and cats can be staged similarly using guidelines proposed by the International Renal Interest Society (IRIS), an international group whose mission is to help veterinarians better understand the diagnosis and management of CKD in dogs and cats. Guidelines for staging CKD in dogs and cats based on SCr are shown in Table 41.2. According to IRIS guidelines, dogs and cats with stages 2, 3, and 4 CKD are azotemic and thus have mild, moderate, or severe CKD, respectively. SCr always should be interpreted along with USG and the physical examination and diagnostic imaging findings, especially renal size. Guidelines established by IRIS also include substaging based on the extent of proteinuria (i.e., magnitude of UPC ratio) and hypertension (see http://www.iris-kidney.com/guidelines/).

BOX 41.2

Causes of CKD in Dogs and Cats

Dog

- Chronic interstitial nephritis (CIN) of unknown cause (most common pathologic diagnosis)
- Chronic pyelonephritis (can be difficult to distinguish histologically from CIN)
- Chronic glomerulonephritis (can be difficult to distinguish histologically from CIN)
- Amyloidosis
- Familial renal disease (several dog breeds can be affected)
- Healing of acute kidney injury

Cat

- CIN of unknown cause (most common pathologic diagnosis)
- Chronic pyelonephritis (can be difficult to distinguish histologically from CIN)
- Chronic glomerulonephritis (can be difficult to distinguish histologically from CIN)
- Amyloidosis (uncommon in mixed-breed cats but familial in Abyssinians)
- Polycystic kidney disease (familial in Persians)
- Healing of acute kidney injury
- Neoplasia (renal lymphoma)
- Pyogranulomatous nephritis caused by feline infectious peritonitis

BOX 41.3

Familial Renal Diseases in Dogs and Cats*

Amyloidosis
- ***Abyssinian cat,*** Beagle, English Foxhound, Oriental Shorthair cat, ***Shar pei,*** Siamese cat

Basement membrane disorder
- Bull Terrier, Bullmastiff, Dalmatian, Doberman Pinscher, English Cocker Spaniel, Newfoundland, Rottweiler, ***Samoyed***

Juvenile glomerulopathy
- Beagle, French Mastiff (Bordeaux)
- Familial glomerulopathy in ***soft-coated Wheaten Terriers*** associated with mutations in NPHS1 and KIRREL2, which encode slit diaphragm proteins nephrin and Neph3/filtrin

Membranoproliferative GN
- Bernese mountain dog, Brittany Spaniel, Soft-C Wheaten Terrier

Multiple renal cystadenocarcinomas
- German Shepherd

Periglomerular fibrosis
- Norwegian Elkhound

Polycystic kidney disease
- ***Bull Terrier***, Cairn Terrier, ***Persian cat***, West Highland White Terrier

Renal dysplasia
- Alaskan Malamute, Chow, Golden Retriever, ***Lhasa apso and Shih tzu***, Miniature Schnauzer, ***Soft-Coated Wheaten Terrier***, Standard Poodle

Renal telangiectasia

Pathophysiology

UREMIA AS INTOXICATION

A uremic toxin is any compound retained because of decreased renal function that can contribute to the clinical signs of uremia (Box 41.4). Many compounds are involved in the pathophysiology of uremia, and no single compound can explain the diversity of uremic symptoms. Parathyroid hormone (PTH) probably is the best-characterized uremic toxin; it plays a major role in development of renal secondary hyperparathyroidism and bone demineralization.

HYPERFILTRATION

Renal disease tends to be progressive when a critical number of nephrons has been destroyed. Glomerular hyperfiltration has been incriminated as an important factor contributing to the progressive nature of renal disease. The total GFR represents the sum of single-nephron GFR (SNGFR) in all nephrons of both kidneys. In a healthy animal, the range of SNGFR is fairly narrow (Fig. 41.5, *lower panel*). During progressive renal disease, the decline in total GFR initially is offset by an increase in SNGFR in functional remnant nephrons (so-called glomerular hyperfiltration). Thus the normally narrow range of SNGFR widens during the development of CKD because diseased nephrons have low SNGFR and

TABLE 41.2

International Renal Interest Society Stages of Chronic Kidney Disease in Dogs and Cats Based on Serum Creatinine Concentration*

	SERUM CREATININE CONCENTRATION (mg/dL)	
STAGE	**DOGS**	**CATS**
1	<1.4 (with impaired concentrating ability, abnormal renal palpation or abnormal renal imaging, or both)	<1.6 (with impaired concentrating ability, abnormal renal palpation or abnormal renal imaging, or both)
2	1.4-2.0 (with mild or no clinical signs)	1.6-2.8 (with mild or no clinical signs)
3	2.1-5.0 (with systemic clinical signs)	2.9-5.0 (with systemic clinical signs)
4	>5.0 (with systemic signs and increased risk of uremic crisis)	>5.0 (with systemic signs and increased risk of uremic crisis)

BOX 41.4

Pathophysiologic Features of Chronic Kidney Disease

- Uremic intoxication (i.e., retention of uremic solutes)
- Hyperfiltration
  - Proteinura
  - Glomerular sclerosis
- Maintenance of external solute balance, despite progressively declining glomerular filtration rate
- Development of polyuria and polydipsia and defective urinary concentrating ability
- Maintenance of calcium and phosphorus balance and development of renal secondary hyperparathyroidism
- Maintenance of acid-base balance and development of metabolic acidosis
- Development of nonregenerative anemia
- Hemostatic disorders (e.g., platelet dysfunction)
- Gastrointestinal disturbances
- Cardiovascular complications (e.g., hypertension)
- Metabolic disturbances (e.g., insulin resistance, euthyroid sick syndrome)

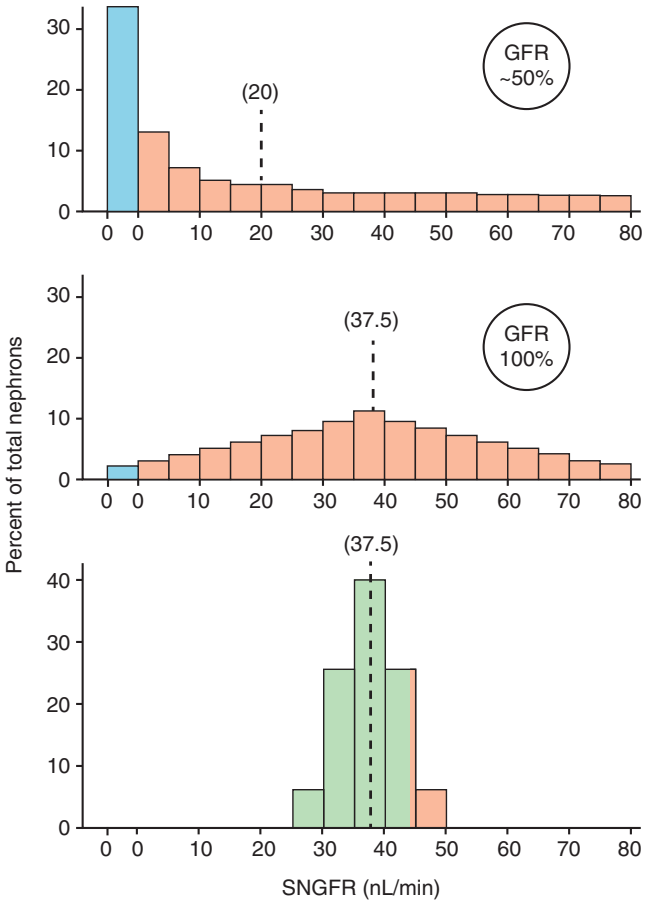

FIG 41.5
Widening range of SNGFR as renal disease progresses. *Lower panel,* Normal situation. *Middle panel,* Situation in which some nephrons are nonfiltering or have decreased SNGFR and others have increased SNGFR but the mean SNGFR remains unchanged and total GFR is still normal. *Upper panel,* The total GFR has been reduced by 50%. In this setting, the mean SNGFR is decreased, many nephrons are nonfiltering or hypofiltering, and many are hyperfiltering. (From Brenner BM: Nephron adaptation to renal injury or ablation, *Am J Physiol* 249:F332, 1985.)

remnant nephrons have supranormal SNGFR (see Fig. 41.5, *middle and upper panels*). This adaptation occurs to such an extent that total GFR increases approximately 40% to 60% in remnant renal tissue over a period of 4 to 6 weeks after experimental renal ablation. For example, if one kidney is removed from a dog with a GFR of 40 mL/min, GFR immediately will decrease to 20 mL/min but within 1 to 2 months will stabilize at approximately 30 mL/min because of hyperfiltration in the remnant nephrons.

FUNCTIONAL AND MORPHOLOGIC CHANGES IN REMNANT RENAL TISSUE

Hyperfiltration increases protein movement across the glomerular capillaries into Bowman's space and the mesangium. Proteinuria and glomerular sclerosis in remnant nephrons are adverse functional and morphologic consequences of glomerular hyperfiltration that contribute to the progression of renal disease. Tubular cells have receptors for hormones and growth factors, some of which are small-MW proteins that are filtered excessively and taken up by the proximal tubular cells, where they promote cellular proliferation and extracellular matrix deposition, leading to tubulointerstitial damage. Tubular cell overload caused by increased reabsorption of filtered proteins also upregulates inflammatory and vasoactive genes that contribute to damage. Ischemia of portions of the nephron downstream from the damaged glomerulus, mineralization in the kidney, and local ammonia accumulation are additional factors that contribute to tubulointerstitial lesions. This progressive damage is independent of the activity of the underlying primary renal disease.

Factors that may affect the progression of CKD include species differences, extent and duration of reduction in renal mass, dietary modifications, and complications. In dogs and cats, 85% to 95% of renal tissue must be destroyed to result in progression, whereas progression occurs in humans and rats after 75% to 80% renal ablation. Dogs with 75% reduction in renal mass followed for 4 years did not show evidence of progression, whereas dogs with 94% reduction in renal mass developed progression over 24 months. In rats, dietary restriction of protein can reverse glomerular hyperfiltration. In one study of dogs, however, a diet containing 17% protein did not prevent glomerular hyperfiltration in dogs with 94% renal ablation. On the other hand, a diet containing 8% protein has been shown to result in malnutrition (e.g., weight loss, hypoalbuminemia) and increased mortality in dogs with experimentally induced renal disease. Decreasing dietary phosphorus content can reverse renal secondary hyperparathyroidism and slow progression of renal disease. Improvement in proteinuria and renal morphologic changes also may be associated with decreased caloric intake. Dietary supplementation with ω-3 polyunsaturated fatty acids (PUFAs) also may have beneficial effects. Hypertension and urinary tract infection are examples of complications that may contribute to progression.

EXTERNAL SOLUTE BALANCE

The concept of external solute balance is important in understanding the compensatory response of the kidneys to chronic, progressive renal disease. An individual animal consumes different amounts of water and solutes each day, and the kidneys must adjust their output of water and solutes to keep the volume and composition of body fluids constant. The challenge to the kidneys in a patient with CKD is to maintain balance, despite advancing disease and progressively declining GFR. In health, as spontaneous increases or decreases in GFR occur, the absolute tubular reabsorption of filtered solutes changes in a similar direction. Thus the fraction of the filtered load that is resorbed remains constant, despite changes in GFR. This principle has been termed the *glomerulotubular balance.* For any given solute, the diseased kidney maintains glomerulotubular balance as the GFR declines by decreasing the fraction of the filtered load of that solute that is resorbed and increasing the fraction of the filtered load of that solute that is excreted. In some cases, the

mechanisms responsible for the adaptive changes have adverse effects on the animal.

This trade-off hypothesis was articulated by Dr. Neil Bricker in 1972, as follows: "The biological price to be paid for maintaining external solute balance for a given solute as renal disease progresses is the induction of one or more abnormalities of the uremic state." Hyperfiltration is an example of the trade-off hypothesis in that total GFR is preserved, but at the expense of proteinuria, glomerular sclerosis, and progressive deterioration of residual renal tissue. Another classic example is the maintenance of normal calcium and phosphorus balance by renal secondary hyperparathyroidism but at the expense of bone density. Buffering of accumulated fixed acid by bone carbonate at the expense of bone density is yet another example. Some maladaptive mechanisms and their consequences can be prevented by a proportional reduction in the intake of the solute in question. This strategy will avoid the need for the kidneys to alter fractional reabsorption and excretion of the solute being manipulated. Using this approach with dietary phosphorus has been shown to prevent or reverse renal secondary hyperparathyroidism and slow the progression of CKD.

The kidneys respond differently to different solutes during development of CKD (Fig. 41.6). Solutes that experience no regulation are handled by glomerular filtration alone (e.g., urea, creatinine). At any given time, the plasma concentrations of these solutes reflect the prevailing GFR. Solutes that experience limited regulation are handled by glomerular filtration and some combination of tubular reabsorption and secretion (e.g., phosphate, hydrogen ions). Normal plasma concentrations of these solutes are maintained until the GFR decreases to below approximately 15% to 20% of normal. Solutes that experience complete regulation also are handled by glomerular filtration and some combination of tubular reabsorption and secretion (e.g., sodium, potassium), but normal plasma concentrations of these solutes are maintained until the GFR decreases below 5% of normal or until oliguria or anuria develops.

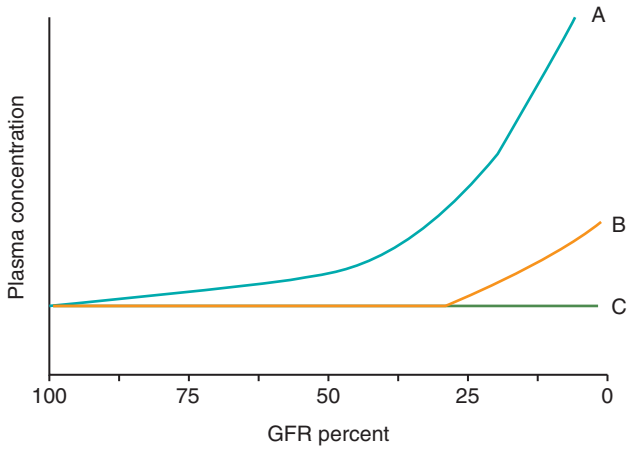

FIG 41.6
Renal regulation of solute balance. Curve A represents solutes experiencing no regulation. Curve B represents solutes experiencing limited regulation. Curve C represents solutes experiencing complete regulation. (From Bricker NS, Fine LG: The renal response to progressive nephron loss. In Brenner BM, Rector FC: *The kidney,* ed 2, Philadelphia, 1981, WB Saunders, p 1058.)

DEVELOPMENT OF POLYURIA AND POLYDIPSIA

The ability to produce concentrated urine (i.e., conserve water) and the ability to excrete a water load are impaired in CKD. The development of this concentrating defect is heralded clinically by the onset of PU and compensatory PD. Increased solute load per residual functioning nephron rather than architectural damage to the tubules and interstitium is the single most important factor contributing to the concentrating defect—that is, the remnant nephrons are functioning under conditions of osmotic diuresis. In most cases, defective concentrating ability develops when 67% of the nephron population has become nonfunctional and is recognized clinically by isosthenuria, a urine osmolality of 300 to 600 mOsm/kg or USG of 1.007 to 1.015. The example in Box 41.5 demonstrates how PU develops in CKD, despite a progressive decline in GFR.

CALCIUM AND PHOSPHORUS BALANCE

Normal calcium and phosphorus metabolism requires the interaction of PTH, 1,25-dihydroxycholecalciferol (calcitriol), fibroblast growth factor-23 (FGF-23), and calcitonin with the kidneys, GI tract, and bone. The kidneys are the site of conversion of 25-hydroxycholecalciferol to

BOX 41.5

Case Example

Consider a normal 10-kg dog with normal daily urine output of 333 mL and urine osmolality of 1500 mOsm/kg. These values imply a solute load of 0.333 × 1500 or 500 mOsm/day. The same dog with CKD might have a relatively fixed urine osmolality of 500 mOsm/kg and would require a urine output of 1000 mL to excrete the same 500 mOsm. Renal handling of water in this dog might change as shown here after the development of chronic renal disease.

	Normal	Diseased
Number of nephrons	1,000,000	250,000
Total GFR (mL/min)	40	15
SNGFR (nL/min)	40	60
Urine output (mL/day)	333	1000
Urine output (mL/min)	0.23	0.69
Urine output per nephron (nL/min)	0.23	2.76
Filtered water reabsorbed	99.4%	95.4%
Filtered water excreted	0.6%	4.6%

Note that the fraction of filtered water that is resorbed is decreased in the disease state and the fraction that is excreted is increased.

1,25-dihydroxycholecalciferol by 1α-hydroxylase. Total serum calcium concentrations are decreased in approximately 10% of dogs with CKD, but decreased serum ionized calcium concentration is found in 40% of dogs with CKD. Ionized hypocalcemia may occur in association with hyperphosphatemia in CKD as a consequence of the mass law effect. The amounts of calcium and phosphorus that can remain in solution together are defined by the $[Ca] \times [P_i]$ product, where [Ca] is the serum calcium concentration and $[P_i]$ is the serum phosphorus concentration. When this value is more than 60 to 70, soft tissue mineralization occurs. In one study, the proportion of CKD dogs with $[Ca] \times [P_i]$ product >70 increased with increased stage of disease, and mortality was higher (and survival time shorter) in dogs with $[Ca] \times [P_i]$ product >70. Decreased production of calcitriol by the diseased kidneys impairs intestinal absorption of calcium, and complexing of calcium with phosphate in the lumen of the intestinal tract further impairs calcium absorption. Approximately 5% to 10% of dogs with CKD develop hypercalcemia, which may damage the kidney additionally by causing renal vasoconstriction and interstitial mineralization. The serum ionized calcium concentration, however, usually is normal or low when measured in dogs with CKD that have increased total serum calcium concentrations.

Hyperparathyroidism is a consistent finding progressive CKD. Development of renal secondary hyperparathyroidism typically has been explained by the effect of phosphorus retention on serum ionized calcium concentration (Fig. 41.7, *A*). Reduction in GFR decreases phosphate excretion and results in hyperphosphatemia, which in turn causes a reciprocal decrease in serum ionized calcium concentration by the mass law effect ($[Ca] \times [P_i]$ = constant). Ionized hypocalcemia stimulates the parathyroid glands to synthesize and secrete PTH. The increase in PTH stimulates increased renal excretion of phosphate and increased release of calcium and phosphate from bone, which returns the serum phosphorus and ionized calcium concentrations to normal. PTH decreases the fractional reabsorption of phosphate in the kidney by decreasing the tubular maximum for phosphate reabsorption. The limit of this compensatory response is reached when the GFR declines to approximately 15% to 20% of normal; when the GFR declines further, hyperphosphatemia develops. Thus calcium and phosphorus balance is maintained by a progressive increase in the serum PTH concentration. A chronically increased PTH concentration leads to bone demineralization and other toxic effects of uremia (e.g., bone marrow suppression, uremic encephalopathy). This sequence of events represents a trade-off for the maintenance of calcium and phosphorus balance in progressive CKD.

The effect of phosphorus retention on renal calcitriol production suggests an additional factor in the development of renal secondary hyperparathyroidism. Phosphorus retention and hyperphosphatemia inhibit renal 1α-hydroxylase, which impairs the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (calcitriol). Impaired production of calcitriol decreases the GI absorption of calcium, which in turn contributes to ionized hypocalcemia and

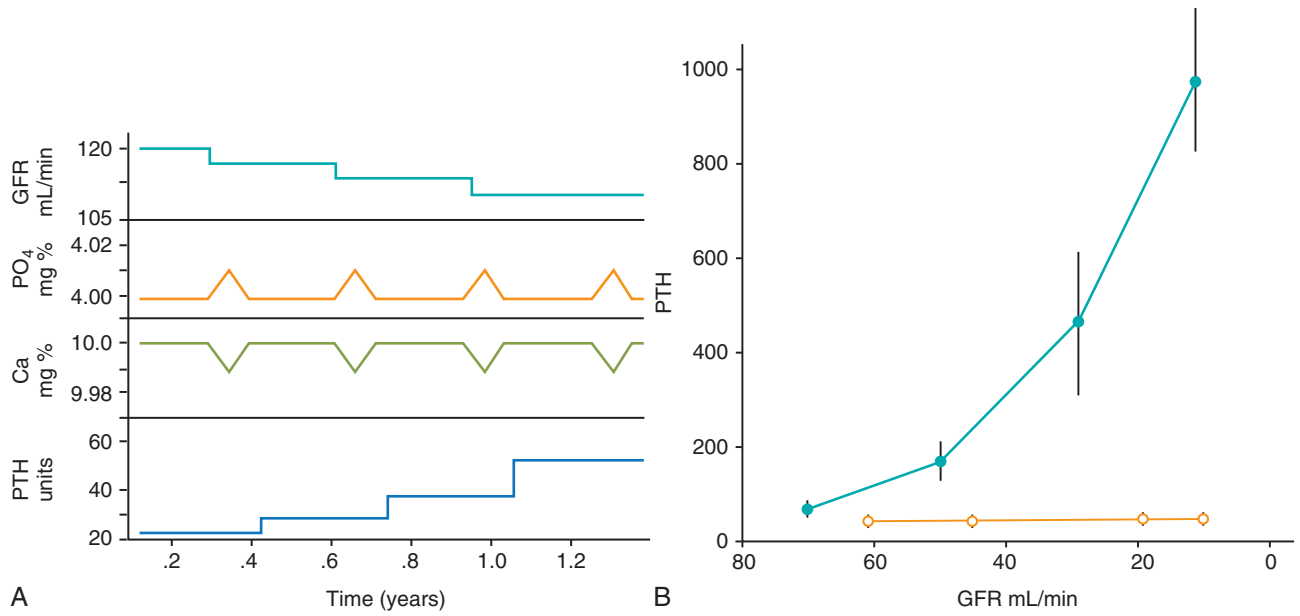

FIG 41.7
(A) Classic theory of the development of renal secondary hyperparathyroidism according to Slatopolsky (see text for explanation). **(B)** Effect of proportional restriction of dietary phosphorus in progressive CKD on serum PTH concentration *(open circles)* as compared with normal unrestricted dietary intake of phosphorus *(closed circles)*. (From Slatopolsky E, et al.: On the pathogenesis of hyperparathyroidism in chronic experimental renal insufficiency in the dog, *J Clin Invest* 50:492, 1971.)

stimulation of PTH secretion. Calcitriol normally feeds back to receptors on the parathyroid gland cells and decreases the synthesis and secretion of PTH. This negative feedback loop is impaired in CKD because of decreased renal production of calcitriol and further contributes to increased PTH secretion.

FGF-23 is a phosphatonin produced in bone that inhibits proximal renal tubular reabsorption of phosphate and also inhibits 1α-hydroxylase activity in the kidney, thus decreasing calcitriol production. It increases in CKD to facilitate phosphate excretion, and may contribute to renal secondary hyperparathyroidism by decreasing the negative feedback of calcitriol to the parathyroid glands. FGF-23 increases with increasing stage of CKD in dogs and cats and has been shown to be predictive of disease progression in cats with CKD. Baseline FGF-23 concentrations were higher in nonazotemic geriatric cats that went on to develop azotemia over 12 months of follow-up as compared with those that did not.

Renal secondary hyperparathyroidism can be prevented or reversed in dogs with experimentally induced CKD by decreasing the dietary intake of phosphorus in proportion to the decrease in GFR (see Fig. 41.7, *B*). Feeding a renal diet decreased FGF-23 concentrations in both normophosphatemic and hyperphosphatemic cats with stable azotemic CKD, indicating that dietary phosphorus restriction allows maintenance of normal serum phosphate concentrations with lower FGF-23 concentrations.

Early in the course of CKD, decreased phosphorus intake stimulates renal 1α-hydroxylase, which results in increased calcitriol production. This increase in calcitriol results in enhanced intestinal absorption of calcium, increased serum ionized calcium concentration, and decreased PTH secretion. Later in the course of CKD, the kidneys are unable to produce sufficient calcitriol to promote normal intestinal absorption of calcium. Phosphorus restriction slows the progression of CKD by blunting renal secondary hyperparathyroidism and limiting renal interstitial mineralization, inflammation, and fibrosis. These observations form the basis for the use of phosphorus restriction in the medical management of dogs and cats with CKD.

ACID-BASE BALANCE

The main cause of metabolic acidosis in CKD is limitation of renal ammonium excretion. The chronically diseased kidney maintains hydrogen ion balance by increased renal ammoniagenesis from glutamine. Absolute ammonium excretion falls during progressive CKD, but ammonium excretion is markedly increased when expressed per remnant nephron. On a per nephron basis, the diseased kidney can increase its ammonium excretion by threefold to fivefold. This adaptive mechanism reaches its limit when the GFR falls to 10% to 20% of normal. At this point, the diseased kidneys can no longer cope with the daily fixed acid load effectively, and a new steady state is established at a lower than normal plasma bicarbonate concentration. The metabolic acidosis of CKD usually is not severe, and the relatively mild decrease in plasma bicarbonate concentration is a consequence of the large reservoir of buffer (e.g., calcium carbonate) in bone. Buffering of metabolic acidosis by the release of calcium carbonate from bone contributes to bone demineralization, and accumulation of ammonia in the kidney may elicit tubulointerstitial inflammation, another example of the trade-off hypothesis. Alkali therapy to correct metabolic acidosis may slow the progression of CKD.

ANEMIA

Erythropoietin is a glycoprotein hormone that regulates red cell production by the bone marrow, and the kidney is the major source of erythropoietin in the adult animal. A nonregenerative (i.e., normochormic normocytic) anemia is common in CKD but variable in severity. Its main cause is inadequate production of erythropoietin by the diseased kidneys to meet the demand for new red cells because of loss from hemolysis and hemorrhage. The life span of red cells in uremic patients is approximately 50% of that of healthy individuals, which is thought to be caused by a uremic toxin in plasma. Platelet dysfunction in CKD promotes insidious, ongoing blood loss (e.g., GI hemorrhage). Recombinant human erythropoietin has been used successfully to correct the anemia of CKD in human patients. This product also is effective in correcting the anemia of CKD in dogs and cats, but the potential for antibody formation limits its usefulness in these species.

HEMOSTATIC DEFECTS

Uremia is characterized by abnormal hemostasis and a predisposition to hemorrhage. GI blood loss is observed more commonly in dogs than cats. A qualitative platelet function defect (platelet numbers are normal) is most important. Risk of hemorrhage is best correlated with the buccal mucosal bleeding time (normally <2-3 minutes). Other coagulation test results (e.g., prothrombin time, partial thromboplastin time, activated coagulation time) usually are normal. Abnormalities of platelet function include abnormal platelet adhesiveness and aggregation, decreased clot retraction, and decreased thromboxane production by platelets. Platelet dysfunction also is thought to be the consequence of uremic toxins (e.g., guanidines, PTH).

GASTROINTESTINAL DISTURBANCES

Erosions and ulcers of the buccal mucosa and tongue may be observed in uremic dogs but much less commonly in cats. Ulcers may be caused by the excretion of urea into saliva and breakdown to ammonia by oral bacteria. Tongue tip necrosis may occur in uremic dogs; it results from fibrinoid necrosis and arteritis with focal ischemia, necrosis, and ulceration. Gastroenteritis with GI hemorrhage is relatively common in dogs with CKD. It arises as a consequence of bleeding caused by platelet dysfunction, ammonia production from urea by bacteria in the GI tract, ischemia caused by vascular lesions, and increased concentrations of gastrin because of impaired renal excretion. In one study, gastric ulceration, edema, and vascular fibrinoid change were not observed in the stomachs of cats with CKD. Serum gastrin concentrations were high

in these CKD cats, but the primary gastric lesions observed were fibrosis and mineralization. Vomiting is more common in uremic dogs than in cats, possibly as a consequence of the differences in gastric lesions observed in cats and dogs with CKD. Stimulation of the chemoreceptor trigger zone by a uremic toxin may contribute to vomiting in patients with CKD.

CARDIOVASCULAR COMPLICATIONS

Systemic hypertension is present in 20% to 30% of dogs and cats with CKD and in 50% to 80% of dogs with glomerular disease. Normal blood pressure in dogs and cats is similar to that of humans (i.e., systolic 120 mm Hg, diastolic 80 mm Hg), but interactions in the hospital setting increase the blood pressure of dogs and cats (so-called white coat effect), making identification of mild to moderate hypertension difficult. Factors contributing to hypertension include renal ischemia associated with CKD that results in activation of the renin-angiotensin system and increased sympathetic nervous system activity. An intrarenal mechanism for sodium retention plays an important role in the hypertension in patients with glomerular disease. Clinical and pathologic manifestations of systemic hypertension include ocular abnormalities (e.g., retinal detachment, retinal hemorrhages, retinal vascular tortuosity) and cardiovascular abnormalities (e.g., left ventricular enlargement, medial hypertrophy of arteries, murmurs, gallop rhythms).

METABOLIC COMPLICATIONS

Many small peptides are normally filtered by the kidney, reabsorbed, and degraded in the proximal tubular cells. Loss of this clearance function can result in metabolic derangements because many of these peptides are hormones. Peripheral insulin resistance and mild fasting hyperglycemia (<150 mg/dL) are common in uremia, but not clinically relevant. Excess gastrin increases the stimulation of acid secretion in the stomach and contributes to uremic gastroenteritis, and excess glucagon may contribute to negative nitrogen balance and tissue catabolism. CKD is an important nonthyroidal illness, which can cause confusion in diagnosis of hyperthyroidism in older cats and must be taken into consideration when evaluating treatment options. Plasma cortisol concentrations may be slightly increased, and increased mineralocorticoids may contribute to hypertension.

Clinical Findings

PU and PD may be the first abnormalities noted by observant owners of dogs and cats with CKD. In dogs, nocturia may be noted first because the animal begins waking the owner up at night to be allowed outside to urinate. If PU and PD are not recognized, nonspecific signs of uremia may be the first abnormalities the owner detects. Anorexia, weight loss, and lethargy are common in dogs and cats with CKD. Client surveys have shown that poor appetite is common in cats with CKD and may negatively impact the animal's quality of life as perceived by the owner. In a study of cats with CKD, affected animals were shown to have lost a median of 8.9% of body weight in the year preceding diagnosis, and weight loss accelerated as the disease progressed. Body weight <4.2 kg at the time of diagnosis was associated with significantly shorter survival time. In a study of dogs with CKD, higher body condition score at the time of diagnosis was associated with improved survival. Vomiting is more common in dogs with CKD than in cats.

On physical examination, poor body condition and dull dry hair coat are evidence of chronic disease. Dehydration is common because of inadequate food intake and insufficient water intake to keep pace with PU. Oral ulcers may be observed in dogs with CKD. Pallor may be evident if anemia is present. Clinical manifestations of bone demineralization are extremely rare in adult dogs and cats with CKD, but fibrous osteodystrophy can be dramatic in young growing dogs with uremia (so-called rubber jaw). Despite a lack of clinical signs, CKD has been shown to be associated with histologic evidence of decreased cancellous and cortical bone mineral density in cats. The presence of subcutaneous edema or ascites suggests the possibility of glomerular disease.

Clinicopathologic Findings and Imaging

Nonregenerative anemia may be observed on the CBC but can be masked by dehydration—that is, the hematocrit should be evaluated in conjunction with total protein concentration. Mature neutrophilia and lymphopenia reflect the stress of chronic disease. Platelet numbers typically are normal, but platelet function may be abnormal. Serum potassium concentrations usually are normal in patients with CKD unless oliguria or anuria develop. Azotemia is present if 75% or more nephrons are nonfunctional, and hyperphosphatemia is observed if 85% or more nephrons are nonfunctional. Serum total calcium concentration is normal to slightly low or, rarely, high. Bicarbonate concentration usually is only mildly decreased, and moderate to severe metabolic acidosis is a late finding in dogs and cats with CKD.

In dogs, isosthenuria develops when 67% or more nephrons become nonfunctional (USG, 1.007-1.015), but some cats with CKD retain concentrating ability after the onset of azotemia. In one study, cats with a 58% to 83% loss of functional nephrons could produce concentrated urine (USG, 1.022-1.067). Thus a cat with azotemia and relatively concentrated urine does not necessarily have prerenal azotemia. The magnitude of proteinuria is a reflection of intraglomerular hypertension and may be an indicator of the rate of progression of renal disease. In one study, a urine protein-to-creatinine (UPC) ratio >1.0 was associated with more rapid progression and increased risk of developing uremic crisis or death. Severe persistent proteinuria with an inactive urine sediment suggests primary glomerular disease. Microalbuminuria refers to urine protein concentrations >1 mg/dL but <30 mg/dL. Microalbuminuria is an early indicator of endothelial damage and may be a risk factor for progression of renal disease. It increases with age and in association with other systemic diseases, but its prognostic value is uncertain

in dogs and cats. Pyuria and bacteriuria suggest the presence of urinary tract infection.

The kidneys may be observed to be irregularly shaped or small on plain abdominal radiographs (<2.5 times the length of the L2 vertebra on the ventrodorsal view) in dogs or cats with CKD, but normal renal shape and size do not rule out CKD. Similarly, renal ultrasonography may show increased echogenicity of renal tissue and loss of corticomedullary distinction when medullary echogenicity increases and becomes similar to cortical echogenicity, but normal ultrasonographic findings do not exclude CKD.

CONSERVATIVE TREATMENT

General Principles

Do not be overly pessimistic when presented with a severely dehydrated dog or cat with CKD. If the patient is dehydrated, appropriate IV fluid therapy to resolve prerenal azotemia should be provided (Box 41.6). Rehydration may require 1 to 5 days. Frequently, the patient and laboratory results look much better after rehydration with a balanced crystalloid solution (e.g., lactated Ringer's). Next, search for potentially reversible causes of renal failure (e.g., pyelonephritis, hypercalcemia, obstructive nephropathy) and treat them appropriately. Finally, treat reversible factors that may be aggravating the renal disease (e.g., urinary tract infection, ongoing electrolyte or acid-base disturbances, hypertension). After these steps, a treatment plan should be devised to maintain fluid, electrolyte, acid–base, and caloric balance while preventing the accumulation of metabolic waste products and minimizing the detrimental effects of lost endocrine functions of the kidney.

Dietary Management

Dogs and cats with CKD should have access to fresh water at all times. Renal diets for dogs and cats have been shown to prolong survival. In one study, 12- to 14-month survival was observed in CKD cats on renal diets as compared with 6 to 12 months for cats eating regular diets. These studies do not necessarily show the effect of a specific nutrient because renal diets differ from regular diets in several ways, such as decreased protein, phosphorus, and sodium and increased B vitamins, soluble fiber, ω-3 PUFA, and antioxidants, but they represent grade I evidence (i.e., evidence obtained from randomized controlled clinical studies in clinical patients of the target species) for the use of renal diets in dogs and cats with CKD. Commercial renal diets designed for dogs and cats with CKD are preferable to homemade diets, which can be highly variable in composition and sometimes nutritionally inadequate.

Theoretical benefits of protein restriction are a reduction in clinical signs associated with uremia by decreasing production of toxic metabolites of protein metabolism and decreasing hyperfiltration in remnant nephrons. A low-protein diet, however, does not lessen the metabolic workload of the kidney because the metabolites of protein catabolism are excreted primarily by glomerular filtration, and most of the metabolic energy expended by the kidneys arises from sodium reabsorption. Moderate protein restriction is indicated to relieve clinical signs of uremia and promote patient well-being, but it is not likely that moderate protein restriction will reverse hyperfiltration in dogs and cats with CKD.

When in the course of progressive renal disease protein restriction should be started is controversial. It is not recommended early in the course of renal disease before symptomatic accumulation of protein catabolic products has become a problem. Dietary modification often is recommended when moderate azotemia is present in a stable, hydrated patient with CKD (e.g., IRIS stage 2 in cats or stage 3 in dogs). Feeding moderately restricted protein diets (e.g., 15%-17% protein) to dogs with CKD is preferable to feeding extremely high- or low-protein diets. A gradual transition

BOX 41.6

Treatment Options for Chronic Kidney Disease

In hospital
- IV crystalloid fluid therapy to restore hydration and resolve prerenal azotemia
- Correction of acid-base disturbances
- Correction of electrolyte disturbances
- Identification and resolution of reversible causes of renal failure (e.g., pyelonephritis, hypercalcemia, obstructive nephropathy)
- Identification and resolution of complicating problems (e.g., lower urinary tract infection, hypertension)

At home
- Dietary management
  - Access to fresh water at all times
  - Provision of a renal diet—decreased protein, phosphorus, sodium; increased B vitamins, soluble fiber, ω-3 PUFAs, antioxidants
  - Provision of adequate nonprotein calories (40-60 kcal/kg/day)
- Additional phosphorus restriction (phosphorus binders)
  - Aluminum hydroxide
  - Aluminum carbonate
  - Calcium carbonate
  - Calcium acetate
  - Sevelamer HCl
  - Lanthanum carbonate
  - Chitosan, calcium carbonate
- Alkali and potassium supplementation (e.g., potassium citrate, potassium gluconate)
- H_2 receptor blockers (e.g., famotidine)
- Angiotensin-converting enzyme inhibitors (e.g., enalapril, benazepril) and angiotensin receptor blockers (e.g., losartan, telmisartan)
- Recombinant human erythropoietin
- Calcitriol
- Additional antihypertensive medications (e.g., amlodipine)
- Crystalloid fluids (e.g., lactated Ringer's solution) administered by the owner

from the previous diet to the prescribed diet over 2 to 4 weeks is recommended. On a low-protein diet, the BUN concentration will decrease as a result of dietary modification alone and will no longer be a good indicator of renal function. SCr is not influenced by diet. It is, however, affected by loss of muscle mass, which can confound interpretation of SCr in cachectic animals with CKD.

The nutritional needs of cats differ from dogs. Dogs require that a minimum of approximately 5% of calories come from protein, whereas cats require that a minimum of 20% of calories come from protein. These represent minimum requirements and do not provide for nitrogen reserves. Healthy adult cats typically maintain lean body mass on 32% to 34% of calories from protein. Cats also seem to prefer diets higher in fat and require a source of taurine in their diet. Stable body weight, stable serum albumin concentration, and decreased BUN concentration are indications that a low-protein diet is being used effectively. Accelerated weight loss, on the other hand, indicates the need for dietary modifications.

Adequate nonprotein calories to maintain body condition should be provided by carbohydrate and fat. Approximately 60 kcal/kg/day are recommended as a general guideline, but older animals may eat fewer calories normally (e.g., 40 kcal/kg/day). Supplementation of the diet with ω-3 PUFAs may be renoprotective. Increasing the amount of ω-3 PUFAs relative to ω-6 PUFAs in the diet decreases the production of proinflammatory, platelet-aggregating, vasoconstrictive prostaglandin (PG) TXA2 and increases the production of vasodilatory prostaglandins (PGE, PGI). Studies of dogs with remnant kidneys have shown beneficial effects of supplementation, including decreased proteinuria, preservation of GFR, and less severe renal morphologic changes. These studies used very low ω-6–to–ω-3 ratios, which may not be easily achievable using commercial diets. An ω-6–to–ω-3 ratio of 2 : 1 may be reasonable in a renal diet. Alternatively, the diet can be supplemented with 1 to 5 g/day of ω-3 PUFAs.

Increased fractional sodium excretion allows maintenance of sodium balance during the course of progressive CKD. Dietary sodium restriction may be advisable in dogs with CKD and hypertension and in those with glomerular disease that have sodium retention and edema. Patients with CKD are less flexible in adjusting to changes in dietary sodium load. Many commercial pet foods provide more sodium than needed, often about 1%, and commercial products marketed for dogs and cats with CKD provide approximately 0.2% to 0.3% sodium.

The metabolic acidosis of CKD generally is well compensated. If metabolic acidosis is severe (serum bicarbonate concentration ≤ 12 mEq/L), sodium bicarbonate may be added to the treatment regimen. The dosage should be adjusted to maintain the serum bicarbonate concentration at 14 mEq/L or higher and the additional sodium intake should be taken into consideration. Potassium gluconate and potassium citrate are alternative sources of alkali that provide potassium and do not pose the problem of an additional sodium load. Hyperkalemia usually is not a problem in dogs and cats with CKD. The kidneys can maintain normal serum potassium concentrations at 5% of normal GFR if urine volume is adequate. Hypokalemia in dogs and cats with CKD may be treated with oral potassium gluconate or potassium citrate.

Phosphorus restriction

Early phosphorus restriction in CKD has been shown to blunt or reverse renal secondary hyperparathyroidism. In a study of dogs with 94% nephrectomy that were fed diets containing 17% protein with 0.5% or 1.5% phosphorus, progression was more rapid and outcome worse in the dogs fed the higher phosphorus diet. Tubulointerstitial lesions also were worse in dogs on the higher phosphorus diet. In another study, renal secondary hyperparathyroidism was documented in 84% of cats with naturally occurring CKD and, as assessed by serum phosphorus and PTH concentrations, responded to dietary phosphorus restriction. Because extremely phosphorus–depleted diets are unpalatable, phosphorus–binding agents may be given orally to trap phosphorus in the gut and hasten its excretion. These drugs should be given with meals or within 2 hours of feeding to maximize their effectiveness. When CKD is diagnosed, phosphorus restriction is initiated by feeding a low-phosphorus, low-protein diet. If necessary, oral phosphorus–binding agents can be added as necessary to the treatment regimen for additional reduction in serum phosphorus concentration.

In humans, chronic aluminum intoxication causing bone disease and encephalopathy has been recognized as an important complication of aluminum-containing phosphorus binders; it is thought that there is no safe dosage of aluminum-containing phosphorus binder that will provide sufficient phosphorus restriction without risking aluminum intoxication. Consequently, other phosphorus binders have replaced aluminum-containing phosphorus binders in humans with CKD. It is not yet clear that aluminum intoxication is a problem in dogs and cats with CKD, but it has been reported in two dogs with AKI. Aluminum-containing phosphorus binders are still used by many veterinary clinicians in dogs and cats with CKD. Aluminum hydroxide (Amphojel) can be used at a dosage of 45 mg/kg q12h given with food. In general, an attempt should be made to maintain the serum phosphorus concentration at less than 5.0 mg/dL. If preferred, calcium carbonate can be used instead, at a starting dosage of 45 mg/kg q12h given with food. It has the advantage of not containing aluminum, which may be toxic if absorbed from the GI tract. Calcium acetate is more effective than the aluminum- or other calcium-containing phosphorus binders and may be used at a slightly lower dosage. The animal should be monitored for the development of hypercalcemia whenever calcium-containing phosphorus binders are used. Constipation may be a complication of phosphorus binders and may be managed by addition of polyethylene glycol 3350 (Miralax) or lactulose to the treatment regimen. Sevelamer HCl is a phosphorus binder that does not contain aluminum or calcium. A dosage of 10 to 20 mg/kg q8h given with food may be considered for dogs

and cats. The use of sevelamer may be associated with adverse GI effects, including constipation, and at extremely high dosages may impair the absorption of folic acid and vitamins K, D, and E. Lanthanum carbonate is not absorbed from the GI tract and should not be retained in patients with CKD. It has no known toxicity and may be used as a phosphorus binder beginning at a dosage of 30 mg/kg/day. It has been shown to be safe and well tolerated in cats up to a dosage of 1 g/kg/day. Lanthanum carbonate decreased digestibility of phosphorus and shifted phosphorus excretion from the urine to the feces of treated cats. Epakitin decreases the absorption of dietary phosphorus and may have additional beneficial effects as an oral adsorbent for urea and ammonia. Used at a dosage of 1 g/5 kg body weight q12h, it provides 20 mg/kg calcium carbonate q12h. There is limited information about its effectiveness in dogs and cats with CKD.

If the patient is not hyperphosphatemic at the time of initial evaluation, phosphorus restriction still may be beneficial in reversing existing renal secondary hyperparathyroidism. The patient must be monitored carefully for hypophosphatemia. All measurements should be made in the fasting state to avoid the effect of feeding on the serum phosphorus concentration, and an attempt should be made to maintain the serum phosphorus concentration in the 2.5- to 5.0-mg/dL range. Serial PTH determinations are an ideal way to monitor treatment of renal hyperparathyroidism, but validated assays for dogs and cats are not widely available.

Therapy for gastrointestinal signs

Hypergastrinemia in uremic patients can result in increased gastric acidity. H_2 receptor antagonists block gastrin–mediated increases in gastric acid secretion and may be helpful in the treatment of gastrointestinal signs such as decreased appetite, nausea, vomiting, and gastrointestinal hemorrhage. Famotidine (1 mg/kg PO, q24h) is commonly used. Failure to observe gastric ulceration in cats with CKD and absence of differences in stomach pH and serum gastrin concentrations between normal cats and cats with CKD are recent observations that cast doubt on the clinical value of using famotidine or other H_2 blockers in cats with CKD.

Antiemetics also may be used to manage vomiting. Drugs used include metoclopramide (0.1-0.4 mg/kg PO or SQ, q8-12h), 5-HT3 (serotonin type 3) receptor antagonists such as ondansetron (0.6-1.0 mg/kg PO, q12h), and the NK1 (neurokinin) receptor antagonist maropitant citrate (1 mg/kg SQ or 2 mg/kg PO, q24h). The 5-HT3 receptor antagonist mirtazapine (1.88 mg PO q48h) increased appetite, activity and body weight and decreased vomiting compared with placebo in a randomized crossover study of 11 CKD cats, indicating that it may be helpful in the management of GI complications in cats with CKD. Gastroprotectants such as sucralfate (0.5-1.0 g/dog PO, q8-12h) can be used in dogs if GI ulceration and hemorrhage are suspected, but sucralfate has been associated with adverse effects in CKD cats (e.g., anorexia, vomiting, constipation, worsening azotemia) and therefore is not recommended for cats with CKD.

Angiotensin-converting enzyme inhibitors

Angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril, benazepril) are renoprotective and may slow the progression of CKD. Angiotensin II increases efferent arteriolar vasoconstriction, which contributes to intraglomerular hypertension and proteinuria. Increased protein traffic in the mesangium promotes glomerular sclerosis. ACE inhibitors decrease the filtration of protein into Bowman's space and the mesangium by lowering intraglomerular hydrostatic pressure. Enalapril can be used at a dosage of 0.5 mg/kg PO, q24h or q12h, or benazepril can be used at a dosage of 0.25 to 0.5 mg/kg PO, q24h or q12h. Benazepril is well tolerated by cats with CKD and decreases proteinuria.

Angiotensin receptor blockers

The angiotensin receptor blockers also may be used alone or in conjunction with ACE inhibitors to decrease proteinuria. Losartan may be used at a dosage of 0.5 mg/kg/day in nonazotemic patients or at a dosage of 0.125 mg/kg/day in azotemic patients. Telmisartan may be used at a dosage of 1.0 mg/kg/day and has been shown to be similar to benazepril in its effectiveness at decreasing the UPC ratio in cats with CKD.

Endocrine replacement therapy

Erythropoietin. Recombinant human erythropoietin or EPO (epoetin alfa [Epogen], darbepoetin alfa [Aranesp]) has been used to correct the nonregenerative anemia in dogs and cats with CKD. Dogs and cats treated with EPO experience resolution of anemia, weight gain, improved appetite, improved hair coat, and improved sociability with their owners. The use of epoetin alfa in dogs and cats carries a 20% to 40% risk of anti-EPO antibody formation within 30 to 90 days of initiating therapy, and antibody development may result in severe anemia and subsequent transfusion dependence. The starting dosage of epoetin alfa is 100 U/kg SQ, three times/wk. The hematocrit must be monitored closely during therapy and the dosage adjusted to achieve and maintain a target hematocrit of 30% to 40%. The frequency of administration is decreased to twice a week as soon as the animal's hematocrit enters the target range. Small sequential decreases in the hematocrit value while an animal is being treated with epoetin alfa are presumptive evidence of anti-EPO antibody formation. Other observed adverse effects include vomiting, seizures, hypertension, uveitis, and mucocutaneous hypersensitivity-like reactions. Because of the potential for adverse effects and expense, epoetin alfa is reserved for animals with severe and symptomatic anemia (e.g., hematocrit < 12%-15%). Iron supplementation should be provided during (and ideally before) EPO treatment to ensure that the animal is iron replete.

Darbepoetin alfa has two additional glycosylation sites that extend its biologic half-life 3-fold. It can be given at a low dosage (0.25-0.5 μg/kg SQ once weekly) and then once every 2 weeks when the lower end of the target range of the hematocrit (30%) is achieved. When the upper end of the target range of the hematocrit (40%) is reached, it can be given every 3 weeks. In one study, 14 of 25 anemic CKD cats responded to darbopoietin at a dosage of 0.45 to 1.0 μg/kg/

wk. Presumptive adverse effects included vomiting, hypertension, seizures, and fever. Because of its structure and lower dosage, darbepoetin alfa is thought to be less likely to result in antibody formation when used in dogs and cats. Canine and feline recombinant erythropoietin have been synthesized and been shown to be effective but are not commercially available.

Calcitriol. In the kidney, 25–hydroxycholecalciferol is converted to the active form of vitamin D_3, 1,25–dihydroxycholecalciferol (calcitriol), by 1α–hydroxylase in the tubular cells. The 1α-hydroxylase is stimulated by PTH and hypophosphatemia and inhibited by calcitriol and FGF-23. The major effects of calcitriol are to increase the intestinal absorption of calcium (and phosphate), facilitate PTH–mediated bone resorption of calcium and phosphorus, increase renal tubular reabsorption of calcium (and phosphate), and provide negative feedback control on PTH synthesis by the parathyroid glands; a relative lack of this effect plays an important role in the development of renal secondary hyperparathyroidism in patients with CKD.

Calcitriol is helpful in the management of renal secondary hyperparathyroidism because of its ability to feed back to calcitriol receptors in the parathyroid glands and decrease PTH synthesis and secretion. If the [Ca] × [P_i] solubility product is more than 60 to 70, calcitriol therapy should be avoided because of the risk of soft tissue mineralization. Calcitriol should only be used after hyperphosphatemia has been adequately controlled by a low-phosphorus diet and oral phosphorus binders, if necessary. A very low dosage of calcitriol (2.5–3.5 ng/kg/day) has been used in dogs and cats with CKD to prevent or reverse renal secondary hyperparathyroidism. Serial serum calcium concentrations should be monitored to detect hypercalcemia. Serum PTH concentrations fall dramatically in dogs and cats with CKD treated with calcitriol, and survival time may be increased.

Anabolic steroids

Many products are available but there are no long-term studies demonstrating the efficacy of anabolic steroids in dogs and cats with CKD. The anabolic steroid stanozolol (Winstrol-V) has equivocal effects in dogs with CKD. In cats, it is hepatotoxic and has been associated with increased liver enzyme activities, vitamin K-responsive coagulopathy, cholestasis, and hepatic lipidosis. Anabolic steroids usually are not recommended for dogs and cats with CKD.

Blood pressure control agents

The presence of systemic hypertension is a risk factor for uremic crises, more rapid progression, and mortality in dogs with CKD. In cats, it can be difficult to decide whether hypertension really is present because of the white coat effect. Dogs and cats with a systolic blood pressure of 150 to 159 mm Hg and evidence of end-organ damage (e.g., cardiovascular or ocular complications) are candidates for antihypertensive treatment. Those with a systolic blood pressure of 160 to 179 mm Hg or higher are candidates for treatment, regardless of evidence of target organ damage.

Most commercial diets formulated for dogs and cats with CKD are low in salt. Sodium restriction may have a limited effect on systemic blood pressure and in cats may contribute to increased urinary loss of potassium and hypokalemia by activation of the renin-angiotensin system. Diuretics (e.g., furosemide, hydrochlorothiazide) generally are not used to treat hypertension in dogs and cats with CKD because of concern about dehydration and prerenal azotemia. The effect of ACE inhibitors on systemic blood pressure may be modest, but other potentially beneficial effects warrant their use in dogs and cats with CKD (see earlier). Dihydropyridine calcium channel blockers (e.g., amlodipine) are effective for treatment of hypertension in cats at a dosage of 0.625 to 1.25 mg PO, q24h. Amlodipine can be used in dogs at a dosage of 0.1 to 0.5 mg/kg PO, q12h. Gingival hyperplasia is an uncommon and reversible adverse effect in dogs. Nondihydropyridine calcium channel blockers (e.g., verapamil, diltiazem) may decrease proteinuria and be renoprotective in humans but have not been evaluated for this purpose in dogs and cats.

SUPPORTIVE CARE

Some owners can be taught to administer fluids subcutaneously to their animals at home. This is particularly convenient for cats and small dogs. For example, if the owner is willing to learn the technique and the cat is cooperative, 60 mL of lactated Ringer's solution can be given subcutaneously two or three times per day. If the owner has noticed that the cat did not absorb previously administered fluids, additional fluid should not be given. Also, if the owner experiences technical difficulty administering fluids subcutaneously, it is preferable for fluids to be administered on an outpatient basis at the veterinary clinic. The additional fluid support appears to have beneficial effects on the animal's quality of life, and in one study, 47% of cats with CKD were reported to be receiving subcutaneous fluids as part of their treatment. If the owner is having difficulty getting the animal to eat, a feeding tube should be considered to ensure adequate caloric intake and facilitate administration of medications. Most cats tolerate percutaneously placed gastrostomy tubes well for extended periods of time, and this approach can make medical management much easier and less stressful for the owner and the cat.

Course and Prognosis

The rate of progression of CKD varies among individual animals, and affected dogs and cats may live months to years. The slope of the relationship of the reciprocal of the SCr (1/SCr) versus time may give a rough indication of the rate of progression of CKD. Findings that warrant a poor prognosis include severe intractable anemia, inability to maintain fluid balance, and progressive azotemia, despite fluid therapy and conservative medical management.

CHAPTER 42

Bacterial Cystitis, Pyelonephritis, and Prostatitis in the Dog and Cat

INTRODUCTION

The entire urinary tract has several built-in defense mechanisms to prevent external pathogens from adhering to the urinary mucosa. Normal micturition itself and frequent and complete voiding can help remove bacteria. Furthermore, the proximal urethra is sterile and contains microplicae that expand as urine is voided, aiding in the removal of the bacteria. Although the distal urethra, preputial tissues, and vulva contain normal flora, some of these bacteria can help prevent access of the pathogens into the urinary tract by producing bacteriocin, which can interfere with the metabolism of other bacteria. In addition, mucosal secretions such as immunoglobulins and glycosaminoglycans can help prevent the adherence of uropathogens to the epithelium. High urine osmolality and high concentrations of urea can also inhibit bacterial growth. Although isosthenuria itself does not appear to be a sole risk factor for bacteria cystitis, diseases that result in isosthenuria (e.g., chronic kidney disease [CKD] and hyperthyroidism) may predispose the dog or cat to bacteria cystitis. In dogs and cats, submitting a urine culture based only on a low urine specific gravity (<1.013) does not appear to be cost-effective in the absence of active urine sediment and high clinical suspicion based on clinical signs.

Bacterial cystitis in general is more common in dogs (females more so than males). The prevalence of bacterial cystitis in cats presenting to referral institutions with lower urinary tract signs (LUTS) ranges from 1% to 3%; higher percentages have been reported from cats presenting to private practices in Europe. Most young cats with LUTS have disorders such as feline idiopathic cystitis (see Chapter 44), which are not associated with bacterial infections. When bacterial cystitis occurs in cats, comorbidities such as diabetes mellitus, hyperthyroidism, CKD, or a combination of these diseases are present. The prevalence of bacterial cystitis in cats with diabetes mellitus is 11% to 13%. In young adult cats, the prevalence of bacterial cystitis is higher in those who have had urinary catheterization and/or perineal urethrostomy. Other factors that may predispose cats to bacterial cystitis are female sex, older age, and lower body weight, although some of these risk factors may also be associated with the comorbidities mentioned earlier. Furthermore, asymptomatic bacteriuria has been associated with these comorbidities in cats, and therefore treatment with antimicrobials may not always be indicated (see later).

The most common uropathogen isolated in sporadic bacterial cystitis in dogs is *Escherichia coli,* which accounts for approximately 50% of all isolates, followed by *Staphylococcus, Proteus, Klebsiella, Enterococcus,* and *Streptococcus* spp. Mycoplasma have also been isolated from the urinary tract of dogs, although its clinical relevance has been unclear because they are usually isolated from dogs that have other disorders of the lower urinary tract, such as underlying neoplasia, urolithiasis, or micturition disorders. The bacteria species isolated from cats with bacterial cystitis are similar to those in dogs.

CLASSIFICATION OF BACTERIAL CYSTITIS

Bacterial cystitis can be classified according to several definitions (Table 42.1). Sporadic bacterial cystitis (which will also be referred to as sporadic UTI in this chapter for simplicity; all other types and locations of urinary infections will be clearly stated) suggests that the animal is otherwise healthy and has no underlying comorbidity that may predispose it to the infection. This term also implies the animal has clinical signs associated with the infection. Complicated bacterial cystitis implied an underlying comorbidity, which can include such disorders as anatomic problems (e.g., ectopic ureters, ureterocoeles), systemic diseases (e.g., diabetes mellitus, hyperthyroidism, hyperadrenocorticism, systemic neoplasia, immunocompromised animals), and those problems related to the urinary tract itself (e.g., urolithiasis, cystic neoplasia, deep seated bacterial cystitis). Subclinical bacteriuria is the presence of bacteria identified in urine and the presence of a positive bacterial urine culture despite the lack of the typical LUTS. These clinical signs can include the following: stranguria, hematuria, pollakuria, peruirua, and

TABLE 42.1

Definitions Applied to Urinary Tract Infections

TERM	DEFINITION
Sporadic bacterial cystitis (i.e., sporadic UTI)	Sporadic bacterial infection of the bladder in an otherwise apparently healthy individual with normal urinary tract anatomy and function
Complicated UTI	UTI that occurs in the presence of an anatomic or functional abnormality or comorbidity that predisposes to persistent UTI, recurrent infection, or treatment failure
Subclinical bacteriuria	Presence of bacteria in the urine as determined by a positive bacterial culture in the absence of lower urinary tract signs (LUTS). Differentiation from subclinical UTI may be difficult.

From Westropp J, Sykes JE: Bacterial infections of the genitourinary tract. In Sykes JE, editor: *Canine and feline infectious diseases,* St. Louis, 2013, Elsevier.

dysuria. In the author's experience, some dogs with urinary incontinence and positive bacterial urine culture respond to antimicrobial therapy suggesting this is a clinical sign associated with UTI. Subclinical bacteriuria has also been referred to as occult UTI and asymptomatic bacteriuria in human medicine.

Animals with comorbidities can have unique bacterial infections such as *Corynebacterium urealyticum,* a gram-positive bacterium that can result in encrusting cystitis (Fig. 42.1). This pathogen also can produce urease, which results in the precipitation of calcium phosphate and struvite plaques that adhere to the uroepithelium. The most common cause is *E. coli,* which ferments the glucose to gas products; *Clostridium* spp. may also be involved. In the absence of glucose, proteins such as albumin may be fermented to gas. Dogs and cats with diabetes mellitus may present with emphysematous cystitis (EC), characterized by the production of gas by bacteria within the bladder wall or lumen (Fig. 42.2). Gas was most commonly detected in the bladder lumen and wall in 14/27 (51%) of dogs with EC in a recent report. Comorbidities were identified in 26/27 (96%) cases reported, the most common of which were diabetes mellitus in 33% of dogs, neurologic disease in 26% of dogs, and adrenal disease in 19% of dogs.

Recurrent bacterial cystitis (UTI) implies that the animals have had three or more infections in a 12-month time period. Recurrent UTI can be subclassified as relapsing infection, reinfection, refractory infection, or persistent infections. Although urine bacterial cultures may help distinguish these types of recurrent infections, advanced molecular diagnostic

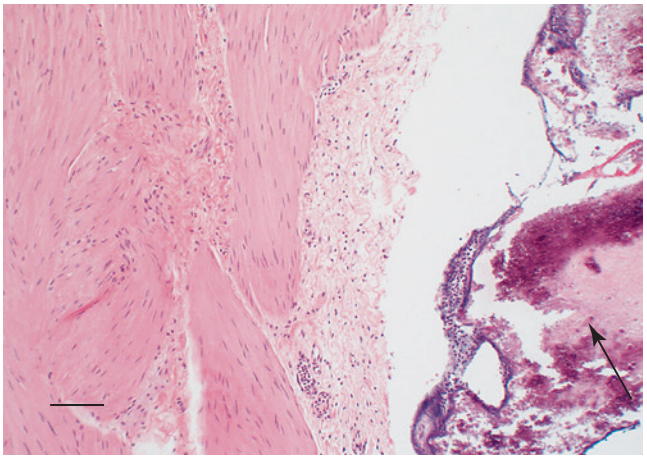

FIG 42.1
Photomicrograph of a section of the urinary bladder from a dog with *C. urealyticum* cystitis. Transitional epithelium overlying the smooth muscle is completely denuded and replaced by a thick mat of partially mineralized (basophilic) degenerate cellular debris and fibrin exudates *(arrow)* (H&E; bar = 100 µm). These plaques must be removed (cystoscopically or surgically) to allow antibiotics to penetrate the bladder wall.

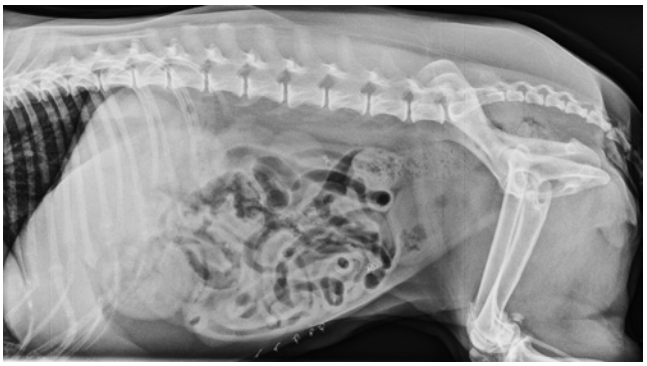

FIG 42.2

procedures are often required, and these tests are not clinically available. It is easy to identify a reinfection when the quantitative urine culture reveals a different bacterial genus and species than the original isolate. The same organism isolated initially causes a relapsing infection; it can be caused by the persistence of an organism that was never completely eradicated. Relapse suggests the organism may be deep-seated in the tissues—inaccessible to the antimicrobial, as in the kidney, prostate, or polyps—or that subtherapeutic concentrations of the antimicrobial were achieved in the urine and/or urinary tissues, or that the organism is resistant to the chosen antimicrobial. A study reported that there was a 17% disagreement between bladder mucosa cultures compared with urine cultures suggesting deep-seated infections may occur in dogs. This difference was not significant

though. A persistent infection implies the bacterial cultures remain positive with the same organism during antimicrobial treatment. In this case, the organism has not been eradicated, even transiently, despite administration of the appropriate urinary antimicrobial agent. Persistent infections imply severe abrogation of local host defenses or that the organism is highly resistant to the administered antimicrobial drug. Animals that present with recurrent UTI should have a thorough diagnostic evaluation (see later) to search for underlying predisposing diseases. See Table 42.2 for a list of disorders and diagnostic considerations for animals with various forms of recurrent bacterial cystitis.

Subclinical bacteriuria is a term used in human medicine to describe the presence of bacteria in the urine, as determined by a positive bacterial culture, in the absence of LUTS. This has generally been referred to as subclinical UTI in the veterinary literature. Subtle signs of bacterial cystitis may be difficult to discern in small animals. Subclinical bacteriuria has been variably reported in dogs and cats with prevalence rates in cats reported from 0.9% to 28.8%, and in one study evaluating 101 healthy adult dogs, it was 8.9%. Cats were oftentimes noted to be older and female. Subclinical bacteriuria is also anecdotally reported more often in animals with underlying endocrinopathies, kidney disease, or micturition disorders; in dogs and cats treated with glucocorticoids or immunosuppressive agents; or in those animals that have had perineal urethrostomies. Choosing what, if any, antimicrobial treatment for dogs or cats with subclinical bacteriuria is not always clear (see later).

Physical Examination Findings

The physical examination in dogs and cats with a simple uncomplicated bacterial cystitis is usually unremarkable. The bladder may be small and thickened, in some cases, because of persistent inflammation and pollakiuria; caudal abdominal discomfort may be present in some patients. On rectal examination, the urethra may be prominent or more severely thickened in cases in which urethral neoplasia or proliferative urethritis (Video 42.1) is present. Urethral stones may also be palpable, if present. Rarely, in more complicated cases, a large bladder is palpated in patients with secondary urethral obstruction caused by neoplasia, usually transitional cell carcinoma (TCC), proliferative urethritis, or urethrolith. In females, the vulva should be examined to be certain no evidence of a recessed vulva and/or perivulvar pyoderma is present (Fig. 42.3). Similarly, the prepuce should be examined for discharge, foreign bodies, or mass lesions.

Diagnosis

For simple sporadic UTI, a quantitative aerobic bacterial urine culture from urine obtained by cystocentesis is indicated, followed by identification and susceptibility testing of

TABLE 42.2

Recurrent Infections

		DIFFERENTIALS DIAGNOSES	DIAGNOSTICS TO CONSIDER
Relapsing	Clinical and microbiologic cure of bacterial cystitis with subsequent recurrence of disease.	Urolithiasis Bladder polyps Cystic neoplasia Deep seated bladder infections Pyelonephritis Chronic prostatitis Altered mucosal immune responses	Abdominal radiographs Contrast cystourethrograms Abdominal ultrasound CBC Serum biochemical panel Cystoscopy with biopsy
Persistent	Continued presence of the same bacterial strain in urine despite clinical cure	Immunocompromised Cystic neoplasia Encrusting cystitis Severe micturition abnormalities Altered mucosal immune responses	Radiographs Abdominal ultrasound CBC Serum biochemistry
Reinfection	Isolation of a different microorganism after apparent resolution of a previous infection	Hooded vulva Cystic diverticulum Ectopic ureter Urinary incontinence (USMI or anatomic) Ureterocele Immunosuppression	Check external confirmation CBC, serum biochemical panel Abdominal ultrasound Contrast cystourethrogram Cystoscopy
Refractory	Lack of clinical and microbiologic response to treatment	Poor owner compliance In appropriate drug or dosing regimen Undetected antimicrobial resistance Inability of antimicrobial(s) to penetrate the site of infection	Review dosing and compliance Radiographs Abdominal ultrasound Cystoscopy

TABLE 42.3

Significant Bacteriuria in Dogs and Cats

COLLECTION METHOD	DOG	CAT
Cystocentesis	≥1000 cfu/mL	≥1000 cfu/mL
Catheterization (male)	≥10,000 cfu/mL	≥10,000 cfu/mL
Catheterization (female)	≥100,000 cfu/mL	Unknown
Midstream voided	Not recommended	Not recommended

the pathogen isolated. Although any pathogen isolated from specimens collected by cystocentesis is likely significant, bacterial contamination from the skin is possible; therefore the presence of more than 10^3 cfu/mL of bacteria is considered clinically relevant. See Table 42.3 for clinically relevant bacterial numbers based on the urine collection method. A complete blood count (CBC), serum biochemical panel, and imaging studies are not usually warranted in those cases in which the animal is otherwise healthy and the suspected infection is an isolated event.

The drugs chosen for susceptibility testing by individual laboratories vary. Similarly, the method of susceptibility testing used is subject to laboratory preference and has direct implications on how results are reported. The clinician should consult with his or her microbiologist to determine whether the susceptibilities reported are based on concentrations of the antimicrobials in the serum or urine. Attainable urine concentrations of some antimicrobials can be much higher than in the serum as long as kidney function is normal and polyuria and polydipsia are not present. Consequently, sterility within the urinary tract can be achieved at times when it would otherwise appear that these drugs would fail to do so at concentrations achieved in the plasma.

Although a urine culture is the gold standard for the diagnosis of a bacterial cystitis, it can be costly; in practice, culture kits, paddles, and other rapid bacterial immunoassays have been marketed for companion animal use. These can be helpful when screening animals for infections; however, inaccuracies with one veterinary specific culture paddle has been reported, particularly when multiple organisms were present. When growth is identified in any "in house" kit, the urine should be submitted to a commercial microbiology laboratory for identification and antimicrobial susceptibility testing. Furthermore, appropriate laboratory facilities and biosafety level 2 containment and waste management protocols need to be followed.

For dogs and cats with a recurrent UTI, not only is a urine culture indicated, but an appropriate diagnostic workup to evaluate the animal for predisposing factors is warranted, assuming the previous infections were treated appropriately (see later). Predisposing factors facilitate the ascent of bacteria and development of an initial infection and also can make it more difficult to eradicate a UTI once established in the urinary tissues. A search for anatomic or structural defects, such as a recessed vulva, ectopic ureter(s), urachal diverticulum, polypoid cystitis, proliferative urethritis, urolithiasis, foreign bodies, prostatic disease, and neoplasia within the urethra or bladder (Video 42.2), should be undertaken. Infection in the kidney is inherently more difficult to eradicate than in the lower urinary tract, especially when chronically infected or if there is a nidus for infection, such as a nephrolith, ureterolith, or partial ureteral obstruction. Micturition problems such as urinary incontinence or urine retention should be identified and corrected when possible. Those with metabolic abnormalities such as diabetes mellitus, hyperadrenocorticism, hyperthyroidism, and CKD may more readily acquire new infections or fail to easily resolve an existing UTI, as is also true for animals receiving corticosteroid therapy or other immunosuppressive drugs. It can be difficult to impossible to achieve long-term urinary tract sterility in patients that continue to receive immunosuppressive drug treatment. The clinician must decide if the animal has subclinical bacteriuria during these cases and if treatment is warranted every time bacteria is isolated. If clinical signs are present or progressive azotemia is noted, treatment should always be initiated.

Imaging studies that include survey abdominal radiography and abdominal ultrasonography are an important part of the evaluation of patients with recurrent lower bacterial cystitis to rule out structural and anatomic problems. Contrast cystourethrography should be considered when ultrasonography is not readily available, and in male dogs and

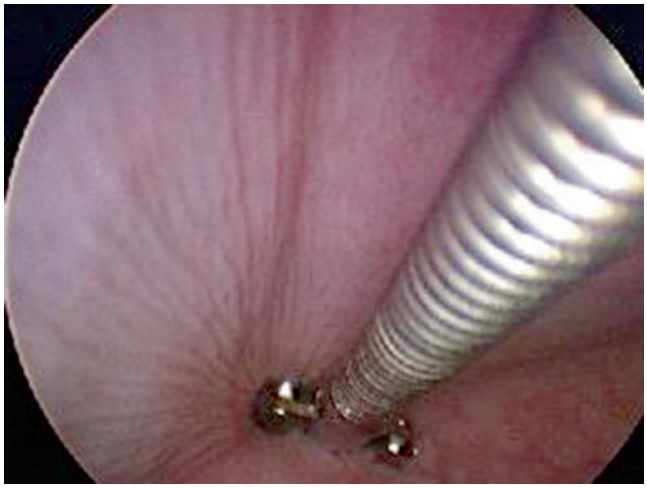

FIG 42.4
Cystoscopic view of biopsy forceps inserted through the working channel of a rigid cystoscope to obtain a mucosal biopsy from a female dog with recurrent UTIs. When obtaining biopsies in this manner, they can be submitted for histopathology as well as cultures for aerobic bacteria and mycoplasma.

cats for proper examination of the urethra. Excretory urography and renal ultrasonography may be needed to evaluate the kidneys more completely, especially to help exclude an element of obstruction within the upper urinary tract. Cystoscopy should be considered if the initial imaging tests do not document structural or anatomic abnormalities and is also excellent to evaluate the urethra. Even when no obvious lesions are observed during cystoscopy, submitting a biopsy of the bladder mucosa for culture to evaluate the patient for a deep-seated infection is ideal (Fig. 42.4; Video 42.3). If uroliths are removed from the patient with a recurrent UTI, a culture of the stone can also be performed.

Treatment

TREATMENT OF UNCOMPLICATED URINARY TRACT INFECTIONS

For empiric therapy, the Antimicrobial Use Working Group of the International Society for Companion Animal Infectious Diseases (ISCAID) recommends urinary antibacterial drugs that are likely to be effective against more than 90% of the urinary isolates when this information is available (Weese et al., 2011). In general, ISCAID recommends initial therapy for sporadic bacterial cystitis with amoxicillin (11-15 mg/kg orally [PO] q8h) or trimethoprim-sulfamethoxazole (15 mg/kg PO q12h). Newer guidelines are in preparation at the time of this writing and, although amoxicillin is still recommended, amoxicillin with clavulanate is a reasonable empiric choice when regional susceptibility data support a high likelihood or resistance to amoxicillin alone. Ampicillin is not recommended due to poor oral bioavailability. Although ciprofloxacin is routinely used in human medicine and often used in veterinary medicine due to lower cost, it is difficult to justify in veterinary medicine due to its lower oral bioavailability in dogs. Clinical and Laboratory Standards Institute (CLSI) have not established ciprofloxacin breakpoints for bacterial isolates from dogs. CLSI breakpoints are only available for other approved fluoroquinolones for dogs.

By convention, sporadic UTI has routinely been treated for 7 to 14 days. In human medicine, numerous studies have evaluated the efficacy of short-duration antimicrobial therapy for uncomplicated UTI in women. In veterinary medicine, one study in dogs with uncomplicated (i.e., sporadic) UTI showed that treatment with enrofloxacin (20 mg/kg) for 3 days was not inferior to treatment with amoxicillin–clavulanic acid for 14 days (Westropp et al., 2012). Adverse effects were rare and similar in both groups. In another clinical trial, cefovecin was administered subcutaneously (8 mg/kg) to 61 dogs with an uncomplicated UTI and was reported to be effective (Passmore et al., 2007). At this time, the ISCAID guidelines recommend short duration for bacterial cystitis (5-7 days). It is possible that 3 to 5 days of therapy may be all that is needed to achieve clinical and microbiologic cure. Reevaluation of sporadic UTI for aerobic bacterial cultures after clinical cure has been achieved in dogs and cats not clinically indicated.

Recurrent and Complicated Bacterial Cystitis

The correction of underlying predisposing factors increases the likelihood for successful long-term eradication of organisms from the animal's urine and urinary tissues. Empiric antimicrobial therapy should be avoided, and drugs should be selected based on culture and susceptibility results. The clinician should be certain that the proper doses of antimicrobials are used and the use of higher doses (for concentration-dependent) and increased number of doses (for time-dependent) should be considered, especially for drugs that are intermediate in their susceptibility.

By convention, treatment for dogs and cats with recurrent UTI has been recommended for up to 4 weeks, but a shorter course of therapy is likely effective in these cases as well. The clinician can consider obtaining urine shortly after beginning the drug regimen and again 7 days after completing the antimicrobial. If a positive culture is found, further diagnostic tests to investigate for underlying comorbidities should be performed. Although prophylactic, daily antimicrobial therapy and pulse therapy have been advocated by some clinicians, no studies exist regarding these protocols, and there is concern for emerging bacterial resistance if pathogens are exposed to daily suboptimal doses of antimicrobials. Nitrofurantoin has been anecdotally considered for clinical recurrent bacterial cystitis that is refractory to other oral antimicrobials but should never be used in animals with prostatitis or pyelonephritis because this drug does not achieve good tissue concentrations.

Adjunct Treatment

Alternative approaches for prevention and treatment of recurrent bacterial cystitis that have been investigated in

human beings as well as animal models include the use of cranberry extract. The efficacy of cranberry extract in women has been mixed but most recently has shown no significant difference in placebo-controlled studies. Although cranberry has been shown to prevent adherence of *E. coli* strains in in vitro studies, one study in dogs with intervertebral disk disease did not appear to reduce the risk of UTI in that placebo-controlled trial. Live biotherapeutic products appear promising for treatment of recurrent UTI for several reasons. Intravesicular administration of *E. coli* ASB 83972 in human beings with recurrent UTI reduced symptoms of UTI and protected some patients from recurrent UTI after serial catheterizations, which might reduce the need to antimicrobial therapy. In a recent veterinary pilot study, intravesicular administration of ASB *E. coli* 2-12 to dogs with recurrent UTI resulted in complete or nearly complete clinical cures in four of nine dogs and three also had microbiologic cures at 2 weeks; one of these dogs had subclinical bacteriuria (in addition to ASB *E. coli* 2-12 and did not require antimicrobial therapy). Three of these four dogs had ASB *E. coli* 2-12 isolated from their urine at day 14. Further studies are underway to investigate this live biotherapeutic in a larger population.

Subclinical Urinary Tract Infections

In humans with asymptomatic bacteriuria, treatment with antimicrobials is not always administered because of potential adverse effects of the drugs, as well as the concern for emerging bacterial resistance. Although prospective studies regarding this issue in cats and dogs are very limited, subclinical bacteriuria in dogs and cats may not always require treatment. In nine healthy dogs with subclinical bacteriuria followed for 3 months, four had persistent bacteriuria and four transient; none developed signs during this time period. The author has carefully followed several dogs with subclinical bacteriuria for many months with no treatment, and no adverse outcomes were noted at this time. If no underlying cause for the bacteriuria is found and the risk for ascending pyelonephritis is low (e.g., an otherwise healthy dog or cat or a very stable animal), antimicrobials may not always be indicated. If the clinician is not certain if clinical signs or labwork abnormalities are due to the bacteria, a short course of antimicrobials can be considered and the animal should be reevaluated. If no improvement is noted, cessation of the antimicrobial should be considered. In mixed infections that involve *Enterococcus* spp., anecdotal evidence suggests that the *Enterococcus* spp. infection will resolve when other organisms present are successfully treated. The need for antimicrobial therapy should be based on a case-by-case basis, and the pros and cons of using an antimicrobial should be considered and discussed with the owner.

Pyelonephritis

Acute pyelonephritis (APN) usually results when bacteria ascend into the renal pelvis and parenchyma from the lower urinary tract; less commonly, hematogenous spread to the kidney occurs. APN can also be classified as noncomplicated and complicated according to human medicine, which we have adapted to veterinary medicine. Complicated implies the presented of a systemic disease such as diabetes mellitus, neoplasia, or an immunocompromised animal or the presence of an anatomic or obstructive lesion in the urinary tract such as a nephrolith or ectopic ureter. Pyelonephritis may also be chronic as well; the diagnosis of chronic pyelonephritis can be challenging, as no sensitive and specific biomarkers are clinically available to aid in this diagnosis. Usually, a single organism is isolated from the urine. The medulla is more sensitive to colonization than the cortex, possibly because of impaired host defenses in a high-osmolality, low-pH, and low–blood flow milieu. Organisms adhere to pelvic and distal and proximal tubular epithelium and have been observed intracellularly. Considerable renal injury results from the inflammatory response to infection. Aggregation of neutrophils within capillaries and induction of vascular spasm by bacterial toxins and/or cytokines can contribute to renal ischemia.

In animals with APN, flank or dorsal abdominal pain may be present. Furthermore, these animals may be dehydrated and show signs of acute kidney injury.

A urinalysis and urine culture with susceptibility testing should be submitted on all patients suspected of having pyelonephritis. Imaging studies can help support the diagnosis of pyelonephritis. Although ultrasonographic findings are not specific, they can include renal pelvic dilation, blunting of the renal papilla, echogenic debris within the renal pelvis, ureteral dilation, or a combination of these findings. Nephropyelocentesis can be considered when renal pelvic dilation is present, particularly when the cystocentesis does not result in positive urine culture results. Blood cultures can also be considered if hematogenous spread is suspected or the animal is immunocompromised. Antimicrobials that reach high tissue levels are recommended; ISCAID suggests the use of the fluoroquinolones.

Empiric antimicrobial therapy should be started to help prevent further renal damage. Enrofloxacin is often prescribed (10-20 mg/kg q24h for dogs; 5 mg/kg PO once daily for cats), but 25% to 50% dose reductions may be required, depending on the severity of renal compromise. Intravenous therapy should be given to dogs and cats requiring hospitalization, and therapy for acute kidney injury should be implemented (see Chapter 44) for more severe cases. Oral antimicrobials can be administered if the patient is stable and not vomiting. Antimicrobial therapy has conventionally been recommended for as long as 4 weeks; shorter courses (7-14 days) in human medicine using both intravenous and oral antimicrobials have been published. Longer duration therapy in dogs is likely not indicated, and these shorter course therapies are likely to be effective in dogs and cats. The author routinely treats APN for 14 days then reassesses the animal. The animal should be reevaluated, including the CBC, serum creatinine, and urine culture results. The urine cultures results must be interpreted in conjunction with the other clinicopathologic parameters.

BACTERIAL PROSTATITIS

Bacterial prostatitis is a chronic or acute condition that usually occurs in sexually intact male dogs and should be suspected in any intact male dog with a positive urine culture. Acute prostatitis can have serious systemic ramifications, including fever, depression, dehydration, vomiting and diarrhea, and even septic shock. A leukocytosis with left shift may be present. Dogs may have LUTS as well as purulent or hemorrhagic urethral discharge and abdominal pain. Tenesmus may also occur because of the enlarged prostate causing compression of the distal colon. On rectal examination, the prostate may be asymmetric, enlarged, and painful. Dogs with chronic prostatitis may be lethargic, have mild LUTS, or have no clinical signs, and the prostate can be symmetric and nonpainful on palpation. Prostatic abscesses can also occur after acute or chronic prostatitis and can cause life-threatening peritonitis if the abscess were to rupture.

Most dogs with bacterial prostatitis also have a bacterial cystitis. The commonly isolated pathogens are similar to isolates that cause UTIs. Although a urine culture will suffice in most dogs, cultures of the prostate can be necessary when there is a negative urine culture or the animal has clinical signs despite appropriate treatment based on the urine susceptibility test results. Diagnostic imaging such as an abdominal ultrasonography (Fig. 42.5) or a retrograde contrast study (Fig. 42.6) should be performed to evaluate the prostate for size, cysts, and abscesses, and to evaluate for findings compatible with neoplasia (e.g., mineralization). Prostatic fluid can be obtained by ejaculation, prostatic massage, and usually by ultrasound-guided fine-needle aspiration of the prostate. The fluid should be analyzed for cytologic abnormalities as well as aerobic culture.

Antimicrobial treatment for acute prostatitis should be continued for at least 4 weeks; longer treatment regimens are often warranted for chronic prostatitis. Because of the blood–prostate barrier, it can be difficult to achieve levels of antimicrobials above the desired minimum inhibitory concentration (MIC) for the bacterial pathogen. Although the blood–prostate barrier is often broken in acute prostatitis, antimicrobials should still be chosen that would penetrate this barrier, which is important as the infection resolves. Because of this barrier, an antibiotic with high lipid solubility, low protein binding, and an appropriate pK_a should be used. Nonionized forms of antibiotics pass through lipid membranes, whereas the ionized forms do not. For gram-negative infections in the prostate, trimethoprim-sulfamethoxazole, chloramphenicol, and the fluoroquinolones are the most appropriate choices. Enrofloxacin is considered the drug of choice for canine bacterial prostatitis because of its high lipid solubility, low protein binding, low MIC profile, and broad spectrum of activity against many uropathogens. Furthermore, unlike the other two antibiotics, adverse effects with enrofloxacin are rare. Oral ciprofloxacin should not be used as a substitute for enrofloxacin because the bioavailability of ciprofloxacin is only approximately 40% in dogs and is widely variable. The typical dose of enrofloxacin for prostatitis is 10 to 20 mg/kg PO q24h. The higher doses may be needed for certain strains of *Pseudomonas* spp. Once-daily dosing is preferred because higher maximum concentrations of the antibiotic are achieved compared with dividing the dose over the day.

In addition to antimicrobials, castration should be performed as soon as the animal is stable for anesthesia and surgery. If castration is not an option for a breeding animal, the 5α-reductase inhibitor, finasteride (0.1-0.5 mg/kg PO

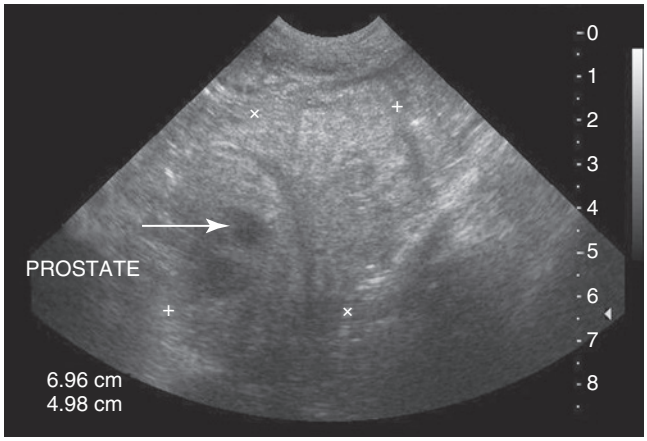

FIG 42.5
Abdominal ultrasonography of a 6-year-old male intact Borzoi that presented for weight loss and tenesmus. The prostate was enlarged, with ill-defined, irregular margins; gas was visualized within the parenchymal tissue and multiple hypoechoic cyst-like regions were noted *(arrow)*. Severe prostatitis and ultrasonographic evidence of septic peritonitis were also evident.

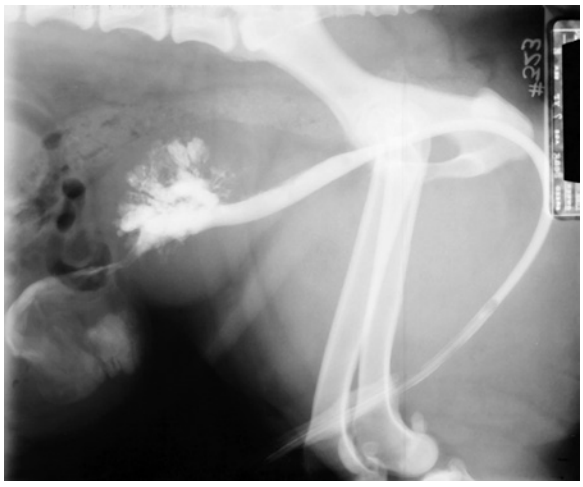

FIG 42.6

q24h), can be used to help decrease the size and secretions from the prostate. Prostatic abscesses may need to be addressed surgically, and omentalization of the prostatic abscess is often performed to prevent fluid and purulent material from accumulating in the area. Ultrasonography-guided drainage of the prostatic cyst can also be carried out, but this may need to be repeated several times and is usually more effective for small cysts.

CHAPTER 43

Canine and Feline Urolithiasis

INTRODUCTION

Urolithiasis is a common urinary tract disorder of dogs and cats. Clinical signs of urolithiasis are variable, depending on the location of the urolith. Pollakiuria, stranguria, dysuria, and hematuria may be noted by owners and suggest a problem in the lower urinary tract of their cat or dog. Clinical signs in cats and dogs with upper urinary tract uroliths are variable and can include hematuria or clinical signs compatible with acute kidney injury secondary to ureteral obstruction; ureterolithiasis may also be an incidental finding.

The most common uroliths in dogs and cats, calcium oxalate (CaOx) and struvite, are radiodense and can usually easily be identified on plain radiography. Cystine and urate uroliths are less radiodense, and contrast cystourethrograms or ultrasonography are often required to identify these stones. Although ultrasonography is a sensitive diagnostic for bladder and proximal urethral uroliths (Fig. 43.1), it is not a good imaging modality for visualizing the entire urethra of male dogs and cats, and urethroliths could be missed if abdominal radiography is not performed. It is important to position the animal's legs properly to obtain diagnostic images of the lower urinary tract (Fig. 43.2). Although ultrasonography does limit exposure to radiation, the size of the stone may be more accurately predicted by radiography. Furthermore, radioopacity can be determined. This information is clinically relevant when developing surgical and minimally invasive strategies for urolith removal.

Urolithiasis as well as other lower urinary tract disorders (e.g., neoplasia, granulomatous urethritis, urethral foreign body, obstructive feline idiopathic cystitis [FIC], functional urethral outflow tract obstruction) can result in urethral obstruction. Obstruction with urethroliths is more common in male dogs because of their longer, narrower urethra. Uroliths will often obstruct the area of the pelvic urethra or become lodged at the base of the os penis. Managing a urethral obstruction is described in Chapter 44; the principles described in that section are similar for dogs.

PRINCIPLES OF STONE ANALYSIS

Stones can be analyzed by a variety of methods. Calculi submitted to the Gerald V. Ling Urinary Stone Analysis Laboratory at the University of California at Davis (http://www.vetmed.ucdavis.edu/usal/index.cfm) are analyzed by quantitative crystallographic analysis primarily with the oil immersion method of optical crystallography using polarized light microscopy. In addition to optical crystallography, infrared spectroscopy (IR) is routinely used to process all calculus specimens suspected of containing uric acid crystals and/or salts of uric acid crystals to determine the presence of xanthine, hypoxanthine, allopurinol, or oxypurinol, a metabolite of allopurinol, which may be present in the specimens. Polarized light microscopy alone is insufficient to identify these metabolites. Other advanced analytic techniques (e.g., microprobe analysis, X-ray diffractometry) are available for certain stones if the mineral composition is not well identified with optical crystallography or IR. The author recommends that stones removed from animals be submitted to a veterinary stone analysis laboratory in order to help properly tailor the best management strategies and track research trends.

STONE REMOVAL

A consensus statement regarding the most common uroliths in small animals has been recently published (Lulich et al., 2016), and the reader is referred to that statement for additional details regarding upper and lower urinary tract urolithiasis and minimally invasive stone removal techniques. The panel agreed that minimally invasive stone removal should be discussed with all clients if clinically appropriate and available in one's area. These include laparoscopic-assisted cystostomy, percutaneous cystolithotomy, voiding urohydropropulsion (VUH) (Video 43.1), basket retrieval of a stone via the cystoscope (Fig. 43.3; Video 43.2), and holmium:YAG laser lithotripsy (Fig. 43.4; Video 43.3). Some uroliths such as struvite, urate, and cystine may be amenable to medical dissolution. Although protocols for dissolution of struvite uroliths in cats and dogs can be successful, protocols for dissolution of suspected urate and cystine stones are

often not as rewarding but can be attempted. It is important when attempting to dissolve struvite stones in dogs, in addition to dietary therapy (see later), to use appropriate antimicrobial therapy as well.

VUH can be performed when small calculi are present in the bladder (Fig. 43.5). The urolith size and shape, as well as the size of the dog or cat, need to be assessed; smoother stones generally pass through the smallest diameter of the urethra easier than those with irregular surfaces. Large uroliths can be removed more easily from larger dogs, although the procedure can be more cumbersome. To perform a VUH, the dog or cat should be anesthetized to help prevent increased urethral pressure and facilitate easier bladder expressions. A urinary catheter is then inserted into the bladder, and the bladder should be distended with sterile saline. The bladder should feel full but not so taut that bladder rupture could occur. With the catheter still in place, the animal should be held upright so that the vertebral column is vertical, and the bladder should be agitated to help promote movement of the stones into the bladder neck. As soon as the catheter is removed, the clinician should express the bladder to create a forceful stream and collect the voided contents. When expressing the bladder, the palm of the hand (not the fingertips) should be used to help prevent trauma to the bladder. Several voids may be required to remove all the stones and stone debris present. Hematuria

FIG 43.5
Dog positioned for VUH. Although this dog also had a cystoscopy, a catheter can be used to fill the bladder with sterile saline before lifting the dog and expressing the bladder, as shown.

can result from this procedure but usually resolves within 24 hours.

Holmium:YAG laser lithotripsy has become widely available at referral institutions and uses laser energy to fragment stones. After fragmentation, the pieces can be removed using a basket inserted through the cystoscope and VUH for the smaller pieces that remain.

CALCIUM OXALATE CALCULI

Etiology

CaOx is the most common urolith from dogs submitted to several veterinary stone laboratories. They appear to be more common in older, castrated male dogs; small-breed dogs such as the Bichon Frise, Miniature Schnauzer, Pomeranian, Cairn terrier, and Maltese are at higher risk for CaOx urolith formation. The Keeshond has also been reported to have a higher risk for forming CaOx uroliths, which may be linked to its genetic predisposition for primary hyperparathyroidism causing hypercalcemia and hypercalciuria. Dogs with CaOx have been reported to have a higher body condition score than dogs without CaOx in a recent study.

CaOx is also the most common urolith removed cats. The most common location for CaOx in both species is the bladder, however, a significant increase in the number of upper urinary tract calculi (kidneys and ureters) was found for CaOx-containing calculi in the cat. Usually when upper tract calculi are seen on abdominal radiographs in cats, they primarily contain CaOx.

Unfortunately, there is a lack of published studies in cats to document specific risk factors for CaOx. There are likely intrinsic and extrinsic factors that predispose certain cats to form CaOx, including breed, age, and environment. Himalayan and Persian cats have been reported to have a higher relative risk for CaOx-containing uroliths. Male cats appear to be predisposed to CaOx urolithiasis. Stress-related events and obesity have not been critically evaluated in cats with urolithiasis, but some hypothesize that they may contribute to stone formation in some cats. Studies evaluating urolithiasis in human beings have supported a relationship among increased body weight, body mass index, waist circumference, and kidney stones. Furthermore, some studies have suggested that stressful life events can result in more clinical events of urinary stone disease in humans. Studies of body mass index, body weight, and environmental stressors as related to urinary stone disease are warranted in cats to see if any relationship exists.

URETEROLITHIASIS IN DOGS AND CATS

Struvite-, CaOx-, urate-, and cystine-containing calculi have been reported to occur in the upper urinary tract of dogs. Renal and ureteral struvite uroliths in dogs are generally associated with infection, and dissolution can be attempted, as long as the dog is stable. Surgical or interventional procedures may be required if the dog has complete ureteral obstruction (see later).

Most ureter and nephroliths in cats are composed primarily of CaOx, sometimes mixed with calcium phosphate or urate, but struvite renal and ureterolithiasis is not reported in the cat in recent literature. The increased incidence of CaOx-containing ureterolithiasis in cats may be associated with increased prevalence of CaOx ureterolithiasis, increased awareness of ureterolithiasis, and/or increased use of

diagnostic imaging in cats with renal disease. Ureterolithiasis tends to develop in middle-aged to older cats, with a median age of 7 years at the time of diagnosis.

Although reported less often, other causes of ureteral obstruction can include soft tissue plugs, which sometimes contain flakes of mineralized material, inflammatory debris in cats with pyelonephritis, and calculi composed of 100% dried solidified blood (DSB). In cats with a chronic upper tract urolithiasis, in which calculi have passed previously, it is relatively common for significant ureteral inflammation and/or stricture to develop, further decreasing the luminal diameter through which material can pass. This can lead to an even higher risk for the development of ureteral obstruction with minerals, whereby debris that would pass in a normal ureter leads to obstruction.

CLINICAL SIGNS OF URETEROLITHIASIS

Because ureterolithiasis is much more common in cats compared with dogs, the discussion will focus on this species, but principles of therapy can be applied to dogs, and the reader is referred to the consensus statement mentioned earlier for specific therapeutic intervention recommendations for each stone type in cats and dogs. Oftentimes, this requires an experienced operator and referral when ureteral obstruction is present.

The clinical signs associated with ureterolithiasis are variable and are often related to the rate at which ureteral obstruction develops; acute obstruction and rapid renal capsular distention in dogs and cats are often more painful compared with animals with more insidious obstructions. Nonspecific signs can include decreased appetite, weight loss, lethargy, and hiding. Cats may also present with hematuria, without concurrent lower urinary tract signs, such as stranguria, pollakiuria, and dysuria. When hematuria alone is noted in a cat without concurrent lower urinary tract signs, evaluation for renal and/or ureteroliths is warranted. Depending on the degree of renal compromise, preexisting before obstruction or secondary to obstruction, many cats have clinical signs associated with azotemia. The author routinely screens azotemic cats with some imaging modality to evaluate for the presence or absence of nephron- or ureterolithiasis.

Some cats with ureteral obstruction may not exhibit any clinical signs, and it is therefore relatively common to diagnose a chronic ureteral obstruction as an incidental finding. One example of this is the so-called big kidney, little kidney syndrome noted most commonly in cats (Fig. 43.6). This is a phrase used to describe cats with bilateral ureteral obstruction, whereby one kidney had a prior obstruction that led to a nonfunctional or minimally functional small kidney caused by a previous ureteral obstruction and the other kidney becomes hydronephrotic because of an acute ureteral obstruction. In many cases the initial obstructing event goes unnoticed by the owner because clinical signs are not evident until the cat develops azotemia, an elevation of blood urea nitrogen (BUN) and serum creatinine concentrations.

FIG 43.6
Struvite uroliths that were removed from a dog.

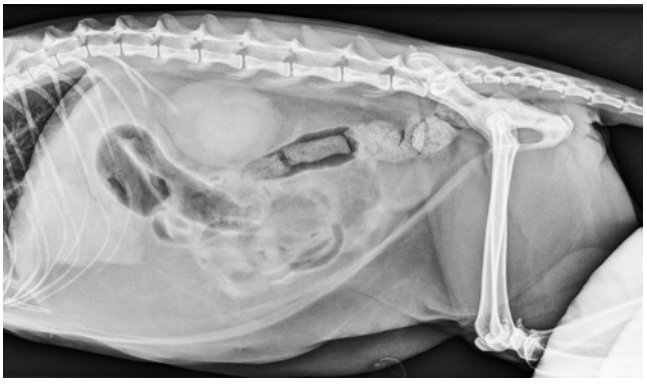

FIG 43.7
Lateral radiograph of a cat that illustrates the so-called big kidney, little kidney syndrome. The smaller kidney is superimposed over the larger kidney in this projection.

DIAGNOSTIC IMAGING

Diagnostic imaging of the abdomen should be performed in all dogs and cats with azotemia. CaOx- and struvite-containing calculi are radiopaque and, if present, can often be visualized on plain abdominal radiography (Fig. 43.7). In dogs, struvite calculi may have a staghorn appearance as the mineral dissects into the renal calices.

The sensitivity of survey abdominal radiography for the diagnosis of ureterolithiasis in cats is 81%. CaOx-containing ureteral calculi are most readily identified in the retroperitoneal area on the lateral radiographic projection; however, visibility on lateral radiographs alone can lead to difficulty in determining which ureter is involved or whether one or both ureters are affected. Therefore abdominal ultrasonography is recommended for cats suspected of having ureteroliths; it has a sensitivity of 77%. Although this is lower than

plain radiography, ultrasonography can help delineate which ureter is obstructed and the severity of hydronephrosis and hydroureter that may be present. A combination of survey radiography and ultrasonography has a sensitivity of 90% for the diagnosis of ureterolithiasis, so it is the preferred approach. In subacute ureteral obstructions, ureteral and pelvic dilation may have not yet developed, so it is critical to consider ureteral obstruction as a differential diagnosis in appropriate cases, even when dilation is not present. Additional imaging modalities, such as antegrade pyelography or computed tomography (CT), are usually not necessary, and interventional procedures are recommended if obstruction is present.

MEDICAL TREATMENT

As mentioned previously, dissolution of suspected struvite, urate, and cystine calculi can be attempted in stable animals (as mentioned previously, these mineral types can occur in the upper tract of dogs) without complete ureteral obstruction. There is no dissolution protocol for CaOx calculi, which is the most common calculi identified in the upper urinary tract of cats and can certainly occur in dogs. Conservative medical management for cats with minimal or no renal compromise can be attempted. Although there are no studies to evaluate the efficacy of any of the treatments mentioned in cats and dogs, most experienced clinicians agree that expulsive therapy may play a role in the management of this disease in stable patients. Suggested therapies can include intravenous fluid diuresis with the administration of the diuretic mannitol, with or without other drug therapies.

In humans with ureterolithiasis, the α-adrenergic antagonist tamsulosin is often used, with favorable outcome, particularly when calculi are in the distal third of the ureter. This and other α-antagonists, such as phenoxybenzamine and prazosin, have been anecdotally used in cats with variable responses. In one report, amitriptyline, a tricyclic antidepressant, was shown to facilitate the passage of urethral plugs in cats. Further studies evaluating ureteral tissue from rats, pigs, and humans found that amitriptyline inhibits smooth muscle contractions, suggesting it might be a useful therapy for ureteral obstruction in cats. Analgesic therapy such as buprenorphine should also be used to prevent ureteral "spasm," which could prevent ureterolith movement.

During conservative management, it is crucial to critically evaluate the cat's stability and fluid status. Animals should be monitored by serial measurements of serum creatinine (and possibly SDMA) because this is often the best clinicopathologic indicator currently available that the obstruction has improved or progressed. Body weight should be assessed at least twice daily to be certain the animal is not becoming overhydrated. It is important to remember that, if significant intrinsic renal damage has occurred, passage of ureteral obstruction does not always lead to immediate improvement in azotemia. In cats with severe kidney disease before obstruction, azotemia may persist. Serial radiography and ultrasonography can be useful for monitoring the success of medical management for ureterolithiasis.

The 12-month survival rate after medical treatment of 52 cats with ureteral obstruction was 66%. However, 32% of these cats did not respond to medical therapy and were euthanized or died within 1 month of diagnosis. Large case series evaluating dogs with ureteral obstructions are not published, likely because this disease is more common in the cat. If azotemia or pyelonephritis is present, surgery or minimally invasive techniques (e.g., ureteral stents) for the restoration of urine flow should be considered. Cats with marked hyperkalemia or fluid overload at the time of initial examination may benefit from aggressive medical management, such as hemodialysis.

SURGICAL INTERVENTION FOR TREATMENT OF URETERAL CALCULI

In cats and dogs, the optimal time for medical management before making a decision to pursue surgery has not been determined, and the improvement in renal function after stone removal is variable. However, early intervention with surgical or minimally invasive procedures is likely indicated in an effort to maintain functional kidneys. Surgical removal of ureteral calculi can be considered when there is evidence of partial or complete ureteral obstruction. The number of stones, degree of obstruction, operator experience, and availability of appropriate equipment should all be considered when deciding whether to proceed with ureterotomy, stent, or subcutaneous ureteral bypass (SUB). Ureterotomy may be preferred when only a single calculus is identified, but the latter two minimally invasive procedures are more often performed for a variety of reasons. Major factors determining the recovery of renal function after reestablishing ureteral patency include the degree of renal dysfunction before the development of the obstruction and the duration and extent of the obstruction. Ureteral strictures secondary to scar tissue formation can also form at the ureterotomy site, leading to reobstruction; these complications are much less likely to occur when ureteral stenting or SUBs is performed. When a subset of cats with ureteral obstruction was followed after surgical intervention, 14 of 35 (40%) had recurrent episodes of ureterolithiasis.

Ureteral stents and subcutaneous ureteral bypass

Placement of ureteral stents or SUB is being performed as the treatment of choice for ureteral obstruction in cats, particularly if there are multiple ureteroliths. Evidence suggests that these less invasive procedures have lower morbidity and mortality rate for ureteral obstruction than do traditional surgical approaches in cats. A lower re-obstruction rate and decreased severity of azotemia have been associated with stent placement. A skilled operator is necessary for these referral procedures. Attempts to place these stents using a retrograde cystoscopic approach have been made but have been largely unsuccessful in cats; however, this technique can be used for many dogs. In cats, a relatively minimally invasive surgical placement is used (Video 43.4), whereby the surgeon performs a laparotomy and places the stent from the kidney and into the bladder using a coaxial

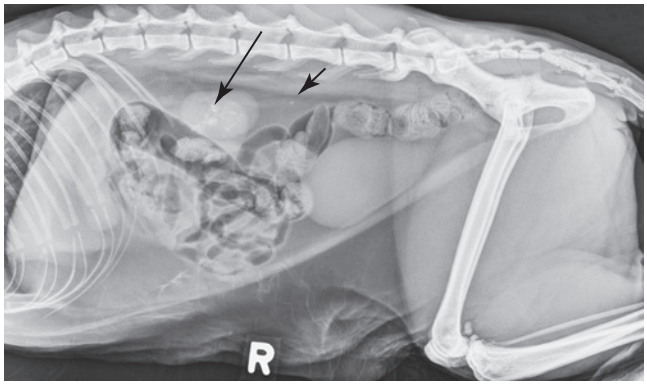

FIG 43.8
Lateral radiograph of a 5-year-old female spayed cat illustrating the multiple renal *(large arrow)* and ureteral calculi *(small arrow)* that are present. Ultrasound is often complimentary to ascertain which ureter is obstructed and to define the degree of obstruction. Ideally, subsequent radiographs should be taken after the pet has defecated in order to fully visualize the retroperitoneal area.

technique. In most cases a needle puncture in the kidney and the cystotomy are the only incisions in the urinary system. After initial placement, urine should flow through the stent lumen, and over time, ureteral dilation develops passively around the stent, allowing further passage of urine, crystals, and possibly stones around the stent (Fig. 43.8). Stents are typically left in place long term unless it becomes contraindicated because of infection or patient discomfort.

SUB was developed an alternative to ureteral stent placement and is preferred by some operators. With this technique, the placement of a nephrostomy and cystotomy tubes that sit subcutaneously are connected at a subcutaneous access port so the system can be flushed if needed. Urine can then bypass the obstructed ureter and be excreted in the bladder in a normal fashion.

Long-term management of cats with ureteral and renal CaOx calculi are similar to those with lower urinary tract CaOx calculi, except that the degree of kidney disease also needs to be considered when choosing dietary and drug therapies. High-sodium diets should be avoided in cats with renal compromise and in those with hypertension. If animals have stage II chronic kidney disease or higher, "renal diets" (i.e., those lower in phosphorus and protein) are recommended.

Prevention of Calcium Oxalate Urolithiasis

Prevention of CaOx-containing calculi is similar for cats and dogs. An outline for the management of CaOx uroliths is presented in Box 43.1.

Dietary modifications

Once a urolith has been removed, it is recommended to increase the moisture content in the diet by feeding a canned diet, if possible, to decrease the urine concentration of stone mineral precursors. See Box 43.2 for recommendations on increasing dietary moisture intake. There is no dissolution protocol for CaOx uroliths, so removal and quantitative mineral analysis of the stones should be performed if they are growing or causing clinical disease. Patient-related factors should be addressed on presentation to ascertain that no potential predisposing factors are present (e.g., hypercalcemia, obesity, other systemic disorders) and

BOX 43.1

Calcium Oxalate Stone Management for Lower Urinary Urolithiasis

1. Remove all uroliths; obtain radiographs to be certain all uroliths have been removed.
2. Submit all uroliths for quantitative crystallographic analysis.
3. Evaluate a serum calcium concentration.
   - If high, pursue further diagnostics, such as an ionized calcium and parathyroid hormone (PTH) panel.
4. Consider evaluating serum triglyceride concentrations.
   - This is particularly important in predisposed breeds, such as Miniature Schnauzers, because it may influence selection of the diet for management.
5. Obtain thorough history, document physical examination, and record body weight and body condition score.
6. Select a diet.
   - Consider all comorbidities of the patient when selecting the diet.
   - High-moisture diets are best (i.e., canned food).
7. Evaluate the following approximately 1 month after the pet is consuming the selected diet well:
   - Radiographs and/or ultrasonography
   - Urinalysis
     - This should be evaluated in-house, because in vitro crystalluria can occur within hours of collection. Refrigeration will exacerbate this artifact.
     - As a guideline, keep the urine specific gravity (USG) consistent, <1.020 in a dog and <1.025 in a cat. USG can be monitored using samples collected from the pet in the home environment.
     - Adjust moisture content or diet selected, depending on urine USG.
     - *Note:* Do not add salt or choose a higher-sodium diet if the dog or cat has kidney disease, is hypertensive, has congestive heart failure, or is hypernatremic.
     - Urine pH—CaOx solubility varies little in ranges of physiologic pH, but acidification may be a risk factor.
8. For animals with recurrent CaOx urolithiasis, consider the addition of hydrochlorothiazide, 2 mg/kg PO q12h for dogs and 1 mg/kg PO q12h for cats.
   - Evaluate serum calcium concentration 1 week after therapy to ensure hypercalcemia is not present.
   - Review and alter dietary strategy as needed.
9. For recurrent CaOx urolithiasis, potassium citrate may also be used, 50-75 mg/kg PO q12h (adjust dosage based on clinical response), which will help chelate calcium and alkalinize the urine.

BOX 43.2

Guidelines for Increasing Dietary Moisture

1. Try feeding the canned formulation of the desired diet if possible.
   - Feeding a high-moisture diet (>75% moisture) is ideal. Canned formulations of diets are the easiest way to achieve this in some animals.
   - Providing a choice of canned and dry foods for cats is recommended because an abrupt change in diet is usually not well tolerated.
2. If this is not practical, begin adding water to the dry diet:
   - Begin with 1 cup of water/cup of dry food.
   - Gradually increase the water content over 3-4 weeks.
   - Ideally, 3-4 cups of water/cup of dry food is recommended (≈70% moisture).
   - Evaluate the urine specific gravity (USG) and urine sediment periodically; free-catch urine collected in the home environment is ideal for this.
3. Adjust moisture intake or consider the addition of salt if necessary.

need to be addressed concurrently. After using strategies to increase the moisture content of the diet, if the urine is still too concentrated or the urine sediment findings remain abnormal, one can try the addition of sodium chloride (table salt) to the diet to increase the urine volume produced daily, unless the patients are hypertensive or have cardiovascular problems or renal disease. Feeding higher-sodium diets (>375 mg/100 kcal) dry foods should not a substitute for feeding a high moisture food but can be considered in dogs and cats where urine dilution is not achieved and recurrence of CaOx is of concern.

There are several diets marketed for CaOx prevention in cats and dogs, but studies on their efficacy are limited. Home-cooked diets can also be an option for some dogs and cats, particularly those with multiple comorbid conditions that need to be managed concurrently. A consultation with a veterinary nutritionist is recommend in these cases, and the readers are encouraged to consult with nutritionists for the most up-to-date marketed diets for stone prevention. Diets for CaOx prevention should not be restricted in calcium, because this could increase the absorption of intestinal oxalate. Excess calcium and oxalate intake should also be avoided. High-moisture, lower-calorie, low-oxalate treats can also be a good option for owners who wish to provide treats for their pet (see www.ohf.org/docs/Oxalate2008.pdf for approximate oxalate contents of many human foods). The list can be reviewed with the client, and foods such as raisins, grapes, and other toxic foods listed that are contraindicated for pets should be discussed with the owner.

Other nutrients to consider in the dietary management of CaOx urolithiasis include magnesium and phosphorus. Urinary magnesium, phosphate, and citrate are thought to act as inhibitors of CaOx urolith formation and therefore should not be restricted in the diet. Dietary phosphorus should not be excessively restricted because it could lead to increased activation of vitamin D_3 to calcitriol by 1α-hydroxylase in the kidney under the action of parathyroid hormone (PTH) and result in increased intestinal absorption of calcium. Finally, dietary fats have been speculated to be involved in CaOx stone formation in rats and humans. Although the pathogenesis of spontaneous CaOx stone formation in animals may differ, it may be prudent to feed animals with hypertriglyceridemia a diet restricted in fat (<2 g/100-kcal diet). When choosing a diet, the animal's entire history, physical examination (including body condition score), and medical conditions need to be considered.

Drug therapy

If dietary manipulations alone are unsuccessful in preventing CaOx urolith recurrence, drug therapy may provide additional benefit. The administration of hydrochlorothiazide (2 mg/kg orally [PO] q12h for dogs; 1 mg/kg PO q12h for cats) can be attempted because this may decrease urinary calcium excretion. Serum calcium concentration should be evaluated shortly after beginning this agent to ensure that hypercalcemia does not occur. Although there are no studies about the efficacy of hydrochlorothiazide in cats with CaOx stones, reports have suggested that this dosage is well tolerated and reduces the relative supersaturation of CaOx in healthy cats. Also, citrate as potassium citrate (50-75 mg/kg PO q12h for cats or dogs) may be helpful because the citrate can complex with calcium, thereby decreasing the urinary concentration of CaOx and alkalinizing the urine.

Struvite Stone Management

For dogs

Struvite uroliths occur more commonly in female dogs compared with male dogs. They are usually larger than CaOx and often smooth in shape (Fig. 43.9). In dogs, unlike cats, almost all struvite calculi are infection-induced, usually by *Staphylococcus intermedius* or, less commonly, by *Proteus mirabilis*. These bacteria have the ability to hydrolyze urea to form ammonia and carbon dioxide. This reaction increases the urine pH and makes ammonium available to form magnesium ammonium phosphate crystals. Occasionally the urine can be supersaturated with the minerals that comprise struvite uroliths, and stone formation can occur without an infection present. If a urine culture is negative in a dog with struvite uroliths, the stone and/or bladder mucosa can also be cultured to be certain that a bacterial pathogen is not present. Dissolution of canine struvite uroliths can be done in the same manner as described for cats (see later), but proper antimicrobials, based on minimum inhibitory concentration (MIC) testing results, should also be administered. By convention, these antimicrobials have been administered throughout the duration of the dissolution protocol. No studies have been performed to see if this duration of antimicrobial therapy is warranted, and shorter courses may be considered. Three diets are currently marketed for struvite dissolution in dogs (Royal Canin Canine

FIG 43.9
Ventrodorsal radiograph of a 7-year-old female spayed cat that required ureteral stent placement for ureteral obstruction. The stent is placed so the coils of the stent are in the renal pelvis and the urinary bladder.

Veterinary S/O, Royal Canin USA, St. Charles, MO; Hill's Prescription Veterinary Diet Canine s/d, Hill's Pet Nutrition, Topeka, KS; and Purina UR Veterinary St/Ox). Struvite dissolution can be attempted so long as the cystic calculi is not so large it is causing urethral obstruction or it encompasses the entire urinary bladder and therefore the "medicated" urine cannot adequately bathe the stone for proper dissolution. Furthermore, if the dog's clinical signs cannot be adequately controlled with diet and antimicrobials, dissolution should be discontinued. The dog should be rechecked in 3 to 4 weeks; if the uroliths have not decreased in size at that time, and owner compliance with the diet trial is good, the stone may have layers of calcium phosphate in the form of apatite or may not contain struvite. However, if clinical signs are well controlled and the stones appear diminished in size, it is advised to continue dissolution, as some larger stones can take longer (months) for dissolution. No published studies in dogs regarding struvite dissolution have currently been published, but some are underway at the time of this writing.

To prevent the recurrence of infection-induced struvite stones in dogs, treatment should be focused on preventing future urinary tract infections (UTIs). No dietary changes are indicated, but urine cultures and periodic radiographs should be assessed as clinically indicated. The dog should be treated with the proper antimicrobial; long-term therapy is usually not required in dogs with uncomplicated infections. For management of recurrent UTIs in dogs, see Chapter 45.

For cats

Determining whether a cat has a struvite urolith is more difficult than in dogs because the uroliths are not caused by bacterial infections. Struvite uroliths are usually larger and can occur as a single, often elliptical calculus, whereas CaOx are often smaller, multiple calculi. Although radiodense, they are often not as "bright" as CaOx on plain radiography. The clinician can attempt to dissolve the urolith(s) by feeding a calculolytic diet (e.g., Royal Canin Feline Veterinary S/O or Hill's Prescription Veterinary Diet s/d, Purina UR St/ox) and monitoring the urolith size with radiography. Because calculolysis usually occurs within 1 month (and can be as soon as 8-10 days based on published data), abdominal radiographs should be evaluated 2 to 3 weeks after the cat has fully adjusted to the dissolution diet. If the urolith(s) appears smaller, the urine is dilute (specific gravity < 1.016), and the pH appropriate (at least <6.5), the diet can be continued and the cat reevaluated in 3 to 4 weeks. If the urolith is not smaller with dietary intervention, the owner should be questioned regarding other food and treats the cat is receiving. If the urine pH and specific gravity are not in the desired range with the calculolytic diet chosen, owner compliance should be questioned. If compliance was good, then the stone likely contains other minerals. For both cats and dogs, contraindications to attempting dissolution for suspected struvite urolithiasis include urethroliths that are causing obstruction, or if the animals' clinical signs are severe, immediate removal may be necessary. In many cases, analgesic therapy can be provided initially to improve the animal's comfort as the dissolution protocol is started.

To help prevent the recurrence of struvite urolithiasis in cats, a high-moisture diet that produces a urine pH less than 6.8 is advised; veterinary diets are marketed for struvite prevention, which in many cases are the same as those marketed for CaOx prevention. Many of these diets are formulated to produce a urine pH that is below the relative supersaturation level for struvite, but they are not highly acidifying. The moisture intake of the cat can be evaluated by periodically assessing the urine specific gravity. Abdominal radiographs, including the entire urinary tract, should be performed to assess for new urolith formation. If no uroliths are present, radiography should be repeated periodically (every 2-3 months initially, then less often as the disease is managed). If small uroliths recur, VUH may be an option for stone removal.

URATE UROLITHIASIS IN DOGS

Etiology

Urate-containing calculi have comprised approximately 25% of the stones analyzed at our laboratory each year from dogs; other data show that 6.4% of canine uroliths were classified as purines when at least 70% of the stone consisted of purine mineral. Unlike most other breeds of dogs, Dalmatian dogs have a well-described alteration in purine metabolism

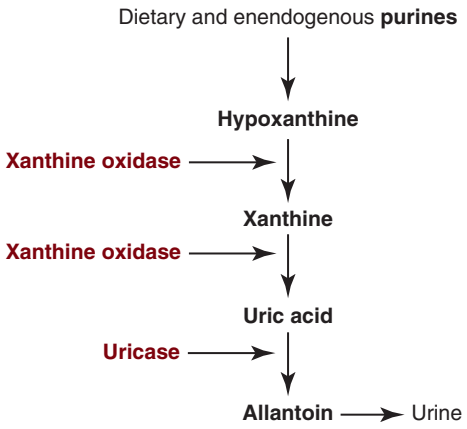

FIG 43.10
Purine metabolism in animals. Most dogs excrete the soluble product, allantoin, in the urine. Because of genetic abnormalities, Dalmatians and other breeds with the *SLC2A9* genetic mutation have larger of amounts of uric acid excreted in the urine, which may predispose them to form urate uroliths.

that leads to the excretion of uric acid in the urine rather than excretion of the more soluble metabolite, allantoin (Fig. 43.10). All Dalmatians excrete relatively high amounts of uric acid (400-600 mg of uric acid/day compared with 10-60 mg/day in non–Dalmatian dogs); however, not all Dalmatians form urate uroliths. Genetic studies have reported that the mode of inheritance is not X-linked, and the prevalence of the clinical disease in male Dalmatians ranges from 26% to 34%. Bannasch et al. (2008) identified the SLC2A9 transporter as the cause of the change in uric acid handling by Dalmatians by positional cloning using an interbreed backcross. Other breeds such as the English Bulldog and Black Russian Terrier were also homozygous for the same mutation. For a list of other predisposed breeds and information on DNA testing to help owners and breeders identify affected and carrier dogs, see http://www.vgl.ucdavis.edu/services/Hyperuricosuria.php.

Urate Urolithiasis Management

Dissolution of urate urolithiasis has been described in a small case series; a low-protein diet and allopurinol (15 mg/kg PO q 12 hr) were administered. This can be considered in dogs if obstruction is not evident. Success rates are quite variable. The prevention of urate urolithiasis in dogs with genetic hyperurocosuria such as the Dalmatian is shown in Box 43.3. A diet low in purines is recommended. This can be accomplished by feeding a diet low in protein; however, diets higher in protein and low in purines are another alternative. A recent pilot study suggested that a diet higher in protein (with added water) but low in purines was beneficial in maintaining a low urinary uric acid excretion in dogs with a history of urate urolithiasis and genetic hyperuricosuria. Vegetarian diets have also been described for use in these breeds for the management of urate urolithiasis recurrence. Ammonium urate is more soluble in alkaline urine, and these diets described should produce a urine pH higher than 7.0. Potassium citrate can be added to help alkalinize the urine in dogs with recurrent urate uroliths if the desired urinary pH is not achieved with dietary therapy alone. As with any animal that forms uroliths, the diet should be high in moisture.

If dietary strategies are not successful, allopurinol (5-7 mg/kg q12-24h), a xanthine oxidase inhibitor, can be considered. This drug will decrease the amount of uric acid formed in the urine. The exact dosage is variable, and studies have shown that the metabolism of this drug varies from dog to dog. Ideally, the amount given should be titrated based on 24-hour urine uric acid excretions, but this is rarely done in practice. Side effects of allopurinol can include

BOX 43.3

Management of Canine Urate Urolithiasis for Dogs With Genetic Hyperuricosuria

1. Can attempt urate urolith dissolution if urinary obstruction not present with a low-protein or low-purine diet and allopurinol. If unsuccessful, remove all uroliths and confirm via ultrasonography or contrast radiography.
2. Submit all uroliths for quantitative analysis as well as infrared spectroscopy, which are required to differentiate uric acid from its metabolites.
3. Select a diet appropriate for the dog, and consider all comorbid conditions that may be present. Diets marketed for urate prevention include the following:
   - Royal Canin Veterinary Diet Urinary U/C
   - Hill's Canine u/d
   - Vegetarian diets may also be acceptable
4. Evaluate the following approximately 1 month after the diet has been implemented:
   - Abdominal ultrasonography (urate uroliths have a low radiographic density)
   - Urinalysis
     - Aim for a target urine pH > 7.0, USG < 1.020, and inactive sediment.
     - If urine pH is not ideal, consider the addition of potassium citrate.
5. If recurrence is a problem, consider using allopurinol.
   - Do not use unless the animal is consuming a low-purine diet.
   - Begin a dosage of 5-7 mg/kg q12-24h
   - Ideally, the dosage should be titrated based on 24-hour urinary uric acid (UA) excretion.
     - If urinary UA < 300 mg/day, lower the allopurinol dose. If stones recur, analyze to be certain they are not xanthine. If xanthine formation occurs, stop or significantly lower dose of allopurinol
   - Adverse effects include xanthine stone formation and hepatotoxicity.
6. Monitor the dogs periodically with imaging and adjust the protocol as needed.

xanthine stone formation (particularly if the animal is not being fed a purine-restricted diet), gastrointestinal upset, and hepatotoxicity.

If urate-containing calculi are found in non–hyperuricosuric breeds, a search for an underlying portovascular anomaly, such as a portosystemic shunt (PSS), should be pursued. Urate uroliths have also rarely been reported from dogs with portal venous hypoplasia (PVH; also referred to as microvascular dysplasia). Dogs with underlying liver disorders are likely predisposed to urate urolith formation because of hyperammonuria and hyperuricosuria, which result from the reduced ability to convert ammonia to urea and uric acid to allantoin. Correction of the vascular disorder should be addressed, if possible, to help prevent urate recurrence. In patients with inoperable PSS or PVH, diets marketed for liver disease may be used to help decrease the urinary ammonium urate and help control any signs of hepatic encephalopathy. If a portovascular anomaly cannot be found, DNA testing for the hyperuricosuric genetic abnormality should be considered.

URATE UROLITHIASIS IN CATS

Etiology

After CaOx- and struvite-containing uroliths, urate uroliths are the third most common mineral type submitted to most stone laboratories from cats. There is no gender predilection for cats with urate urolithiasis; recurrence rates are variable. Specific breeds such as the Egyptian Mau and Siamese have been reported to be at higher risk. The pathophysiology of feline urate urolithiasis is largely unknown. Unlike dogs, genetic studies have not been published, and it is thought that most cats do not have underlying hepatic dysfunction such as a PSS. However, in one study, most cats seen by primary care veterinarians with urate urolithiasis did not have advanced diagnostic studies to investigate the presence of a PSS fully, but a normal physical examination, clinicopathologic findings, and no clinical signs (e.g., ptyalism, neurologic signs, lethargy) suggestive for a hepatopathy were present.

Urate Urolithiasis Management

In any cat that has been diagnosed with urate urolithiasis, a full complete blood count (CBC) and serum biochemical profile are warranted. If clinical signs and/or clinicopathologic abnormalities (e.g., microcytosis, high liver enzyme activities, abnormal liver function parameters) are suggestive for a hepatopathy or vascular anomaly, further diagnostic studies such as abdominal ultrasonography and measuring serum bile acid concentrations are recommended. If urate uroliths are diagnosed in a cat with no history, clinical signs, and clinicopathologic abnormalities suggestive for a hepatopathy, the costs of further tests can be discussed with the owner, because not all cats will require further evaluation. In older cats, further testing may not be necessary.

To prevent recurrence of urate uroliths in otherwise healthy cats, a high moisture diet that is restricted in protein is often recommended, such as those diets marketed for kidney disease (e.g., Hill's k/d; Royal Canin Renal LP; Purina NF Kidney Function, Purina, Vevey, Switzerland). Anecdotally, a commercially available hydrolyzed soy protein diet has been fed to these cats in hopes of providing an adequate protein intake with low purine content (Royal Canin Feline Hypoallergenic Hydrolyzed Adult HP). No evidence of the effectiveness of any of these approaches has been evaluated in controlled trials in cats with urate urolithiasis. As with all cases of urolithiasis, feeding a high-moisture diet is the cornerstone of urolith prevention management. Periodic imaging using ultrasonography—because urate can be difficult to see on plain radiography—is also important to monitor for recurrence.

CALCIUM PHOSPHATE CALCULI IN CATS AND DOGS

Apatite (calcium hydroxyl phosphate)-containing calculi in dogs is usually found as a so-called "tag-along mineral" because it usually is associated with struvite uroliths, either mixed throughout or as single layers. Apatite-containing uroliths are not very common in cats but can be seen in association with struvite, CaOx, or by themselves. Unlike brushite, apatite is generally less soluble in alkaline urine. Brushite (calcium hydrogen phosphate dihydrate) is another form of calcium phosphate that is much less common in dogs and very rare in cats. Brushite tends to occur as multiple small uroliths. Prevention measures for these uroliths in cats and dogs are unknown. Similar to CaOx management, a search for predisposing disorders that could result in hypercalcemia is recommended. Often it is recommended that the dog or cat be evaluated and managed similarly to those patients with CaOx uroliths. A high moisture diet that produces a neutral urinary pH is advised.

CYSTINE AND SILICA UROLITHIASIS IN CATS AND DOGS

Etiology and Management

Cystine- and silica-containing uroliths are uncommon in dogs and very rare in cats. They represented 1.3% and 6.6%, respectively, of all the canine uroliths we analyzed. Cystine urolithiasis is much more common in dogs compared with cats. Cystinuria in dogs results from a mutation in 1 of 2 genes, SLC3A1 (type I-A; autosomal recessive inheritance, and II-A; autosomal dominant inheritance) and SLC7A9 (type II-B; autosomal dominant inheritance), which encode subunits required for the dibasic amino acid transporter system that enables cystine reabsorption form the glomerular filtrate. Furthermore, an androgen dependent type III cystinuria has been reported in several breeds of intact male dogs. Cystine urolithiasis has also been reported more commonly in intact male dogs. Recently, a mutation in the SLC3A1 gene has also been reported in the cat.

Dietary management includes feeding a diet high in moisture and low in protein (e.g., Hill's Prescription Diet u/d®, Royal Canin Veterinary Diet® Urinary U/C™); or feeding

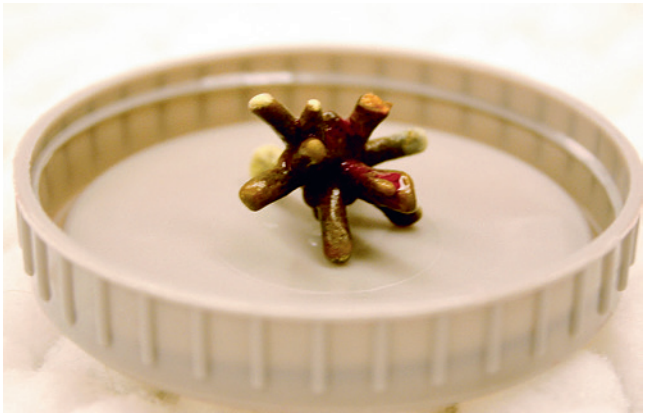

FIG 43.11
Silica urolith that was removed from a dog; note the characteristic "jack-like" appearance.

FIG 43.12
Characteristic appearance of dried solidified blood calculi that were removed from a cat.

a vegetarian-based diet. Cystine is more soluble in alkaline urine, and the recommended dietary therapy should result in a urine pH > 6.5 to 7.0. If the optimal urinary pH is not achieved in this manner, potassium citrate (starting dose of 50-75 mg/kg q12h) can be added to alkalinize the urine, because citrate salts serve as a source of bicarbonate. The drug, tiopronin (Thiola®, 2-MPG; 15-20 mg/kg PO q12h), can also be administered to help prevent (or possibly dissolve) cystine stones; however, this sulfhydryl compound can be cost prohibitive and limited in its availability. When using this medication, gastrointestinal and hematologic adverse effects can occur. Dogs and cats should be monitored with appropriate imaging studies to evaluate the effectiveness of the therapeutic approach. Due to the possible androgen-dependent cystinuria, if male intact dogs are diagnosed with cystine uroliths, castration is recommended.

Dogs with silica-containing uroliths are usually older, and most affected dogs are male. Most silica uroliths have a so-called jack stone appearance (Fig. 43.11), giving them a characteristic look on plain radiography. The recurrence rate of silica is not well known, but these uroliths are generally slow-growing. Dietary prevention strategies focus on providing a high-moisture diet that is higher in animal proteins and lower in plant origins, particularly rice, soybean hulls, and corn gluten feed.

DRIED SOLIDIFIED BLOOD CALCULI IN CATS

We have reported another urolith type called DSB calculi that we have only identified in cats. Although we have rarely noted small amounts of DSB on the surface of various canine stones, none of them was ever composed of 100% DSB, as in cats. DSB calculi can occur in various places in the upper and lower urinary tract. DSB calculi are very firm and "stone-like" but usually do not contain crystalline material (Fig. 43.12). Although these uroliths are not common, they can be a diagnostic challenge. They are generally radiolucent unless they contain a significant portion of CaOx, calcium phosphate, or other radiodense mineral. Furthermore, they can be difficult to identify on ultrasonographic examination. Management for the prevention of DSB includes evaluating the patient for underlying evidence of renal or lower urinary hematuria and increasing the moisture content of the diet.

XANTHINE UROLITHS

Xanthine uroliths are very rare in cats and dogs. The most common cause of xanthine urolithiasis in dogs is iatrogenic because of the administration of the xanthine oxidase inhibitor allopurinol, primarily in Dalmatians and those breeds genetically predisposed to urate urolithiasis. Higher levels of urinary xanthine and hypoxanthine will occur if the dosage of this drug is too high, and/or the dog is not receiving a purine-restricted diet. Xanthine uroliths have also been described in Cavalier King Charles Spaniels, caused by an autosomal recessive trait that results in increased urinary hypoxanthine and xanthine excretion. This is likely because of a deficiency in the enzyme xanthine oxidase. Secondary renal failure is relatively common when this occurs in the Cavaliers. Diets similar to those used for urate prevention, which are restricted in protein and high in moisture, are generally recommended for this condition in this breed.

CONCLUSIONS

Whenever a urolith is obtained from a dog or cat (surgically, catheter-assisted, voided, or by lithotripsy), it is important that it be submitted for crystallographic analysis to identify the minerals present. Evaluating trends in feline and canine urolithiasis is important because it may assist clinicians in determining what, if any, effect current stone prevention strategies, including dietary modifications and drug therapy, are having in cats and dogs with urolithiasis. Diets high in moisture are the cornerstone of therapy for preventing

urolithiasis recurrence in patients. Serial monitoring of urine specific gravity from samples collected in the home environment can be an easy, cost-effective method to monitor dietary moisture intake. Animals should be monitored with imaging studies appropriate for the urolith type.

CHAPTER 44

Obstructive and Nonobstructive Feline Idiopathic Cystitis

INTRODUCTION

Feline lower urinary tract disease (FLUTD) is an inclusive term used to describe any disorder affecting the urinary bladder or urethra of cats. Signs of LUTD in cats can include variable combinations of pollakiuria, stranguria, periuria, dysuria, and hematuria. These lower urinary tract signs (LUTS) are not specific for any one particular disease; they can be seen in cats with cystic calculi, bacterial urinary tract infections, or neoplasia. The prevalence of LUTS in pet cats in the United Kingdom and the United States have been reported at 0.6% (veterinary data) up to 6.4% (owner-reported data). Up to two-thirds of young (<10 years of age) cats that present with LUTS will be diagnosed with feline idiopathic cystitis (FIC). However, cats with recurrent episodes of FLUTD have been reported to present with different causes at different times. Although FIC can be obstructive or nonobstructive in its presentation, urethral obstruction is far more common in male cats. In published studies, excessive body weight, decreased activity, multiple cats in the household, cats using nonclumping litter, and indoor housing have been associated with increased risk for FIC. Environmental stressors such as conflict with another cat in the household have also been identified as risk factors.

PATHOPHYSIOLOGY

HISTOPATHOLOGY

Histologically, FIC can be classified in two different forms, nonulcerative (type I) and ulcerative (type II). Cats with FIC almost always present with the nonulcerative form; however, the classic Hunner's ulcers seen in humans (type II) have been described rarely in cats. It is possible that the etiopathogenesis of these two forms of FIC is different. The type II form appears to be more inflammatory, whereas type I might be associated with neuroendocrine abnormalities. Furthermore, various proinflammatory serum cytokine profiles have been identified in some cats with FIC compared with healthy cats.

In cats with chronic nonulcerative FIC, histopathologic changes in the bladder wall are generally nonspecific and may include an intact or damaged urothelium with submucosal edema, dilation of submucosal blood vessels with marginated neutrophils, submucosal hemorrhage, and sometimes increased mast cell density. Histopathologic abnormalities are usually not specific for FIC and do not correlate well with clinical signs.

BLADDER ABNORMALITIES

Because cats with FIC present primarily for LUTS, many research studies have been published describing various bladder abnormalities. Although a decrease in bladder compliance has been found in cats with FIC, no evidence of spontaneous bladder contractions (overactive bladder) was noted in *female* cats with FIC when cystometrograms were evaluated. It has been proposed that the urothelial cells themselves can be targets of various stimuli, including adenosine triphosphate (ATP) and nitric oxide, which could potentiate inflammation and exacerbate clinical signs. The bladder afferent neurons in cats with FIC exhibit an increased excitability to physical and chemical stimuli as compared with unaffected cats. An increase in the release of nitrous oxide and subsequent increase in urothelial permeability suggest that the sympathetic nervous system may mediate these alterations by norepinephrine via this mechanism.

INFECTIOUS AGENTS

The role of viruses has been evaluated in cats with FIC. The feline caliciviruses, FCV-U1 and FCV-U2, have been the most studied. Feline calicivirus (FCV) viruria was detected in cats with FIC and in cats with upper respiratory infections; however, its etiologic significance was not ascertained. Serologic results suggest increased FCV exposure in FIC cats compared with controls. A weak association between seropositivity for *Bartonella* spp. and FIC has also been reported. What, if any, relationship these infectious agents play in the etiopathogenesis of LUTS in FIC thus remains unknown at this time, and to the authors' knowledge their role(s) in the

systemic manifestations of the syndrome have not been investigated.

SYSTEMIC ABNORMALITIES

Clinical signs of FIC can wax and wane, and appear to be exacerbated by internal and external stressors. Elevations in catecholamines and a decrease in serum cortisol concentrations in cats with FIC compared with healthy cats during times of acute and chronic stress have been reported, suggesting an uncoupling of these two parameters of the stress response. Therefore it appears that, although the sympathoneural system is fully activated in this disorder, the hypothalamic-pituitary-adrenal axis is not. The increased concentrations of catecholamines that were observed in cats with FIC may provide a clue to the observation that clinical signs of FIC follow a waxing and waning course and can be exacerbated by environmental stressors. Unfortunately, providing corticosteroid administration does not prevent or cure this disease.

Research in other species (e.g., rats) suggests that events experienced during development may affect visceral sensory systems and result in chronic idiopathic disorders. Although the cause of FIC has not been determined, it appears that some cats have a disorder that affects the LUT, and because systemic abnormalities have been documented in some cats, FIC should not be considered solely a bladder disease. A recent study of healthy cats and cats with FIC found that environmental stressors resulted in increased number of sickness behaviors (e.g., vomiting, lethargy, anorexia) in cats with FIC when the results were controlled for other factors. Cats with FIC have a variable combination of comorbid disorders such as behavioral, endocrine, cardiovascular, and gastrointestinal (GI) problems, and it is imperative that a detailed environmental history and complete physical examination be performed in these cats and that the focus be not just on the bladder. This will alter the therapeutic approach to management of the disease.

PATHOPHYSIOLOGY OF THE BLOCKED CAT

Urethral plugs are the most common cause of urinary tract obstruction in male cats; however, urethrolithiasis, strictures, and, rarely, neoplasia or a foreign body can result in a urethral obstruction. It is unlikely for the urethra of female cats to become obstructed, but male cats have a narrow penile urethral lumen and are predisposed to obstruction with a urolith or urethral plug. Oftentimes, the cause of the obstruction is not found, and it is thought the urethral pressure may be elevated or "spasm," although to the author's knowledge data to support urethral spasms have not been published. Many urethral plugs are composed of struvite with a proteinaceous matrix, and this composition has not changed over time (Fig. 44.1). The cause(s) of urethral plugs is still unknown; it is hypothesized that vasodilation and leakage of plasma proteins from the suburothelial capillary plexus and secondary urethritis, which can be seen cystoscopically in cats with FIC, may trap crystals and other debris in the urine within the lumen of the male cat and result in obstruction. It is likely that oozing of plasma proteins into the urine during active inflammation increases the urinary pH, which further contributes to the precipitation of struvite crystals that participate in urethral plug formation. Once the cat is unblocked and stabilized, management for obstructive FIC is very similar to that for nonobstructive FIC.

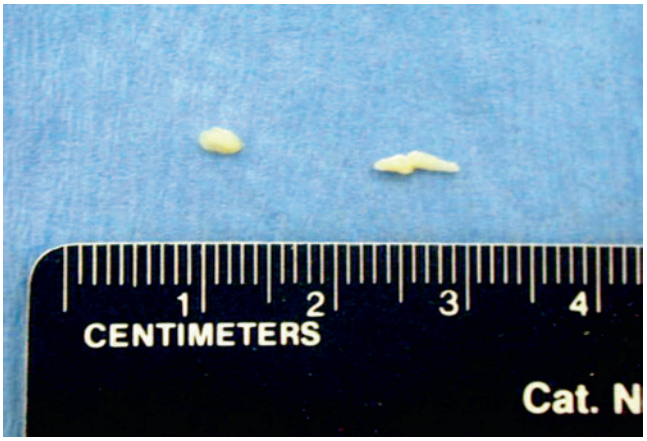

FIG 44.1
Urethral plug removed from an obstructed male cat. These plugs generally contain albumin and albumin breakdown products, as well as struvite crystals.

DIAGNOSTIC TESTS FOR CATS WITH LOWER URINARY TRACT SIGNS

When choosing the appropriate diagnostic tests for a cat that presents with LUTS, several factors need to be taken into consideration, including the number of episodes the cat has had, the severity of the cat's clinical signs, and how much the owner is willing to spend. No well-accepted diagnostic test for FIC currently exists, although research in urinary biomarkers for this disease continues. In humans, various markers such as antiproliferative factor and heparin-binding epidermal growth factor have been investigated but are not clinically available. In humans and cats, a candidate serum biomarker has been reported, and findings suggest the potential usefulness of infrared microspectroscopy to diagnose FIC (Rubio-Diaz et al., 2009). However, FIC currently remains a diagnosis of exclusion.

Because approximately 20% of cats that present with LUTS have cystic calculi, abdominal radiography is recommended. Abdominal ultrasonographic findings in cats with urethral obstruction are generally not as helpful because the urethra cannot be imaged. If a cat presents with a urethral obstruction, obtain an abdominal radiograph before a decompressive cystocentesis as long as the cat is stable. A urinalysis and urine bacterial culture should be evaluated at least once in cats with LUTS, but most young, otherwise healthy cats do not have a true bacterial cystitis. Advanced

diagnostic tests such as contrast cystourethrography, abdominal ultrasonography, and even cystoscopy (Figs. 44.2 and 44.3; Video 44.1, cystoscopy of FIC cat) can be performed in recurrent cases to be certain no other disease could account for the present clinical signs.

TREATMENT OPTIONS

ACUTE EPISODES

Obstructive Feline Idiopathic Cystitis

Once the diagnosis of a urethral obstruction is made, the cat should be assessed and stabilized with intravenous (IV) fluids. A serum biochemical panel should be submitted to evaluate for postrenal azotemia, possible hyperkalemia, and other electrolyte and acid–base disturbances such as hypocalcemia and acidosis. If hyperkalemia is present, IV treatment with fluids, regular insulin (0.25-0.5 U/kg, slow bolus), and 50% dextrose should be administered. An electrocardiogram should be evaluated and, in more severe cases, 10% IV calcium gluconate may be warranted to counteract the effects of the hyperkalemia on cardiac conduction. Acidosis is usually corrected with fluid therapy, but IV sodium bicarbonate (1-2 mEq/kg) can also be considered for cats with severe hyperkalemia. Care should be taken with bicarbonate infusions because exacerbation of hypocalcemia can occur when the acidosis is corrected.

Once the cat is stabilized, an abdominal radiograph should be obtained to evaluate for the most common calculi reported in cats (struvite and calcium oxalate [CaOx]). To provide an immediate reservoir for urine flow, a decompressive cystocentesis should then be performed. Usually a 22-gauge 1- or 1.5-inch needle is inserted into the bladder, with the bevel aimed at the trigone. The needle is connected to an extension set, three-way stopcock, and 20- or 35-mL syringe (Fig. 44.4). By doing this, all the urine can be drained without repeated needle insertions into the bladder. Analgesics should be provided (e.g., buprenorphine, 0.01 mg/kg intravenously q8-12h initially) and once the cat is anesthetized (e.g., with isoflurane, sevoflurane, or propofol), the urethral obstruction can be removed.

In rare cases, one can remove a urethral plug by massaging the distal penis. In most cases, urethral catheterization with an open-ended nonmetal catheter provides the easiest, safest means to alleviate the obstruction. The penile urethra should be clipped and scrubbed; using sterile technique, the catheter is then inserted into the distal urethra. The catheter should also be attached to an extension set and three-way stopcock. This may help lessen the trauma to the urethra during catheter insertion by allowing the assistant more room to flush the urethra with sterile saline, which is usually required to dislodge the obstruction; a smaller syringe provides a more forceful flow, which can be helpful in some cases.

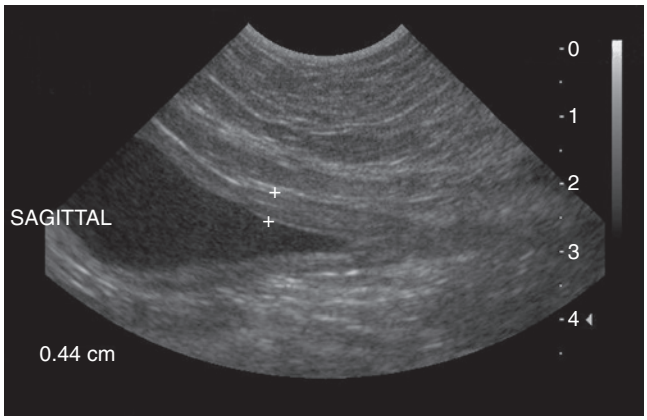

FIG 44.2
Abdominal ultrasonogram from a cat with a urethral obstruction. The findings are generally nonspecific and include a thickened bladder wall. This imaging modality is not ideal for evaluating the urethra of cats.

FIG 44.3
Cystoscopic view of a bladder from a female cat with FIC. The cat has severe edema and increased bladder friability. These findings do not appear to correlate well with the clinical signs.

FIG 44.4
Decompressive cystocentesis in a cat with urethral obstruction.

Indwelling urinary catheters are not mandatory for every urethral obstruction. An indwelling catheter might be irritating to the urethra and potentiate urethral irritation and subsequent reobstructions once the catheter is removed. However, an indwelling catheter should be placed in cats with severe azotemia, an abundance of debris and hemorrhage noted in the urine, or the presence of detrusor atony, or in cats with urethral obstructions caused by calculi (until surgery can be performed). A soft 3.5F or 5F catheter (e.g., red rubber or Slippery Sam catheter) can be left in place; strict aseptic technique should be followed. A closed collection system should be used to aid in sterility as well as to monitor urine output (Fig. 44.5). Azotemic cats can have a pronounced postobstructive diuresis, and it is imperative to provide adequate IV fluid therapy for these patients. Urine output should be recorded every 4 hours initially, and the amount recorded. The rate of IV fluids administered can then be adjusted based on the recorded urine output. Renal parameters and potassium concentration should be monitored; hypokalemia can develop during the diuresis phase. A urine culture can be considered after the urinary catheter is removed; there is no indication to culture the catheter tip.

In addition to analgesics, α_1-antagonists such as phenoxybenzamine (2.5 mg/cat orally [PO] q12h) or prazosin (0.5 mg/cat PO q12h) is often administered to cats with urethral obstruction to decrease urethral "spasms" and hopefully prevent reobstruction. Anecdotally, veterinarians have also used the more selective α_1-antagonist, tamsulosin (Flomax; anecdotal doses are 0.004-0.006 mg/kg PO q24h or q12h), with variable success. Because hypotension could develop with the administration of these drugs, they should not be given until the cat is stable and alert; blood pressure should be monitored if clinically indicated. In one study, prazosin had no effect on the incidence of urethral reobstruction in cats with naturally occurring obstructive FIC; however the authors were concerned their study was underpowered. No other medications, including oral meloxicam administered for 5 days, intravesical lidocaine infusion, or intravesical glycosaminoglycans, have been reported to have a beneficial effect in preventing urethral reobstruction in FIC cats. If bladder atony is suspected, the parasympathomimetic bethanechol can also be administered (2.5 mg/cat PO q12h). Adverse effects with this class of drugs are primarily GI (vomiting and diarrhea). Once the diuresis is complete, the IV fluids can be tapered and the catheter removed. Once the catheter is removed, chronic management is the same as for nonobstructive FIC.

FIG 44.5
Closed collection system used for a cat with significant hematuria postobstruction. By doing this, the clinician can also record the amount of urine produced by the cat to guide intravenous fluid therapy.

Nonobstructive Feline Idiopathic Cystitis

FIC has a variable outcome; clinical signs resolve in as many as 85% of cats within 2 to 3 days, with or without treatment. When a cat is diagnosed with FIC, analgesic therapy for acute management of the disease should be provided. Providing analgesia for cats with FIC seems prudent given the clinical manifestation. Nonsteroidal antiinflammatory drugs (NSAIDs) have been described for this disease, with variable results. Because of the risk for dehydration-associated reductions in blood flow to the kidneys and the potential for acute kidney injury, these medications might increase the risk for adverse outcomes. It is important the cat is eating and drinking well when NSAIDs are administered.

CHRONIC MANAGEMENT

Environmental Alterations

No cure is currently available for FIC; treatment options are aimed at clinical recovery, keeping the cat's clinical signs to a minimum, and increasing the disease-free interval. After the diagnosis of FIC is made, a thorough environmental history, as well as notation of all other comorbidities present, needs to be obtained so the clinician can establish that all the environmental needs of the cat have been met. A technician-based program, in which a staff member works with these patients as often as necessary to be sure the cat's problems are thoroughly explained to the owners so they can understand the disease process enough to feel comfortable with managing their cat's disease, can also be of great benefit.

Following a staged approach to therapy that begins with client education and multimodal environmental modifications (MEMO) seems beneficial in many cats with FIC. MEMO therapy involves obtaining a thorough environmental history, including but not limited to the topics presented in Box 44.1. The client should answer these questions for all cats in the household, and the clinician can then review the list and identify issues that may be contributing to the cat's clinical signs. After the questionnaire is completed, it should

BOX 44.1

Suggested Environmental Questionnaire for Cat Owners

1. Where did the owner obtain the cat—shelter, abandoned, breeder?
2. Number of cats in the household
   - Is intercat conflict an issue?
3. Number and type of other pets
4. Number of family members
5. Size and type of the household dwelling
6. Litter pans
   - Number?
   - How often are they cleaned?
   - How often are they changed?
   - Location in the house?
   - Type of litter used?
   - Depth of litter preferred by the cat?
7. Feeding
   - Type of food (including brand, canned versus dry)?
   - Location of bowls?
   - Food preferences?
   - Is competition for food present in the household?
8. Play and rest activity
   - Preferred toys?
   - Space in house available for play?
   - Preferred type of play?
9. Indoor or outdoor status?
10. Resting or hiding areas preferred?
    - Number of beds for the cat(s)?
11. Changes in household
12. Behavioral concerns
    - Aggression
    - Fear
    - Nervousness
    - Separation anxiety
13. Other sickness behaviors or comorbid diseases present?

be reviewed and modifications recommended. Recommend only one or two changes initially to the client so as not to overwhelm them or the cat. The goal is to optimize the environment for the cat and decrease external stressors. Based on previous findings, in which catecholamine concentrations decreased and clinical signs improved after environmental modifications, MEMO therapy was found to be successful in most cats with FIC followed over a 1-year period.

As a part of the MEMO therapy, dietary modifications may be warranted and should be discussed with clients. Increasing water intake by feeding canned food—or other methods, such as broths or automatic water dispensers—may be beneficial for cats with FIC. Efforts to acidify the urine using dry foods have no proven value in the treatment of cats with FIC; however, if pronounced struvite crystalluria is present in an obstructed male cat, a diet formulated for struvite dissolution may be warranted. Finally, obesity may be a risk factor for FIC, and implementing a weight loss program may be of benefit. Diets that have additives that

BOX 44.2

Drug Therapy for Chronic Feline Idiopathic Cystitis*

Amitriptyline—tricyclic antidepressant; 2.5-5 mg/cat PO q12-24h; adverse effects can include sedation, lethargy, urine retention.

Clomipramine—tricyclic antidepressant; 0.25-0.5 mg/kg PO q24h; adverse effects can include sedation, lethargy, and urine retention.

Fluoxetine—serotonin reuptake inhibitor; 1 mg/kg PO q24h; adverse effects can include gastrointestinal upset.

Buspirone—nonbenzodiazepine anxiolytic; 2.5-5 mg/cat PO q12h; adverse effects can include sedation.

Pentosan polysulfate sodium†—semi-synthetic carbohydrate derivative similar to glycosaminoglycans; used to help manage chronic feline idiopathic cystitis; doses vary depending on product; adverse effects are rare, but can include prolonged prothrombin time, bleeding problems, and diarrhea.

*Controlled studies are limited regarding these drugs.
†Studies in cats reported no significant differences when comparing pentosan polysulfate sodium to placebo. All groups had a clinical benefit, suggesting a strong "placebo" effect.

reportedly decrease anxiety in the cat (e.g., alpha casozepine and L-tryptophan) have also been anecdotally provided for cats with FIC. In fearful cats, feeding this diet reduced the cat's anxiety response "to placement in an unfamiliar location." All the cat's needs must be taken into consideration when making dietary and environmental recommendations.

Pheromones

Pheromones are fatty acids that transmit highly specific information among animals of the same species. Although the exact mechanisms of action are unknown, pheromones reportedly induce changes in the limbic system and hypothalamus that alter the emotional state of the animal. Feliway (Ceva Animal Health, St. Louis) is the synthetic F3 fraction of the naturally occurring feline facial pheromone. Treatment with this pheromone has been reported to reduce the amount of anxiety experienced by cats in unfamiliar circumstances, a response that may be helpful for FIC cats and others that experience anxiety-related problems. Feliway can be purchased as a spray formulation or a room diffuser. The spray can be used in areas such as where the litter pan is kept or sprayed in carriers 10 to 15 minutes before car transport. Room diffusers can be placed in designated rooms for cats and may help decrease anxiety and clinical signs of FIC.

Drug Therapy

A variety of drugs have been tried in cats with FIC, but placebo-controlled studies are lacking to confirm their clinical efficacy. If MEMO and pheromone therapy have failed, the medications listed in Box 44.2 can be considered. These drugs should not be used for cats with acute FIC, should be

considered only for cats if their environmental needs have been addressed, and should not be stopped abruptly. It can take longer than 1 week to see beneficial effects from many of these drugs; if no improvement in the cat's clinical signs is noted, these drugs should be tapered over 1 to 2 weeks.

CONCLUSIONS

FIC is a complex disease process that is not fully understood at this time. It is clear that the clinician and client must understand that this disease is not limited to abnormalities related solely to the bladder. Because FIC can be a chronic, frustrating disease, excellent client communication in conjunction with MEMO therapy, analgesics, and possibly other pharmacologic agents can be of benefit in treating acute and chronic cases.

CHAPTER 45

Disorders of Micturition

ANATOMY AND PHYSIOLOGY

Micturition depends on the coordinated actions among the sympathetic, parasympathetic (PS), and somatic nervous systems and central control centers (Fig. 45.1). The coordination among these systems in animals takes place in the pontine micturition center (PMC), also known as Barrington's nucleus, which is located in the dorsomedial pontine tegmentum in the brainstem. The PMC receives input from other sensory stimuli to determine the onset of micturition.

The thoracolumbar sympathetic pathway provides excitatory input to the bladder neck and urethra, and inhibitory input to the PS ganglia. Sympathetic preganglionic fibers exit the lumbar spinal cord (L1-L4 in dogs and L2-L5 in cats) and synapse in the caudal mesenteric ganglia. Postganglionic fibers (hypogastric nerve) release norepinephrine (NE) to activate β-receptors in the urinary bladder and α-receptors in the smooth muscle of the proximal urethra. This allows the bladder to relax and fill continuously, with little increase in intravesical pressure (via β-receptors), and provides tone to the smooth muscle near the trigone of the proximal urethra of female dogs, which is traditionally known as *the internal urethral sphincter* (via α-receptors). In male dogs the sphincter mechanism is likely associated with the striated muscle in the prostatic and postprostatic urethra.

The PS preganglionic motor neurons arise from the sacral spinal cord segments S1 to S3. Preganglionic fibers travel in the pelvic nerve and synapse in the peripheral ganglia in the wall of the bladder. Short postganglionic fibers provide excitatory input to the bladder through ACh acting on cholinergic (muscarinic) receptors in the bladder and also provide inhibitory input to the urethra, thus facilitating voiding.

Somatic innervation, supplied via the pudendal nerve, also arises from the sacral spinal cord segments S1 to S3 and provides stimulation (via ACh on nicotinic receptors) to the *external urethral sphincter*, an area of striated muscle. Cell bodies of this nerve are located in the ventrolateral nucleus of Onuf.

DEFINITIONS AND TYPES OF URINARY INCONTINENCE

Often owners will present their pet for evaluation of urinary incontinence (UI); however, there are several types of UI that a clinician must consider. Usually veterinarians use the term *UI* when referring to a dog or cat that unconsciously voids urine. Incontinence is usually due to failure of urine storage during filling, although multiple etiologies may contribute to UI. UI is more common in spayed bitches but can be seen in intact female dogs as well as male dogs and occasionally cats. Disorders associated with UI can be caused by anatomic problems as well as by alterations in urethral closure pressure. Animals may also consciously void small amounts of urine in inappropriate locations (pollakiuria), and this is what is commonly referred to as *urge incontinence.* Furthermore, it is important to evaluate if the dog is polyuric and/or polydipsic (PU-PD). An animal can also present with multiple problems, such as UI and PU or for behavioral causes of abnormal voiding. Obtaining a detailed history and ascertaining whether the animal is aware of micturition are essential to help formulate proper differential diagnoses and an appropriate diagnostic plan.

ECTOPIC URETERS

Ectopic ureters (EUs) are the most common cause of UI in young dogs. An EU is defined as a ureteral opening in an area other than the normal position in the trigone of the bladder (Fig. 45.2). UI is the most common clinical sign in dogs with EUs, and this disorder is usually diagnosed in dogs younger than 1 year of age; however, EUs should be considered in any dog with UI, particularly when the history is unknown. The severity of UI is variable, and some dogs may only be incontinent when at rest or at night (i.e., nocturia). Breeds that appear over-represented include: Golden Retriever, Labrador Retriever, Siberian Husky, Newfoundland, and English Bulldog. EUs are uncommon in male dogs and, if present, affected dogs may have few or no clinical signs or present with clinical signs at an older age. EUs are extremely rare in cats.

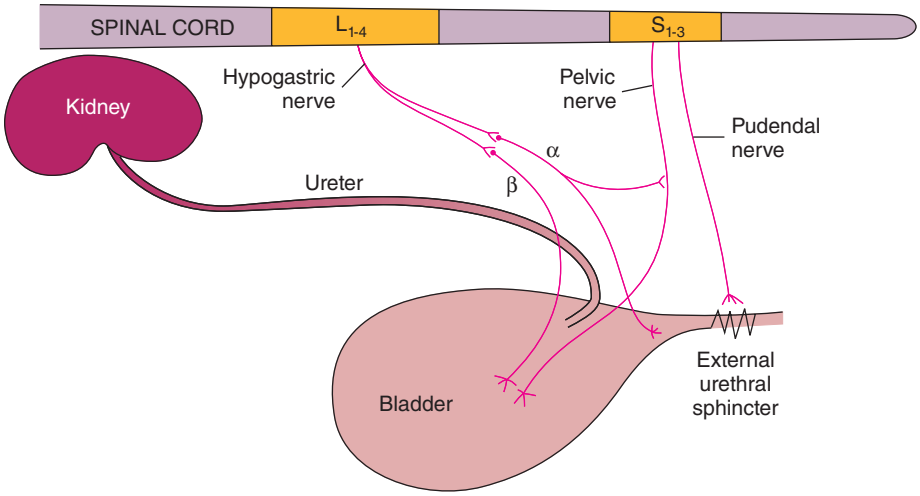

FIG 45.1
Schematic diagram of the sympathetic, parasympathetic, and somatic innervation to the lower urinary tract. The micturition pathway is much more complex than what is pictured here; the sensory pathways and higher centers are not depicted in this diagram.

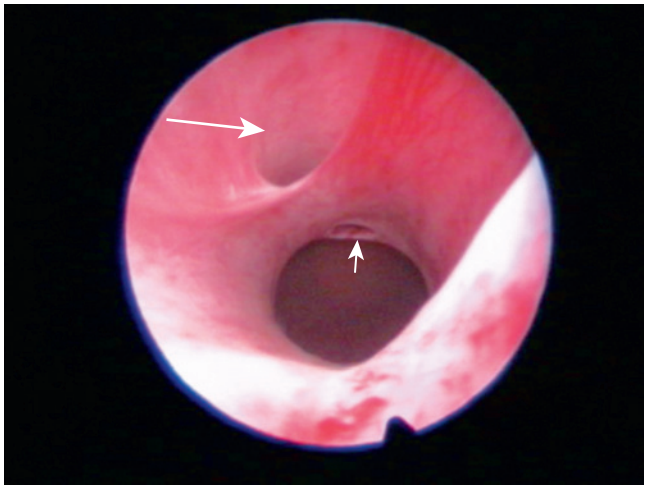

FIG 45.2
Cystoscopic view of a left unilateral ectopic ureter *(large arrow)* in a young Labradoodle. The smaller right ureter can be seen entering in the trigone region *(small arrow)*.

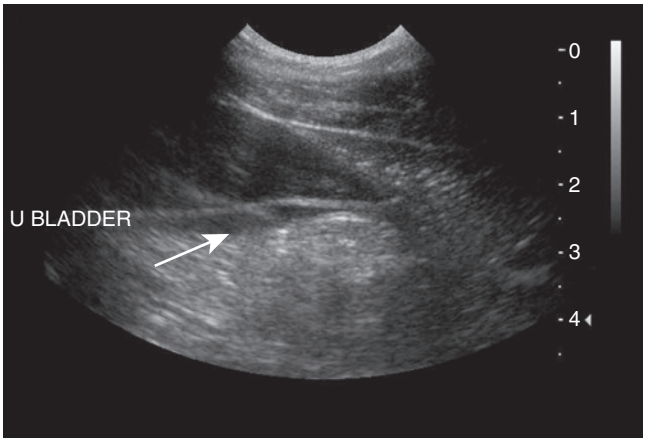

FIG 45.3
Transverse ultrasonographic image from a young Golden Retriever that presented with persistent urinary incontinence. A dilated ureter can be seen ventral to the bladder and entering the lower urinary tract distal to the trigone *(arrow)*. Hydronephrosis and hydroureter were also present on that side. Cystoscopy confirmed an ectopic ureter, and the ureter was corrected with cystoscopy-guided laser ablation.

A diagnosis of EUs can be made by excretory urography, fluoroscopic urethrography or ureterography, abdominal ultrasonography (Fig. 45.3) (Video 45.1), cystoscopy (Video 45.2), helical computed tomography (CT), or a combination of these diagnostic procedures. The latter two are reported to be the most sensitive diagnostics for confirming the presence of EUs. Furthermore, when using cystoscopy to diagnose EU, laser ablation can be done to correct the anomaly (see later). Other congenital abnormalities (e.g., renal agenesis, severe hydronephrosis) can also occur in dogs with EUs; therefore it is essential to evaluate the entire urinary system with other imaging modalities such as abdominal ultrasonography prior to correcting the EU to evaluate the upper urinary tract. Urine cultures should always be performed in dogs with suspected EUs as secondary UI can be a risk factor for bacterial cystitis. Treatment with proper antimicrobials for urinary tract infection (UTI) is clinically indicated before laser ablation or surgical correction of EUs.

EUs can be corrected via surgery, but laser ablation of EU has become the standard of care at most referral institutions. Complete continence is achieved after surgical correction in approximately 65% of cases. It has been reported that dogs weighing less than 20 kg have a better outcome postoperatively. Only intramural EUs can be corrected via cystoscopic laser ablation (Video 45.3); approximately 85% of dogs with EU have this type of anomaly. In 30 female dogs that had laser ablation to correct an EU, 47% were completely continent at a median follow-up of 2.7 years; an additional 20% were continent with additional medical management; others needed urethral bulking agents or a static hydraulic urethral occlude (see later). The variable success rate is likely due to concurrent urethral sphincter mechanism incompetence

(USMI) or other concurrent anatomic abnormalities that may have been present in the dog.

URETHRAL SPHINCTER MECHANISM INCOMPETENCE

Decreased urethral closure pressure can occur because of lumbosacral disorders such as intervertebral disk disease, degenerative myelopathy, trauma, malformations of the spinal vertebrae (e.g., in Manx cats), and rare disorders such as dysautonomia. A thorough neurologic examination should be performed on all dogs and cats that present for UI. USMI is a diagnosis of exclusion once all other disorders have been ruled out and can usually be made based on a compatible signalment and history, and absence of abnormalities on the physical examination.

USMI is similar to stress incontinence that occurs in women. USMI is primarily a disease of dogs; all cats suspected of having USMI should be tested for feline leukemia virus (FeLV) because associations between these two problems have been suggested. USMI usually occurs in spayed bitches but can occur in intact females and male dogs as well. In spayed females, the onset of clinical signs can vary from immediately after spaying to 10 years after the surgery. Nocturia appears to be the most common complaint from owners. UI can be daily or episodic and can range from mild to very severe. There appears to be a higher risk for USMI in larger-breed dogs after spaying as compared with small breeds. Although male dogs can develop USMI, it is critical to ascertain a residual urine volume because voiding disorders associated with urinary retention and paradoxical UI is more often seen in male dogs.

The exact cause of USMI is unclear. Estrogen deficiency is unlikely to be the sole cause of the UI because estrogen concentrations are similar between continent anestrous dogs and incontinent spayed dogs. Estrogen has been shown to increase urethral sphincter closure pressure in sexually intact and spayed female dogs without UI, but the urodynamic effects of estradiol are still not completely understood. Other risk factors for USMI have been reported to include larger-breed dogs (>20 kg), tail docking, obesity, and neutered status. Timing of spay with regards to USMI risk is still controversial, and the literature is variable. There is some weak evidence that "early" spay ("early" has not been well defined in studies) may increase the risk of acquiring USMI, particularly if dogs are >25 kg.

Although a urethral pressure profile (UPP) is the gold standard to document decreased urethral closure pressure (Box 45.1), the diagnosis of USMI can often be made based on signalment, history, and the absence of any other cause(s) for the UI. Response to drug therapy (see later) provides further evidence for USMI. Urodynamic tests can be performed in cats and dogs, are usually performed with propofol sedation, and provide data related to bladder and urethral function. A UPP evaluates the pressure along the entire length of the urethra; a cystometrogram evaluates the detrusor reflex, bladder fill volumes, and compliance.

BOX 45.1

Considerations for Referral for Urethral Pressure Profile and Cystometrography

Before ectopic ureter correction
If drug therapy with phenylpropanolamine (PPA) for urethral sphincter mechanism incompetence (USMI) was not effective
If drug therapy with diethylstilbestrol (DES) for USMI was not effective
If the patient with suspected USMI has a higher risk of side effects with medical management for USMI, then confirming the diagnosis is advised.

A list of drugs and suggested dosages for managing various micturition disorders is presented in Table 45.1. Medical management of USMI includes the use of drugs aimed at improving urethral pressures via the α_1-adrenoceptors (α_1-ARs), such as phenylpropanolamine (PPA). Rarely pseudoephedrine is used, but PPA is usually is more effective than PSE and has fewer adverse effects. The therapeutic benefit with α-agonists is usually seen within 2 to 3 days. If no benefit is seen after 1 week, the dosage can be increased up to 1.5 mg/kg orally (PO) q12h; if clinical signs are still present or side effects exist, another agent, such as an estrogen compound, should be considered. Adverse effects in dogs receiving α-agonists can include restlessness, anxiety, hyporexia, and possibly hypertension. A reflex bradycardia has also been reported. In a study, hypertension was not reported in healthy dogs at dosages typically used for USMI. α_1-AR agonists are not recommended for animals with cardiac disease, hypertension, or kidney disease, and PPA has not been studied in these groups of dogs. If required for dogs with kidney disease, lower dosages should be administered and the dog's blood pressure should be monitored regularly, ideally 2 to 4 hours post–PPA administration.

Estrogens may also be administered for treatment of USMI because these hormones are thought to sensitize the α_1-AR to NE and indirectly result in an improvement in the closure pressure, but the exact mechanism of action of these drugs is unclear. A U.S. Food and Drug Administration (FDA)-approved estrogen compound, estriol (Incurin, Merck Animal Health, Summit, NJ) is available (see Table 45.1). The same dosage is provided to every dog regardless of body weight (2 mg PO q24h per dog) and is initially administered daily for 2 weeks and then titrated down to the lowest effective dose. However, the author had success administering only 1 mg daily as a loading dosage to smaller-breed dogs (to avoid the potential side effect of vulvar hyperplasia). The therapeutic effect is often noted within the first week. If no benefit is seen this time, other therapeutic options should be considered. In some cases of USMI, a beneficial effect is noted when combining PPA and estrogen therapy. Older estrogen compounds such as diethylstilbestrol (DES) are also usually available and can often be administered

TABLE 45.1

Commonly Used Drugs for Micturition Disorders in Small Animal Patients

DRUG (TRADE NAME)	CLASS	MECHANISM OF ACTION	CLINICAL INDICATION(S) FOR USE	DOSAGE	POTENTIAL ADVERSE EFFECTS
Phenylpropanolamine (PPA)	α_1-agonist	Indirectly stimulates α- and β-receptors by causing release of norepinephrine (NE)	To increase urethral closure pressure for urethral sphincter mechanism incompetence (USMI)	1-1.5 mg/kg PO q12-24h	Restlessness, anxiety, tachycardia, hypertension
Diethylstilbestrol (DES)	Synthetic estrogen	May sensitize α_1-adrenergic receptors to NE	To increase urethral closure pressure for USMI	0.5-1 mg/dog PO; give total dose daily for 3-5 days, then titrate down to lowest effective dose to maintain continence (once or twice/wk)	Blood dyscrasias (rare when used at very low doses); mammary neoplasia
Estriol (Incurin)	Natural estrogen	May sensitize α_1-adrenergic receptors to NE	To increase urethral closure pressure for USMI	Begin loading dose of 2 mg/dog PO q24h; titrate down every 2 wk to lowest effect dose	Alopecia, blood dyscrasia
Acepromazine (PromAce)	Phenothiazine derivative	Varying degrees of antispasmodic and α-adrenergic blocking capabilities	To decrease urethral closure pressure for functional urethral outflow tract obstruction	0.01-0.05 mg/kg SC q8-12h	Sedation, hypotension
Prazosin (Minipress)	α-adrenergic antagonist	Inhibits α_1-receptors	To decrease urethral closure pressure for functional urethral outflow tract obstruction	1 mg/15 kg BW PO q8-12h (dog); 0.5 mg/cat PO q12h	Sedation, hypotension

Continued

TABLE 45.1

Commonly Used Drugs for Micturition Disorders in Small Animal Patients—cont'd

DRUG (TRADE NAME)	CLASS	MECHANISM OF ACTION	CLINICAL INDICATION(S) FOR USE	DOSAGE	POTENTIAL ADVERSE EFFECTS
Phenoxybenzamine (Dibenzyline)	α-adrenergic antagonist	Inhibits α_1-receptors	To decrease urethral closure pressure for functional urethral outflow tract obstruction	2.5 mg/cat PO q12h (cat); 0.25 mg/kg PO q12h (dog)	Sedation, hypotension
Tamsulosin (Flomax)	α_1-adrenergic antagonist	Inhibits α_1-receptors	To decrease urethral closure pressure for functional urethral outflow tract obstruction; anecdotal use for ureteral obstructions	Anecdotal: 0.1-0.2 mg/10 kg BW/day PO (dog); 0.004-0.006 mg/kg PO q12-24h (cat)	Sedation, hypotension
Bethanechol (Urecholine)	Parasympathomimetic	Stimulates primarily muscarinic receptors	To improve bladder contractility (i.e., detrusor atony)	2.5 mg/cat PO q12h; 5-15 mg/dog PO q12h	Vomiting, diarrhea, salivation
Amitriptyline (Elavil)	Tricyclic antidepressant	NE reuptake inhibition; central and peripheral anticholinergic activity; antagonism of the H_1 receptor; 5-HT reuptake inhibition; glutamate and sodium channel receptor antagonist	Idiopathic overactive bladder (OAB); refractory chronic feline idiopathic cystitis; submissive urinations (only in conjunction with behavior modification)	2.5-5 mg/cat PO q12h; 1-2 mg/kg PO q12h (dog)	Weight gain, lethargy, urine retention
Oxybutynin (Ditropan)	Anticholinergic	Antimuscarinic	Idiopathic OAB	0.2 mg/kg PO q8-12h (dog), no more than 5 mg total dose; 0.5-1 mg/cat PO q8-12h	Constipation, diarrhea, sedation, vomiting

tapered to a twice-weekly dose; however, this drug is considered off-label use in dogs.

Bone marrow suppression has been described in dogs receiving older-generation depot estrogens and in those receiving much higher doses of DES than those recommended for USMI. However, a complete blood count (CBC) should be monitored periodically in all dogs receiving estrogen therapy. Estriol differs from other estrogen compounds because it occupies the nuclear-bound receptors for a shorter period of time. Although it is reported to be safer than DES, a CBC can be monitored once to twice a year because leukopenia, anemia, and thrombocytopenia have also been rarely reported with its use. Other side effects reported include local and generalized alopecia and vulvar hyperplasia, particularly in small-breed dogs (in the author's opinion).

Submucosal urethral bulking agents such as polydimethylsiloxane (PDMS-Macroplastique), calcium hydroxylapetite (Coaptite), carbon-coated beads (Durasphere), and a newly available cross-linked bovine collagen material (ReGain) are commercially available in the United States and can be considered for those dogs that are refractory to medications or for owners who do not wish to medicate their pet continually. To perform this procedure, dogs are anesthetized, and three to four deposits of the bulking agent are injected in a circular fashion approximately 1.5 cm distal to the trigone via the cystoscope (Video 45.4). Some dogs still require medications after this procedure, but greater continence is usually gained following the implants. Response rates to collagen in 40 dogs were variable, and these dogs were continent for a mean of 17 months (range 1-64 months). Interestingly, the duration of effectiveness of collagen varied among dogs; this procedure often needs to be repeated several times, particularly in younger dogs. In older dogs, this treatment may be more appealing because no surgery is required and the duration of response may be adequate. A short-term study evaluating Macroplastique had positive results 3 months after the injections were administered to dogs; however, no long-term studies are currently available.

If dogs are nonresponsive to medical therapy, urethral occluders can also be considered. The occluders can be surgically placed around the proximal third of the urethra; they act as an external occluder to maintain continence. If the occluder alone is not enough, these devices are attached to an access port (Fig. 45.4) and saline can be infused into the occluder to increase their effectiveness. In one study evaluating 27 dogs (24 females, 3 males) with urethral occluder placement, continence scores were significantly improved postsurgery, and 22/27 (81%) of owners were very satisfied with the procedure. Two dogs developed partial urethral obstructions.

URINARY INCONTINENCE

Increased Urethral Closure Pressure

A persistent increase in urethral closure pressure from a mechanical or functional obstruction can lead to secondary bladder dysfunction (atony) and overflow incontinence. Mechanical causes for urinary retention can include urethroliths, bladder and/or urethral neoplasia, proliferative urethritis, urethral strictures and foreign bodies, urethral plugs, prostatic diseases (e.g., abscess, paraprostatic cyst, benign prostatic hypertrophy), and extraluminal urethral compressions. Functional obstructions can be seen with suprasacral or brainstem disease (upper motor neuron bladders), urethritis or a mechanical obstruction, and idiopathic functional urethral outflow tract obstruction, also known as detrusor-urethral dyssynergia (reflex dyssynergia).

The diagnosis of overflow incontinence is made based on history, thorough physical and neurologic examination, and complete imaging of the urinary tract. Most animals will have a history of intermittent to persistent stranguria before the UI. Watching the animal void and assessing the residual urine volume is also helpful. Normal animals will have less than 0.5 to 1 mL/kg of urine remaining in the bladder after voiding. Plain radiography, cystourethrography, and cystoscopy can all be beneficial to evaluate the dog or cat for mechanical obstructions. An enema should be given before radiographic studies to evaluate the proximal urethra. Cystoscopy is useful to evaluate the urethral mucosa, obtain samples for biopsy and culture, and aid in the placement of

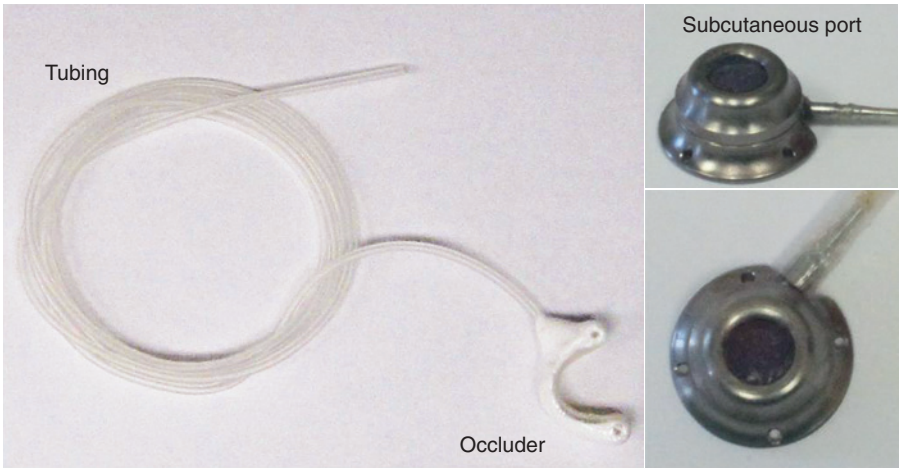

FIG 45.4
Urethral occluder. These occluders can be placed around the proximal urethra to increase the urethral closure pressure and improve or resolve urinary incontinence. The results appear to last longer than those achieved with urethral bulking agents. If the occluder is not sufficient to maintain continence, the subcutaneous port can be injected with saline to increase the pressure in the silicone occluder. (Courtesy Dr. William Culp, University of California, Davis.)

urethral stents if needed (Video 45.5). If no mechanical obstructions are present, urodynamic studies may help provide insight for functional obstructions, but oftentimes the increased urethral pressure may only occur during the act of micturition. The diagnosis of idiopathic functional urethral outflow tract obstruction (detrusor-urethral dyssynergia [DUD]) is usually made when all other causes for the increased urethral closure pressure have been excluded. This disease usually occurs in large-breed male dogs, both castrated or intact.

Treatment for mechanical obstructions is to remove the obstruction, if possible. Urethral stones can be removed via surgery or holmium:YAG laser lithotripsy. Bladder and urethral neoplasia, usually transitional cell carcinoma (TCC; Fig. 45.5), should be treated with piroxicam or another nonsteroidal antiinflammatory drug (NSAID); other chemotherapeutics such as mitoxantrone or platinum compounds may improve survival. Proliferative urethritis is usually seen in female dogs and may result from chronic UTIs. More recent unpublished data suggests that deep-seated UTIs may be associated with some of these cases, and fluorescent in situ hybridization (FISH) studies can be submitted if urethral biopsies are obtained. Cystoscopically, proliferative urethritis appears as multiple frond-like pieces of tissue in the urethral lumen that can be very dense and cause urethral obstruction. A biopsy is necessary to differentiate this from TCC. In addition to proper antimicrobials, NSAID therapy has been reported to help manage this disease. In one case study, azathioprine was also reported to be effective. If urethral obstruction occurs, urethral stenting should be considered.

For idiopathic, functional, urethral outflow tract obstruction, α_1-adrenoceptor antagonists such as prazosin can be used to help decreased the closure pressure of the internal urethral sphincter. Prazosin is much more cost-effective that phenoxybenzamine, another α-antagonist, particularly when used in larger-breed dogs. More selective α_1-antagonists, such as tamsulosin (Flomax), have been used anecdotally for functional urethral outflow obstructions, with variable and better results for DUD. In some cases, a skeletal muscle relaxant such as diazepam is also beneficial. Once these drugs have taken effect, or a urinary catheter is in place, parasympathomimetics can be started if secondary bladder atony is also present. Bethanechol, a muscarinic agent, might help restore bladder tone and facilitate bladder emptying. In severe cases, a tube cystotomy, indwelling urinary catheter, or urethral stent (Fig. 45.6) may be needed for urine evacuation.

Overactive Bladder

Animals that present with pollakiuria may have an overactive bladder (OAB), which results in urge incontinence. Usually animals with OAB have underlying cystitis caused by bacteria, cystic calculi, neoplasia, polyps, or drugs (e.g., cyclophosphamide). A detailed history is necessary to document whether other lower urinary tract signs are present. Physical examination of animals with pollakiuria is generally unremarkable; the bladder is usually small on palpation. In some dogs and cats, masses or numerous cystic calculi may be palpable, if present. A urinalysis should be performed and a urine culture should be evaluated. If the culture is negative and clinical signs persist, further diagnostic studies such as abdominal ultrasonography and radiography are indicated. If an underlying cause for the clinical signs is not found, referral for a cystometrogram and advanced imaging may be considered.

Occasionally idiopathic OAB (iOAB) is thought to occur and medical treatment may be beneficial for controlling

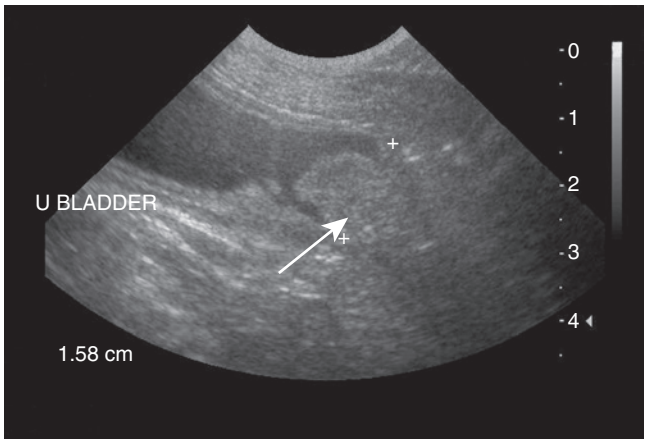

FIG 45.5
An ultrasonographic image from an 11-year-old female spayed Brittany Spaniel Mix that presented for stranguria and urinary incontinence. A urethral mass is noted that extends into the bladder lumen *(arrow)*. Fine-needle aspiration confirmed this mass to be a transitional cell carcinoma. In addition to piroxicam therapy, a urethral stent was placed in this dog.

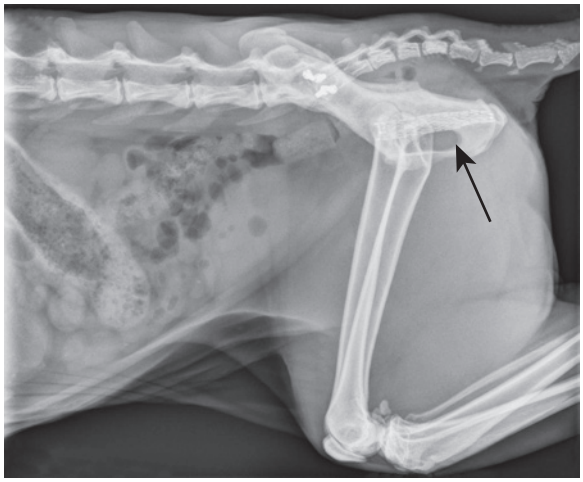

FIG 45.6
Later radiograph of a 1.5-year-old male, castrated domestic shorthair that presented for a urethral stricture secondary to trauma. After the stricture was ballooned, a urethral stent *(arrow)* was placed. Because of concern for bladder atony, the parasympathomimetic bethanechol was also administered.

clinical signs. Idiopathic OAB may occur with USMI, and the dog can have mixed UI as the reason for the clinical signs. Oxybutynin and tolterodine are anticholinergics that may help stop iOAB and promote urine retention. The tricyclic antidepressants—amitriptyline, imipramine, clomipramine—have anticholinergic properties, which can be considered for the treatment of dogs suspected of having iOAB. This class of drugs can also be considered for dogs that have urge incontinence secondary to behavioral problems as well. However, they should only be used when behavioral modifications have been unsuccessful, and discontinued when clinical signs improve.

Drugs Used in Dogs and Cats With Urinary Tract Disorders

DRUG	TRADE NAME	ACTION	DOSAGE
Allopurinol	Zyloprim	Xanthine oxidase inhibitor	5-10 mg/kg PO q12h (dog)
Aluminum carbonate, aluminum hydroxide	Basaljel, Amphojel	Enteric phosphate binders	10-30 mg/kg PO q8h, with or immediately after meals
Amitriptyline	Elavil	Norepinephrine (NE) reuptake inhibition	2.5-5 mg/cat PO q12h; 1-2 mg/kg PO q12h (dog)
Amlodipine	Norvasc	Calcium antagonist	0.1-0.2 mg/kg PO q12-24h (dog); 0.625-1.25 mg PO q24h (cat)
Ammonium chloride		Urinary acidifier	100 mg/kg PO q12h (dog); 800 mg mixed with food daily (≈ ¼ tsp, cat)
Aspirin		Antiplatelet, antiinflammatory	0.5-5 mg/kg PO q12h (dog); 0.5-5 mg/kg PO q48-72h (cat)
Azathioprine	Imuran	Immunosuppressant	1-2 mg/kg PO q24h initially, then 0.5-1 mg/kg PO q48h (dogs only)
Benazepril	Lotensin	Angiotensin-converting enzyme inhibitor	0.25-0.5 mg/kg PO q24h
Bethanechol	Urecholine	Parasympathomimetic	5-15 mg total dose PO q8h (dog); 2.5 mg/cat PO q12h (cat)
Calcium acetate	PhosLo	Enteric phosphate binder	5-25 mg/kg PO q8h, immediately after meals

Continued

Drugs Used in Dogs and Cats With Urinary Tract Disorders—cont'd

DRUG	TRADE NAME	ACTION	DOSAGE
Chlorpromazine	Thorazine	Antiemetic	0.25-0.5 mg/kg IM, SC, PO q6-8h (after dehydration only)
Colchicine	Generic	Antiinflammatory, antifibrotic, inhibition of serum amyloid A synthesis and secretion	0.03 mg/kg/day PO (dog)
Cyclophosphamide	Cytoxan, Neosar	Immunosuppressant	50 mg/m^2 PO q48h (dogs); 200-300 mg/m^2 PO q3wk (cats)
Cyclosporine	Neoral, Sandimmune	Immunosuppressant	3-7 mg/kg PO q12-24h, adjust dose via monitoring
Darbepoetin alfa	Aranesp	Stimulates erythropoiesis	0.25-0.5 µg/kg SC once/wk adjusted according to PCV
Diazepam	Valium	Skeletal muscle relaxant for functional urethral outflow tract obstruction	2-5 mg total dose PO q8h (dog); give 30 min before urination
Diethylstilbestrol (DES)		Increases urethral closure pressure	0.5-1 mg/dog PO; give total dose daily for 3-5 days, then titrate down to lowest effective dose to maintain continence (once or twice/wk)
Dimethylsulfoxide	Domoso	Antiinflammatory	90 mg/kg/wk SC (dogs)
Dopamine	Inotropin	Adrenergic (α and β_1) and dopaminergic agent; positive inotropic effect; may increase renal blood flow and urine output	2-5 µg/kg/min CRI (dogs)
Estriol (Incurin)	Natural estrogen	Increases urethral closure pressure	Begin loading dose of 2 mg/dog PO q24h; titrate down every 2 wk to lowest effect dose
1,25-Dihydroxycholecalciferol, calcitriol	Rocaltrol	Active vitamin D_3, decreases parathyroid hormone	2.5-3.5 ng/kg PO q24h
Enalapril	Enacard	Angiotensin-converting enzyme inhibitor	0.5 mg/kg PO q12-24h (dog); 0.25-0.5 mg/kg PO q12-24h (cat)
Erythropoietin (r-Hu-EPO), epoetin alfa	Epogen	Stimulates erythropoiesis	35-50 U/kg IV, SC three times/wk or 400 U/kg IV, SC weekly; adjust dose to PCV of 30%-35%
Famotidine	Pepcid	H_2 blocker	0.5 mg/kg IM, SC, PO q12-24h
Furosemide	Lasix	Loop diuretic	2-4 mg/kg IV, PO q8-12h
Hydralazine	Apresoline	Arterial vasodilator	0.5-2 mg/kg PO q12h (dog); 2.5 mg PO q24h-q12h (cat)
Imipramine	Tofranil	Tricyclic antidepressant, antimuscarinic, mild α-agonist activity	5-15 mg/dog PO q12h; 2.5-5 mg/cat PO q12h
Lanthanum carbonate	Fosrenol, Renalzin	Enteric phosphate binder	20-30 mg/kg/day PO given immediately after meals
Lisinopril	Prinivil, Zestril	Angiotensin-converting enzyme inhibitor	0.5 mg/kg PO q24h (dog)
Mannitol	Osmitrol	Osmotic diuretic	0.5-1 g/kg as 20%-25% solution, slow IV bolus over 5-10 min

Drugs Used in Dogs and Cats With Urinary Tract Disorders—cont'd

DRUG	TRADE NAME	ACTION	DOSAGE
Maropitant citrate	Cerenia	Antiemetic	1-2 mg/kg, SC or PO (dog); 1 mg/kg SC (cat)
Tiopronin 2-MPG	Thiola	Promotes disulfide bond formation with cysteine for prevention of cystine urolithiasis	10-20 mg/kg PO q12h (dog); higher end of dose range used for attempting cystine dissolution
Metoclopramide	Reglan	Antiemetic; promotility	0.2-0.5 mg/kg PO, SC q8h
Ondansetron	Zofran	Antiemetic	0.6-1 mg/kg PO q12h
Oxybutynin	Ditropan	Anticholinergic	0.2 mg/kg PO q8-12h (dog), no more than 5 mg total dose; 0.5-1 mg/cat PO q8-12h
Phenoxybenzamine	Dibenzyline	α-antagonist, decreases urethral closure pressure	0.25 mg/kg PO q12h (dog); 2.5 mg total dose PO q12h (cat)
Phenylpropanolamine	Proin	α-adrenergic, increases urethral closure pressure	1-1.5 mg/kg PO q12-24h
Prazosin	Minipress	α-blocker	1 mg/15 kg BW PO q8-12h (dog); 0.5 mg total dose PO q12h (cat)
Propantheline bromide	Pro-Banthine	Anticholinergic, decreases detrusor contractility	0.25-0.5 mg/kg PO q8-12h (dog)
DL-Methionine	Uroeze, Methio-Form	Urinary acidifier	100 mg/kg PO q12h (dog); 1-1.5 g/day PO (cat)
Ranitidine	Zantac	H_2 blocker	2 mg/kg PO, IV q8h (dog); 2.5 mg/kg IV q12h, 3.5 mg/kg PO q12h (cat)
Sevelamer HCl	Renagel	Enteric phosphate binder	10-20 mg/kg PO q8h given with food
Sucralfate	Carafate	Gastrointestinal protectant	0.5-1 g PO q8-12h

PCV, Packed cell volume.

Richard W. Nelson and Ann-Marie Della Maggiore

CHAPTER 46

Disorders of the Hypothalamus and Pituitary Gland

POLYURIA AND POLYDIPSIA

Water consumption and urine production are controlled by complex interactions between plasma osmolality, fluid volume in the vascular compartment, the thirst center, the kidney, the pituitary gland, and the hypothalamus. Dysfunction in any of these areas results in the clinical signs of polyuria (PU) and polydipsia (PD). In dogs normal water intake is usually less than 80 mL/kg of body weight/24 h. Water intake between 80 and 100 mL/kg/24 h is suggestive of PD but may be normal in some dogs. Water intake greater than 100 mL/kg/24 h confirms PD. Similar values are used for cats, although most cats drink considerably less than these amounts. Normal urine output ranges between 20 and 45 mL/kg/24 h (1-2 mL/kg/h). PU in the dog and cat has been defined as urine production greater than 50 mL/kg/24 h, although it is possible for urine production to be abnormal within the limits of these normal values in individual dogs and cats.

A variety of metabolic disturbances can cause PU-PD. Primary polyuric disorders can be classified on the basis of the underlying pathophysiology into primary pituitary (central) and nephrogenic diabetes insipidus (NDI), secondary NDI, osmotic diuresis-induced PU, and interference with the hypothalamic-pituitary secretion of arginine vasopressin (AVP). The most common form of diabetes insipidus is acquired secondary NDI. This form includes a variety of renal and metabolic disorders in which the renal tubules lose the ability to respond adequately to AVP. Most of these acquired forms are potentially reversible after elimination of the underlying illness.

Secondary NDI results from interference with the normal interaction of AVP and renal tubular AVP receptors, problems with the generation of intracellular cyclic adenosine monophosphate (cAMP), problems with renal tubular cell function, or loss of the renal medullary interstitial concentration gradient. Primary polydipsic disorders occur in dogs and usually have a psychogenic or behavioral basis for the compulsive water consumption (see the discussion of psychogenic PD, p. 7). A complete discussion of the diagnostic approach to PU-PD is presented in Chapter 38. An index of suspicion for most of the endocrinopathies that cause PU-PD can be raised after a review of the history, physical examination findings, and results of a complete blood count (CBC), serum biochemistry panel, serum thyroxine (T_4) concentration (cat), urinalysis, and urine culture. Specific tests may be necessary to confirm the diagnosis (Table 46.1). See the appropriate chapters in this section for a more complete discussion of the diagnosis and treatment of each of these endocrinopathies.

Occasionally, physical examination findings and initial blood and urine test results are normal in dogs and cats with PU and PD. Differential diagnoses in these dogs and cats include diabetes insipidus, psychogenic PD, hyperadrenocorticism, mild renal insufficiency without azotemia, mild hepatic insufficiency (most notably with portosystemic shunts), and the early stages of hypoadrenocorticism. Hyperadrenocorticism, hypoadrenocorticism, renal insufficiency, and hepatic insufficiency should be ruled out before diagnostic tests for diabetes insipidus or psychogenic PD are performed. Diagnostic tests to consider include evaluation of the range of urine specific gravities obtained from several urine samples (discussed in the next paragraph), tests for hyperadrenocorticism (e.g., urine cortisol/creatinine ratio, low-dose dexamethasone suppression test), hypoadrenocorticism (e.g., baseline serum cortisol concentration), liver function tests (e.g., measurement of preprandial and postprandial bile acid concentrations), determination of the urine protein/creatinine (P:C) ratio, and abdominal ultrasonography. Ideally, all realistic causes of secondary acquired NDI should be ruled out before tests for primary pituitary and NDI and psychogenic PD are performed.

Critical evaluation of urine specific gravity measured from several urine samples obtained by the client at different

times of the day and night for 2 to 3 days may provide clues to the underlying disorder (Table 46.2). Urine samples should be stored in the refrigerator until they can be brought to the veterinary hospital for determination of urine specific gravity. Urine specific gravity varies widely among healthy dogs and can range from less than 1.006 to greater than 1.040 within a 24-hour period. Wide fluctuations in urine specific gravity have not been reported in healthy cats.

TABLE 46.1

Endocrine Disorders Causing Polyuria and Polydipsia in the Dog and Cat

DISORDER	TESTS TO ESTABLISH THE DIAGNOSIS
Diabetes mellitus	Fasting blood glucose, urinalysis
Hyperadrenocorticism	Urine C:C ratio, low-dose dexamethasone suppression test
Hypoadrenocorticism	Blood electrolytes, ACTH stimulation test
Primary hyperparathyroidism	Blood calcium/phosphorus, cervical ultrasound, serum PTH concentration
Hyperthyroidism	Serum T_4, free T_4, and TSH concentrations
Diabetes insipidus Pituitary Nephrogenic	Modified water deprivation test, response to DDAVP therapy
Acromegaly	Baseline GH or IGF-1 concentration, CT or MR scan
Primary hyperaldosteronism	Blood electrolytes, plasma aldosterone concentration

ACTH, Adrenocorticotropic hormone; *C:C,* cortisol/creatinine; *CT,* computed tomographic; *DDAVP,* desmopressin; *GH,* growth hormone; *IGF-1,* insulin-like growth factor 1; *MR,* magnetic resonance; *PTH,* parathyroid hormone; *T_4,* tetraiodothyronine (thyroxine); *TSH,* thyroid-stimulating hormone.

Urine specific gravities measured from multiple urine samples that are consistently less than 1.020 support the presence of PU and PD and the need for a diagnostic evaluation to determine the cause; the lower the urine specific gravities, the stronger the support for the existence of a PU-PD disorder. Identification of one or more urine specific gravities greater than 1.030 supports normal urine concentrating ability and an intact, functioning pituitary vasopressin-renal tubular cell axis. Dogs and cats may still have PU and PD despite identification of concentrated urine; possible differentials include disorders causing an osmotic diuresis (e.g., diabetes mellitus), psychogenic PD, and disorders in the regulation of AVP secretion.

If the urine specific gravity is consistently in the isosthenuric range (1.008-1.015), renal insufficiency should be considered the primary differential diagnosis, especially if the blood urea nitrogen and serum creatinine concentration are at the upper end of the reference range or increased (i.e., ≥25 mg/dL and 1.6 mg/dL, respectively). Although isosthenuria is relatively common in dogs with hyperadrenocorticism, psychogenic water consumption, hepatic insufficiency, pyelonephritis, and partial central diabetes insipidus (CDI) with concurrent water restriction, urine specific gravities tend to fluctuate above and/or below the isosthenuric range with these disorders. In contrast, if the urine specific gravity is consistently less than 1.006, renal insufficiency is ruled out and central and primary NDI, psychogenic water consumption, hyperadrenocorticism, and hepatic insufficiency should be considered the primary differential diagnoses. CDI and primary NDI are ruled out if the urine specific gravity exceeds 1.025. Urine specific gravities that range from less than 1.005 to greater than 1.030 are suggestive of psychogenic PD.

DIABETES INSIPIDUS

Etiology

AVP plays a key role in the control of renal water resorption, urine production and concentration, and water balance.

TABLE 46.2

Results of Urinalysis in Dogs With Selected Disorders Causing Polyuria and Polydipsia

DISORDER	NO. OF DOGS	URINE SPECIFIC GRAVITY		PROTEINURIA	WBC (>5/HPF)	BACTERIURIA
		MEAN	RANGE			
Central diabetes insipidus	20	1.005	1.001-1.012	5%	0%	0%
Psychogenic polydipsia	18	1.011	1.003-1.023	0%	0%	0%
Hyperadrenocorticism	20	1.012	1.001-1.027	48%	0%	12%
Renal insufficiency	20	1.011	1.008-1.016	90%	25%	15%
Pyelonephritis	20	1.019	1.007-1.045	70%	75%	80%

HPF, High-power field; *WBC,* white blood cells.

AVP is produced in the supraoptic and paraventricular nuclei of the hypothalamus, is stored in and secreted from the posterior pituitary gland in response to an increase in plasma osmolality or a decrease in extracellular fluid volume, and interacts with distal tubular and collecting duct cells of the kidney to promote water resorption and the formation of concentrated urine. The defective synthesis or secretion of AVP or an inability of the renal tubules to respond to AVP causes diabetes insipidus.

CENTRAL DIABETES INSIPIDUS

CDI is a polyuric syndrome that results from insufficient secretion of AVP to concentrate urine for water conservation. This deficiency may be absolute or partial. An absolute deficiency of AVP, referred to as *complete CDI,* causes persistent hyposthenuria and severe diuresis. The urine specific gravity in dogs and cats with complete CDI remains hyposthenuric (i.e., ≤1.005), even with severe dehydration. A partial deficiency of AVP, referred to as *partial CDI,* also causes persistent hyposthenuria and marked diuresis as long as the dog or cat has unlimited access to water. During periods of water restriction, the urine specific gravity can increase into the isosthenuric range (i.e., 1.008-1.015), but typically the urine cannot be concentrated to more than 1.015 to 1.020 even when the animal is severely dehydrated. In any dog or cat with partial CDI, maximum urine-concentrating ability during dehydration is inversely related to the severity of the deficiency in AVP secretion—that is, the more severe the AVP deficiency, the less concentrated is the urine specific gravity during dehydration.

CDI may result from any condition that damages the neurohypophyseal system (Box 46.1). Idiopathic CDI is the most common form, appearing at any age in any breed, and affecting animals of either sex. Necropsies performed in dogs and cats with idiopathic CDI fail to identify an underlying reason for the AVP deficiency. Although CDI is well documented in kittens and puppies, a hereditary form of CDI has not yet been documented. The most common identifiable causes of CDI in dogs and cats are head trauma (accidental or neurosurgical), neoplasia, and hypothalamic-pituitary malformations (e.g., cystic structures). Head trauma may cause transient (typically lasting 1-3 weeks) or permanent CDI, depending on the viability of the cells in the supraoptic and paraventricular nuclei.

Primary intracranial tumors associated with diabetes insipidus in dogs and cats include craniopharyngioma, pituitary chromophobe adenoma, and pituitary chromophobe adenocarcinoma. Metastatic mammary carcinoma, lymphoma, malignant melanoma, and pancreatic carcinoma have been reported to cause CDI in dogs through their presence in the pituitary gland or hypothalamus. Metastatic neoplasia has not yet been reported to be a cause of CDI in cats.

NEPHROGENIC DIABETES INSIPIDUS

NDI is a polyuric disorder that results from impaired responsiveness of the nephron to AVP. Plasma AVP concentrations are normal or increased in animals with this disorder. NDI may be classified as primary (familial) or secondary (acquired). Secondary or acquired NDI is common in dogs and cats and is discussed in an earlier section (Polyuria and Polydipsia) and in Chapter 38. Primary NDI is a rare congenital disorder in dogs and cats, with only a few reports in the literature. The etiology of primary NDI in dogs and cats is unknown, although decreased binding affinity of AVP receptors was identified in a family of Siberian Huskies. Affected puppies showed antidiuretic responses to high doses of synthetic vasopressin (desmopressin [DDAVP]).

Clinical Features

SIGNALMENT

No breed-, sex-, or age-related predilection for CDI is apparent. The age at the time of diagnosis of CDI in dogs ranges from 7 weeks to 14 years, with a median age of 5 years. Most cats with CDI are domestic short- and long-haired cats, although the disorder has been documented in Persians and Abyssinians. The age at the time of diagnosis of CDI in cats ranges from 8 weeks to 6 years, with a mean of 1.5 years. Primary NDI has been identified only in puppies, kittens, and young adult dogs and cats younger than 18 months of age. PU and PD have been present since the clients acquired these pets.

CLINICAL SIGNS

PU and PD are the hallmark signs of diabetes insipidus and are typically the only signs seen in dogs and cats with congenital and idiopathic CDI and in those with primary NDI. PU and PD can be quite severe with 24-hour water intake exceeding 200 mL/kg. Clients may believe that affected animals are incontinent because of the frequency of urination and the loss of normal housebroken behavior or because

of observed problems with urine dribbling, especially when resting or asleep. Owners of cats with diabetes insipidus often complain that they need to change the kitty litter more frequently than expected. Additional clinical signs may be found in dogs and cats with secondary causes of diabetes insipidus. The most worrisome are neurologic signs and inappetence, which may indicate the presence of an expanding hypothalamic or pituitary tumor in the adult dog or cat that has not had head trauma.

PHYSICAL EXAMINATION

The physical examination findings are usually unremarkable in animals with CDI, although some dogs and cats are thin, presumably because the pet's strong desire for water overrides its normal appetite. As long as access to water is not restricted, the animal's hydration status, mucous membrane color, and capillary refill time remain normal. The presence of neurologic abnormalities is variable in dogs and cats with trauma-induced CDI or neoplastic destruction of the hypothalamus or pituitary gland. When present, neurologic signs may include stupor, disorientation, ataxia, circling, pacing, and convulsions. Severe hypernatremia may also cause neurologic signs in the traumatized dog or cat with undiagnosed CDI given inadequate fluid therapy (see Chapter 53) and the dog or cat with undiagnosed CDI that has prolonged restricted access to water. Hyposthenuria in the presence of persistent hypernatremia should raise suspicion for diabetes insipidus.

Diagnosis

The diagnostic workup for PU and PD should initially rule out causes of acquired secondary NDI (see Chapter 38). Recommended initial diagnostic studies include CBC; a serum biochemistry panel; serum T_4 concentration (older cat); urinalysis with bacterial culture; abdominal ultrasonography; and in dogs, a urine cortisol/creatinine ratio or low-dose dexamethasone suppression test, or both; a baseline serum cortisol concentration if hypoadrenocorticism is suspected; and pre- and postprandial bile acids if hepatic insufficiency is suspected.

Results of these screening tests are normal in dogs and cats with CDI, primary NDI, and psychogenic water consumption, although a low-normal serum urea nitrogen concentration (5-10 mg/dL), and mild hyponatremia and hypokalemia may be found. Random urine specific gravity is usually less than 1.006 and is often as low as 1.001 if the dog or cat has unlimited access to water. The urine osmolality is less than 300 mOsm/kg. A urine specific gravity in the isosthenuric range (i.e., 1.008-1.015) does not rule out diabetes insipidus (Fig. 46.1), especially if the urine has been obtained after water is knowingly or inadvertently withheld (e.g., after a long car ride and wait in the veterinary office). The urine of dogs and cats with partial diabetes insipidus can be concentrated into the isosthenuric range if they become dehydrated. Erythrocytosis (packed cell volume of 50%-60%), hyperproteinemia, hypernatremia, and azotemia may be found in animals whose access to water has been restricted.

Diagnostic tests to confirm and differentiate among CDI, primary NDI, and psychogenic water consumption include the modified water deprivation test, random plasma osmolality determination, and the response to AVP supplementation. Results of these tests can be interpreted only after known causes for acquired secondary NDI have been ruled out, most notably hyperadrenocorticism. Pituitary-dependent hyperadrenocorticism can mimic CDI in the adult dog. Pituitary-dependent hyperadrenocorticism commonly causes severe PU and PD, and occasionally dogs have no other clinical signs, do not have the typical abnormalities (e.g., increased serum alkaline phosphatase activity, hypercholesterolemia) associated with the disease, and adrenal gland size is in the reference interval with ultrasonography. Results of the modified water deprivation test in dogs with hyperadrenocorticism are similar to results in dogs with partial CDI and, sometimes, dogs with psychogenic PD. Severity of PU and PD may improve noticeably to the owner after initiating treatment with DDAVP in these dogs, but improvement tends to be transient, lasting only a few months, and the dog typically presents to the hospital with owner concerns that the DDAVP is no longer working. For these reasons, we always perform screening tests for hyperadrenocorticism in

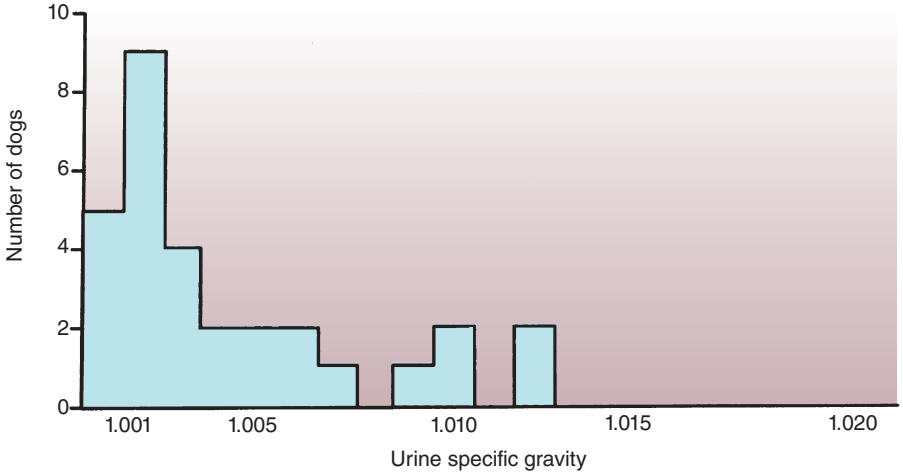

FIG 46.1
Urine specific gravity measured in 30 dogs with central diabetes insipidus at the time of initial presentation to the veterinarian. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

an adult dog in which CDI and psychogenic PD have risen to the top of the differentials and always before initiating DDAVP treatment.

RESPONSE TO TRIAL THERAPY WITH DESMOPRESSIN ACETATE

CDI, primary NDI, and psychogenic PD are uncommon to rare causes of PU and PD in dogs and cats, and of these three differentials, partial CDI and psychogenic PD are the most common. Because CDI is treated with DDAVP, a viable approach to establishing the diagnosis is to evaluate the animal's response to trial therapy with DDAVP (Desmopressin acetate®, Aventis Pharmaceuticals). Oral DDAVP tablets or conjunctival drops of DDAVP nasal spray (see Treatment section) should be administered every 12 hours for 7 days. The effect of DDAVP should not be critically evaluated until after 5 to 7 days of therapy because renal medullary washout may prevent the dog or cat with CDI from concentrating its urine and decreasing water intake after only 1 or 2 days of DDAVP treatment. Clients should notice a definite improvement in the severity of PU and PD by the end of the treatment period if the PU and PD are caused by CDI. Urine specific gravity should be measured on several urine samples collected by the client on the last couple of days of trial therapy. An increase in urine specific gravity by 50% or more, compared with pretreatment specific gravities, supports the diagnosis of CDI, especially if the urine specific gravity exceeds 1.030. There should be only minimal improvement in dogs and cats with primary NDI, although a response may be observed with very high doses of DDAVP. Dogs and cats with psychogenic water consumption may exhibit a mild decline in urine output and water intake because the chronically low serum osmolality tends to depress AVP production. Theoretically, dogs with psychogenic PD could develop clinical signs of hyponatremia during DDAVP therapy, but we have only identified this complication with excess DDAVAP administered by SC injection. This approach to diagnosis requires that all other causes of PU and PD, except CDI, primary NDI, and psychogenic PD, must be previously ruled out.

A thorough review of the diagnostic evaluation of the patient, owner compliance in treating their pet, and adjustments in the DDAVP treatment protocol should be undertaken in dogs and cats that fail to respond to DDAVP before considering the modified water deprivation test.

MODIFIED WATER DEPRIVATION TEST

The technique, interpretation, contraindications, and complications of the modified water deprivation test are described in Chapter 39. The test consists of two phases. In phase I, AVP secretory capabilities and renal distal and collecting tubule responsiveness to AVP are evaluated by assessing the effects of dehydration (i.e., water restriction until the animal loses 3%-5% of its body weight) on urine specific gravity. The normal dog and cat, as well as those with psychogenic water consumption, should be able to concentrate urine to greater than 1.030 (1.035 in the cat) if dehydrated. Dogs and cats with partial and complete CDI and primary NDI have an impaired ability to concentrate urine in the face of dehydration (Table 46.3 and Fig. 46.2). The time required to attain 3% to 5% dehydration can sometimes be helpful in establishing the diagnosis. It often takes less than 6 hours for dogs and cats with complete CDI to attain 3% to 5% dehydration, whereas it often takes longer than 8 to 10 hours for dogs and cats with partial CDI, especially those with psychogenic water consumption, to attain 3% to 5% dehydration.

Phase II of the water deprivation test is indicated for dogs and cats that do not concentrate urine to greater than 1.030 during phase I of the test. Phase II determines the effect, if any, that exogenous AVP has on the renal tubular ability to concentrate urine in the face of dehydration (see Fig. 46.2). This phase differentiates impaired AVP secretion from impaired renal tubular responsiveness to AVP (see Table 46.3).

RANDOM PLASMA OSMOLALITY

Measurement of random plasma osmolality may help identify primary or psychogenic PD. Plasma osmolality in normal dogs and cats is approximately 280 to 300 mOsm/kg. Diabetes insipidus is a primary polyuric disorder, with compensatory

TABLE 46.3

Guidelines for Interpretation of the Modified Water Deprivation Test

DISORDER	URINE SPECIFIC GRAVITY			TIME TO 5% DEHYDRATION	
	INITIAL	5% DEHYDRATION	POST ADH	MEAN (h)	RANGE (h)
Central Di					
Complete	<1.006	<1.006	>1.008	4	3-7
Partial	<1.006	1.008-1.020	>1.015	8	6-11
Primary nephrogenic DI	<1.006	<1.006	<1.006	5	3-9
Primary polydipsia	1.002-1.020	>1.030	NA	13	8-20

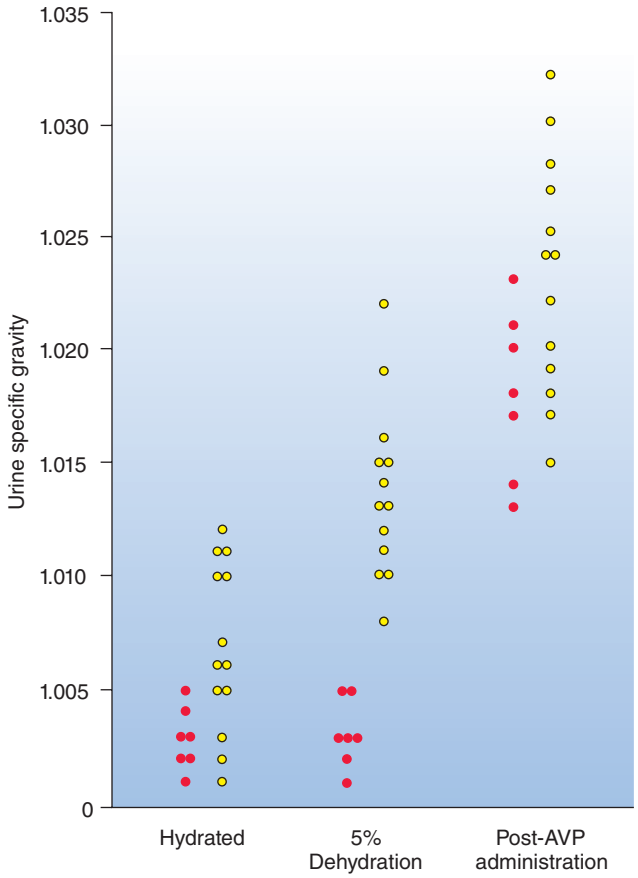

FIG 46.2
Urine specific gravity in seven dogs with complete central diabetes insipidus *(red circle)* and in 13 dogs with partial central diabetes insipidus *(yellow circle)* at the beginning (hydrated), at the end of phase I (5% hydrated), and at the end of phase II (after arginine vasopressin administration) of the modified water deprivation test. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

PD to prevent severe hyperosmolality. Random plasma osmolality should be greater than 300 mOsm/kg. Psychogenic PD is a primary polydipsic disorder, with compensatory PU to prevent hyposmolality and water intoxication. Random plasma osmolality should be less than 280 mOsm/kg. Unfortunately, considerable overlap in random plasma osmolality is seen in dogs with these disorders. A random plasma osmolality of less than 280 mOsm/kg obtained while the dog has free access to water suggests the presence of psychogenic PD, whereas a plasma osmolality of 280 mOsm/kg or greater is consistent with CDI, NDI, or psychogenic PD.

ADDITIONAL DIAGNOSTIC TESTS

Neoplasia in the region of the pituitary gland and hypothalamus should be considered in the older dog or cat in which CDI develops. A complete neurologic evaluation, including computed tomographic (CT) or magnetic resonance (MR) scan, may be warranted before idiopathic CDI is arbitrarily diagnosed, especially if the client is willing to consider radiation therapy or chemotherapy should a tumor be identified. Similarly, a more complete evaluation of the kidney (e.g., creatinine clearance studies, intravenous pyelogram, CT or MR scan, kidney biopsy) may be warranted in the older dog or cat tentatively considered to have primary NDI.

BOX 46.2

Therapies Available for Polydipsic/Polyuric Dogs and Cats With Central Diabetes Insipidus, Nephrogenic Diabetes Insipidus, or Primary (Psychogenic) Polydipsia

A. Central diabetes insipidus (severe)
  1. DDAVP (desmopressin acetate)
    a. Effective
    b. Expensive
    c. Oral tablets or drops of nasal solution in conjunctival sac
  2. LVP (lypressin [Diapid])
    a. Short duration of action; less potent than DDAVP
    b. Expensive
    c. Requires drops into nose or conjunctival sac
  3. No treatment—provide continuous source of water
B. Central diabetes insipidus (partial)
  1. DDAVP
  2. LVP
  3. Chlorpropamide
    a. 30%-70% effective
    b. Inexpensive
    c. Pill form
    d. Takes 1-2 weeks for effect of drug to be noted
    e. May cause hypoglycemia
  4. Thiazide diuretics
    a. Mildly effective
    b. Inexpensive
    c. Pill form
    d. Should be used with low-sodium diet
  5. Low-sodium diet (NaCl < 1.0 g/1000 kcal/ME)
  6. No treatment—provide continuous source of water
C. Nephrogenic diabetes insipidus
  1. Thiazide diuretics
  2. Low-sodium diet (NaCl < 1.0 g/1000 kcal/ME)
  3. No treatment—provide continuous source of water
D. Primary (psychogenic) polydipsia
  1. Water restriction at times
  2. Water limitation
  3. Change in environment or daily routine; exercise; increased contact with humans or dogs

ME, Metabolizable energy.

Treatment

Therapeutic options for dogs and cats with diabetes insipidus are listed in Box 46.2. The synthetic analog of vasopressin, DDAVP, is the standard therapy for CDI. DDAVP has almost three times the antidiuretic action of AVP, with minimal to no vasopressor or oxytocic activity. The intranasal DDAVP preparation (DDAVP nasal drops, 2.5- and 5.0-mL bottles

containing 100 μg DDAVP/mL) is used most commonly in treating CDI in dogs and cats. Administration of medication to animals via the intranasal route is possible but is not recommended. The DDAVP nasal preparation may be transferred to a sterile eye dropper bottle and drops placed into the conjunctival sac of the dog or cat. Although the solution is acidic, ocular irritation rarely occurs. One drop of DDAVP contains 1.5 to 4 μg of DDAVP, and a dosage of one to four drops administered once or twice daily controls signs of CDI in most animals.

Because of the expense of DDAVP nasal drops and loss of DDAVP drops from the conjunctival sac with head shaking, blinking, and inadvertent application of excessive amounts, our preference is to initially try oral DDAVP (DDAVP tablets, 0.1 and 0.2 mg) when using response to DDAVP to establish the diagnosis of CDI and when providing long-term treatment for CDI. Clinical response in humans is variable, in part because the bioavailability of oral DDAVP is approximately 5% to 15% of the intranasal dose in humans. Similar information is not available for dogs and cats. Our initial dose of oral DDAVP is 0.05 mg for dogs weighing less than 5 kg and for cats, 0.1 mg for dogs weighing 5 to 20 kg, and 0.2 mg for dogs weighing more than 20 kg given every 12 hours. The frequency of administration is increased to every 8 hours if unacceptable PU and PD persist 1 week after therapy is initiated. Treatment should be switched to the intranasal DDAVP preparation if minimal to no response to oral DDAVP administered three times a day is noted. Decreasing the frequency of administration, decreasing the dose of DDAVP, or both can be tried once clinical response has been documented. Periodic monitoring of serum electrolytes is also recommended and the dose of DDAVP adjusted if hyponatremia develops. To date, most dogs have required 0.1 to 0.2 mg of DDAVP two to three times a day, and most cats have required 0.025 to 0.05 mg of DDAVP two to three times a day, for control of PU and PD.

DDAVP parenteral (2 mL vials containing 4 μg/mL) can be used in lieu of the nasal formulation or oral tablets. In humans, parenteral administration of DDAVP is 5 to 20 times as potent as DDAVP nasal. The initial parenteral dosage of DDAVP is 0.5 to 1.0 μg administered SC once a day. Subsequent adjustments in the dose and frequency of administration are based on improvement in PU and PD, duration of clinical response, and changes in serum sodium concentration. Hyponatremia is more apt to develop with parenteral DDAVP than with tablets or nasal spray and can mimic the syndrome of inappropriate vasopressin secretion.

The maximal effect of DDAVP, regardless of the route of administration, occurs from 2 to 8 hours after administration, and the duration of action ranges from 8 to 24 hours. Larger doses of DDAVP appear both to increase its antidiuretic effects and to prolong its duration of action; however, expense becomes a limiting factor. The medication may be administered exclusively in the evening as insurance against nocturia.

We have had excellent results in dogs and cats receiving daily medication for longer than 5 years. Owners of dogs and cats with CDI have reported that their pets become accustomed to receiving eye drops, mentioning eye or conjunctival irritation as an infrequent complication. If PU and PD recur despite DDAVP therapy, several possibilities should be considered, including problems with owner compliance or administration technique, inadequate dose, outdated or inactivated DDAVP, or development of a concurrent disorder causing PU and PD. Hyperadrenocorticism is the primary differential when PU and PD recur despite DDAVP treatment in a dog with CDI.

Chlorpropamide, thiazide diuretics, and oral sodium chloride restriction have limited efficacy in the treatment of NDI. DDAVP may control the clinical signs if administered in massive amounts (i.e., five to ten times the amount used for the treatment of CDI), but the cost of the drug obviously detracts from the attractiveness of this therapeutic approach. Fortunately, therapy for CDI or NDI is not mandatory as long as the dog or cat has unlimited access to water and is housed in an environment that cannot be damaged by severe PU. A constant water supply is of paramount importance because relatively short periods of water restriction can have catastrophic results (i.e., the development of hypernatremic, hypertonic dehydration, and neurologic signs).

Prognosis

Dogs and cats with idiopathic or congenital CDI usually become asymptomatic with appropriate therapy, and with proper care these animals have an excellent life expectancy. Unfortunately, many owners discontinue DDAVP therapy or elect euthanasia of their pet after a few months because of the expense of DDAVP. Without therapy, these animals often lead acceptable lives as long as water is constantly provided and they are housed in an environment that cannot be damaged by severe PU. However, the untreated animal is always at risk for developing life-threatening dehydration if water is withdrawn for longer than a few hours. PU and PD frequently resolve in dogs and cats with trauma-induced CDI, often within 2 weeks of the traumatic incident. The prognosis in dogs and cats with hypothalamic and pituitary tumors is guarded to grave. Neurologic signs typically develop within 6 months after the diagnosis of CDI, and clinical response to radiation therapy and chemotherapy is variable and unpredictable.

The prognosis for animals with primary NDI is guarded to poor because of limited therapeutic options and a generally poor response to therapy. The prognosis for animals with secondary NDI depends on the prognosis of the primary problem.

PRIMARY (PSYCHOGENIC) POLYDIPSIA

Primary PD is defined as a marked increase in water intake that cannot be explained as a compensatory mechanism for excessive fluid loss. In humans, primary PD results from a defect in the thirst center or may be associated with mental illness. Primary dysfunction of the thirst center resulting in

compulsive water consumption has not been reported in the dog or the cat, although an abnormal vasopressin response to hypertonic saline infusion has been reported in dogs with suspected primary PD. A psychogenic or behavioral basis for compulsive water consumption has been described in the dog, typically in young hyperactive dogs that have been placed in exercise-restricted environments but has not been reported in the cat. Psychogenic PD may be induced by concurrent disease (e.g., hepatic insufficiency, hyperthyroidism) or may represent a learned behavior after a change in the pet's environment. PU is compensatory to prevent overhydration. Psychogenic PD can be diagnosed in dogs of any age, either gender, and numerous breeds.

Dogs (and presumably cats) with primary or psychogenic PD have an intact hypothalamic-pituitary-renal axis for controlling fluid balance and variable severity of renal medullary solute washout. Because AVP production and renal tubular response to AVP are normal, these dogs can concentrate urine in excess of 1.030. Depending on the severity of renal medullary solute washout, a period of 24 hours or longer of water deprivation may be necessary to attain concentrated urine. Urine specific gravity may vary widely over time and concentrated urine may be identified on random urine evaluation. Identification of concentrated urine implies hypothalamic AVP production, pituitary AVP secretion, and renal tubular responsiveness to AVP.

Psychogenic PD is diagnosed by exclusion of other causes of PU and PD and by demonstrating that the dog or cat can concentrate urine to a specific gravity in excess of 1.030 during water deprivation.

Treatment is aimed at gradually limiting water intake to amounts in the upper end of the normal range. The client should determine the dog's approximate water intake over a 24-hour period when free-choice water is allowed; this volume of water is then reduced by 10% per week until water volumes of 60 to 80 mL/kg/24 h are reached. The total 24-hour volume of water should be divided into several aliquots, with the last aliquot given at bedtime. Oral salt (1 g/30 kg q12h) and/or oral sodium bicarbonate (0.6 g/30 kg q12h) may also be administered for 3 to 5 days to help reestablish the renal medullary concentration gradient. Changes in the dog's environment or daily routine should be considered, such as initiating a daily exercise routine; bringing a second pet into the home; providing some distraction, such as a radio playing when the clients are not at home; or moving the dog to an area that will ensure an increased amount of contact with humans.

ENDOCRINE ALOPECIA

Symmetric alopecia without historical or clinical evidence of inflammation usually results from hair cycle arrest induced by hormonal disease or imbalance—hence the term *endocrine alopecia* (Fig. 46.3). Hair follicles are atrophic, the hairs are easily epilated, the skin is often thin and hypotonic, and hyperpigmentation is common. Other dermatologic lesions, such as scales, crusts, and papules, are absent. Seborrhea and pyoderma may develop, depending on the underlying cause.

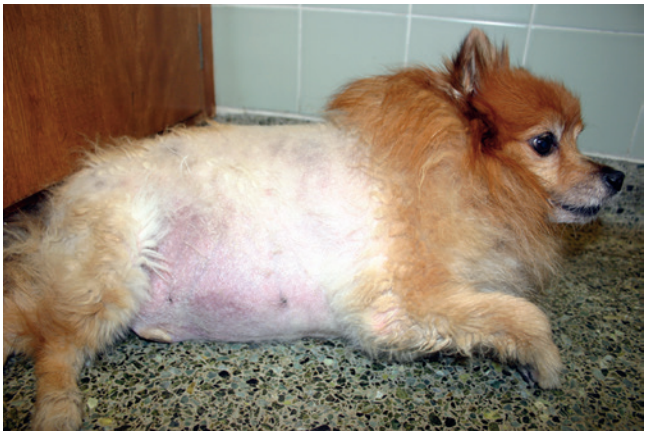

FIG 46.3
Endocrine alopecia, thin skin, and severe obesity in a 7-year-old male castrated Pomeranian with iatrogenic hyperadrenocorticism caused by long-term administration of prednisone for a seizure disorder. Note the symmetric truncal alopecia with sparing of the head and distal extremities.

Causes of endocrine alopecia are listed in Table 46.4. In dogs the most common causes are hypothyroidism and glucocorticoid excess (iatrogenic or spontaneous). Hormone-induced causes of alopecia are not common in cats. The diagnostic evaluation for endocrine alopecia begins with a complete history, physical examination, CBC, serum biochemistry panel, and urinalysis. Results of these tests often provide evidence of hypothyroidism and hyperadrenocorticism; appropriate diagnostic tests can then be performed to confirm these diagnoses (see Chapters 48 and 50, respectively).

Once hypothyroidism and hyperadrenocorticism have been ruled out, the next diagnostic step is to rule out an excess or less commonly a deficiency of one of the sex hormones, most notably estrogen and progesterone. Dermatologic manifestations are similar for most sex hormone–induced dermatoses and include endocrine alopecia that initially begins in the perineal, genital, and ventral abdominal regions and spreads cranially; dull, dry, easily epilated hair; failure of the haircoat to regrow after clipping; and variable presence of seborrhea and hyperpigmentation. Additional clinical signs of hyperestrogenism may include gynecomastia, a pendulous prepuce, the attraction of other male dogs, squatting to urinate, and unilateral testicular atrophy (contralateral to the testicular tumor) in the male dog, and vulvar enlargement and persistent proestrus or estrus in the female dog. Results of a CBC may reveal aplastic anemia. Histologic assessment of a skin biopsy specimen can be used to identify nonspecific endocrine-related alterations and to support the diagnosis of endocrine alopecia (Table 46.5). No pathognomonic histologic changes are noted for sex hormone–induced dermatoses. Identification of cornified epithelial cells on cytologic examination of vaginal or preputial smears provides a clue

TABLE 46.4

Disorders Causing Endocrine Alopecia

DISORDER	COMMON CLINICOPATHOLOGIC ABNORMALITIES	DIAGNOSTIC TESTS
Hypothyroidism	Lipemia, hypercholesterolemia, mild nonregenerative anemia	Serum T_4, free T_4, TSH concentrations
Hyperadrenocorticism	Stress leukogram, increased ALP, hypercholesterolemia, hyposthenuria, proteinuria, urinary tract infection	Urine cortisol/creatinine ratio, low-dose dexamethasone suppression test, abdominal US
Hyperestrogenism		
Functional Sertoli cell tumor in male dog	None (bone marrow depression uncommon)	Physical findings, abdominal US, cytologic or histopathologic findings, plasma estrogen concentration
Hyperestrogenism in intact female dog (follicular cyst)	None (bone marrow depression uncommon)	Vaginal cytology, abdominal US, plasma estrogen concentration, response to ovariohysterectomy
Hyperprogesteronism Luteal cyst in intact female dog Adrenocortical tumor	None	Physical findings, abdominal US, serum progesterone concentrati
Increased adrenocortical steroid hormone intermediates Occult (atypical) hyperadrenocorticism	None	Measure adrenocortical steroid hormone intermediates before and after ACTH administration
Growth hormone deficiency pituitary dwarfism	None	Signalment, physical findings
Alopecia X*	None	Measure adrenocortical steroid hormone intermediates before and after ACTH administration
Feline endocrine alopecia	None	Response to progestin therapy
Telogen defluxion (effluvium)	None	History of recent pregnancy or diestrus
Diabetes mellitus	Hyperglycemia, glycosuria	Blood and urine glucose measurement

ACTH, Adrenocorticotropic hormone; *ALP,* alkaline phosphatase; *T_4,* tetraiodothyronine; *TSH,* thyroid-stimulating hormone; *US,* ultrasonography.
*Alopecia X encompasses previously named syndromes such as growth hormone–responsive dermatosis, castration-responsive dermatosis, estrogen-responsive dermatosis, biopsy-responsive dermatosis, and congenital adrenal hyperplasia–like syndrome.

to the presence of hyperestrogenism (see Chapter 54), and documenting an increased plasma estrogen (i.e., estradiol) concentration provides further evidence for the presence of a functional Sertoli cell tumor in the dog and hyperestrogenism in the bitch (assuming that the bitch is not in proestrus or early estrus). Abdominal ultrasound may identify ovarian cysts or neoplasia in the bitch with hyperestrogenism, and abdominal and testicular ultrasound may identify testicular neoplasia in the male dog. Hyperestrogenism and endocrine alopecia should resolve after surgical removal of the ovarian cyst, ovarian tumor, or testicular tumor.

An abnormal increase in serum progesterone may result from adrenocortical neoplasia (more common in cats than dogs) or functional ovarian luteal cysts in the bitch and may serve as a component of an imbalance in adrenocortical steroid hormone intermediates. Functional luteal cysts may cause prolonged anestrus or failure to cycle in the bitch. Clinical features of progesterone-secreting adrenocortical tumors mimic hyperadrenocorticism (see Chapter 50). Documenting increased serum progesterone concentration establishes the diagnosis, especially in a male or female spayed cat or dog. Serum progesterone is normally increased in an intact female dog or cat in diestrus. A history of recent cycling behavior and examination of the ovaries and adrenal glands with abdominal ultrasound will help differentiate diestrus, functional luteal cysts, and adrenal neoplasia.

Alopecia X is a syndrome in dogs characterized by hair cycle arrest, endocrine alopecia, and hyperpigmentation. Alopecia X has been identified in many breeds, most notably Nordic Breeds, Poodles, and "plush-coated dogs" such as the Pomeranian, Chow, Samoyed, and Keeshond (Fig. 46.4). Alopecia occurs in young adult dogs and occurs equally in males and females, intact or neutered. Systemic illness is not a feature of Alopecia X. Routine blood and urine test results are typically normal. Skin biopsy specimens from affected dogs show the typical changes of endocrine alopecia (see

TABLE 46.5

Dermatohistopathologic Alterations Associated With Endocrinopathy-Induced Alopecia

ABNORMALITY	SPECIFIC ENDOCRINE DISORDER
Nonspecific Abnormalities Supporting an Endocrinopathy

Thick dermis	Hypothyroidism
Comedones	Hyperadrenocorticism
Calcinosis cutis	Hyperadrenocorticism
Absence of arrector pili muscles	Hyperadrenocorticism

Table 46.5) and may also show features of follicular dysplasia. The cause is unknown and may be multifactorial or may differ between breeds. *Alopecia X* is somewhat of an umbrella term that encompasses previously named syndromes such as growth hormone (GH)–responsive dermatosis, castration-responsive dermatosis, biopsy-responsive dermatosis, and congenital adrenal hyperplasia–like syndrome. An increase in one or more of the adrenocortical steroid hormone intermediates such as progesterone, 17-hydroxyprogesterone, and androstenedione was initially proposed as the underlying cause of Alopecia X, but subsequent studies failed to confirm adrenal hormone imbalance as the cause, although steroid hormone intermediates may play a role in some dogs. The diagnosis of Alopecia X is based on ruling out other endocrine diseases known to cause endocrine alopecia.

Melatonin is perhaps the least innocuous nonspecific treatment option for dogs with suspected Alopecia X. Melatonin, a neurohormone produced by the pineal gland, controls the circadian and seasonal reproductive and hair growth cycles. One reported treatment protocol for dogs with Alopecia X is 3 mg of melatonin for dogs weighing 15 kg or less and 6 mg for dogs weighing more than 15 kg administered every 12 hours initially for 6 to 8 weeks, with subsequent adjustments based on clinical response (i.e., regrowth of hair). Partial to complete hair regrowth occurred in 62% of 29 dogs treated with melatonin. Trilostane and mitotane have also been used to treat Alopecia X and occult (atypical) hyperadrenocorticism in dogs (see Chapter 50, Occult [Atypical] Hyperadrenocorticism section). Response to melatonin, trilostane, and mitotane treatment has not been uniform or predictable.

Many clients elect not to treat their dog once hypothyroidism, hyperadrenocorticism, ovarian cysts, and neoplasia of the adrenal gland, ovary, and testis have been ruled out. For these dogs, the long-term prognosis is good, even without treatment. Dogs remain healthy, aside from the alopecia and hyperpigmentation.

FELINE ACROMEGALY

Etiology

Chronic excessive secretion of GH in adult cats results in acromegaly, a disease characterized by overgrowth of connective tissue, bone, and viscera. In cats acromegaly is caused by a functional adenoma of the somatotropic cells of the pituitary pars distalis that secretes excess GH (Fig. 46.5). In most cats, the pituitary tumor is a macroadenoma that extends dorsally above the sella turcica. Progestogen-induced acromegaly has not been documented in the cat. Progestogens, including megestrol acetate, do not appear to increase serum GH or insulin-like growth factor 1 (IGF-1) concentrations in the cat. In contrast, acromegaly in the dog is seen most commonly after prolonged exposure to progestogens, administered either exogenously (e.g., medroxyprogesterone acetate) or late in life after years of endogenous progesterone secretion during the diestrual phase of the estrous cycle in the intact bitch. Acromegaly caused by a pituitary somatotroph adenoma and by GH-producing mammary tumors has been reported in the dog but is rare.

Chronic excessive secretion of GH has catabolic and anabolic effects. The anabolic effects are caused by increased concentrations of IGF-1. The growth-promoting effects of IGF-1 result in proliferation of bone, cartilage, and soft tissues, and in organomegaly, most notably of the kidney and heart. These anabolic effects are responsible for producing the classic clinical manifestations of acromegaly (Box 46.3). The catabolic effects of GH are a direct result of GH-induced insulin resistance, which ultimately leads to carbohydrate intolerance, hyperglycemia, and the development of diabetes mellitus that quickly becomes resistant to insulin treatment. Most but not all cats with acromegaly have

FIG 46.4

diabetes mellitus at the time acromegaly is diagnosed, and most eventually develop severe resistance to exogenously administered insulin.

Clinical Features

Acromegaly typically occurs in male, mixed-breed cats that are 8 years of age or older (range, 4-17 years). Clinical signs result from the catabolic and diabetogenic effects of GH, the anabolic actions of chronic IGF-1 secretion by the liver, and the growth of the pituitary macroadenoma (see Box 46.3). The earliest clinical signs are usually PU, PD, and polyphagia resulting from concurrent diabetes mellitus. Polyphagia can become quite intense. Weight loss varies and depends in part on whether the anabolic effects of IGF-1

or the catabolic effects of uncontrolled diabetes predominate. Most cats initially lose weight and then experience a period of stabilization, followed by a slow, progressive gain in body weight as the anabolic effects of IGF-1 begin to dominate the clinical picture. Severe insulin resistance eventually develops. Insulin dosages in cats with acromegaly frequently exceed 2 to 3 U/kg of body weight twice a day, with minimal to no apparent decline in the blood glucose concentration.

Clinical signs related to the anabolic actions of excessive GH secretion (see Box 46.3) may be evident before or at the time diabetes mellitus is diagnosed. More commonly, however, they become apparent several months after diabetes has been diagnosed, often in conjunction with the realization that hyperglycemia is difficult to control with exogenous insulin therapy. Because of the insidious onset and slowly progressive nature of the anabolic clinical signs, clients are often not aware of subtle changes in the appearance of their cat until the clinical signs are quite obvious. Anabolic changes in acromegalic cats include an increase in body size; enlargement of the abdomen, head, and paws; development of prognathia inferior; widening of the interdental spaces; and weight gain (Fig. 46.6). Weight gain in a cat with poorly regulated diabetes mellitus is an important diagnostic clue to acromegaly. Over time, organomegaly, especially of the heart, kidney, liver, and adrenal gland, may develop. Cardiac abnormalities are common and include concentric left ventricular hypertrophy, diastolic functional abnormalities, and left atrial enlargement. Systemic hypertension may also be present. Cardiomegaly may lead to congestive heart failure. Diffuse thickening of soft tissues in the pharyngeal region can lead to extrathoracic upper airway obstruction and respiratory distress.

Neurologic signs may develop as a result of pituitary tumor growth and resultant invasion and compression of the hypothalamus and thalamus. Signs include altered mentation, adipsia, anorexia, temperature deregulation, circling, seizures, and changes in behavior. Blindness is not common because the optic chiasm is located anterior to the pituitary gland. Papilledema may be evident during an ophthalmic examination. Peripheral neuropathy causing weakness, ataxia, and a plantigrade stance may develop as a result of poorly controlled diabetes mellitus. Other endocrine and metabolic abnormalities resulting from the compressive effects of the tumor on the pituitary are uncommon.

Clinical Pathology

Concurrent, poorly controlled diabetes mellitus is responsible for causing most of the abnormalities identified on a serum biochemistry panel and urinalysis, including hyperglycemia, glycosuria, hypercholesterolemia, and a mild increase in alanine transaminase and alkaline phosphatase activities. Ketonuria is an infrequent finding. Mild erythrocytosis, persistent mild hyperphosphatemia without concurrent azotemia, and persistent hyperproteinemia (total serum protein concentration of 8.2-9.7 mg/dL) with a normal pattern of distribution on protein electrophoretic studies

may also be found. Renal failure is a potential sequela of acromegaly and, if present, will be associated with azotemia, isosthenuria, and proteinuria.

Diagnosis

Clinical suspicion for acromegaly is based on the identification of conformational alterations (e.g., increased body size, large head, prognathia inferior, organomegaly) associated with acromegaly and a stable or progressive increase in body weight in a cat with insulin-resistant diabetes mellitus. Measurement of serum IGF-1 concentrations provides further evidence for the diagnosis of acromegaly. Measurement of serum IGF-1 is commercially available (e.g., the Diagnostic Center for Population and Animal Health, Michigan State University, East Lansing, Mich; www.dcpah.msu.edu). Concentrations are usually increased in acromegalic cats, but values may be in the reference range in the early stages of the disease (Fig. 46.7). Repeat measurements performed 3 to 6 months later usually reveal an increase in serum IGF-1 if acromegaly is present. This increase in serum IGF-1 typically coincides with development and growth of the pituitary somatotropic adenoma. Serum IGF-1 concentrations are lower in newly diagnosed untreated diabetic cats, compared with healthy cats, and serum IGF-1 concentrations increase after initiation of insulin treatment. Fortunately, most cats are diabetic and being treated with insulin at the time acromegaly is diagnosed. Increased serum IGF-1 concentrations have been identified in a small number of poorly controlled diabetic cats in which the poor control was not caused by acromegaly and in cats with acromegaly that do not have concurrent diabetes mellitus. In the nondiabetic cats, acromegaly is usually suspected based on the presence of a large cat with prognathia inferior, organomegaly, and cardiac abnormalities.

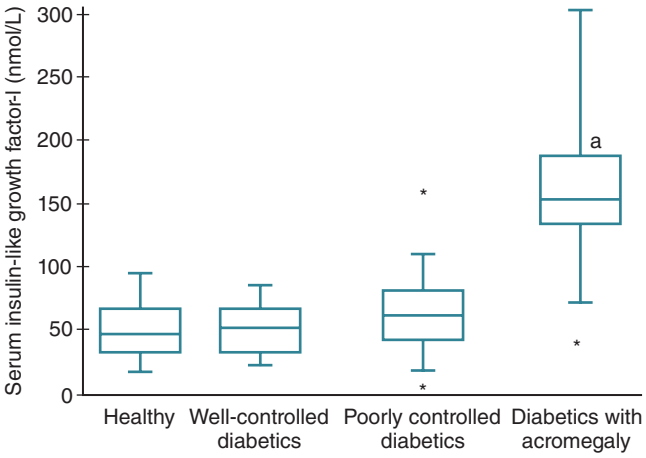

FIG 46.7
Box plots of serum concentrations of insulin-like growth factor 1 (IGF-1) in 38 healthy cats, 15 well-controlled diabetic cats, 40 poorly controlled diabetic cats, and 19 poorly controlled diabetic cats with acromegaly. For each box plot, T-bars represent the main body of data, which in most instances is equal to the range. Each box represents the interquartile range (twenty-fifth to seventy-fifth percentile). The horizontal bar in each box is the median. Asterisks represent outlying data points. a, $P < 0.0001$, compared with healthy cats and well-controlled and poorly controlled diabetic cats. (From Berg RIM, et al.: Serum insulin-like growth factor-I concentration in cats with diabetes mellitus and acromegaly, *J Vet Intern Med* 21:892, 2007.)

Interpretation of serum IGF-1 test results should always take into consideration the status of control of the diabetic state, the presence and severity of insulin resistance, and the index of suspicion for acromegaly based on review of the history, physical examination, and results of routine blood and urine tests and diagnostic imaging. Identification of an increased serum IGF-1 concentration in a poorly controlled diabetic cat with insulin resistance and clinical features suggestive of acromegaly supports the diagnosis and provides justification for CT or MR imaging of the pituitary gland. A pituitary mass documented by CT or MR scanning (see Fig. 46.5) adds further evidence for the diagnosis and is indicated whenever the client is considering radiation treatment. It is usually necessary to administer a positive contrast agent for visualization of a pituitary mass when CT or MR imaging is used.

A definitive diagnosis of acromegaly requires documentation of an increased baseline serum GH concentration. Baseline serum GH concentration in cats with acromegaly typically exceeds 10 ng/mL (reference range varies with the laboratory but is typically < 7.2-7.9 ng/mL in cats). Unfortunately, a commercial GH assay is not currently available for cats in the United States.

ACROMEGALY VERSUS HYPERADRENOCORTICISM

Hyperadrenocorticism and acromegaly are uncommon disorders that occur in older cats, have a strong association with diabetes mellitus, can cause severe insulin resistance, and are often caused by a functional pituitary macrotumor. Clinical signs related to poorly controlled diabetes mellitus are common in cats with hyperadrenocorticism and acromegaly. Additional clinical signs differ dramatically between the two disorders. Hyperadrenocorticism is a debilitating disease that results in progressive weight loss leading to cachexia and dermal and epidermal atrophy causing extremely fragile, thin, and easily torn and ulcerated skin (i.e., feline fragile skin syndrome). In contrast, conformational changes caused by the anabolic actions of chronic IGF-1 secretion dominate the clinical picture in acromegaly, most notably an increase in body size, prognathia inferior, and weight gain despite poorly regulated diabetes mellitus. Feline fragile skin syndrome does not occur with acromegaly. With both disorders most of the abnormalities identified on routine blood and urine tests are caused by concurrent poorly controlled diabetes mellitus. Abdominal ultrasound may reveal mild bilateral adrenomegaly with both disorders. Ultimately, differentiation between the two diseases is based on results of tests of the pituitary-adrenocortical axis (see Chapter 50) and serum GH and/or IGF-1 concentrations.

Treatment

Radiation therapy is currently considered the most viable treatment option for acromegaly in cats. Types and techniques of radiation, treatment protocols, and follow-up schedules vary widely between institutions. Radiation therapy is effective in improving insulin resistance and clinical signs of diabetes mellitus, and in decreasing tumor size, in 50% or more of treated acromegalic cats. However, the clinical response to radiation therapy is unpredictable and ranges from no response to a dramatic response, characterized by shrinkage of the tumor; elimination of hypersomatotropism; resolution of insulin resistance; and reversion to a subclinical diabetic state. Typically, tumor size and plasma GH and, and less reliably, serum IGF-1 concentrations are decreased and insulin responsiveness improves after radiation therapy, although this improvement is difficult to predict and may occur within a few weeks or not for several months after radiation treatment is finished. Treated cats that respond to radiation therapy are at risk for developing potentially severe hypoglycemia. Close monitoring of blood glucose concentrations, preferably by the owner at home, is highly recommended (see Chapter 49). In most treated cats that respond to radiation therapy, diabetes mellitus and/or insulin resistance recurs 6 months or longer after treatment, although growth of the pituitary mass is often not evident on CT or MR imaging.

Successful use of both microsurgical transsphenoidal hypophysectomy and transsphenoidal cryotherapy of a pituitary tumor has been described in a cat with acromegaly. Although preliminary studies evaluating newer somatostatin analogs (e.g., pasireotide are promising, a cost-effective medical treatment for acromegaly in cats has yet to be identified.

MANAGING INSULIN-RESISTANT DIABETES

Diabetes mellitus is difficult to control in an acromegalic cat, even with the administration of large doses of insulin (≥20 U/injection) twice daily. Cats typically have blood glucose concentrations that remain in excess of 400 mg/dL regardless of the dosage or type of insulin administered. In our experience, control of hyperglycemia is difficult to attain in most acromegalic cats. The goal of insulin treatment is to avoid severe hyperglycemia (blood glucose concentrations >500 mg/dL) and hypoglycemia—not to attain control of the diabetic state per se. Increases in the insulin dose should not be based on the severity of PU, PD, or polyphagia, or persistent hyperglycemia and glycosuria but rather on the owner's perception of how the cat is doing in terms of activity, ambulation, grooming behavior, and interactions with family members. Severe hyperglycemia causes lethargy, obtundation, and the perception that the cat is "not feeling well." We consider increasing the insulin dose if owners report these problems, especially if the blood glucose concentration is consistently greater than 500 mg/dL. We are cautious when increasing the insulin dose because of concerns for the development of severe life-threatening hypoglycemia, which can occur unexpectedly after months of severe insulin resistance, presumably as a result of sporadic reductions in GH secretion and subsequent improvement in insulin resistance. We rarely exceed 12 to 15 units of insulin per injection, and then only because of owner concerns that the cat is "not feeling well" and only after blood glucose concentrations are measured to confirm the presence of severe hyperglycemia. Home blood glucose monitoring and testing of urine for the presence of glucose by the owner should be encouraged to help prevent hypoglycemia and to identify when insulin resistance has improved (see Chapter 49).

Prognosis

The short- and long-term prognosis for cats with tumor-induced acromegaly is guarded to good and poor, respectively. In our experience, survival time has ranged from 4 to 60 months (typically, 1.5-3 years) from the time the diagnosis of acromegaly is established. The GH-secreting pituitary tumor usually grows slowly, and neurologic signs associated with an expanding tumor are uncommon until late in the disorder. Most cats with acromegaly eventually die or are euthanized because of the development of kidney failure, congestive heart failure, respiratory distress from severe thickening of soft tissues in the oropharyngeal region, coma caused by severe hypoglycemia, or neurologic signs caused by an expanding pituitary tumor.

PITUITARY DWARFISM

Etiology

Pituitary dwarfism results from a congenital deficiency of GH. Studies in German Shepherd dog dwarfs suggest that congenital GH deficiency is caused by primary failure of differentiation of the craniopharyngeal ectoderm into normal tropic hormone-secreting pituitary cells. Pituitary cysts are commonly identified through diagnostic imaging of the pituitary region using CT or MR imaging and may enlarge as the pituitary dwarf ages. However, current belief is that pituitary cysts develop secondary to primary failure of anterior pituitary formation in most pituitary dwarfs. Pituitary dwarfism is encountered most often as a simple, autosomal recessive inherited abnormality in the German Shepherd dog. A similar mode of inheritance has been reported in Karelian Bear dogs and Saarloos and Czechoslovakian Wolfdogs. Inherited pituitary dwarfism may be due to isolated GH deficiency or may be part of a combined pituitary hormone deficiency. Concurrent deficiencies in thyroid-stimulating hormone (TSH) and prolactin and impaired release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are most commonly identified in affected German Shepherd dogs; adrenocorticotropic hormone (ACTH) secretion is preserved. An LHX3 mutation is associated with pituitary dwarfism in German Shepherd dogs and Wolfdogs. Kooistra et al (2000) hypothesize that the disorder is caused by a mutation in a developmental transcription factor that precludes effective expansion of a

pituitary stem cell after differentiation of the corticotropic cells that produce ACTH. Pituitary dwarfism resulting from a mutant GH or insensitivity to GH owing to lack of or a defect in GH receptors (e.g., Laron-type dwarfism in human beings) has not been documented in dogs or cats.

Clinical Features

SIGNALMENT

Pituitary dwarfism occurs primarily in German Shepherd dogs, Karelian Bear dogs, and Saarloos and Czechoslovakian Wolfdogs, although pituitary dwarfism in other dog breeds, including the Weimaraner, Spitz, Miniature Pinscher, Golden Retreiver, and Labrador Retriever, and in cats has been observed. A sex-related predilection is not apparent.

CLINICAL SIGNS

The most common clinical manifestations of pituitary dwarfism are lack of growth (i.e., short stature), endocrine alopecia, and hyperpigmentation of the skin (Box 46.4). Affected animals are usually normal in size during the first 2 to 3 months of life but after that grow more slowly than their litter mates. By 4 to 5 months of age, affected dogs and cats are obviously runts of the litter and do not attain full adult dimensions. Dwarfs with an isolated GH deficiency typically maintain a normal body contour and body proportions as they age (i.e., proportionate dwarfism), whereas dwarfs with combined deficiencies (most notably TSH) may acquire a square or chunky contour typically associated with congenital hypothyroidism (i.e., disproportionate dwarfism; Fig. 46.8).

The most notable dermatologic sign is retention of the lanugo, or secondary hairs, with concurrent lack of the primary or guard hairs. As a result, the haircoat in a dwarf is initially soft and woolly. The lanugo hairs are easily epilated, and a bilateral symmetric alopecia gradually develops in most dwarfs. Initially, hair loss is confined to areas of wear, such as the neck (collar) and posterolateral aspects of the thighs (from sitting). Eventually, the entire trunk, neck, and proximal limbs become alopecic, with primary hairs remaining only on the face and the distal extremities. The skin is initially normal but becomes hyperpigmented, thin, wrinkled, and scaly. Comedones, papules, and secondary pyoderma frequently develop in the adult dwarf. Secondary bacterial infections are common long-term complications.

Hypogonadism may also develop, although normal reproductive function has been observed in some animals with pituitary dwarfism. In the male animal, cryptorchidism, testicular atrophy, azoospermia, and a flaccid penile sheath are typical; in the female, persistent anestrus is common with impaired secretion of pituitary gonadotropins.

Clinical Pathology

Results of CBC, a serum biochemical panel, and urinalysis are usually normal in animals with uncomplicated pituitary dwarfism and isolated GH deficiency. Concurrent deficiency of TSH may result in clinicopathologic abnormalities affiliated with hypothyroidism, such as hypercholesterolemia and anemia (see Chapter 48). Deficiency of GH, IGF-1, and TSH may also affect kidney development and function, resulting in azotemia.

Shrill, puppy-like bark*
Signs of secondary hypothyroidism
Signs of secondary adrenal insufficiency (uncommon)

*Common findings.

Diagnosis

The signalment, history, and physical examination usually provide sufficient evidence for inclusion of pituitary dwarfism among the tentative diagnoses of short stature. Strong presumptive evidence can be obtained by ruling out other potential causes of small size (Box 46.5) after a thorough evaluation of the history and physical examination findings, results of routine laboratory studies (i.e., CBC, fecal examinations, serum biochemical panel, serum T_4 and TSH concentration, urinalysis), and radiographic studies (Fig. 46.9). Serum IGF-1 concentrations may be decreased or may be in the reference range in pituitary dwarfs. Because baseline

FIG 46.8

All of the pituitary dwarfs were presented with the primary owner complaint of failure of the pet to grow.

plasma GH concentrations may be low in healthy dogs and cats, a definitive diagnosis of hyposomatotropism has relied on documenting failure of plasma GH concentration to increase during a GH stimulation test using human GH-releasing hormone (GHRH), clonidine, or xylazine. Because a commercial GH assay is currently not available in the United States, a presumptive diagnosis of pituitary dwarfism is based on exclusion of other causes of failure to grow. A genetic test for the LHX3 gene is now available through the University of Utrecht and several other laboratories. GH testing is not necessary if a dwarf tests positive for the mutation.

Treatment

Treatment for pituitary dwarfism relies on the administration of GH. Unfortunately, an effective GH product is not available for use in dogs. Canine GH is not available for therapeutic use, GH antibody formation and legal restrictions preclude the use of biosynthetic human GH, and the concentration of biosynthetic bovine GH in commercial products for use in cattle precludes its use in dogs. The amino acid sequence of porcine GH is identical to that of canine GH, but porcine GH is difficult to find. If available, the recommended subcutaneous dose is 0.1 IU/kg three times per week for 4 to 6 weeks. Because of the synergistic

influence of GH and thyroid hormone on growth processes, subnormal concentrations of thyroid hormone may diminish the effectiveness of GH therapy. Dogs and cats with suspected concurrent TSH deficiency should be treated with daily thyroid hormone supplementation, as discussed in Chapter 48.

Hypersensitivity reactions and insulin resistance leading to diabetes mellitus are the primary adverse reactions associated with GH injections. An increase in height is dependent on the status of the growth plates at the time treatment is initiated. A significant increase in height may occur if the growth plates are open, and minimal to no change in height will occur if the growth plates have closed.

An increase in body size and regrowth of a complete haircoat have been reported in pituitary dwarfs treated with medroxyprogesterone acetate). Progestogens induce expression of the GH gene in the mammary gland of dogs, resulting in GH secretion from foci of hyperplastic ductular epithelial cells and increased plasma concentrations of GH and IGF-1. Adverse reactions associated with progestogen treatment include recurrent pruritic pyoderma, abnormal skeletal development, mammary tumors, diabetes mellitus, acromegaly, and cystic endometrial hyperplasia.

Prognosis

The prognosis for dogs with pituitary dwarfism is unpredictable and dependent on the severity of GH deficiency (i.e., partial or complete); the impact of GH deficiency on development of organ systems such as the skeletal, neuromuscular, and immune systems; presence and expansion of concurrent pituitary cyst; and the severity of changes to the skin that develop over time. In our experience, pituitary dwarf dogs have typically lived 3 to 6 years, with outliers living up to 10 years.

CHAPTER 47

Disorders of the Parathyroid Gland

CLASSIFICATION OF HYPERPARATHYROIDISM

Hyperparathyroidism is a sustained increase in parathyroid hormone (PTH) secretion. Chief cells located within the parathyroid gland synthesize and secrete PTH—a peptide hormone that controls the minute-to-minute concentration of ionized calcium in the blood and extracellular fluid (ECF). The major regulator of PTH secretion is the concentration of ionized calcium in the blood. Decreased serum ionized calcium increases PTH secretion and vice versa. PTH stimulates calcium absorption from the intestine, stimulates calcium reabsorption and inhibits phosphate reabsorption by the kidney, stimulates synthesis of the active form of vitamin D (calcitriol) in the kidney, and stimulates bone resorption. The net effect consists of increased serum ionized and total calcium concentrations, and decreased serum phosphorus concentration.

Hyperparathyroidism can result from a normal physiologic response to decreased serum ionized calcium concentrations (renal, nutritional, and adrenal secondary hyperparathyroidism) or from a pathologic condition caused by excessive synthesis and secretion of PTH by abnormal, autonomously functioning parathyroid chief cells (i.e., primary hyperparathyroidism [PHP]). In PHP increased secretion of PTH is maintained regardless of the serum ionized calcium concentration. Hypercalcemia and hypophosphatemia develop as a result of the physiologic actions of PTH.

In *renal secondary hyperparathyroidism,* renal failure causes retention of phosphorus, which in turn stimulates secretion of the phosphaturic hormone phosphatonin (fibroblast growth factor-23). Phosphatonin inhibits renal tubular 1α-hydroxylase activity, causing a relative deficiency of calcitriol (the most active form of vitamin D) and decreased intestinal calcium absorption. Retention of phosphorus also directly stimulates PTH secretion and promotes deposition of calcium phosphorus complexes in tissues. The decrease in serum ionized calcium, in turn, stimulates PTH secretion. The net effect consists of increased serum phosphate, normal to low serum ionized calcium, increased serum PTH, and decreased calcitriol concentrations as well as diffuse parathyroid gland hyperplasia. The etiogenesis of hyperparathyroidism is similar in *nutritional secondary hyperparathyroidism,* except that the decrease in calcium results from feeding diets low in calcium and vitamin D or excessive in phosphorus, such as the exclusive feeding of liver or beef heart. Chronic dietary calcium deficiency or phosphorus excess increases PTH secretion and induces parathyroid gland hyperplasia. Depletion of skeletal calcium leads to osteoporosis and pathologic bone fractures. An increase in serum PTH has been documented in dogs with hyperadrenocorticism and is believed to be a compensatory response to increased calcium loss and/or increased serum phosphorus concentrations—hence the term *adrenal secondary hyperparathyroidism.* Serum phosphorus and PTH decrease and serum calcium increases after successful treatment of hyperadrenocorticism.

PRIMARY HYPERPARATHYROIDISM

Etiology

PHP is a disorder resulting from the excessive, relatively uncontrolled secretion of PTH by one or more abnormal parathyroid glands. The physiologic actions of PTH ultimately cause hypercalcemia and hypophosphatemia (Table 47.1). It is an uncommon disorder in the dog and rare in the cat. Parathyroid adenoma is the most common histologic finding in dogs and cats, identified in approximately 80% of dogs and 70% of cats with PHP. Parathyroid carcinoma and parathyroid hyperplasia have also been described in dogs and cats. Parathyroid adenomas are typically small, well-encapsulated, light brown to red tumors located in close apposition to the thyroid gland (Fig. 47.1). The remaining parathyroid glands are normal, atrophied, or not visible at surgery. Parathyroid carcinomas grossly appear similar to adenomas; the diagnosis of carcinoma is based on the finding of certain histologic features such as capsular or vascular invasion by the tumor. The biologic behavior of parathyroid carcinoma is not well characterized in dogs and cats. Similarly, the histologic criteria for differentiating between adenoma and hyperplasia are not well established. Although

involvement of multiple parathyroid glands suggests hyperplasia, adenoma involving two parathyroid glands and hyperplasia involving only one gland have been identified in dogs with PHP. In addition, hyperplasia caused by renal and nutritional secondary hyperparathyroidism may not cause uniform enlargement of the parathyroid glands even though the stimulus for enlargement is presumably the same for each gland. Differentiating hyperplasia from adenoma has important prognostic implications. The surgical removal of parathyroid adenoma(s) results in a cure, if at least one normal parathyroid gland remains to prevent hypoparathyroidism. In contrast, hypercalcemia caused by parathyroid hyperplasia may persist or recur weeks to months after surgery if the remaining grossly normal-appearing parathyroid tissue is hyperplastic at the time of surgery or becomes hyperplastic in the future.

SIGNALMENT

The age at which clinical signs of PHP appear in dogs ranges from 4 to 16 years, with a mean age of 10 years. No sex-related predilection has been noted. Any breed of dog and mixed-breeds can be affected, although PHP is most commonly diagnosed in the Keeshond and is an autosomal dominant, genetically transmitted disease in this breed. The age at the time of diagnosis of PHP in cats has ranged from 8 to 20 years, with a mean age of 13 years. Most affected cats have been mixed breed and Siamese. No apparent sex predisposition has been reported.

CLINICAL SIGNS

Clinical signs of PHP result from the physiologic actions of excessive PTH secretion rather than from the space-occupying nature of the tumor. Clinical signs are caused by hypercalcemia, which is the hallmark of this disorder, and by the presence of cystic calculi and lower urinary tract infection, which are consequences of the hypercalcemia. Clinical signs are absent in most dogs and cats with the mildest form of PHP, and hypercalcemia is discovered only after a serum biochemistry panel is performed, often for unrelated reasons. When clinical signs do develop, they initially tend to be nonspecific and insidious in onset. Clinical signs in dogs are typically renal, gastrointestinal, and neuromuscular in origin (Box 47.1). The most common clinical signs in cats with PHP are lethargy, anorexia, and vomiting. Less common clinical signs in cats include constipation, polyuria, polydipsia, and weight loss.

PHYSICAL EXAMINATION

The physical examination is usually normal, which is an important diagnostic finding when dogs with PHP are differentiated from dogs with hypercalcemia of malignancy (see Chapter 53). Lethargy, generalized muscle atrophy, weakness, and cystic calculi (calcium phosphate, calcium oxalate, or both types) may be noted in some dogs with PHP. The severity of weakness is variable, but it is usually subtle. Cervical palpation of a parathyroid mass is rare in dogs with PHP. If a mass is palpated in the neck of a dog with hypercalcemia, then thyroid gland carcinoma, squamous cell carcinoma, lymphoma, and, least likely, parathyroid gland carcinoma should be considered. In contrast, cats with PHP often have a palpable parathyroid mass that is typically located in the region of the thyroid gland. Therefore a palpable mass in the ventral cervical region of the neck should raise suspicion for hyperthyroidism (common) as well as PHP (rare) in cats.

Diagnosis

PHP should be suspected in a dog or cat with persistent hypercalcemia and normophosphatemia to hypophosphatemia. The serum calcium concentration is typically 12 to 15 mg/dL but can exceed 16 mg/dL (reference range, 9.0-11.7 mg/dL [dog]; 8.0-10.5 mg/dL [cat]). The serum ionized calcium concentration is typically 1.4 to 1.8 mmol/L but can exceed 2.0 mmol/L (reference range, 1.1-1.4 mmol/L for dog and cat). The serum phosphorus concentration is typically less than 4 mg/dL, unless concurrent renal insufficiency is present. Although hypercalcemia in dogs and cats has several causes (Table 47.2), the primary differential diagnoses for hypercalcemia and hypophosphatemia are humoral hypercalcemia of malignancy (most notably lymphoma in dogs and carcinomas in cats) and PHP (see Chapter 53). The history, findings on physical examination, results of routine blood and urine tests, thoracic radiographs, abdominal and cervical ultrasound, and measurement of PTH and parathyroid hormone–related peptide (PTHrP) will usually establish the diagnosis. With PHP, clinical signs are usually mild to absent, the physical examination is normal, and results of routine blood tests, thoracic and abdominal radiography, and abdominal ultrasonography are unremarkable, except for hypercalcemia, hypophosphatemia, and cystic calculi. Additional tests used to identify lymphoma as the cause of hypercalcemia (i.e., cytologic evaluations of bone marrow, lymph node, liver, and splenic aspirates and PTHrP concentrations) are normal in dogs with PHP.

Renal failure in a dog with hypercalcemia can create a diagnostic dilemma. Fortunately, development of hypercalcemia-induced renal failure rarely occurs in dogs with PHP. Prolonged severe hypercalcemia may cause progressive nephrocalcinosis, renal damage, and azotemia, but most dogs with PHP have mild hypercalcemia and concurrent hypophosphatemia; the latter protects the kidney by keeping the calcium × phosphorus product less than 50.

Measurement of serum ionized calcium concentration will help reveal the cause of hypercalcemia in dogs with concurrent renal failure. Serum ionized calcium concentration is typically normal in dogs with renal failure–induced hypercalcemia and is increased in dogs with PHP and concurrent renal failure. Urine specific gravity usually is not helpful when renal function in dogs with hypercalcemia is assessed, because of the interference of calcium with the actions of vasopressin on renal tubular cells. Urine specific gravities less than 1.015 are common in dogs with PHP. Hematuria, pyuria, bacteriuria, and crystalluria may be identified if cystic calculi and secondary bacterial cystitis develop. Hypercalciuria, proximal renal tubular acidosis with impaired bicarbonate resorption, and the production of alkaline urine may predispose dogs to the development of cystic or renal calculi and bacterial cystitis. In one study, urinary tract infection was identified in 29% and cystic calculi in 31% of 210 dogs with PHP (Feldman et al., 2005). Uroliths are typically composed of calcium phosphate, calcium oxalate, or mixtures of the two salts.

Cervical ultrasound should identify one or more enlarged parathyroid glands in dogs and cats with PHP (Fig. 47.2) and (Video 47.1). The parathyroid glands of healthy dogs are typically 3 mm or less in maximum width when visualized ultrasonographically. The maximum width of the abnormal parathyroid glands ranged from 3 to 23 mm (median, 6 mm) in 130 dogs with PHP (Feldman et al., 2005). A solitary parathyroid mass was identified in 89%, and two parathyroid masses were identified in 10%, of the dogs.

Measurement of baseline serum PTH concentration is used to establish the diagnosis of PHP. The two-site immunoradiometric assay (IRMA) system is currently used by most veterinary laboratories and is considered the most reliable assay system for PTH quantification in dogs and cats. In the United States, serum PTH concentrations are usually measured at the Diagnostic Center for Population and Animal Health, Michigan State University East Lansing, Mich; www.dcpah.msu.edu, and the current PTH reference ranges for dogs and cats are 0.5 to 5.8 pmol/L and 0 to 4.0 pmol/L, respectively. The major regulator of

TABLE 47.2

Causes of Hypercalcemia in Dogs and Cats

DISORDER	TESTS TO HELP ESTABLISH THE DIAGNOSIS
Primary hyperparathyroidism*	Serum PTH concentration, cervical ultrasound, surgery
Hypercalcemia of malignancy* Humorally mediated: LSA, apocrine gland adenocarcinoma, carcinoma (nasal, mammary gland, gastric, thyroid, pancreatic, pulmonary), thymoma Locally osteolytic (multiple myeloma, LSA, squamous cell carcinoma, osteosarcoma, fibrosarcoma)	Physical examination; thoracic and abdominal radiography; abdominal ultrasonography; aspiration of lymph nodes, liver, spleen, and bone marrow; serum PTHrP
Hypervitaminosis D* Cholecalciferol rodenticides, plants *(Cestrum diurnum)* Excessive supplementation	History, serum biochemistry panel, serum vitamin D concentration
Hypoadrenocorticism*	Serum electrolytes, ACTH stimulation test
Renal failure (especially chronic)*	Serum biochemistry panel, urinalysis
Idiopathic*—cats	Rule out by exclusion
Granulomatous disease (uncommon) Systemic mycosis—blastomycosis, histoplasmosis, coccidioidomycosis Schistosomiasis, FIP	Thoracic radiography, abdominal ultrasonography, fundic examination, cytologic studies of pulmonary wash samples or intestinal biopsy specimens, serum fungal titers
Nonmalignant skeletal disorder (rare) Osteomyelitis Hypertrophic osteodystrophy	Radiography of peripheral skeleton
Iatrogenic disorder Excessive calcium supplementation Excessive oral phosphate binders Grape/raisin toxicity Anti-psoriasis cream (calcipotriol)	History

*Common causes.

PTH secretion is the concentration of ionized calcium in the blood. Decreased serum ionized calcium increases PTH secretion and vice versa. Serum PTH test results should always be interpreted in conjunction with serum calcium or, preferably, with serum ionized calcium measured from the same blood sample. If the parathyroid gland is functioning normally, the serum PTH concentration should be below the reference range or undetectable in the face of hypercalcemia because of the inhibitory effects of an increased serum calcium concentration on parathyroid gland function. Dogs with non–parathyroid-induced hypercalcemia should also have low to undetectable serum PTH concentrations. Serum PTH concentration within or above the reference range is inappropriate in the face of hypercalcemia and is indicative of an autonomously functioning parathyroid gland (Fig. 47.3). Among 185 dogs with PHP, none had serum PTH concentration below the reference range (2-13 pmol/L at the time of the study), 45% were in the lower half of the reference range (2.3-7.9 pmol/L), 28% were in the upper half of the reference range (8.0-13.0 pmol/L), and 27% had increased serum PTH concentrations (13-121 pmol/L; Feldman et al., 2005).

Treatment

(See Chapter 53 for details on the medical treatment of hypercalcemia in dogs and cats.)

Surgical removal of the abnormal parathyroid tissue is the treatment of choice. Johnston and Tobias (2018) have adequately described surgical techniques for the thyroparathyroid complex (see Suggested Readings). Almost all dogs

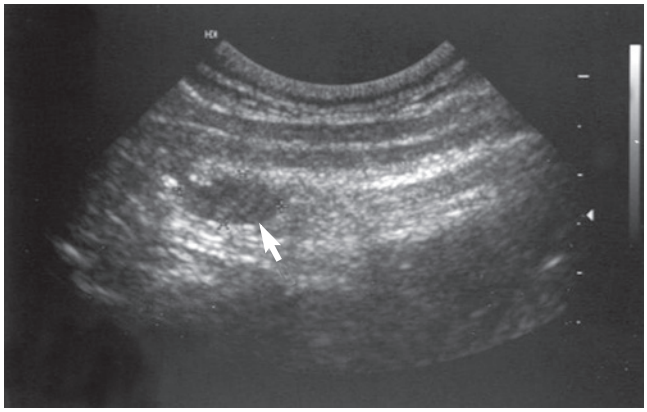

FIG 47.2
Ultrasound image of the right thyroid lobe of a 13-year-old Labrador Retriever with hypercalcemia and primary hyperparathyroidism. A hypoechoic mass is seen in the region of the parathyroid gland *(arrow)*. Hypercalcemia resolved after heat ablation of the parathyroid mass.

and cats with PHP have a solitary, easily identified parathyroid adenoma (see Fig. 47.1). Enlargement of more than one parathyroid gland indicates the presence of multiple adenomas or parathyroid hyperplasia. If none of the parathyroid glands appears enlarged, or if all appear small, the diagnosis of PHP must be questioned, and hypercalcemia stemming from occult neoplasia or PTH production by a parathyroid tumor in an ectopic site (often located in the soft tissues near the thyroid gland) or by a nonparathyroid tumor should be considered.

Chemical (i.e., ethanol) or radiofrequency heat ablation of abnormal parathyroid tissue performed under ultrasound guidance is effective treatment for PHP (Fig. 47.4). Surgery is avoided, anesthetic time is significantly reduced, and no incisions or issues related to wound healing are involved. However, management of the dog after chemical or heat ablation is identical to management after surgical removal of the parathyroid nodule. In one retrospective study, surgical removal, heat ablation, and chemical ablation of the

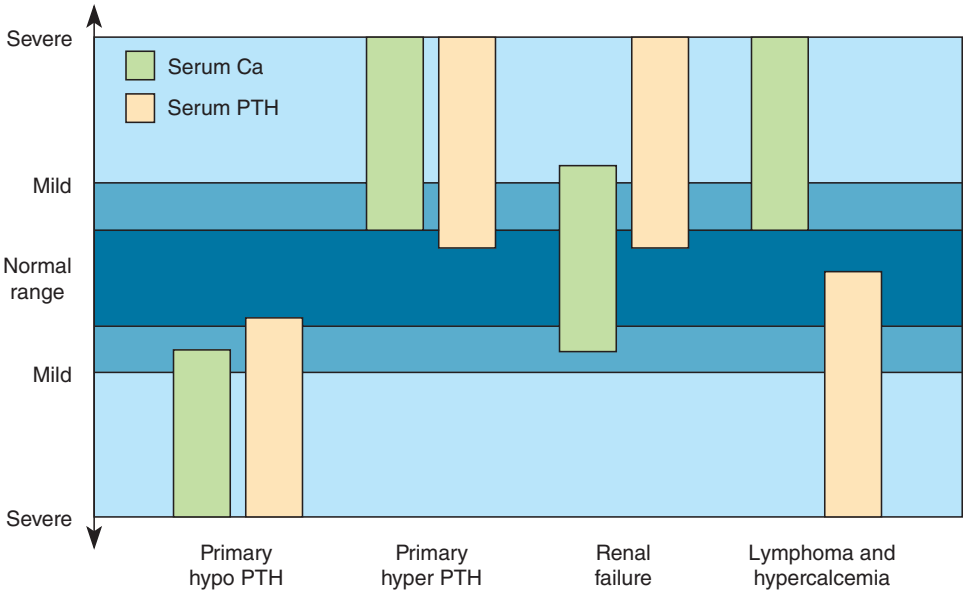

FIG 47.3

parathyroid nodule were successful in controlling hypercalcemia in 94%, 90%, and 72% of dogs treated for PHP, respectively (Rasor et al., 2007). Not all dogs are candidates for chemical or heat ablation. Surgery is indicated if more than one parathyroid nodule is identified with cervical ultrasound, the parathyroid nodule is less than 4 mm or greater than 15 mm in maximum width, a parathyroid nodule is not identified, the parathyroid nodule is too close to the carotid artery, or cystic calculi are identified with abdominal radiographs or ultrasound. Ablation of a parathyroid nodule is also difficult in dogs with concurrent hypothyroidism and loss of thyroid parenchyma that provides resistance to the movement of the parathyroid nodule.

An attempt must be made to ensure that at least one parathyroid gland remains intact to maintain calcium homeostasis and prevent permanent hypocalcemia. Removal or ablation of the parathyroid nodule results in a rapid decline in circulating PTH and a decrease in serum calcium. In the early stages of PHP, the remaining parathyroid glands may secrete PTH in response to the decrease in serum calcium, thereby preventing development of severe hypocalcemia. In dogs with more advanced PHP, atrophy of the normal parathyroid glands may prevent a response to the decrease in serum calcium, leading to severe hypocalcemia and clinical signs typically within 2 to 4 days of surgery or ablation. In these dogs intravenous and oral calcium, and oral vitamin D therapy must be initiated to correct and/or prevent hypocalcemia.

Two approaches may be used in managing the dog before and after the parathyroid nodule has been removed with surgery or ablation. One approach is to treat dogs with oral calcium and calcitriol (the most active form of vitamin D) beginning 24 hours before surgical removal or ablation of the parathyroid nodule. Another approach is to treat dogs with oral calcium while withholding calcitriol therapy until the serum calcium concentration decreases to below an arbitrarily designated concentration—typically a serum calcium or ionized calcium concentration of 9.0 mg/dL or 0.9 mmol/L, respectively—and before clinical signs of hypocalcemia develop. The hope with the latter approach is that the remaining parathyroid glands will secrete enough PTH to prevent hypocalcemia, reestablish normal serum calcium concentration, and avoid the expense of vitamin D therapy and its subsequent gradual withdrawal and monitoring over several months.

Unfortunately there are no reliable predictors for identifying which dogs do and do not need calcitriol after surgery or ablation. We rely most heavily on the severity of hypercalcemia and the duration of hypercalcemia, if known. The longer the duration of hypercalcemia and the higher the serum calcium concentration, the more likely we are to start calcitriol therapy the day before surgery or ablation. As a general rule, we do not initially treat hyperparathyroid dogs with calcitriol if the serum calcium or ionized calcium concentration before surgery or ablation is less than 14 mg/dL or 1.6 mmol/L, respectively. Serum calcium or ionized calcium concentrations greater than 14 mg/dL and 1.6 mmol/L, respectively, and hypercalcemia known to be present for longer than 3 months suggest the existence of significant atrophy of the remaining parathyroid glands and a high probability for the development of signs of hypocalcemia after surgery or ablation. In these dogs oral calcium (dairy products and supplements) and calcitriol therapy are started 24 hours before the time that treatment for PHP is provided. Regardless of which approach is taken, the diet should be supplemented with calcium-rich foods (e.g., dairy products), oral calcium tablets should be administered, exercise restricted, and serum total or ionized calcium should be monitored once or twice a day until the serum calcium concentration is stable and in the reference range.

Therapy for hypocalcemia includes the administration of intravenous calcium to control immediate clinical signs and the long-term oral administration of calcium and vitamin D supplements to maintain low-normal blood calcium concentrations while the parathyroid gland atrophy resolves. (See Chapter 53 and Box 53.7 for details about the management of hypocalcemia.) The goal of calcium and vitamin D therapy is to maintain the serum calcium concentration within the lower end of the reference range (9.5-10.5 mg/dL). Maintaining the serum calcium concentration in the lower end of the reference range prevents the development of clinical signs of hypocalcemia, minimizes the risk of hypercalcemia, and stimulates a return of function in the remaining atrophied parathyroid glands. Once the parathyroid glands regain control of calcium homeostasis and the serum calcium concentration is stable in the dog or cat in the home environment, calcium and vitamin D supplements can be gradually withdrawn over a period of 3 to 4 months. This gradual withdrawal allows time for the parathyroid glands to become fully functional, thereby preventing hypocalcemia. Vitamin D therapy is withdrawn by gradually increasing the number of days between administrations. The dosing interval should be increased by 1 day every 2 to 3 weeks, after the serum calcium concentration has been measured and found to be 9.5 mg/dL or greater. Vitamin D therapy can be discontinued once the dog or cat is clinically normal, the serum calcium concentration is stable between 9.5 and 11.5 mg/dL, and the vitamin D dosing interval is every 6 to 7 days.

Prognosis

The prognosis for dogs and cats undergoing surgical or ablation therapy for PHP is excellent, assuming severe hypocalcemia is avoided postoperatively and PHP is caused by a parathyroid adenoma. Hypercalcemia may recur weeks to months after surgery in dogs and cats with PHP caused by parathyroid hyperplasia, if one or more parathyroid glands have been left in situ.

PRIMARY HYPOPARATHYROIDISM

Etiology

Primary hypoparathyroidism develops as a result of an absolute or relative deficiency in the secretion of PTH. This

deficiency ultimately causes hypocalcemia and hyperphosphatemia resulting from loss of the effects of PTH on bone, kidney, and intestine (see Table 47.1). The major signs of hypoparathyroidism are directly attributable to the decreased concentration of ionized calcium in the blood, which leads to increased neuromuscular activity.

Spontaneous primary hypoparathyroidism is uncommon in dogs and cats. Most cases are classified as idiopathic (i.e., there is no evidence of trauma, malignant or surgical destruction, or other obvious damage to the neck or parathyroid glands). The glands are difficult to locate visually and show microscopic evidence of atrophy. Histologic evaluation of the parathyroid gland may reveal a diffuse lymphocytic, plasmacytic infiltration and fibrous connective tissue, suggesting an underlying immune-mediated cause of the disorder.

Iatrogenic hypoparathyroidism after performance of bilateral thyroidectomy for the treatment of hyperthyroidism is common in cats. The parathyroid tissue in such animals may be excised or traumatized, or its blood supply may be compromised during surgery. This form of hypoparathyroidism may be transient or permanent, depending on the viability of the parathyroid gland or glands saved at the time of surgery. Only one viable parathyroid gland is needed to maintain a normal serum calcium concentration.

Transient hypoparathyroidism may develop secondary to severe magnesium depletion (serum magnesium concentration < 1.2 mg/dL). Severe magnesium depletion may suppress PTH secretion without parathyroid destruction, increase end-organ resistance to PTH, and impair the synthesis of the active form of vitamin D (i.e., calcitriol). The end result is mild hypocalcemia and hyperphosphatemia. Magnesium repletion reverses the hypoparathyroidism. Serum magnesium concentrations in dogs and cats with spontaneous primary hypoparathyroidism usually have been normal when measured. (See Chapter 53 for more information on magnesium.)

Clinical Features

SIGNALMENT

The age at which the clinical signs of hypoparathyroidism appear in dogs ranges from 6 weeks to 13 years, with a mean of 5 years. A sex-related predisposition may be present in female dogs. No apparent breed-related predisposition has been noted, although Toy Poodles, German Shepherd dogs, Labrador Retrievers, Miniature Schnauzers, and Terriers are commonly affected. However, this increased prevalence may merely reflect the popularity of these breeds. Only a few cases of naturally acquired primary hypoparathyroidism in cats have been reported. To date, most of these cats have been young to middle-aged (range, 6 months to 11 years), of several breeds, and usually male.

CLINICAL SIGNS

Clinical signs and physical examination findings in dogs and cats with primary hypoparathyroidism are similar. The major clinical signs are directly attributable to hypocalcemia, most notably its effects on the neuromuscular system. Neuromuscular signs include muscle tremors and twitching, tetany, rear limb muscle cramping, pain, stiff gait, and generalized seizures. Additional clinical signs include nervous or anxious behavior, weakness, facial rubbing, and intense biting or licking of the paws (Box 47.2). The onset of clinical signs tends to be abrupt and severe and to occur more frequently during exercise, excitement, and stress. Clinical signs also tend to occur episodically. Episodes of clinical hypocalcemia are interspersed with relatively normal periods, lasting minutes to days. Hypocalcemia persists during these clinically "normal" periods.

PHYSICAL EXAMINATION

The most common physical examination findings are related to muscular tetany and include a stiff gait; muscle rigidity; a tense, splinted abdomen; and muscle fasciculations. Fever, panting, and nervousness are also common. Potential cardiac abnormalities include bradycardia, paroxysmal tachyarrhythmias, muffled heart sounds, and weak femoral pulses. In a few dogs and cats with primary hypoparathyroidism, cataracts were noted as small, punctate to linear, white opacities that were randomly distributed in the anterior and posterior cortical subcapsular region of the lens; no loss of vision was noted. The physical examination is occasionally normal, despite the previous history of neuromuscular disorders.

Diagnosis

Primary hypoparathyroidism should be suspected in a dog or cat with persistent hypocalcemia, hyperphosphatemia, and normal kidney function. The serum calcium concentration is usually less than 7 mg/dL, serum ionized calcium is usually less than 0.8 mmol/L, and serum phosphorus is usually greater than 6 mg/dL. Low serum calcium and high serum phosphorus concentrations can also be encountered during nutritional and renal secondary hyperparathyroidism, after phosphate-containing enema, and during tumor

lysis syndrome. (See Chapter 53 for more information on causes of hypocalcemia and hyperphosphatemia in dogs and cats.) The diagnosis of primary hypoparathyroidism is established by identifying an undetectable serum PTH concentration in the face of severe hypocalcemia in a dog or cat in which other causes of hypocalcemia have been ruled out (Table 47.3). Most causes of hypocalcemia can be identified after evaluation of the history, findings on physical examination, and results of routine blood and urine tests and review of an abdominal ultrasound. The history and physical examination findings are essentially unremarkable in dogs and cats with primary hypoparathyroidism, other than those findings caused by hypocalcemia. The only relevant abnormalities identified on routine blood and urine tests are severe hypocalcemia and, in most dogs and cats, hyperphosphatemia. Serum total protein, albumin, urea nitrogen, creatinine, and magnesium concentrations are normal. Abdominal ultrasound is also normal.

TABLE 47.3

Causes of Hypocalcemia in Dogs and Cats

DISORDER	TESTS TO HELP ESTABLISH THE DIAGNOSIS
Primary hypoparathyroidism Idiopathic Postthyroidectomy	History, serum PTH concentration, rule out other causes
Puerperal tetany	History
Renal failure Acute Chronic	Serum biochemistry panel, urinalysis
Ethylene glycol toxicity	History, urinalysis
Acute pancreatitis	Physical findings, abdominal ultrasound, serum cPLI (dog), fPLI (cat)
Sepsis, systemic inflammatory response syndrome (SIRS)	History, physical findings, CBC
Intestinal malabsorption syndromes	History, digestion and absorption tests, intestinal biopsy
Hypoproteinemia or hypoalbuminemia	Serum biochemistry panel
Hypomagnesemia	Serum total and ionized Mg
Diabetic ketoacidosis	Serum biochemistry panel, urinalysis
Nutritional secondary hyperparathyroidism	Dietary history
Hypovitaminosis D (rickets)	History
Soft tissue trauma/ rhabdomyolysis	History
Tumor lysis syndrome	History
Phosphate-containing enemas	History
Anticonvulsant medications	History
$NaHCO_3$ administration	History
Laboratory error	Repeat calcium measurement

CBC, Complete blood count; *cPLI,* canine pancreatic lipase immunoreactivity; *fPLI,* feline pancreatic lipase immunoreactivity; *Mg,* magnesium; *$NaHCO_3$,* sodium bicarbonate; *PTH,* parathyroid hormone.

Measurement of serum PTH concentration helps confirm a diagnosis of primary hypoparathyroidism. Blood for PTH determination should be obtained before the initiation of calcium and vitamin D therapy, while the animal is still hypocalcemic. The two-site IRMA system is currently used by most veterinary laboratories and is considered the most reliable assay system for PTH quantification in dogs and cats. Serum PTH concentration must be interpreted in conjunction with the serum calcium concentration. If the parathyroid gland is functioning normally, the serum PTH concentration should be increased in the face of hypocalcemia because of the stimulatory effects of a decreased serum ionized calcium concentration on parathyroid gland function. A low to undetectable serum PTH concentration in a hypocalcemic dog or cat is strongly suggestive of primary hypoparathyroidism (see Fig. 47.3). A serum PTH concentration at the lower end of the reference range is inappropriate in the presence of severe hypocalcemia and also supports primary hypoparathyroidism. Dogs and cats with non–parathyroid-induced hypocalcemia should have normal or high serum PTH concentrations; the exceptions are those with disorders causing severe hypomagnesemia (see Chapter 53 for causes of hypomagnesemia).

Treatment

Treatment for primary hypoparathyroidism involves the administration of vitamin D and calcium supplements (see Chapter 53 and Box 53.7). Therapy is typically divided into two phases. The first phase (i.e., acute therapy) should initially control hypocalcemic tetany and involves the slow administration of 10% calcium gluconate (not calcium chloride) intravenously, to effect. Once clinical signs of hypocalcemia are controlled, calcium gluconate should then be administered by continuous intravenous infusion until orally administered calcium and vitamin D therapy (i.e., second phase of therapy) becomes effective. A solution of 10% calcium gluconate contains 9.3 mg Ca/mL and is initially administered IV at an initial dose of 0.5 to 1.5 mL/kg body weight added to the infusion solution. Calcium should not be added to solutions containing lactate, bicarbonate, acetate, or phosphates because of the potential for precipitation problems. Serum calcium concentrations should be monitored frequently and the rate of infusion adjusted as needed to control clinical signs and maintain the serum calcium concentration between 8 and 10 mg/dL.

The second phase of therapy (i.e., maintenance therapy) should maintain the blood calcium concentration between 8 and 10 mg/dL through daily administration of vitamin D

and calcium. These calcium concentrations are above the level at which there is risk of clinical hypocalcemia and below the level at which hypercalciuria (risk of calculi formation) or severe hypercalcemia and hyperphosphatemia (risk of nephrocalcinosis and kidney failure) may occur. Maintenance therapy should be initiated once the hypocalcemic tetany is controlled with intravenous calcium therapy. The onset of action of vitamin D varies depending on the formulation of vitamin D that is administered. 1,25-dihydroxyvitamin D_3 (calcitriol) has the fastest onset of action and is preferred for treating hypoparathyroidism. The initial dosage of calcitriol is 20 to 30 ng/kg/day. Dogs and cats should ideally remain hospitalized until their serum calcium concentration remains between 8 and 10 mg/dL without parenteral support. Serum calcium concentrations should be monitored weekly, and the vitamin D dose should be adjusted to maintain a serum calcium concentration of 8 to 10 mg/dL. The aim of therapy is to prevent hypocalcemic tetany—not to induce hypercalcemia. Serum calcium concentrations greater than 10 mg/dL are unnecessary to prevent tetany and increase the likelihood of unwanted hypercalcemia.

Once the serum calcium concentration has stabilized, attempts can be made to slowly taper the dose of oral calcium and then vitamin D to the lowest dose that maintains the serum calcium concentration at between 8 and 10 mg/dL. Vitamin D is critical for establishing and maintaining a normal blood calcium concentration. Most dogs and cats with primary hypoparathyroidism require permanent vitamin D therapy. The calcium supplement often can be gradually tapered over a period of 2 to 4 months and then stopped once the animal's serum calcium concentration is stable at between 8 and 10 mg/dL. Calcium in the diet is often sufficient for meeting the calcium needs of the animal. Supplementing the diet with calcium-rich foods (e.g., dairy products) helps ensure an adequate source of dietary calcium. Once the animal's serum calcium concentration is stable and maintenance therapy has become established, reevaluation of the serum calcium concentration every 3 to 4 months is advisable.

Prognosis

The prognosis depends on the dedication of the client. The prognosis is excellent if proper therapy is instituted and timely reevaluations are performed. Proper management requires close monitoring of the serum calcium concentration. The more frequent the rechecks, the better the chance of preventing extremes in the concentration, and the better the chance of a normal life expectancy.

CHAPTER 48

Disorders of the Thyroid Gland

HYPOTHYROIDISM IN DOGS

Etiology

Structural or functional abnormalities of the thyroid gland can lead to deficient production of thyroid hormones. A convenient classification scheme for hypothyroidism has been devised based on the location of the problem within the hypothalamic-pituitary-thyroid gland complex (Fig. 48.1). Primary hypothyroidism is the most common form of this disorder in dogs; it results from problems within the thyroid gland, usually destruction of the thyroid gland (Box 48.1). The two most common histologic findings in this disorder are lymphocytic thyroiditis and idiopathic atrophy of the thyroid gland (Fig. 48.2). Lymphocytic thyroiditis is an immune-mediated disorder characterized by a diffuse infiltration of lymphocytes, plasma cells, and macrophages into the thyroid gland. The factors that trigger the development of lymphocytic thyroiditis are poorly understood. Genetics undoubtedly plays a major role, especially given the increased incidence of this disorder in certain breeds and in certain lines within a breed (Table 48.1). Environmental risk factors have not been well defined in the dog. A link between infection-induced damage to the thyroid gland and development of lymphocytic thyroiditis has been the subject of speculation but has not been proven. Vaccine administration has been hypothesized to be a contributing factor to the development of lymphocytic thyroiditis, but this also has not been proven.

Destruction of the thyroid gland is progressive, and clinical signs may not become evident until more than 80% of the gland is destroyed. Development of decreased serum thyroid hormone concentrations and clinical signs is usually a gradual process, often requiring 1 to 3 years, which suggests that the destructive process is slow.

Idiopathic atrophy of the thyroid gland is characterized by loss of the thyroid parenchyma. There is no inflammatory infiltrate, even in areas where small follicles or follicular remnants are present in the thyroid gland. Tests for lymphocytic thyroiditis are negative. The cause of idiopathic thyroid atrophy is not known. It may be a primary degenerative disorder or may represent an end stage of autoimmune lymphocytic thyroiditis. There are no blood tests that establish the diagnosis of idiopathic atrophy; it is a diagnosis by exclusion.

Secondary hypothyroidism results from failure of pituitary thyrotrophs to develop (pituitary hypoplasia causing pituitary dwarfism; see Chapter 46) or from dysfunction within the pituitary thyrotropic cells, causing impaired secretion of thyroid-stimulating hormone (TSH) and a "secondary" deficiency in thyroid hormone synthesis and secretion. Follicular atrophy in the thyroid gland gradually develops as the result of lack of TSH. Secondary hypothyroidism could also result from destruction of pituitary thyrotrops (e.g., pituitary neoplasia [rare]) or from suppression of thyrotroph function by hormones or drugs (e.g., glucocorticoids [common]; see Box 48.1).

Tertiary hypothyroidism is a deficiency in the secretion of thyrotropin-releasing hormone (TRH) by peptidergic neurons in the supraoptic and paraventricular nuclei of the hypothalamus. Neoplastic infiltration of the hypothalamus is the only recognized cause in dogs, to date. Lack of TRH secretion results in deficient TSH secretion and secondary follicular atrophy in the thyroid gland.

Congenital primary hypothyroidism is uncommon in dogs and has been caused by deficient dietary iodine intake, dyshormonogenesis (i.e., usually an iodine organification defect), and thyroid hypoplasia, aplasia, and dysgenesis. Secondary hypothyroidism resulting from an apparent deficiency of TSH has also been reported in a family of Giant Schnauzers and in a Boxer. Pedigree analysis showed that it may be inherited in an autosomal recessive fashion in the family of Giant Schnauzers (Voorbijj et al., 2016). Secondary hypothyroidism may be genetic in Miniature Schnauzers (Voorbijj et al., 2016). Development of an enlarged thyroid gland (i.e., goiter) depends on the etiology. If the hypothalamic-pituitary-thyroid gland axis is intact, TSH receptors are functional, and signal transduction is appropriate (e.g., as occurs with an iodine organification defect), goiter will develop as a result of increased serum TSH concentrations. Goiter does not develop if there are problems

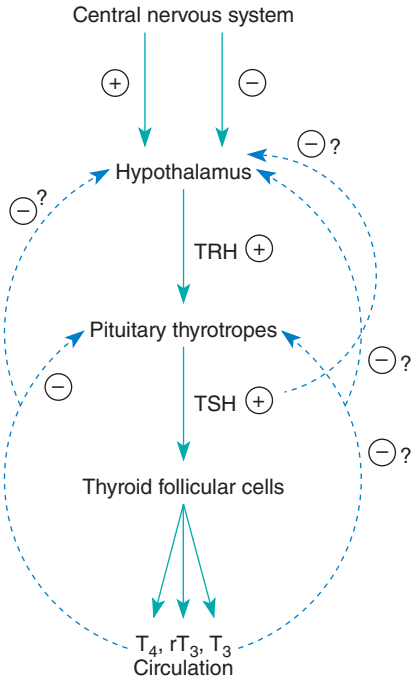

FIG 48.1

with the hypothalamic-pituitary-thyroid gland axis, TSH receptors, or signal transduction (e.g., as occurs with pituitary TSH deficiency).

Clinical Features

Clinical signs of the more common forms of primary hypothyroidism usually develop during middle age (i.e., 2-6 years). Clinical signs tend to develop at an earlier age in breeds at increased risk than in other breeds (see Table 48.1). No sex-related predilection is apparent.

Clinical signs are variable and depend in part on the age of the dog at the time a deficiency in thyroid hormone develops (Box 48.2). Clinical signs may differ between breeds. For example, truncal alopecia may dominate in some breeds, whereas thinning of the haircoat may dominate in other breeds. In adult dogs the most consistent clinical signs of hypothyroidism result from decreased cellular metabolism and its effects on the dog's mental status and activity. Most dogs with hypothyroidism show some mental dullness, lethargy, exercise intolerance or unwillingness to exercise, and a propensity to gain weight without a corresponding increase in appetite or food intake. These signs are often gradual in onset, subtle, and not recognized by the client until after thyroid hormone supplementation has been initiated. Additional clinical signs of hypothyroidism typically involve the skin and, less commonly, the neuromuscular system.

BOX 48.1

Potential Causes of Hypothyroidism in Dogs

Primary Hypothyroidism

Lymphocytic thyroiditis
Idiopathic atrophy
Neoplastic destruction
Iodine deficiency
Iatrogenic causes
- Surgical removal
- Antithyroid medications
- Radioactive iodine treatment
- Drugs (e.g., sulfamethoxazole)

Secondary Hypothyroidism

Pituitary malformation
- Pituitary cyst
- Pituitary hypoplasia

Pituitary destruction
- Neoplasia

Pituitary thyrotropic cell suppression
- Naturally acquired hyperadrenocorticism
- Nonthyroidal illness syndrome (Euthyroid sick syndrome)

Iatrogenic causes
- Drug therapy, most notably glucocorticoids
- Radiation therapy
- Hypophysectomy

Tertiary Hypothyroidism

Congenital hypothalamic malformation (?)
Acquired destruction of hypothalamus (?)

Congenital Hypothyroidism

Thyroid gland dysgenesis (aplasia, hypoplasia, ectasia)
Dyshormonogenesis: iodine organification defect
Deficient dietary iodine intake

DERMATOLOGIC SIGNS

Alterations in the skin and haircoat are the most common observable abnormalities in dogs with hypothyroidism. Classic cutaneous signs include bilaterally symmetric, nonpruritic truncal alopecia that tends to spare the head and the extremities (Fig. 48.3). Alopecia may be local or generalized and symmetric or asymmetric, it may involve only the tail (i.e., "rat tail"), and it often starts over sites of wear and friction. Although nonpruritic endocrine alopecia is not pathognomonic for hypothyroidism (see Chapter 46), hypothyroidism is certainly the most likely diagnosis in an affected dog with lethargy, weight gain, and no polyuria-polydipsia.

Seborrhea and pyoderma are common signs of hypothyroidism. Depletion of thyroid hormone suppresses humoral immune reactions, impairs T-cell function, and reduces the number of circulating lymphocytes—defects that can be reversed by exogenous thyroid hormone therapy. All forms of seborrhea (i.e., sicca, oleosa, dermatitis) are possible.

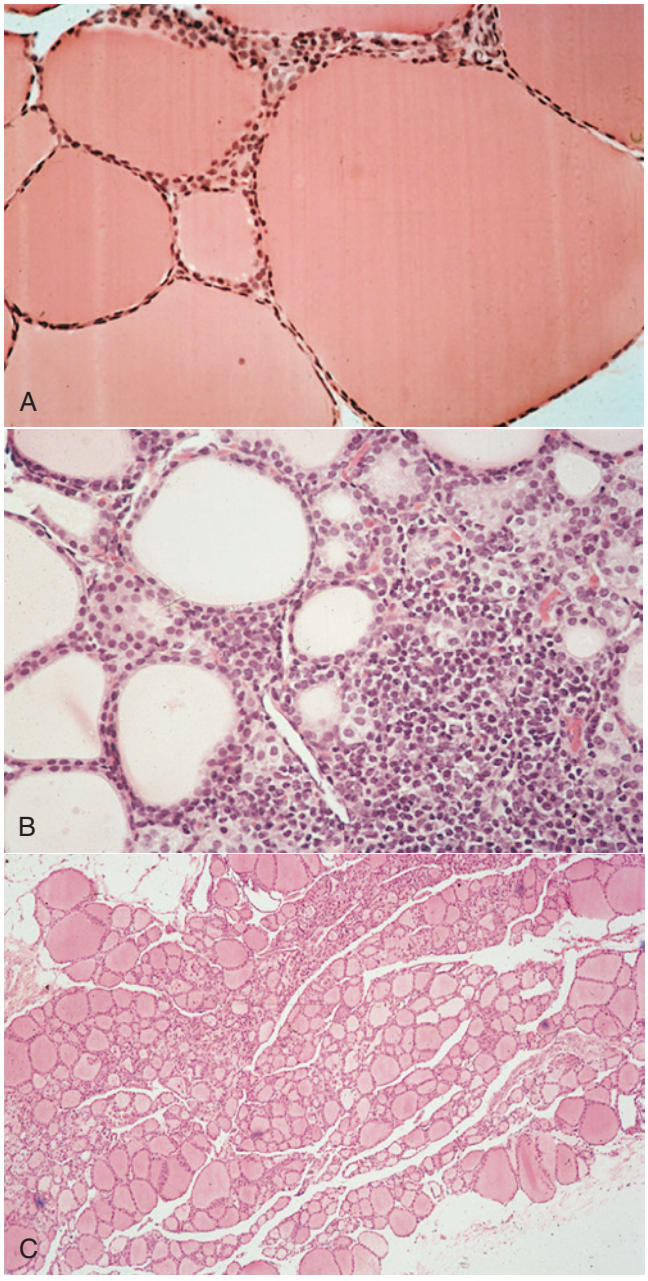

FIG 48.2

*Odds of serum thyroid hormone autoantibodies (THAA) among breeds with an increased risk of having THAA, compared with dogs of all other breeds.
From Nachreiner RF et al: Prevalence of serum thyroid hormone autoantibodies in dogs with clinical signs of hypothyroidism, *J Am Vet Med Assoc* 220:466, 2002.

Seborrhea and pyoderma may be focal, multifocal, or generalized. Because both frequently result in pruritus, hypothyroid dogs with secondary pyoderma or seborrhea initially may be brought to the veterinarian because of a pruritic skin disorder.

The haircoat in dogs with hypothyroidism is often dull, dry, and easily epilated. Hair regrowth is slow. Hyperkeratosis leads to the development of scales and dandruff. Variable degrees of hyperpigmentation may be noted. Chronic otitis externa has been noted in some dogs with hypothyroidism. In severe cases of hypothyroidism, acidic and neutral

Coagulopathy

Behavior Abnormalities (?)

*Common.

mucopolysaccharides may accumulate in the dermis and bind water, causing the skin to thicken. Referred to as *myxedema,* this condition causes the skin to thicken predominantly in the forehead and face of dogs, resulting in rounding of the temporal region of the forehead, puffiness and thickening of the facial skin folds, and drooping of the upper eyelids. Myxedema contributes to the classic "tragic facial expression" sometimes observed in dogs with hypothyroidism.

NEUROMUSCULAR SIGNS

Neuromuscular signs may be the predominant problem in some dogs with hypothyroidism (see Box 48.2). Clinical signs may be multifocal, acute or chronic, and static or progressive. Other findings consistent with hypothyroidism may be absent. Hypothyroidism-induced segmental demyelination and axonopathy may cause signs referable to the central or peripheral nervous system. Clinical signs referable to the central nervous system (CNS) may also appear after mucopolysaccharide accumulates in the perineurium and endoneurium, or after cerebral atherosclerosis, transient ischemia or brain infarction, or the development of severe hyperlipidemia; they include seizures, ataxia, circling, weakness, and proprioceptive and postural reaction deficits. These signs are often seen in conjunction with vestibular signs (e.g., head tilt, nystagmus) or facial nerve paralysis. Peripheral neuropathies identified in hypothyroid dogs include facial nerve paralysis, generalized weakness associated with diffuse lower motor neuron tetraparesis, and knuckling or dragging of the feet, with excessive wear of the dorsal part of the toenail. Hypothyroid myopathy is characterized by type II myofiber atrophy, myofiber degeneration, and depletion in skeletal muscle carnitine, and may result in skeletal muscle wasting, weakness, exercise intolerance, and increased serum of creatine kinase, aspartate aminotransferase, and lactate dehydrogenase activities. Thyroxine-responsive unilateral forelimb lameness has also been observed in dogs. The relationship between hypothyroidism and laryngeal paralysis or esophageal hypomotility remains controversial, in part

FIG 48.3
(A) A 6-year-old female spayed Samoyed with hypothyroidism; a dry, lusterless haircoat; hyperpigmentation; and endocrine alopecia. **(B)** and **(C)** A 2-year-old female spayed Golden Retriever with hypothyroidism, diffuse thinning of the haircoat, and development of a "rat tail." In both dogs note the truncal distribution of the dermatologic problem with sparing of the head and distal extremities. **(D)** An 8-year-old male castrated Beagle with hypothyroidism, obesity, and myxedema of the face. Note the "tragic facial expression" and "mental dullness" evident from the dog's facial expression. **(E)** A 7-month-old female Malamute with congenital hypothyroidism. Note the retention of the puppy haircoat and the small stature of the dog.

because it is difficult to prove a cause-and-effect relationship between these disorders, and because treatment of hypothyroidism often does not improve the clinical signs caused by laryngeal paralysis or esophageal hypomotility.

REPRODUCTIVE SIGNS

Historically, hypothyroidism was believed to cause lack of libido, testicular atrophy, and oligospermia to azoospermia in male dogs. However, work by Johnson et al. (1999) in Beagles failed to document any deleterious effect of experimentally induced hypothyroidism on any aspect of male reproductive function. Although other classic clinical signs and clinicopathologic abnormalities of hypothyroidism developed in the dogs studied, libido, testicular size, and total sperm count per ejaculate remained normal. These findings indicate that hypothyroidism may, at best, be an uncommon cause of reproductive dysfunction in male dogs, assuming that the Beagle is representative of other dog breeds.

Clinical experience has shown that hypothyroidism can cause prolonged interestrus intervals and failure to cycle in the bitch. Additional reproductive abnormalities include

weak or silent estrous cycles, prolonged estrual bleeding (which may be caused by acquired problems in the coagulation system), and inappropriate galactorrhea and gynecomastia. An association between hypothyroidism and fetal resorption, abortion, stillbirth, and the birth of weak puppies that die shortly after birth has been suggested in the bitch. Work undertaken by Panciera et al. (2007) to examine the effects of short-term (19 weeks) experimentally induced hypothyroidism on reproduction in the bitch revealed no difference in interestrus interval, conception, litter size, or gestation length between hypothyroid and control bitches. However, parturition was prolonged, uterine contractions were weaker, stillbirths were more prevalent, puppies were smaller and more distressed at birth, and periparturient mortality was significantly higher in hypothyroid bitches than in control bitches.

MISCELLANEOUS CLINICAL SIGNS

Ocular, cardiovascular, gastrointestinal, and clotting abnormalities are uncommon clinical manifestations of hypothyroidism (see Box 48.2). More commonly, biochemical or functional abnormalities of these organ systems are identified in dogs exhibiting the more common clinical signs of hypothyroidism. Echocardiography may identify a decrease in cardiac contractility that is usually mild and asymptomatic but that may become relevant during a surgical procedure requiring prolonged anesthesia and aggressive fluid therapy. Hypothyroidism does not play a role in the etiology or progression of dilated cardiomyopathy in Doberman Pinschers (Beieret et al., 2015).

A reduction in the activity of factor VIII–related antigen (von Willebrand factor) activity has been inconsistently documented in dogs with hypothyroidism, and the development of clinical signs of a bleeding disorder in hypothyroid dogs is uncommon. An evaluation of the coagulation cascade or of von Willebrand factor activity is not indicated in dogs with untreated hypothyroidism unless concurrent bleeding problems are reported. Thyroid hormone supplementation has a variable and sometimes deleterious effect on the blood concentration of von Willebrand factor in euthyroid dogs with von Willebrand disease.

A cause-and-effect relationship between hypothyroidism and behavioral problems (e.g., aggression) has not been well established in dogs. Proposed mechanisms for hypothyroid associated aggression have focused on possible disturbances in serotonergic or adrenergic pathways in the CNS. To date, most reports have been anecdotal and based on improvement in behavior following initiation of thyroid hormone treatment. A study by Radosta et al. (2012) found no difference in thyroid function test results between aggressive and nonaggressive dogs. The benefits, if any, of using thyroid hormone to treat behavioral disorders such as aggression in dogs remain to be clarified.

Hypothyroidism may decrease glomerular filtration rate (GFR) in dogs and could worsen azotemia in dogs with concurrent kidney disease. It is interesting to note that in one study involving experimentally induced hypothyroidism, plasma creatinine concentrations did not increase despite a reduction in GFR, presumably because of decreased production of creatinine (Panciera and Lefebvre, 2009). Treatment with sodium levothyroxine improves GFR in hypothyroid dogs.

MYXEDEMA COMA

Myxedema coma is an uncommon syndrome of severe hypothyroidism characterized by profound weakness, hypothermia, bradycardia, and a diminished level of consciousness that can rapidly progress to stupor and then coma. Physical findings include profound weakness; hypothermia; nonpitting edema of the skin, face, and jowls (i.e., myxedema); bradycardia; hypotension; and hypoventilation. Laboratory findings may include hypoxemia, hypercarbia, hyponatremia, and hypoglycemia in addition to the typical findings of hyperlipidemia, hypercholesterolemia, and nonregenerative anemia. Serum thyroid hormone concentrations are usually extremely low or undetectable; serum TSH concentration is variable but typically increased. Treatment consists of intravenous levothyroxine (5 µg/kg q12h) because of concerns of sluggish absorption from the gut and subcutaneous tissues and supportive care aimed at correcting hypothermia, hypovolemia, electrolyte disturbances, and hypoventilation. Early recognition and aggressive treatment is critical to survival. The diagnosis should be made based on clinical findings and treatment initiated without waiting for thyroid hormone test results. Once the dog has stabilized, oral levothyroxine can be started. Unfortunately, mortality is high because of late recognition and concurrent illness.

CRETINISM

Hypothyroidism in puppies is termed *cretinism.* Retarded growth and impaired mental development are the hallmarks of cretinism (Box 48.3). Clinical signs are not usually present

BOX 48.3

Clinical Signs of Cretinism

Disproportionate dwarfism
Short, broad skull
Shortened mandible
Enlarged cranium
Shortened limbs
Kyphosis
Mental dullness
Constipation
Inappetence
Gait abnormalities
Delayed dental eruption
Alopecia
"Puppy haircoat"
Dry hair
Thick skin
Lethargy
Dyspnea
Goiter

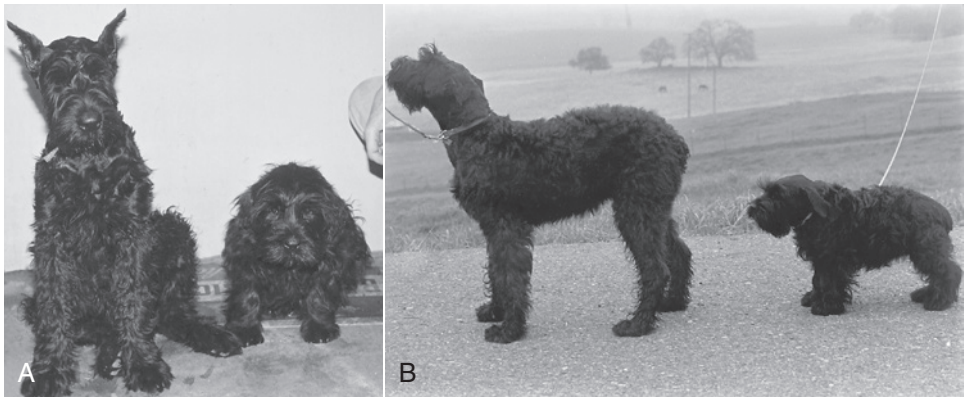

FIG 48.4
(A) and **(B)** Eight-month-old female Giant Schnauzer litter mates. The dog on the left is normal, whereas the smaller dog on the right has congenital hypothyroidism (cretinism). Note the small stature; disproportionate body size; large, broad head; wide, square trunk; and short limbs in the cretin. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 4, St Louis, 2015, WB Saunders.)

at birth but become apparent between 1 and 3 months of age. Dogs with cretinism have a disproportionate body size, with a large, broad head; a thick, protruding tongue; a wide, square trunk; and short limbs (Fig. 48.4). This contrasts with the proportionate dwarfism caused by growth hormone deficiency. Cretins are mentally dull and lethargic, and do not show the typical playfulness seen in normal puppies. Persistence of the puppy haircoat, alopecia, inappetence, delayed dental eruption, and goiter are additional signs. Differential diagnoses for failure to grow include endocrine (e.g., dwarfism) and nonendocrine causes (see Box 46.5 and Fig. 46.9). The presence of goiter is variable and dependent on the underlying cause.

AUTOIMMUNE POLYENDOCRINE SYNDROMES

Because autoimmune mechanisms play an important role in the pathogenesis of lymphocytic thyroiditis, it is not surprising that lymphocytic thyroiditis may occur in conjunction with other immune-mediated endocrinopathies. Presumably, the immune-mediated attack is directed against antigens shared by the endocrine system. In human beings autoimmune polyglandular syndrome type II (Schmidt's syndrome) is the most common of the immunoendocrinopathy syndromes, and it usually consists of primary adrenal insufficiency, autoimmune thyroid disease, and type 1 diabetes mellitus. Autoimmune polyendocrine syndromes are uncommon in dogs and should be suspected in a dog found to have multiple endocrine gland failure. Hypothyroidism, hypoadrenocorticism, and, to a lesser extent, diabetes mellitus, hypoparathyroidism, and lymphocytic orchitis are recognized combined syndromes. In most affected dogs each endocrinopathy is manifested separately, with additional disorders ensuing one by one after variable periods (months to years). Diagnostic tests and treatment are directed at each disorder as it is recognized, because it is not possible to reliably predict or prevent any of these problems. Immunosuppressive drug therapy is not indicated for dogs with these syndromes because the adverse effects of immunosuppressive therapy and the difficulty posed by suppression of the immune destruction of affected endocrine glands outweigh the potential benefits of such therapy.

Clinical Pathology

The most consistent clinicopathologic findings in dogs with hypothyroidism are hypercholesterolemia and hypertriglyceridemia; the latter is identified as lipemia. Hypercholesterolemia is identified in approximately 75% of hypothyroid dogs, and the cholesterol concentration can exceed 1000 mg/dL. Although fasting hypercholesterolemia and hypertriglyceridemia can be associated with several other disorders (see Chapter 52), their presence in a dog with appropriate clinical signs is strong evidence for hypothyroidism.

A mild normocytic, normochromic, nonregenerative anemia (packed cell volume [PCV] of 28%-35%) is a less consistent finding, identified in approximately 30% of dogs. Evaluation of red blood cell morphology may reveal an increase in the numbers of leptocytes (target cells), which develop as a result of increased erythrocyte membrane cholesterol loading. The white blood cell count is typically normal, and platelet counts are normal to increased.

A mild to moderate increase in lactate dehydrogenase, aspartate aminotransferase, alanine transaminase, alkaline phosphatase, and, rarely, creatine kinase activities may be identified but is an extremely inconsistent finding and may not be directly related to the hypothyroid state. Mild hypercalcemia may be noted in some dogs with congenital hypothyroidism. Results of urinalysis are usually normal. Polyuria, hyposthenuria, and urinary tract infection are not typical of hypothyroidism.

DERMATOHISTOPATHOLOGIC FINDINGS

Skin biopsies are often performed in dogs with suspected endocrine alopecia, especially if screening diagnostic tests

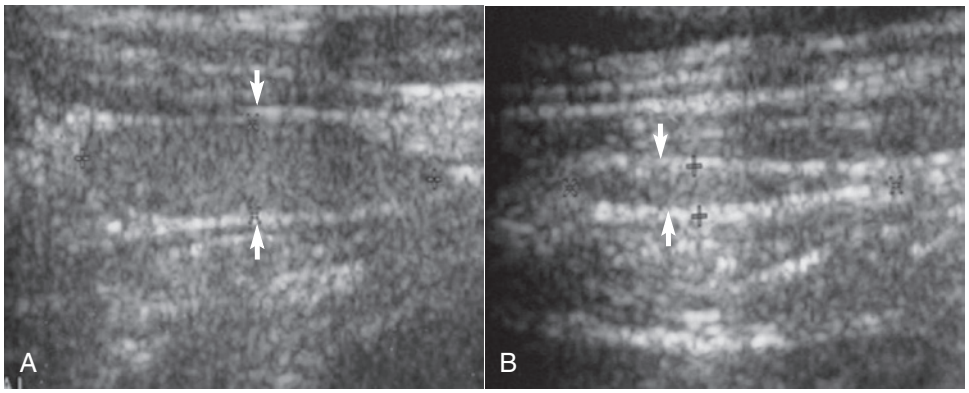

FIG 48.5
(A) Ultrasound image of the normal-appearing left thyroid lobe *(arrows)* of a healthy adult Golden Retriever. **(B)** Ultrasound image of the left thyroid lobe *(arrows)* of an adult Golden Retriever dog with primary hypothyroidism. Note the significant reduction in the size of the thyroid lobe in the dog with hypothyroidism, compared with the thyroid lobe image from the healthy dog.

(including tests to assess thyroid gland function) have failed to identify the cause. Nonspecific histologic changes are associated with various endocrinopathies, including hypothyroidism (see Table 46.5); histologic alterations that are claimed to be specific to hypothyroidism may also be seen, including vacuolated and/or hypertrophied arrector pili muscles, increased dermal mucin content, and thickened dermis. A variable inflammatory cell infiltrate may be present if a secondary pyoderma has developed.

ULTRASONOGRAPHIC FINDINGS

Ultrasound evaluation of the thyroid lobe may be helpful in differentiating dogs with hypothyroidism from euthyroid dogs with nonthyroidal illness causing low thyroid hormone test results. In early hypothyroidism the thyroid lobes may appear relatively normal. Lymphocytic thyroiditis and idiopathic atrophy eventually cause a decrease in size and alterations in echogenicity of the thyroid lobe. The thyroid lobe in euthyroid dogs is usually fusiform and triangular to oval in shape on longitudinal and transverse views, respectively; has a homogeneous echogenic pattern; is hyperechoic to isoechoic, compared with the echogenicity of the surrounding musculature; and has a hyperechoic capsule (Fig. 48.5). Although thyroid lobe shape is often similar between euthyroid and hypothyroid dogs, a significant reduction in size and volume of the thyroid lobe is often seen in hypothyroid versus euthyroid dogs. In addition, the echogenicity of the thyroid lobe in hypothyroid dogs tends to be isoechoic to hypoechoic with hyperechoic foci, and the echogenic pattern often differs between thyroid lobes in the same dog. A direct correlation between size of the dog and size and volume of the normal thyroid gland may exist; the smaller the dog, the smaller the size and volume of the thyroid lobe (Fig. 48.6). This must be considered when thyroid lobe size is evaluated in a dog with suspected hypothyroidism.

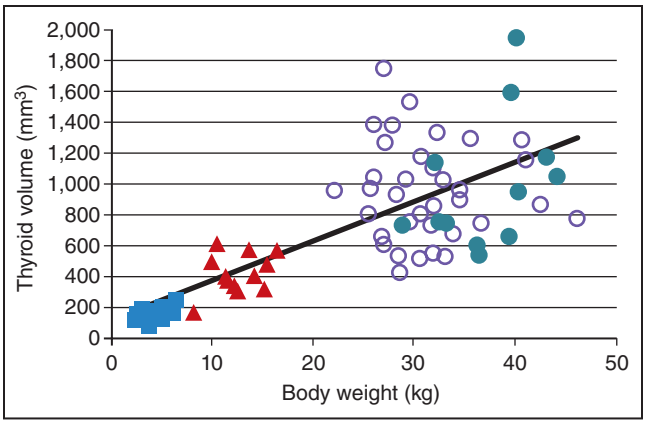

FIG 48.6
The relationship between total thyroid gland volume as determined by ultrasound and body weight in 12 healthy Akitas *(closed circles)*, 36 Golden Retrievers *(open circles)*, 12 Beagles *(triangles)*, and 12 Miniature and Toy Poodles *(squares)*. Note the positive correlation between body weight and size of the thyroid gland. TESTS OF THYROID GLAND FUNCTION

Overview

Function of the thyroid gland is typically assessed by measuring baseline serum thyroid hormone concentrations. Most of the thyroid hormone secreted by the thyroid gland consists of 3,5,3′5′-tetraiodothyronine (thyroxine [T_4]), and only small quantities of 3,5,3′-triiodothyronine (T_3) and minor amounts of 3,3′,5′-triiodothyronine (reverse T_3 [rT_3]) are released. Once secreted into the circulation, more than 99% of T_4 is bound to plasma proteins; this serves as a reservoir and a buffer to maintain a steady concentration of free T_4 (fT_4) in the plasma. Unbound, or free, T_4 is biologically

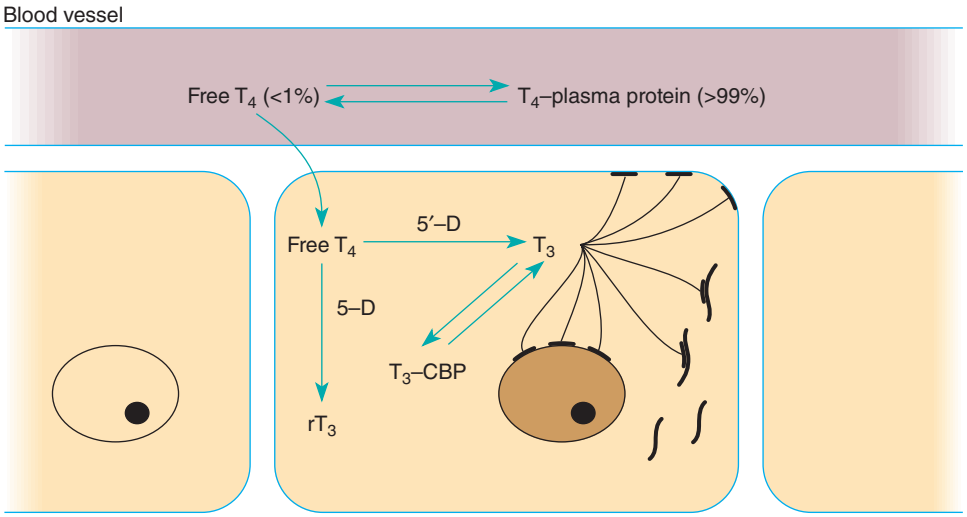

FIG 48.7
Intracellular metabolism of free T_4 to either T_3 or reverse T_3 by 5′- or 5-monodeiodinase, respectively. Intracellular T_3 formed from monodeiodination of free T_4 can interact with T_3 receptors on the cell membrane, mitochondria, or nucleus of the cell and stimulate the physiologic actions of thyroid hormone or bind to cytoplasmic binding proteins *(CBP)*. The latter form an intracellular storage pool for T_3. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

active, exerts negative feedback inhibition on pituitary TSH secretion (see Fig. 48.1), and is capable of entering cells throughout the body (Fig. 48.7). Within the cell, fT_4 is deiodinated to form either T_3 or rT_3, depending on the metabolic demands of the tissues at that particular time. T_3 is preferentially produced during normal metabolic states; rT_3 is biologically inactive and produced during periods of illness or excessive endogenous catabolism. T_3 is believed to be the primary hormone that induces physiologic effects.

All serum T_4, both protein bound and free, comes from the thyroid gland. Therefore tests that measure serum total and fT_4 concentrations, in conjunction with the serum TSH concentration, are currently recommended for assessment of thyroid gland function in dogs suspected of having hypothyroidism. Serum T_3 concentration is a poor gauge of thyroid gland function because of its predominant location within cells and the minimal amount secreted by the thyroid gland in comparison with the amount of T_4 secreted (Fig. 48.8). Thus measurement of serum T_3, free T_3, and rT_3 concentration is not recommended for assessment of thyroid gland function in dogs.

Baseline Serum T_4 Concentration

The baseline serum T_4 concentration is the sum of protein-bound and free levels circulating in the blood. Measurement of serum T_4 concentration can serve as the initial screening test for hypothyroidism or can be part of a thyroid panel containing T_4, fT_4, TSH, an antibody test for lymphocytic thyroiditis, or some combination of these tests (Box 48.4).

Most reference laboratories use radioimmunoassay (RIA) or, more commonly, chemiluminescent immunoassays for measuring serum T_4 in dogs and cats. Point-of-care enzyme-linked immunosorbent assays (ELISAs) for measuring serum T_4 are also available; are economical, quick, and easy to perform; and allow the clinician to make recommendations the same day the dog (or cat) is evaluated. Studies evaluating one point-of-care ELISA (Snap T_4 test kit and VetTest Snap Reader, IDDEX laboratories) have been conflicting. In one study, discrepancies, both overestimation and underestimation of the T_4 concentration, between the in house ELISA and RIA results were detected (Lurye et al., 2002). In contrast, serum T_4 concentrations determined in dogs and cats by RIA, chemiluminescent enzyme immunoassay, and a point-of-care ELISA provided similar and consistent results (Kemppainen and Birchfield, 2006).

For most laboratories, the lower limit of the reference range for serum T_4 in dogs is approximately 0.8 to 1.0 µg/dL (10-13 nmol/L), although in some breeds the normal range may extend to as low as 0.5 µg/dL (6 nmol/L) (see the discussion of breed variations, p. 781).

Theoretically, interpretation of baseline serum T_4 concentration should be straightforward in that dogs with hypothyroidism should have values below the reference range. Unfortunately, the serum T_4 concentration range in healthy dogs overlaps with that in hypothyroid dogs, and the serum T_4 concentration can be suppressed below the reference range in euthyroid dogs by a variety of factors, most notably nonthyroidal illness and medications (Table 48.2). Clinicians often find it difficult to judge the effects that extraneous factors, especially concurrent illness, have on serum T_4 concentration. Because these variables can suppress a baseline serum T_4 concentration to less than 0.5 µg/dL in a euthyroid dog, and because hypothyroid dogs in early stages of the disease may have a serum T_4 concentration near the lower end of the reference range, the serum T_4 concentration should be used to confirm normal thyroid gland function, not hypothyroidism per se. A serum T_4 concentration in the reference range, especially a value in the upper half of the reference range, establishes normal thyroid gland function. The exception is seen in a very small number (<2%) of hypothyroid dogs with lymphocytic thyroiditis that have serum T_4 autoantibodies that may interfere with the assay used to measure T_4. A serum T_4 concentration below the lower limit of the reference range is consistent with hypothyroidism, especially if the T_4 concentration is less than 0.5 µg/dL and all other findings are consistent with the diagnosis.

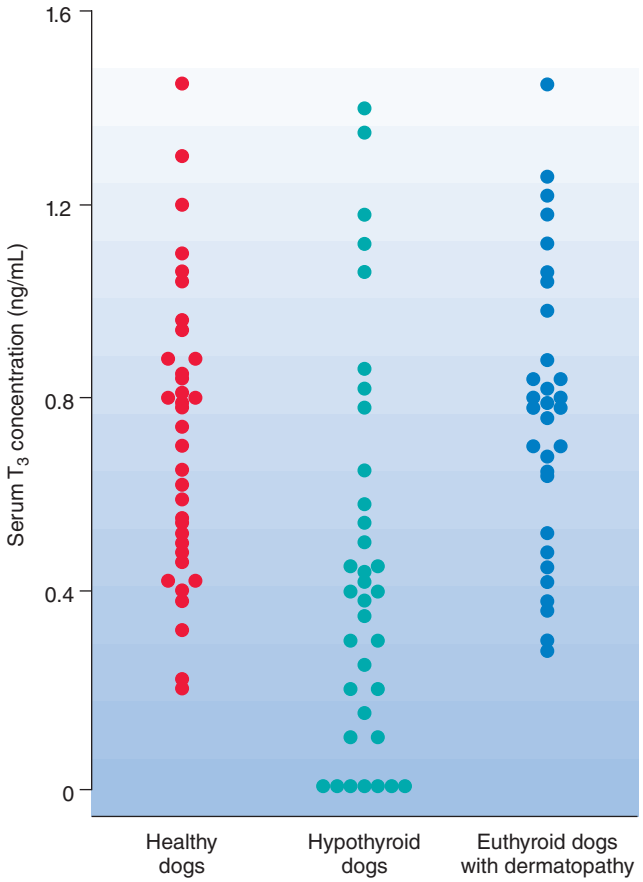

FIG 48.8
Baseline serum T_3 concentrations in 35 healthy dogs, 35 dogs with hypothyroidism, and 30 euthyroid dogs with concurrent dermatopathy. Note the overlap in serum T_3 concentrations among the three groups of dogs.

Additional diagnostic tests are indicated if the serum T_4 concentration is below the reference range, but other factors (e.g., concurrent illness, questionable clinical signs, lack of hyperlipidemia) raise doubt about hypothyroidism (see Diagnosis, p. 782).

Baseline Serum fT_4 Concentration

Free T_4, the non–protein-bound fraction of T_4 circulating in blood, accounts for less than 1% of circulating T_4. Currently, measurement of fT_4 is done by one of three methods: modified equilibrium dialysis, analog RIA, and analog chemiluminescent assay. Studies evaluating these assays for assessment of thyroid gland function in dogs and cats found comparable sensitivity, specificity, and accuracy, suggesting that any one of these three assays is acceptable for measuring fT_4 concentrations in dogs and cats. It is important that the assay used by the reference laboratory has been validated for use in dogs and reference ranges established in dogs. In general, serum fT_4 concentrations greater than 1.5 ng/dL (20 pmol/L) are consistent with euthyroidism, and values less than 0.8 ng/dL (10 pmol/L) especially less than 0.5 ng/dL (6 pmol/L) are supportive of hypothyroidism, assuming the history and

BOX 48.4

Diagnostic Tests for Evaluating Thyroid Gland Function in the Dog

The decision to assess thyroid gland function should be based on results of the history, physical examination, and routine blood work (complete blood count, serum biochemistry panel, urinalysis).

Serum Thyroxine (T_4)

This is the most commonly used initial screening test for hypothyroidism.
Normal serum T_4 rules out hypothyroidism.
Exception: T_4 autoantibodies that interfere with T_4 assay and cause spuriously high results (uncommon).
Low serum T_4 does not, by itself, confirm hypothyroidism.
Serum T_4 is commonly suppressed below the reference range by nonthyroidal illness, drugs, and other factors in dogs with normal thyroid gland function.

Serum Free Thyroxine (fT_4)

This is usually measured in dogs with nondiagnostic serum T_4 test results, severe nonthyroidal illness, or both, and is a common component of canine thyroid panels.
Normal serum fT_4 rules out hypothyroidism.
Low serum fT_4 does not, by itself, confirm hypothyroidism; severe nonthyroidal illness and drugs can suppress serum fT_4 to below the reference range.

Serum Thyrotropin (TSH)

Should be measured in conjunction of serum T_4 during initial evaluation of thyroid function but is usually measured in dogs with nondiagnostic serum T_4 test results, severe nonthyroidal illness, or both, and is a common component of canine thyroid panels.
TSH provides additional evidence for or against the diagnosis of hypothyroidism.
False-positive and false-negative serum TSH test results are common.
Serum TSH should not be used, by itself, to diagnose hypothyroidism.

Serum 3,5,3′-Triiodothyronine (T_3)

This may be a component of canine thyroid panels.
This is not the primary hormone secreted by the thyroid gland; T_3 is primarily produced from deiodination of fT_4 within cells of the body.
T_3 is a poor gauge of thyroid gland function and should not be used, by itself, to diagnose hypothyroidism.

Serum Thyroglobulin (Tg) and Thyroid Hormone (T_3 and T_4) Autoantibody Tests

This is a common component of canine thyroid panels.
These are tests of thyroid gland pathology—not of thyroid gland function.
These tests are used to identify lymphocytic thyroiditis and to explain unusual serum T_4 and T_3 test results.
They should never be used to diagnose hypothyroidism.

TABLE 48.2

Variables That May Affect Baseline Serum Thyroid Hormone Function Test Results in the Dog

FACTOR	EFFECT
Age	T_4 and free T_4 negatively correlated with age TSH positively correlated with age
Body size	T_4 and free T_4 negatively correlated with body weight TSH positively correlated with body weight
Breed Sighthounds (e.g., Greyhounds) Nordic breeds (e.g., Huskies) English Setters, Whippet, Saluki, Sloughi, Basenji, Irish Wolfhound, Conditioned Alaskan Sled Dogs, Other breeds?	T_4 and free T_4 lower than normal range established for dogs; TSH may be increased in Whippet and Sloughi; no difference for TSH in other breeds
Gender	No effect
Time of day	No effect
Weight gain/obesity	Increased T_4 and T_3
Weight loss/fasting	Decreased T_4, no effect on free T_4
Acute exercise	Decreased T_4, no effect on free T_4
Prolonged strenuous exercise	Decreased T_4 and free T_4
Estrus (estrogen)	No effect on T_4
Pregnancy (progesterone)	Increased T_4
Surgery/anesthesia	Decreased T_4
Concurrent illness*	Decreased T_4 and free T_4; depending on illness, TSH may increase, decrease, or not change
Moderate/severe osteoarthritis	No effect on T_4, free T_4, or TSH
Drugs	See Table 48.3
Dietary iodine intake	If excessive, decreased T_4 and free T_4; increased TSH
Thyroid hormone autoantibodies	Increased or decreased T_4; no effect on free T_4 results measured by equilibrium dialysis but results may be increased with chemiluminescent immunoassyays; No effect on TSH

TSH, Thyroid-stimulating hormone.
*A direct correlation has been noted between the severity and the systemic nature of the illness and suppression of serum T_4 and free T_4 concentrations.

findings on physical examination and routine bloodwork are supportive of hypothyroidism.

Measurement of serum fT_4 is usually reserved for dogs with suspected hypothyroidism and nondiagnostic serum T_4 and TSH test results, severe concurrent illness, or both. Serum fT_4 is more resistant to the suppressive effects of nonthyroidal illness and medications than is serum T_4, although severe illness can cause serum fT_4 concentrations to decrease to below 0.5 ng/dL (6 pmol/L). Serum T_4 autoantibodies do not affect serum fT_4 results determined with the use of equilibrium dialysis but can increase serum fT_4 results determined by the analog veterinary fT_4 chemiluminescent immunoassay. Serum thyroglobulin autoantibodies may also interfere with fT_4 test results measured by chemiluminescent immunoassay, resulting in an increased fT_4 test result that does not support a diagnosis of hypothyroidism (Randolph et al., 2015). Interpretation of serum fT_4 test results is similar to interpretation of serum T_4 test results. Serum fT_4 values in the reference range are consistent with normal thyroid gland function, and values below the lower limit of the reference range are consistent with hypothyroidism, given that other findings are consistent with the diagnosis. In general, serum fT_4 concentrations less than 0.8 ng/dL (10 pmol/L), especially less than 0.5 ng/dL (6 pmol/L), are supportive of hypothyroidism, assuming the history and findings on physical examination and routine bloodwork are supportive of hypothyroidism.

Baseline Serum TSH Concentration

Measurement of serum TSH provides information on the interaction between the pituitary and the thyroid gland. In theory, serum TSH concentration should be increased in dogs with hypothyroidism. The assay most commonly utilized to measure TSH in dogs is the chemiluminescent TSH

assay (Imulite Canine TSH), which has been shown to have the highest precision compared with immunoradiometric and enzyme immunometric assays (Marca et al., 2001). Unfortunately, all TSH assays have poor sensitivity for the diagnosis of hypothyroidism. In dogs with hypothyroidism, 20% to 40% have serum TSH concentrations in the reference range. However, studies have shown that a high serum TSH concentration has high specificity (>90%) for diagnosis of hypothyroidism when serum T_4 and/or fT_4 is low in the same serum sample. Proposed reasons for the poor sensitivity include loss of TSH response by pituitary thyrotophs to low serum T_4 concentrations over time, pulsatile TSH secretion resulting in fluctuations in serum TSH concentration, suppression of the TSH response by concurrent illness or drugs, and secondary hypothyroidism.

Most clinical laboratories use a serum TSH concentration of 0.6 ng/mL as the upper limit of the reference range. The lower limit of the reference range is currently below the sensitivity of these assays; differentiation between low and normal serum TSH concentrations is not possible.

Measurement of serum TSH concentration should be part of the routine evaluation of thyroid gland function or may be reserved for dogs with suspected hypothyroidism and nondiagnostic serum T_4 test results. A serum TSH concentration greater than 0.6 ng/mL in conjunction with a low serum T_4 or fT_4 is consistent with hypothyroidism. Unfortunately, serum TSH concentrations can be normal in dogs with histologically confirmed hypothyroidism and increased in euthyroid dogs with concurrent nonthyroidal illness or dogs receiving drugs such as phenobarbital (Fig. 48.9). Serum TSH test results should always be interpreted in conjunction with results of serum T_4, fT_4, or both and should not be used alone in the diagnosis of hypothyroidism. Serum TSH test results increase the likelihood of euthyroidism or hypothyroidism when results are consistent with results of serum T_4 and fT_4 tests. Normal serum T_4 and fT4 concentrations and increased serum TSH concentrations occur in the early stages of primary hypothyroidism in humans. Although similar thyroid hormone and TSH test results have been identified in dogs, it is not known what percentage of these dogs progress to clinical hypothyroidism. Clinical signs of hypothyroidism usually are not evident in these dogs, presumably because serum T_4 and fT_4 concentrations are in the reference range. Treatment with sodium levothyroxine is not indicated. Rather, assessment of thyroid gland function should be repeated in 3 to 6 months, especially if antibody tests for lymphocytic thyroiditis are positive. If progressive destruction of the thyroid gland is occurring, serum T_4 and fT_4 concentrations will gradually decrease and clinical signs will eventually develop.

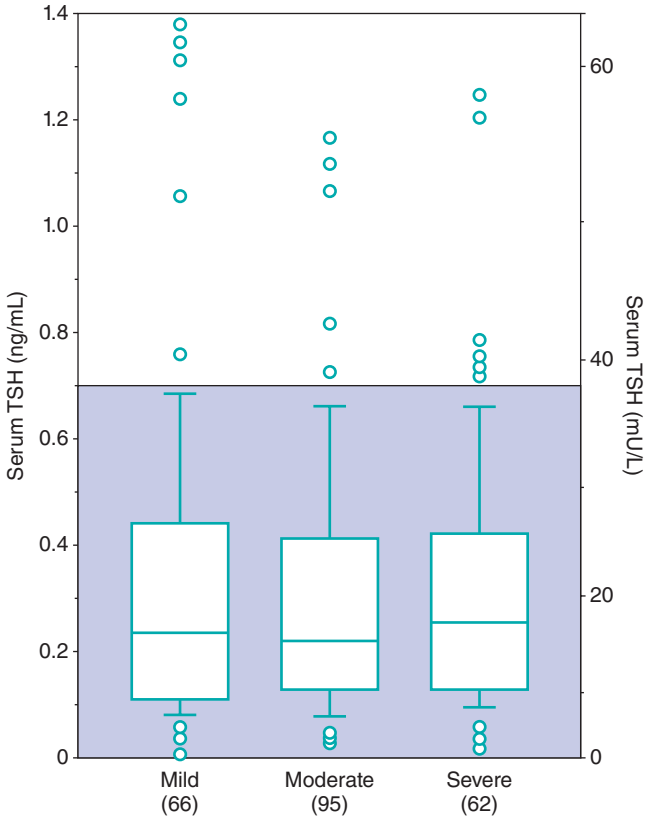

FIG 48.9
Box plots of serum concentrations of thyrotropin *(TSH)* in 223 dogs with nonthyroidal disease stratified according to severity of disease. For each box plot T-bars represent the main body of data, which in most instances is equal to the range. Each box represents an interquartile range (25th to 75th percentile). The horizontal bar in each box is the median. Open circles represent outlying data points. Numbers in parentheses indicate the numbers of dogs in each group. Shaded area is the normal range. (From Kantrowitz LB et al: Serum total thyroxine, total triiodothyronine, free thyroxine, and thyrotropin concentrations in dogs with nonthyroidal disease, *J Am Vet Med Assoc* 219:765, 2001.)

TSH and TRH Stimulation Tests

TSH and TRH stimulation tests evaluate the responsiveness of the thyroid gland to exogenous TSH and TRH administration, respectively. The primary advantage of these tests is that they help differentiate between hypothyroidism and nonthyroidal illness in dogs with low serum T_4 and fT_4 concentrations. Unfortunately, TRH for injection is currently not available. Recombinant human TSH (rhTSH) for injection is effective in stimulating thyroid hormone secretion in dogs but is not available at a reasonable cost. The current TSH stimulation protocol for dogs is 75 µg of rhTSH per dog administered intravenously, and blood for serum T_4 concentration is obtained before and 6 hours after rhTSH administration. Administration of a higher TSH dose (150 µg IV) results in significantly higher post-TSH T_4 concentrations in healthy dogs and better differentiation between euthyroid and hypothyroid dogs, suggesting that the higher dose should be used in dogs that have concurrent disease or are receiving medications (Boretti et al., 2009). In a euthyroid dog serum, T_4 concentration should be ≥ 2.5 µg/dL (30 nmol/L) 6 hours after rhTSH administration, and the 6-hour post-rhTSH serum T_4 concentration should be ≥ 1.5

times the baseline serum T_4 concentration. Reconstituted rhTSH can be stored at 4° C for 4 weeks and at −20° C for 8 weeks without loss of biological activity (De Roover et al., 2006).

Antibody Tests for Lymphocytic Thyroiditis

Circulating thyroglobulin (Tg) and thyroid hormone (T_3 and T_4) autoantibodies correlate with the presence of lymphocytic thyroiditis in dogs. Tests for the presence of Tg, T_3, and T_4 autoantibodies in the serum of dogs can be used to identify lymphocytic thyroiditis, to explain unusual serum T_4 test results, and possibly to serve as a genetic screening test for hypothyroidism caused by lymphocytic thyroiditis. Autoantibodies predominantly develop against Tg. T_3 and T_4 are haptens and are not antigenic by themselves. Tg is the protein that provides the antigenic stimulus. Because T_3 and T_4 are attached to the Tg molecule, autoantibodies develop against them as well. Dogs with T_3 and T_4 autoantibodies typically have autoantibodies against Tg, but the converse is not true. As such, the better screening test for lymphocytic thyroiditis is the Tg autoantibody test. ELISAs for detection of Tg autoantibodies are sensitive and specific for identification of Tg autoantibodies in dogs and are commercially available. Results are reported as negative, positive, and inconclusive.

A positive Tg autoantibody test suggests the possibility of lymphocytic thyroiditis but does not provide information on the severity or progressive nature of the inflammatory process. Positive Tg autoantibody test results may remain positive or may revert to negative on subsequent testing. Tg autoantibody is not a thyroid function test. Positive results increase the suspicion for hypothyroidism if serum T_4 and fT_4 concentrations are low but have no bearing on generation of clinical signs if serum T_4 and fT_4 concentrations are normal. Tg autoantibodies should not be used alone in the diagnosis of hypothyroidism. Dogs with confirmed hypothyroidism can be negative, and euthyroid dogs can be positive for Tg autoantibodies. Identification of Tg autoantibodies would support hypothyroidism caused by lymphocytic thyroiditis if the dog has clinical signs, physical findings, and thyroid hormone test results consistent with the disorder. Positive serum T_4 and T_3 autoantibody test results are interpreted in a similar manner.

The value of serum Tg autoantibodies as a marker for eventual development of hypothyroidism remains to be clarified. A 1-year prospective unpublished study performed by Graham et al at Michigan State University found that approximately 20% of 171 dogs with positive Tg autoantibody and normal fT_4 and TSH test results developed changes in fT_4, TSH, or both test results consistent with hypothyroidism; 15% reverted to a negative Tg autoantibody test with no change in fT_4 and TSH test results; and 65% remained Tg autoantibody positive or had an inconclusive result with no change in fT_4 and TSH test results 1 year later. Currently, a positive Tg autoantibody test is considered suggestive of lymphocytic thyroiditis and supports retesting of thyroid gland function in 3 to 6 months.

Testing for serum T_4 or Tg autoantibodies is indicated in dogs with unusual serum T_4 values. T_4 autoantibodies may interfere with RIAs used to measure serum T_4 concentrations and yield spurious and possibly unreliable values. Similar interference does not occur with chemiluminescence immunoassay (Piechotta et al., 2010). The type of interference depends on the separation system used in the RIA. Most T_4 RIAs use a single-step separation system with antibody-coated tubes, which results in falsely increased T_4 values. Fortunately, spurious T_4 values resulting from clinically relevant concentrations of thyroid hormone antibody account for less than 1% of such results from commercial endocrine laboratories. The effect of T_4 autoantibodies on serum fT_4 results is dependent on the fT_4 assay used (see Baseline Serum fT_4 Concentration, p. 776).

FACTORS AFFECTING THYROID GLAND FUNCTION TESTS

Many factors affect baseline thyroid hormone and endogenous TSH concentrations (see Table 48.2). Unfortunately, most of these factors decrease baseline thyroid hormone concentrations and may increase endogenous TSH in euthyroid dogs, potentially causing misdiagnosis of hypothyroidism if the clinician accepts the results out of context. The factors that most commonly result in lower baseline thyroid hormone concentrations in euthyroid dogs are nonthyroidal illness (i.e., euthyroid sick syndrome), drugs (especially glucocorticoids, phenobarbital, and sulfonamide antibiotics; see Table 48.2), and variation in the reference range between breeds (most notably sighthounds and Nordic breeds).

Nonthyroidal Illness Syndrome (Euthyroid Sick Syndrome)

Nonthyroidal Illness Syndrome (NTIS), historically referred to as euthyroid sick syndrome, refers to suppression of serum thyroid hormone concentrations in euthyroid dogs in response to concurrent illness. A decrease in serum thyroid hormone concentrations may result from a decrease in TSH secretion secondary to suppression of the hypothalamus or pituitary gland, from decreased synthesis of T_4, from decreased concentration or binding affinity of circulating binding proteins (e.g., thyroid binding globulin), from the presence of serum protein binding inhibitors, from inhibition of the deiodination of T_4 to T_3, from increased hepatic metabolism and excretion of T_4, or from any combination of these factors. The subsequent decrease in serum total T_4 and, in many cases, fT_4 concentrations is believed to represent a physiologic adaptation by the body, with the purpose being to decrease cellular metabolism during periods of illness. It is not indicative of hypothyroidism, per se. Generally, the type and magnitude of most alterations in serum thyroid hormone concentrations are not unique to a specific disorder but reflect the severity of the illness or the catabolic state and appear to represent a continuum of changes. Systemic illness has more of an effect in lowering serum thyroid hormone concentrations than do, for example, dermatologic disorders.

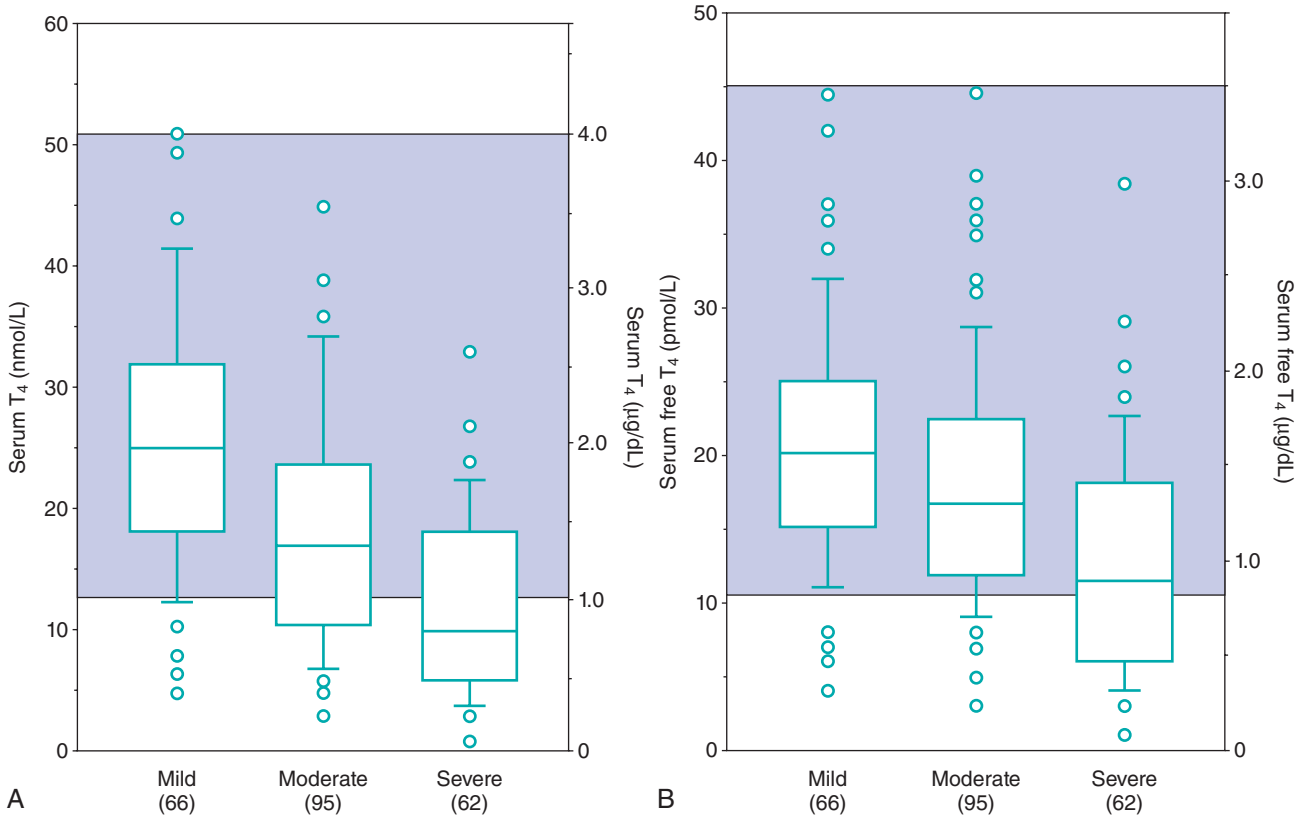

FIG 48.10
Box plots of serum total T_4 **(A)** and free T_4 **(B)** concentrations in 223 dogs with nonthyroidal disease stratified according to severity of disease. See Fig. 48.9 for an explanation. (From Kantrowitz LB et al: Serum total thyroxine, total triiodothyronine, free thyroxine, and thyrotropin concentrations in dogs with nonthyroidal disease, *J Am Vet Med Assoc* 219:765, 2001.)

In addition, the more severe the systemic illness, the more suppressive the effect on the serum thyroid hormone concentration (Fig. 48.10).

Unfortunately, euthyroid dogs with concurrent illness can have serum T_4 concentrations that often fall between 0.5 and 1.0 µg/dL (6 and 13 nmol/L), and with severe illness (e.g., cardiomyopathy, severe anemia), these concentrations can be less than 0.5 µg/dL. Alterations in serum concentrations of fT_4 and TSH are more variable and probably depend in part on the pathophysiologic mechanisms involved in the illness. In general, serum fT_4 concentrations tend to be decreased in dogs with concurrent illness but to a lesser extent than total T_4 concentrations. However, fT_4 concentrations can be less than 0.5 ng/dL if severe illness is present. TSH concentrations may be normal or increased depending, in part, on the effect of the concurrent illness on fT_4 concentrations and on pituitary function. If pituitary function is suppressed, TSH concentrations will be in the reference range or undetectable. If pituitary response to changes in fT4 concentration is not affected by the concurrent illness, TSH concentrations will increase in response to a decrease in fT_4. Serum TSH concentrations can easily exceed 1.0 ng/mL in dogs with NTIS.

It can be difficult to establish a diagnosis of hypothyroidism in a dog with NTIS, especially when relying on a single test of thyroid function, specifically serum T_4 concentration. Normal test results are indicative of euthyroidism, but abnormal test results do not confirm hypothyroidism. If possible, evaluation of thyroid function should wait until the nonthyroidal illness has resolved. If necessary, evaluation of thyroid gland function should include careful review of the history, findings on physical examination, and results of bloodwork and serum T_4, FT_4 and TSH concentrations. The simultaneous finding of low serum T_4 and f T_4 and increased serum TSH concentration is uncommon with NTIS and would suggest the presence of hypothyroidism.

Treatment of NTIS should be aimed at the concurrent illness. Serum thyroid hormone concentrations return to normal once the concurrent illness is eliminated. Treatment of NTIS with sodium levothyroxine is not recommended.

Drugs

Clinical knowledge of the effect, if any, of various drugs and hormones on serum thyroid hormone and TSH concentrations in dogs is expanding as investigators continue to examine the interplay between medications and thyroid

TABLE 48.3

Drugs That May Affect Baseline Serum Thyroid Hormone Function Test Results in the Dog

DRUG	POSSIBLE IMPACT ON TEST RESULTS
Amiodarone	Increased T_4; no effect on fT_4
Aspirin	Decreased T_4, free T_4; no effect on TSH
Cephalexin	No effect on T_4, free T_4, or TSH
Clomipramine	Decreased T_4, free T_4; no effect on TSH
Carprofen	Decreased T_4, free T_4, and TSH
Deracoxib	No effect on T_4, free T_4, or TSH
Etodolac	No effect on T_4, free T_4, or TSH
Glucocorticoids	Decreased T_4 and free T_4; decreased or no effect on TSH
Furosemide	Decreased T_4
Ipodate	Increased T_4; decreased T_3
Ketoprofen	No effect on T_4, free T_4, or TSH
Meloxicam	No effect on T_4, free T_4, or TSH
Methimazole	Decreased T_4 and free T_4; increased TSH
Phenobarbital	Decreased T_4 and free T_4; delayed increase in TSH
Phenylbutazone	Decreased T_4
Potassium bromide	No effect on T_4, free T_4, or TSH
Progestagens	Decreased T_4
Propranolol	No effect on T_4, free T_4, or TSH
Propylthiouracil	Decreased T_4 and free T_4; increased TSH
Sulfonamides	Decreased T_4 and free T_4; increased TSH

TSH, Thyroid-stimulating hormone.

hormone test results (Table 48.3). As a general rule, any drug should be suspected of affecting thyroid hormone test results, especially if the history, clinical signs, and clinicopathologic abnormalities do not support a diagnosis of hypothyroidism. Glucocorticoids, phenobarbital, and sulfonamides are the most commonly used drugs known to significantly affect serum thyroid hormone test results.

Glucocorticoids

Glucocorticoids cause a decrease in serum T_4 and fT_4 concentrations into the range consistent with a diagnosis of hypothyroidism—a decrease that can occur within days of initiation of glucocorticoid treatment. A similar effect occurs with naturally acquired hyperadrenocorticism. Serum TSH concentration is variable but usually within the reference range. The magnitude and duration of suppression of serum thyroid hormone concentrations depend on the type of glucocorticoid, dosage, route of administration, and duration of glucocorticoid administration. The higher the dosage, the longer the administration, and the more potent the glucocorticoid administered, the more severe the suppression of serum thyroid hormone concentrations. Topical glucocorticoids can have a similar effect as parenterally administered glucocorticoids, especially in small dogs. If glucocorticoids have been administered in the recent past, assay of serum thyroid hormone concentrations should be delayed or must be interpreted carefully. Ideally, glucocorticoids should be discontinued and serum thyroid hormone and TSH concentrations assessed 4 to 8 weeks later.

Typically, administration of exogenous glucocorticoids does not result in clinical signs of hypothyroidism. The exception is seen in dogs receiving daily glucocorticoids for prolonged periods (months to years) to treat chronic steroid-responsive disorders (e.g., immune-mediated disease). In these dogs the prolonged glucocorticoid-induced decrease in serum T_4 and fT_4 concentrations can result in lethargy, weight gain, and dermatologic signs that resolve after sodium levothyroxine treatment is initiated. Treatment for drug-induced hypothyroidism is indicated if the glucocorticoids cannot be discontinued.

Phenobarbital

In dogs long-term phenobarbital treatment at therapeutic dosages may decrease serum T_4 and fT_4 concentrations into the range consistent with hypothyroidism. A delayed increase in the serum TSH concentration may occur secondary to loss of negative feedback as serum T_4 and fT_4 concentrations decline. Increased serum TSH concentrations quickly return to the reference range after discontinuation of phenobarbital treatment, whereas serum T_4 and fT_4 concentrations may take up to 4 weeks to return to pretreatment values. Potassium bromide treatment does not appear to have a significant effect on serum T_4, fT_4, and TSH concentrations in dogs, and may be indicated if clinical signs of hypothyroidism develop in a dog being treated with phenobarbital.

Sulfonamide antibiotics

A decrease in serum T_4 and fT_4 and an increase in TSH concentrations have been documented in dogs treated with sulfonamides (e.g., sulfamethoxazole, sulfadiazine). Serum T_4 concentrations can decrease into the hypothyroid range within 1 to 2 weeks, and serum TSH concentrations can increase above the reference range within 2 to 3 weeks after sulfonamide therapy is initiated. Clinical signs of hypothyroidism can develop with long-term sulfonamide administration. The increase in the serum TSH concentration can lead to thyroid hyperplasia and goiter. Alterations in results of thyroid gland function tests may resolve within 1 to 2 weeks or last as long as 8 to 12 weeks after cessation of the antibiotic.

Breed Variations

Current reference ranges were established in large populations of dogs without regard for breed. It is now recognized that the reference range for serum T_4 and fT_4 concentrations

but not TSH concentration is lower in sighthounds, most notably Greyhounds, and in Nordic breeds such as the Siberian Husky, and may be lower in other breeds as well (see Table 48.2). The lower end of the reference range for serum T_4 and fT_4 in these breeds may be as low as 0.4 µg/dL (5 nmol/L) and 0.4 ng/dL (5 pmol/L), respectively. Serum T_4 and fT_4 concentrations consistent with hypothyroidism according to standard reference ranges may actually be normal in these breeds. Establishing the diagnosis of hypothyroidism in these breeds must rely on the strength of clinical signs, physical examination findings, and results of routine blood work, as well as on documentation of extremely low T_4 and fT_4 concentrations and ideally an increased serum TSH concentration.

Diagnosis

The diagnosis of hypothyroidism is based on a combination of clinical signs; findings on physical examination; and results of complete blood count (CBC), serum biochemistry panel, and tests of thyroid gland function. The presence of appropriate clinical signs is imperative, especially when one is relying on baseline thyroid hormone concentrations for a diagnosis. In the adult dog the most consistent clinical signs include lethargy, weight gain, and abnormalities affecting the skin (e.g., alopecia, seborrhea, pyoderma) and neuromuscular system (e.g., weakness). Other organ systems may be affected by thyroid hormone deficiency, but clinical signs related to these other systems are not usually the primary reason for presentation of the dog to the veterinarian. Identification of a mild nonregenerative anemia on the CBC, and especially lipemia (hypertriglyceridemia) in the blood sample and an increased serum cholesterol concentration on a serum biochemistry panel, adds further evidence for hypothyroidism.

Baseline serum T_4 concentration is often used as the initial screening test for thyroid gland function because it is widely available at low cost and can be measured in-house. It is important to remember that serum T_4 concentrations can be suppressed by a variety of factors, most notably nonthyroidal illness and medications such as prednisone and phenobarbital. As such, measurement of the serum T_4 concentration should be used to confirm normal thyroid gland function, not hypothyroidism per se. A normal serum T_4 concentration establishes normal thyroid gland function unless serum T_4 autoantibodies are present and are interfering with the assay. A low serum T_4 concentration (ideally <0.5 µg/dL [6 nmol/L]) in conjunction with hypercholesterolemia and clinical signs strongly suggestive of the disease supports the diagnosis of hypothyroidism, especially if systemic illness is not present. The definitive diagnosis must then rely on response to trial therapy with synthetic levothyroxine. Additional tests of thyroid gland function (i.e., TSH and fT_4) are warranted if the serum T_4 concentration is equivocal.

Evaluation of a thyroid panel that includes serum T_4, fT_4, TSH, and Tg autoantibody provides a more informative analysis of the pituitary-thyroid axis and thyroid gland function, can be used as the initial screening test for hypothyroidism, and should be used when serum T_4 concentration alone fails to establish the diagnosis. Low serum T_4 and fT_4 and increased serum TSH concentrations in a dog with appropriate clinical signs and clinicopathologic abnormalities strongly support the diagnosis of hypothyroidism. Concurrent presence of Tg autoantibodies suggests lymphocytic thyroiditis as the underlying cause.

Unfortunately, discordant thyroid hormone test results are common. When this occurs, the appropriateness of clinical signs, clinicopathologic abnormalities, and clinician index of suspicion become the most important parameters in determining whether to treat the dog with levothyroxine or repeat testing in 3 to 6 months.

Normal serum T_4 or fT_4 and high TSH may suggest early compensated hypothyroidism, but one has to wonder why clinical signs would develop when the serum T_4 and fT_4 concentration are normal. Positive Tg autoantibody findings merely suggest the possibility of lymphocytic thyroiditis; Tg autoantibody determination is not a thyroid function test. Positive results increase the suspicion for hypothyroidism if serum T_4 and fT_4 concentrations are low but have no bearing on the generation of clinical signs if serum T_4 and fT_4 concentrations are normal.

Interpretation of serum T_4, fT_4, and TSH concentrations is not always simple. Because of the expense and frustration of working with tests that are not always reliable, many veterinarians and some clients prefer trial therapy as a diagnostic test. Trial therapy should be done only when thyroid hormone supplementation does not pose a risk to the patient. Response to trial therapy with sodium levothyroxine is nonspecific. A dog that has a positive response to therapy has either hypothyroidism or "thyroid hormone–responsive disease." Because of its anabolic nature, thyroid hormone supplementation can create an effect in a dog without thyroid dysfunction, especially regarding quality of the haircoat. Therefore if a positive response to trial therapy is observed, thyroid supplementation should be gradually discontinued once clinical signs have resolved. If clinical signs recur, hypothyroidism is likely and the supplement should be reinitiated. If clinical signs do not recur, a thyroid hormone–responsive disorder or a beneficial response to concurrent therapy (e.g., antibiotics, flea control) should be suspected.

DIAGNOSIS IN A PREVIOUSLY TREATED DOG

Occasionally, a clinician wishes to determine whether a dog receiving thyroid hormone supplementation is in fact hypothyroid. Exogenous administration of thyroid hormone, either T_4 or T_3, will suppress pituitary TSH secretion and cause pituitary thyrotroph atrophy and subsequent thyroid gland atrophy in a healthy euthyroid dog. Serum T_4, fT_4, and TSH concentrations are decreased or undetectable; the severity of the decrease is dependent on the severity of thyroid gland atrophy induced by the thyroid supplement. Serum T_4 and fT_4 results are often suggestive

of hypothyroidism, even in a previously euthyroid dog, if testing is performed within a month of treatment discontinuation. Thyroid hormone supplementation must be discontinued, either by stopping all at once or by gradual reduction over 2 to 3 weeks, and the pituitary-thyroid axis allowed to regain function before meaningful baseline serum thyroid hormone concentrations can be obtained. The time between discontinuation of thyroid hormone supplementation and acquisition of meaningful test results depends on the duration of treatment, the dose and frequency of administration of the thyroid hormone supplement, and individual variability. As a general rule, thyroid hormone supplements should be discontinued for a minimum of 4 weeks, preferably 6 to 8 weeks, before thyroid gland function is critically assessed.

DIAGNOSIS IN PUPPIES

An approach similar to that discussed for the adult dog is used to diagnose congenital hypothyroidism. However, serum TSH concentrations are dependent on the cause of the disorder. TSH concentrations will be increased in dogs with primary dysfunction of the thyroid gland (e.g., iodine organification defect) and an intact hypothalamic-pituitary-thyroid gland axis. TSH concentrations will be within the reference range or undetectable in dogs with pituitary or hypothalamic dysfunction as the cause of the hypothyroidism. Identification of an enlarged thyroid gland (i.e., goiter) implies an intact hypothalamic-pituitary-thyroid gland axis, functional TSH receptors, and appropriate signal transduction following binding of TSH to receptors and suggests a post-TSH receptor problem in the follicular cells, such as an iodine organification defect as the cause of the hypothyroidism.

Treatment

THERAPY WITH SODIUM LEVOTHYROXINE (SYNTHETIC T_4)

Initial treatment and monitoring recommendations are summarized in Box 48.5. Synthetic levothyroxine is the treatment of choice for hypothyroidism. Its oral administration should result in normal serum concentrations of T_4, T_3, and TSH, which attests to the fact that these products can be converted to the more metabolically active T_3 by peripheral tissues. A sodium levothyroxine product approved for use in dogs is recommended. Liquid and tablet formulations are effective. The initial dosage is 0.01 to 0.02 mg/kg body weight. The plasma half-life of sodium levothyroxine ranges from 9 to 14 hours and depends, in part, on the dosage and frequency of administration. Twice-daily administration is recommended initially unless the levothyroxine product has been specifically formulated for once-daily administration (Le Traon et al., 2009). Because of the variability in levothyroxine absorption and metabolism, the dose and frequency may have to be adjusted before a satisfactory clinical response is observed; this variability is one reason for monitoring therapy in dogs.

BOX 48.5

Recommendations for Initial Treatment and Monitoring of Hypothyroidism in Dogs

Initial Treatment

- Use a synthetic levothyroxine product approved for use in dogs.
- Tablet and liquid formulations of levothyroxine are effective.
- The initial dosage per administration should be 0.01 to 0.02 mg/kg of body weight./
- The initial frequency of administration is every 12 hours unless the levothyroxine product has been specifically formulated for once-daily administration.

Initial Monitoring

- Response to treatment should be critically evaluated 4 to 8 weeks after treatment initiation.
- Serum T_4 and TSH concentrations should be measured 4 to 6 hours after administration of levothyroxine.
- Serum T_4 should be in the reference range or mildly increased.
- Serum TSH concentration should be in the reference range.
- Measuring serum T_4 concentration immediately before levothyroxine administration (i.e., trough level) is optional but is recommended if levothyroxine is being given once a day.
- The trough concentration of serum T_4 should be in the reference range.

TSH, Thyroid-stimulating hormone.

Response to Sodium Levothyroxine Therapy

Thyroid hormone supplementation should be continued for a minimum of 4 weeks before the effectiveness of treatment is critically evaluated. With appropriate therapy, all clinical signs and clinicopathologic abnormalities associated with hypothyroidism are reversible. Improvement in mental alertness and activity usually occurs within the first week of treatment; this is an important early indicator that the diagnosis of hypothyroidism was correct. Although some hair regrowth usually occurs within the first month in dogs with endocrine alopecia, it may take several months for complete regrowth and a marked reduction in hyperpigmentation of the skin to occur. Initially, the haircoat may worsen as large amounts of hair in the telogen stage of the hair cycle are shed. Improvement in neurologic manifestations is usually evident within days of treatment initiation; complete resolution of neurologic signs is unpredictable and may require treatment for 4 to 8 weeks or longer before it occurs.

Failure to Respond to Sodium Levothyroxine Therapy

Problems with levothyroxine therapy should be suspected if clinical improvement is not seen by 8 weeks after therapy is

initiated. An inappropriate diagnosis of hypothyroidism is the most obvious. Hyperadrenocorticism can be mistaken for hypothyroidism if other clinical signs (e.g., polyuria, polydipsia) commonly associated with hyperadrenocorticism are not present because of the suppressive effects of cortisol on serum thyroid hormone concentrations (see p. 781). Failure to recognize the impact of concurrent illness on thyroid hormone test results is another common reason for misdiagnosing hypothyroidism. Concurrent disease (e.g., allergic skin disease, flea hypersensitivity) is common in dogs with hypothyroidism and may affect the clinical impression of response to levothyroxine therapy if the disease is not recognized. Other possible reasons for a poor response to therapy are listed in Box 48.6. Whenever a dog shows a poor response to levothyroxine therapy, the history, physical examination findings, and diagnostic test results that prompted the initiation of levothyroxine therapy should be critically reevaluated and serum thyroid hormone concentrations measured.

THERAPEUTIC MONITORING

Therapeutic monitoring includes evaluation of the clinical response to levothyroxine treatment, measurement of serum T_4 concentration before or after levothyroxine administration, or both, and measurement of serum TSH concentration. These concentrations should be measured 4 weeks after therapy is initiated, whenever signs of thyrotoxicosis develop, or in the event that minimal or no response to therapy has occurred. Concentrations should also be measured 2 to 4 weeks after an adjustment in levothyroxine therapy in dogs showing a poor response to treatment.

Serum T_4 and TSH concentrations are typically evaluated 4 to 6 hours after administration of levothyroxine in dogs. Measuring serum T_4 concentration immediately before levothyroxine administration (i.e., trough level) is optional but is recommended if levothyroxine is being given once a day. Measurement of serum fT_4 can be done in lieu of measurement of T_4 but is more expensive and usually does not offer additional information, except in dogs with T_4 autoantibodies. The presence of thyroid hormone autoantibodies does not interfere with the physiologic actions of levothyroxine.

Ideally, the serum T_4 concentration should be in the upper half of the reference range, typically between 2.0 and 5.0 µg/dL (26 and 65 nmol/L) when measured 4 to 6 hours after thyroid hormone administration, and the TSH concentration should be in the reference range (i.e., <0.6 ng/mL). Postdosing serum T_4 concentrations measured at times other than 4 to 6 hours after sodium levothyroxine administration should be interpreted with the realization that serum T_4 concentrations may not be at peak concentrations. The postpill serum T_4 concentration may also be affected by diet (i.e., decreased absorption). Consistency between the timing of levothyroxine administration and feeding should be maintained when monitoring therapy.

Postdosing serum T_4 concentrations are frequently above the reference range. The finding of an increased postdosing serum T_4 concentration is not an absolute indication to reduce the dose of levothyroxine, especially if no clinical signs of thyrotoxicosis are noted. However, a reduction in the dose is recommended whenever serum T_4 concentrations exceed 6.0 µg/dL (75 nmol/L). Postdosing serum T_4 concentrations may also be less than 2 µg/dL. In this situation, an increase in the dose or frequency of administration of levothyroxine is indicated if clinical manifestations of hypothyroidism persist, the serum TSH concentration remains increased, or both but is not necessarily indicated if the clinical response to treatment is good and the serum TSH concentration is in the reference range. Resolution of clinical signs and a satisfied owner are the most important parameters when one is considering adjusting the levothyroxine dose simply because the postpill serum T_4 concentration is near the lower end of the reference interval. Postdosing serum T_4 and TSH concentrations and recommendations for changes in therapy are given in Fig. 48.11.

BOX 48.6

Potential Reasons for Poor Clinical Response to Treatment With Sodium Levothyroxine (Synthetic T_4)

- Client compliance problems
- Use of inactivated or outdated product
- Inappropriate levothyroxine dose
- Inappropriate frequency of administration
- Low tablet strength*
- Poor bioavailability (e.g., poor gastrointestinal tract absorption)
- Inadequate time for clinical response to occur
- Concurrent illness causing similar clinical signs (e.g., flea hypersensitivity)
- Incorrect diagnosis of hypothyroidism

**Tablet strength* refers to the actual amount of active drug in a tablet, as opposed to the stated amount.

THYROTOXICOSIS

Thyrotoxicosis may develop in dogs receiving excessive amounts of levothyroxine; in dogs in which the plasma half-life for levothyroxine is inherently prolonged, especially in those receiving levothyroxine twice daily; in dogs with impaired metabolism of levothyroxine (e.g., concurrent renal or hepatic insufficiency); and in dogs consuming all-meat commercial dog food. Rarely, thyrotoxicosis develops in a dog given minute amounts of levothyroxine. The reason for this marked sensitivity to the hormone is not known. Diagnosis of thyrotoxicosis is based primarily on the presence of clinical signs, which include nervousness, panting, tachypnea, tachycardia, aggressive behavior, polyuria, polydipsia, polyphagia, and weight loss. Documenting increased serum T_4 and fT_4 and undetectable serum TSH concentrations supports the diagnosis. However, serum T_4 and fT_4 concentrations can occasionally be within the reference range in a dog with signs of thyrotoxicosis and are

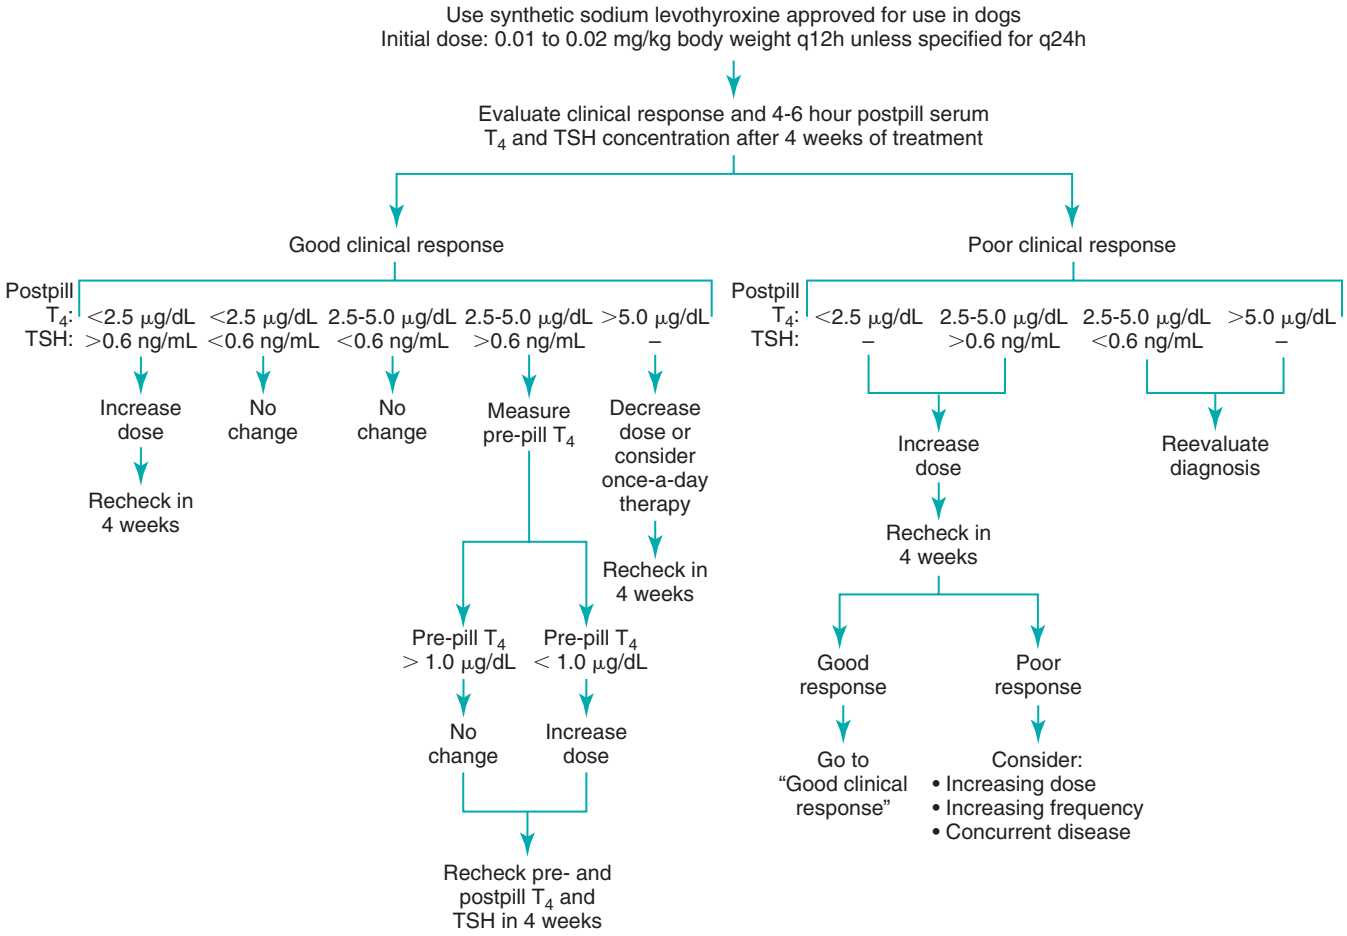

FIG 48.11
Initial therapeutic approach and monitoring recommendations for dogs with hypothyroidism.

commonly increased in dogs with no signs of thyrotoxicosis. Adjustments in the dose or frequency of administration of levothyroxine, or in both measures, are indicated if clinical signs of thyrotoxicosis develop in a dog receiving thyroid hormone supplements. Supplementation should be discontinued for a few days if clinical signs are severe. Signs of thyrotoxicosis should resolve within 1 to 3 days if they are due to the thyroid medication and the adjustment in treatment has been appropriate.

Prognosis

The prognosis for adult dogs with primary hypothyroidism receiving appropriate therapy is excellent. The prognosis for puppies with hypothyroidism (i.e., cretinism) is guarded and depends on the severity of skeletal and joint abnormalities at the time treatment is initiated. Although many of the clinical signs resolve with therapy, musculoskeletal problems, especially degenerative osteoarthritis, may develop as the result of abnormal bone and joint development. The prognosis for dogs with secondary hypothyroidism caused by congenital malformation of the pituitary gland (i.e., pituitary dwarfism) is guarded and dependent on the extent of pituitary hormone deficiencies (see Chapter 46). The prognosis for dogs with acquired secondary hypothyroidism caused by suppression of pituitary function by medications (e.g., glucocorticoids) is excellent, although treatment with levothyroxine may be necessary if the medication cannot be discontinued. The prognosis for dogs with acquired secondary hypothyroidism caused by destruction of the pituitary region by a space-occupying mass is grave.

HYPOTHYROIDISM IN CATS

Etiology

Iatrogenic hypothyroidism is the most common cause of hypothyroidism in cats and can result from bilateral thyroidectomy, radioactive iodine treatment, or an overdose of antithyroid drugs. Naturally acquired adult-onset primary hypothyroidism is rare. Low serum T_4 concentrations are commonly identified in blood samples submitted for a feline geriatric panel that includes serum T_4 measurement, but the low serum T_4 result is almost always a result of the suppressive effects of nonthyroid illness. Congenital primary

hypothyroidism causing disproportionate dwarfism is recognized more frequently in cats than adult-onset hypothyroidism. Reported causes of congenital hypothyroidism include a defect in thyroid hormone biosynthesis, most notably an iodine organification defect, and thyroid dysgenesis. Goiter is common in cats with defects in thyroid hormone biosynthesis because the hypothalamic-pituitary-thyroid gland axis and post-TSH receptor signal transduction remain intact. A suspected autosomal recessive inherited defect in iodine organification was documented in a family of Abyssinian cats with congenital hypothyroidism. Although rare, iodine deficiency may cause hypothyroidism in kittens fed a strict all-meat diet.

Clinical Signs

Clinical signs of feline hypothyroidism are listed in Box 48.7. The most common are lethargy, inappetence, obesity, and seborrhea sicca. Lethargy and inappetence may become severe. Additional dermatologic signs may include a dry, lusterless, unkempt haircoat; easily epilated hair; poor regrowth of hair; and alopecia. Bradycardia and mild hypothermia may be additional findings on physical examination.

The clinical signs of congenital hypothyroidism are similar to those in dogs. Affected kittens typically appear normal at birth, but delayed growth usually becomes evident by 8 weeks of age. Disproportionate dwarfism develops over ensuing months, with a large head, a short broad neck, and short limbs developing in affected kittens (Fig. 48.12). Additional findings include lethargy, mental dullness, constipation, hypothermia, bradycardia, and prolonged retention of deciduous teeth. The haircoat may consist mainly of an undercoat with primary guard hairs scattered thinly throughout.

BOX 48.7

Clinical Manifestations of Feline Hypothyroidism

Adult-Onset Hypothyroidism

- Lethargy
- Inappetence
- Obesity
- Dermatologic events
  - Seborrhea sicca
  - Dry, lusterless haircoat
  - Easily epilated hair
  - Poor regrowth of hair
  - Endocrine alopecia
  - Alopecia of pinnae
  - Thickened skin
  - Myxedema of the face
- Reproduction
  - Failure to cycle
  - Dystocia
- Bradycardia
- Mild hypothermia

Congenital Hypothyroidism

- Disproportionate dwarfism
- Failure to grow
- Large head
- Short, broad neck
- Short limbs
- Lethargy
- Mental dullness
- Constipation
- Hypothermia
- Bradycardia
- Retention of kitten haircoat
- Retention of deciduous teeth

Diagnosis

Establishing a diagnosis of hypothyroidism in the cat should be based on a combination of history, clinical signs, physical examination findings, results of routine blood and urine tests, and baseline serum T_4, fT_4, and TSH concentrations. Abnormalities identified on routine blood and urine tests include hypercholesterolemia and a mild nonregenerative anemia. Serum T_4 concentration is often used as the initial screening test of thyroid gland function. A normal serum T_4 concentration indicates that the cat is euthyroid. A low serum T_4 concentration in a cat that has undergone thyroidectomy or radioactive iodine treatment or in a kitten with disproportionate dwarfism supports the diagnosis of hypothyroidism. The effect of age should be considered when serum T_4 concentrations in kittens are interpreted (see Table 48.2). Because naturally acquired primary hypothyroidism is

FIG 48.12
A 1-year-old domestic long-haired cat with pituitary dwarfism. A comparably aged cat is also present to illustrate the small size of the pituitary dwarf. Note the square, chunky contour of the head and the dull facial expression of the cat—findings that are suggestive of cretinism (see Fig. 49.8, for comparison). The cat had concurrent growth hormone and thyroid hormone deficiency. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

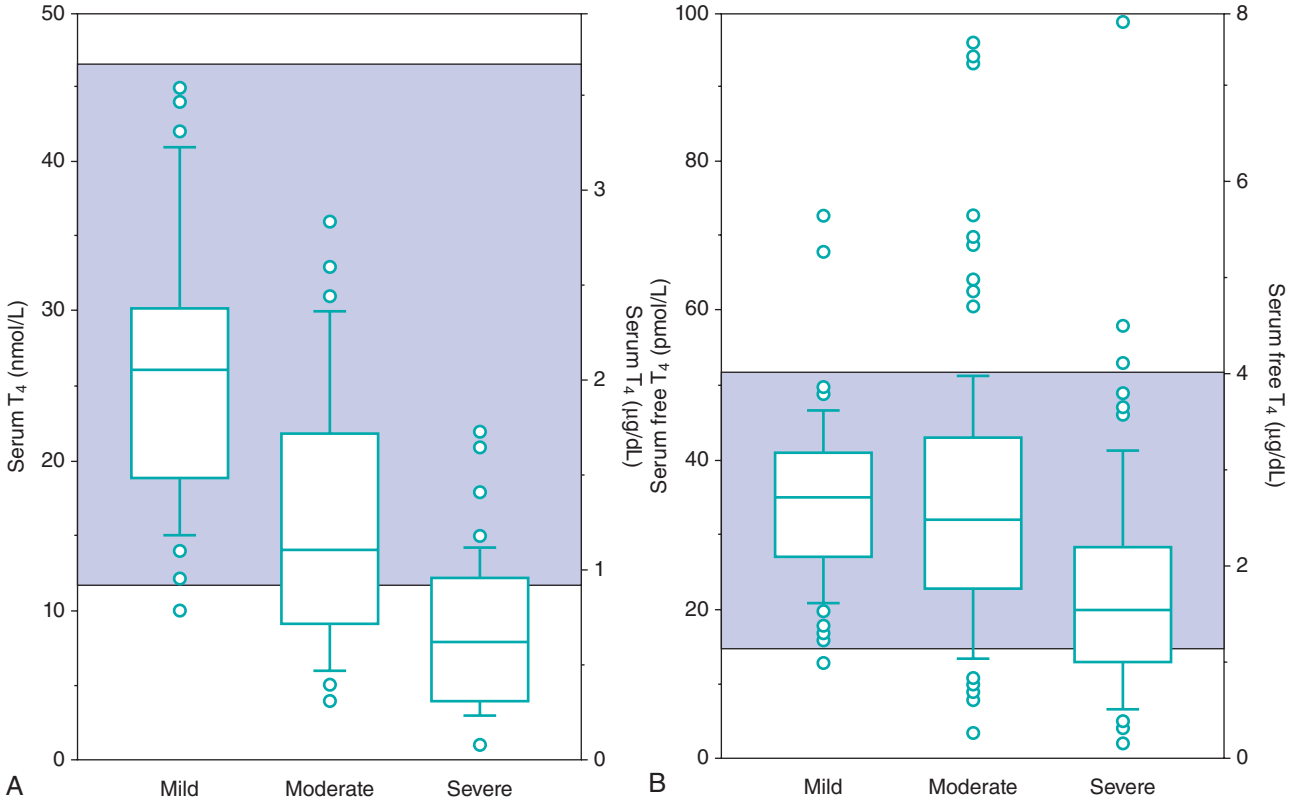

FIG 48.13
Box plots of serum total T_4 **(A)** and free T_4 **(B)** concentrations in 221 cats with nonthyroidal disease, grouped according to severity of illness. Of 221 cats with nonthyroidal illness, 65 had mild disease, 83 had moderate disease, and 73 had severe disease. See Fig. 48.9 for explanation. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal disease, *J Am Vet Med Assoc* 218:529, 2001.)

rare and low serum T_4 concentrations in adult cats are almost always caused by nonthyroidal illness (Fig. 48.13) or some other nonthyroidal factor, the diagnosis of hypothyroidism should not be made solely on the basis of the serum T_4 concentration in an adult cat that has not been previously treated for hyperthyroidism. Documenting a low serum fT_4 and a high serum TSH concentration adds further evidence for the diagnosis of hypothyroidism. The definitive diagnosis relies on the cat's response to trial therapy with levothyroxine.

Treatment

Treatment of hypothyroidism in cats is similar to that in dogs, which is described in detail on page 783. Treatment with levothyroxine is indicated for cats with congenital and naturally acquired adult-onset hypothyroidism and for cats with iatrogenic hypothyroidism that are symptomatic for the disease following treatment for hyperthyroidism. Asymptomatic cats with a low serum T_4 concentration after receiving treatment for hyperthyroidism should not be treated until clinical signs become evident, in the hope that additional time will allow atrophied or ectopic thyroid tissue to become functional. Kidney function should be monitored because hypothyroidism may decrease GFR and unmask or exacerbate azotemia in cats (see page 790) versus bilateral thyroid lobe involvement. Synthetic levothyroxine is recommended at an initial dosage of 0.05 or 0.1 mg once daily initially. A minimum of 4 weeks should elapse before the cat's clinical response to treatment is critically assessed. Subsequent evaluations should include a history, physical examination, and measurement of serum T_4 and TSH concentrations (see the discussion of therapeutic monitoring, p. 784). The goal of therapy is to eliminate the clinical signs of hypothyroidism and prevent signs of hyperthyroidism. This can usually be accomplished by maintaining the serum T_4 concentration at between 1.0 and 3.0 µg/dL (13 and 40 nmol/L). Normalization of the serum TSH concentration supports an effective levothyroxine treatment regimen. The dose and frequency of levothyroxine administration should be adjusted accordingly to attain these goals. If the serum T_4 concentration is within the reference range after 4 to 8 weeks of treatment but there is minimal or no clinical response, the clinician should reassess the diagnosis.

Prognosis

The prognosis for adult cats with hypothyroidism receiving appropriate therapy is excellent. The prognosis for kittens with congenital hypothyroidism is guarded and depends on the severity of skeletal changes at the time treatment is initiated. Many of the clinical signs resolve and body size may increase if hypothyroidism is identified early, before abnormal bone and joint development occurs.

HYPERTHYROIDISM IN CATS

Etiology

Hyperthyroidism is a multisystemic disorder resulting from excessive production and secretion of T_4 and T_3 by the thyroid gland and is almost always a result of chronic intrinsic disease in one or both thyroid lobes. One or more usually small, discrete thyroid masses are palpable in the ventral region of the neck in most cats with hyperthyroidism. Follicular cell adenoma and multinodular adenomatous hyperplasia are the most common histologic findings. Both are benign and both may occur together within the same thyroid lobe. Less common are thyroid adenomas that cause the lobes to become markedly enlarged and distorted; thyroid carcinoma accounts for less than 5% of clinical cases.

One or both thyroid lobes can be affected in thyrotoxic cats. Approximately 30% of hyperthyroid cats have involvement of a single thyroid lobe (Fig. 48.14). The contralateral unaffected thyroid lobe is nonfunctioning and atrophied because of the suppressive effects of the hyperactive thyroid tissue on TSH secretion. Approximately 65% of hyperthyroid cats have involvement of both thyroid lobes (Fig. 48.15). Among these cats the thyroid lobes are symmetrically enlarged in 10% to 15% and asymmetrically enlarged in the remainder. Approximately 10% of enlarged thyroid lobes descend to the thoracic inlet and can be difficult to palpate. Less than 5% of thyrotoxic cats have hyperactive thyroid tissue in an ectopic location, most commonly the anterior mediastinum, with or without a palpable mass in the neck (Fig. 48.16). Functional thyroid carcinoma is the most likely diagnosis if more than two thyroid masses are present (see Fig. 48.16), although adenomatous hyperplasia of ectopic sites in addition to the thyroid lobes is possible. Some cats with thyroid carcinoma initially have only one or two thyroid masses, emphasizing the importance of histologic evaluation of surgically removed tissue.

The pathogenesis of adenomatous hyperplastic changes in the thyroid gland remains unclear. It has been postulated that immunologic, infectious, nutritional, environmental, or genetic factors may interact to cause pathologic changes. Nondietary risk factors identified by case-controlled studies include increasing age; indoor housing; use of fertilizers, herbicides, flea powders, and sprays; and use of cat litter. Epidemiologic studies have identified consumption of commercial canned cat foods as a risk factor for development of hyperthyroidism, suggesting that a goitrogenic compound may

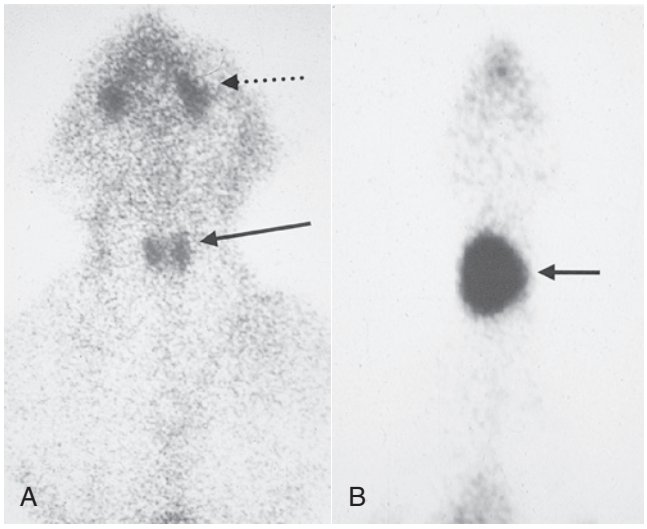

FIG 48.14

This is the most common form of the disease. **(B)** Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by bilateral, symmetric disease affecting both thyroid lobes *(arrows)*. Hypocalcemia after bilateral thyroidectomy is a major concern.

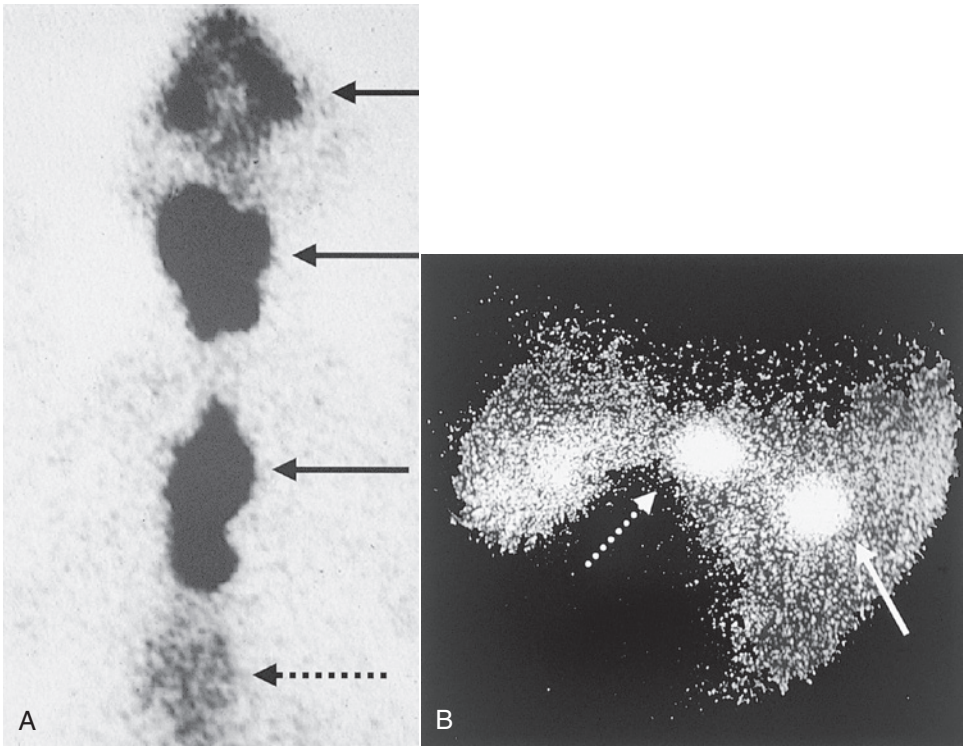

FIG 48.16
(A) Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by metastatic thyroid adenocarcinoma with multiple masses present in the head, neck, and anterior mediastinum *(solid arrows)*. Heart *(broken arrow)*. **(B)** Sodium pertechnetate scan of the head, neck, and proximal thorax of a cat with hyperthyroidism caused by two hyperfunctioning masses: one located in the neck *(broken arrow)* and one in the anterior mediastinum (i.e., ectopic site) *(solid arrow)*. ^{131}I therapy is the treatment of choice for both forms of hyperthyroidism illustrated in this figure.

be present in the diet. Excessive or deficient iodine content, isoflavones from soybeans, chemicals lining pop-top canned foods (specifically bisphenol A) that have migrated into the food during storage, and exposure to endocrine disruptors such as polybrominated diphenyl ethers (PBDEs) identified in cat food and house dust have been proposed as possible etiologic factors. Studies have identified overexpression of the *c-ras* oncogene in areas of nodular follicular hyperplasia in feline thyroid glands (Merryman et al., 1999) and altered expression of G proteins involved in TSH receptor signal transduction in hyperthyroid cats (Ward et al., 2010). The significance, if any, of these findings in the development of hyperthyroidism and the pathogenesis of adenomatous hyperplastic changes in the thyroid gland is not known.

Clinical Features

SIGNALMENT

Hyperthyroidism is the most common endocrine disease affecting cats older than 8 years. The average age at the time of initial presentation to the veterinarian is 13 years, with a range of 4 to 20 years. Less than 5% of cats with this disorder are younger than 8 years. No sex-related predisposition has been noted; domestic short-haired and long-haired cats are the most frequently affected breeds. Siamese and Himalayans are at decreased risk for development of hyperthyroidism.

CLINICAL SIGNS

Clinical signs are a result of excessive secretion of thyroid hormone by the thyroid mass. Rarely, a client will seek veterinary care because of an observed mass in the ventrocervical region of the neck. The classic clinical signs of hyperthyroidism are weight loss and muscle wasting (which may progress to cachexia), polyphagia, and restlessness or hyperactivity. Additional clinical signs include haircoat changes (patchy alopecia, matted hair, minimal or excessive grooming behavior), polyuria, polydipsia, vomiting, and diarrhea (Table 48.4). Some cats develop aggressive behavior that resolves in response to successful treatment of the hyperthyroid state. In some cats lethargy, weakness, and anorexia are the dominant clinical features, in addition to weight loss. Because of the multisystemic effects of hyperthyroidism, the variable clinical signs, and its resemblance to many other diseases of the cat, hyperthyroidism should be suspected in any aged cat with medical problems.

PHYSICAL EXAMINATION

Physical examination findings are listed in Table 48.4. A discrete thyroid mass is palpable in approximately 90% of cats with hyperthyroidism (Video 48.1). However, palpation of a cervical mass is not pathognomonic for hyperthyroidism. Some cats with palpable thyroid lobes are clinically normal, and some palpable cervical masses are not thyroid in origin. It is frequently difficult to accurately assess unilateral on the basis of palpation. Two distinct masses cannot always be appreciated on palpation, even if both lobes are large. Large thyroid masses may gravitate to the region of the thoracic inlet, and this can interfere with their palpation. The thyroid mass may even descend into the anterior mediastinum. This should be suspected when a thyroid mass is not palpable in a hyperthyroid cat, although a small, nonpalpable mass is also possible.

TABLE 48.4

Clinical Signs and Physical Examination Findings in Cats With Hyperthyroidism

CLINICAL SIGNS	PHYSICAL EXAMINATION FINDINGS
Weight loss*	Palpable thyroid*
Polyphagia*	Thin cat*
Unkempt haircoat, patchy alopecia*	Hyperactive cat, difficult to examine*
Polyuria-polydipsia*	Tachycardia*
Vomiting*	Hair loss, unkempt haircoat*
Nervous, restless, hyperactive*	Small kidneys
Diarrhea, bulky stools	Heart murmur
Decreased appetite	Easily stressed cat
Tremor	Cachectic appearance, muscle wasting
Weakness	Premature beats
Dyspnea, panting	Gallop rhythm
Decreased activity, lethargy	Aggressive cat
Anorexia	Lethargic, weak cat Ventral flexion of the neck

*Common.

Clinical Pathology

Results of a CBC are usually normal. The most common abnormalities are a mild increase in PCV and mean corpuscular volume. Neutrophilia, lymphopenia, eosinopenia, or monocytopenia is identified in less than 20% of hyperthyroid cats. Common serum biochemical abnormalities include an increase in serum activities of alanine aminotransferase, alkaline phosphatase, and aspartate aminotransferase; this increase is typically in the mild to moderate range (i.e., 100-400 IU/L). One or more of these liver enzymes are increased in approximately 90% of hyperthyroid cats. Additional evaluation of the liver should be considered if liver enzyme activities are greater than 500 IU/L. Hyperthyroid-induced increases in liver enzymes resolve following treatment of hyperthyroidism. Increased serum urea nitrogen and creatinine concentrations are identified in approximately 25%, and hyperphosphatemia in 20%, of hyperthyroid cats at our clinic—findings that have important implications regarding treatment (see the discussion on chronic kidney disease [CKD], p. 790). Urine specific gravity ranges from 1.008 to greater than 1.050. Most hyperthyroid cats have urine specific gravities greater than 1.035. Mild proteinuria is also common and is a risk factor for the development and progression of CKD. The severity of proteinuria, as determined by UPC, tends to decrease once a euthyroid state is attained. The remainder of the urinalysis is usually unremarkable unless concurrent diabetes mellitus or urinary tract infection exists.

COMMON CONCURRENT PROBLEMS

Thyrotoxic Cardiomyopathy

Hypertrophic and, less commonly, dilative thyrotoxic cardiomyopathy may develop in cats with hyperthyroidism. Cardiovascular abnormalities detectable during physical examination include tachycardia; a pounding heartbeat noted on palpation of the ventral thorax; and, less frequently, pulse deficits, gallop rhythms, cardiac murmur, and muffled heart sounds resulting from a pleural effusion. Electrocardiographic abnormalities include tachycardia; increased R-wave amplitude in lead II; and, less commonly, a right bundle branch block, a left anterior fascicular block, widened QRS complexes, and atrial and ventricular arrhythmias. Thoracic radiographs may reveal cardiomegaly, pulmonary edema, or a pleural effusion. Echocardiographic abnormalities identified in cats with hypertrophic thyrotoxic cardiomyopathy include left ventricular hypertrophy, thickening of the interventricular septum, left atrial and ventricular dilation, and myocardial hypercontractility. Those seen in cats with dilative thyrotoxic cardiomyopathy include subnormal myocardial contractility and marked ventricular dilation. Either form of cardiomyopathy may result in the development of congestive heart failure. Hypertrophic thyrotoxic cardiomyopathy is usually reversible once the hyperthyroid state is corrected, whereas dilative thyrotoxic cardiomyopathy is not.

Chronic Kidney Disease and Iatrogenic Hpothyroidism

Hyperthyroidism and CKD are common in older cats and often occur concurrently. Identification of small kidneys on physical examination, increased serum urea nitrogen and creatinine concentrations, and urine specific gravity between 1.008 and 1.020 should raise suspicion for concurrent CKD in a cat with hyperthyroidism. Unfortunately, hyperthyroidism increases GFR, renal blood flow, and renal tubular resorptive and secretory capabilities in normal and compromised kidneys. Renal perfusion and GFR may acutely decrease, and azotemia or clinical signs of CKD become apparent or significantly worsen after treatment of the hyperthyroid state. It is not easy to determine what impact the hyperthyroid state is having on kidney function in cats. The clinical and biochemical manifestations of CKD may be masked in cats with both thyroid and kidney disease in which renal perfusion is enhanced by the circulatory dynamics produced by hyperthyroidism. Biochemical parameters, blood pressure, urine specific gravity, and proteinuria are poor predictors of the onset of azotemia following treatment of hyperthyroidism. For these reasons cats with hyperthyroidism should initially be given reversible therapy (i.e., oral antithyroid drugs or limited iodine diet) until the impact of establishing euthyroidism on kidney function can be determined. Maximum reduction in GFR is usually attained

within 1 month of establishing euthyroidism. Fortunately, most hyperthyroid cats will stay within or increase only one IRIS (International Renal Interest Society) stage in the classification of CKD.

It is important to maintain serum T_4 concentration in the lower half of the reference range when assessing kidney status during methimazole treatment. Iatrogenic hypothyroidism is associated with an increased incidence of azotemia in hyperthyroid cats as a result of hypothyroid–induced decrease in GFR. Restoration of serum T_4 concentration into the reference range may improve GFR, decrease serum creatinine concentration, and provide a more accurate assessment of kidney function.

Urinary Tract Infection

Urinary tract infection is relatively common in untreated hyperthyroid cats, with a reported prevalence of 12% to 22%. The most common bacterial isolate is *Escherichia coli*. Urine culture is indicated in hyperthyroid cats with lower urinary tract signs or the presence of bacteriuria, pyuria, or both on urinalysis. Unfortunately, most hyperthyroid cats are asymptomatic for urinary tract infection, suggesting that urine culture should be a routine part of the complete diagnostic evaluation of cats with newly diagnosed hyperthyroidism.

Systemic Hypertension

Systemic hypertension is common in cats with hyperthyroidism and results from the effects of increased β-adrenergic activity on heart rate, myocardial contractility, systemic vasodilation, and activation of the renin-angiotensin-aldosterone system. Hypertension caused by hyperthyroidism is usually clinically silent. Retinal hemorrhage and retinal detachment are the most common clinical complications of systemic hypertension in hyperthyroid cats, but in general, ocular lesions are not commonly identified. Resolution of systemic hypertension following treatment of the hyperthyroid state is unpredictable and dependent, in part, on the underlying cause of the hypertension. Hyperthyroid-induced hypertension will resolve in most cats following treatment. As a general rule, we initiate amlodipine treatment if the systolic blood pressure is consistently greater than 180 mm Hg or if ocular lesions are identified. Otherwise we prefer to reevaluate blood pressure once the hyperthyroidism is treated and initiate amlodipine if hypertension persists despite correction of the hyperthyroid state (see Chapter 11).

Gastrointestinal Tract Disorders

Gastrointestinal tract signs are common in cats with hyperthyroidism and include polyphagia, weight loss, anorexia, vomiting, diarrhea, increased frequency of defecation, and increased volume of feces. Intestinal hypermotility and malassimilation have been documented in some cats with hyperthyroidism and are responsible for producing some of the gastrointestinal tract signs. Inflammatory bowel disease is a common concurrent gastrointestinal tract disorder that should be considered in any hyperthyroid cat that shows persistence of gastrointestinal signs after correction of the hyperthyroid state (see Chapter 31). Intestinal neoplasia, most notably lymphoma, is perhaps the most important differential diagnosis in cats seen because of polyphagia and weight loss. The abdomen should be carefully palpated in a search for thickening of the intestinal tract and mesenteric lymphadenopathy—findings that may be the only clues for intestinal lymphoma. Abdominal ultrasonography may also provide clues to the possibility of lymphoma.

Diagnosis

The diagnosis of hyperthyroidism is based on identification of appropriate clinical signs, palpation of a thyroid mass, and documentation of an increased serum T_4 concentration.

Baseline Serum T_4 Concentration

Measurement of random baseline serum T_4 concentrations has been extremely reliable in differentiating hyperthyroid cats from those without thyroid disease (Fig. 48.17). The typical reference range for serum T_4 is approximately 1.0 to 4.0 µg/dL (50-65 mmol/L), although reference ranges for individual laboratories vary. A serum T_4 concentration above the reference range strongly supports the diagnosis of hyperthyroidism, especially if appropriate clinical signs are present, and a low serum T_4 concentration rules out hyperthyroidism (Table 48.5). Serum T_4 concentrations that fall within the upper half of the reference range create a diagnostic dilemma, especially if clinical signs are suggestive of hyperthyroidism and a mass is palpable in the ventral region of the neck. This combination of findings is referred to as *occult hyperthyroidism* and is most commonly identified in cats in the early stages of hyperthyroidism. Serum T_4 concentrations are more likely to be influenced by nonthyroidal factors such as concurrent illness and are more likely to randomly fluctuate into the reference range in cats with mild hyperthyroidism, compared with cats with more advanced disease (Fig. 48.18; see also Fig. 48.13). The diagnosis of hyperthyroidism should not be excluded on the basis of one "normal" serum T_4 test result, especially in a cat with appropriate, albeit often mild, clinical signs and a palpable mass in the neck. Additional diagnostic tests for consideration

TABLE 48.5

Interpretation of Baseline Serum Thyroxine (T_4) Concentration in Cats With Suspected Hyperthyroidism

SERUM T_4 CONCENTRATION[+]	PROBABILITY OF HYPERTHYROIDISM
>4.0 µg/dL	Likely
3.0-4.0 µg/dL	Possible
2.0-3.0 µg/dL	Unlikely*
<2.0 µg/dL	Very unlikely*

[+]Reference range: 1.0-4.0 µg/dL
*If a severe systemic illness is not present.

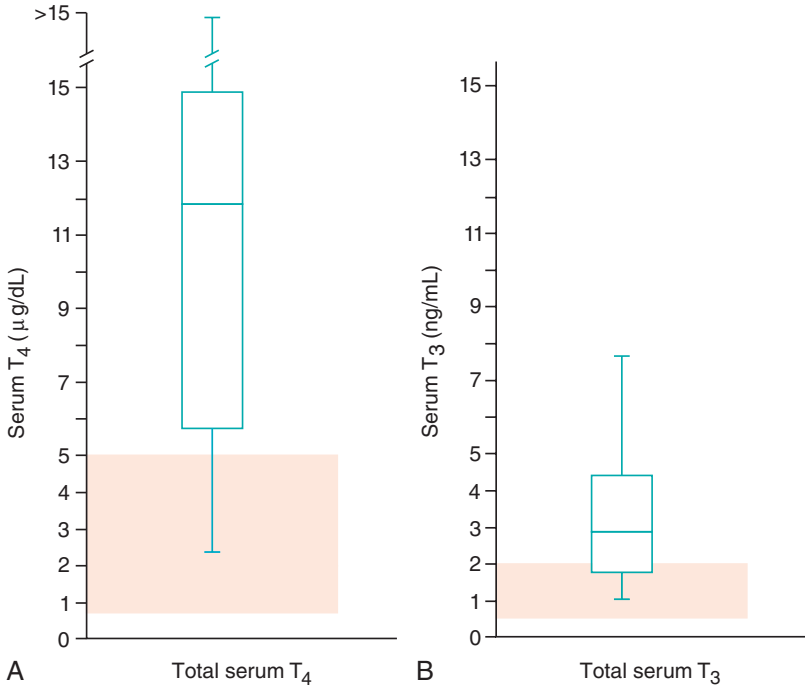

FIG 48.17
Mean and range of random total serum T_4 **(A)** and total serum T_3 **(B)** concentrations in hyperthyroid cats. Seventy-five percent of hyperthyroid cats have values within the box, and the balance is within the limitation bars above and below the box. Note that virtually all hyperthyroid cats have abnormal or borderline serum T_4 concentrations, whereas serum T_3 concentrations are less sensitive. The pink region represents the normal reference range.

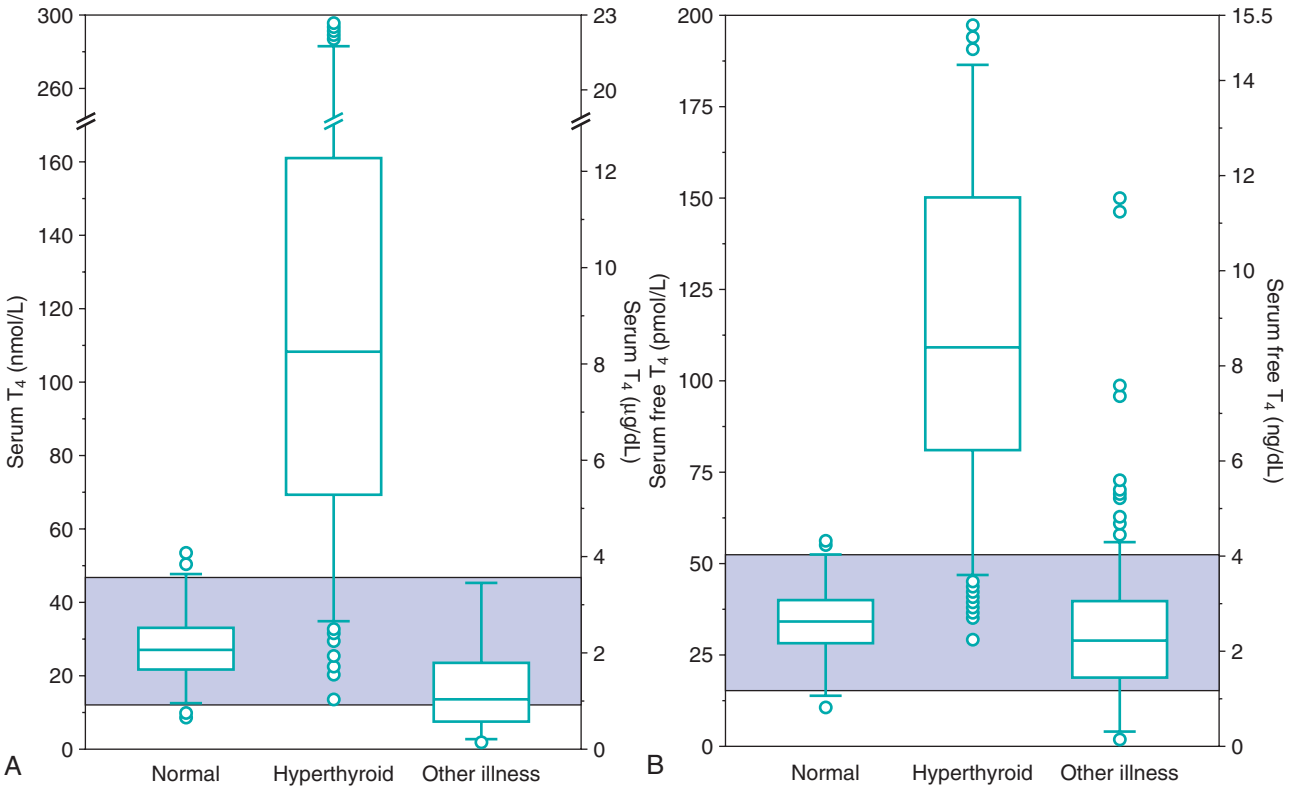

FIG 48.18
Box plots of serum total T_4 **(A)** and free T_4 **(B)** concentrations in 172 clinically normal cats, 917 cats with untreated hyperthyroidism, and 221 cats with nonthyroidal disease. See Fig. 48.9 for explanation. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal disease, *J Am Vet Med Assoc* 218:529, 2001.)

in a cat with a nondiagnostic serum T_4 test result include measurement of serum free T_4 (fT_4) and TSH concentrations, the T_3 suppression test, sodium pertechnetate thyroid scan, or repetition of the serum T_4 test 4 to 8 weeks later. It is important to remember that the thyroid mass may be nonfunctional, and the clinical signs may be the result of another disease.

Serum Free T_4 Concentration

Measurement of serum fT_4 using one of the methods discussed under Canine Hypothyroidism (see p. 776) is the current recommendation of choice to try to confirm hyperthyroidism in a cat with nondiagnostic serum T_4 test results. Measurement of serum fT_4 is considered a more reliable means of assessing thyroid gland function than measurement of serum T_4 concentration, in part because nonthyroidal illness has less of a suppressive effect on serum fT_4 than on T_4 (see Fig. 48.13), and serum fT_4 is increased in many cats with occult hyperthyroidism and "normal" T_4 test results. Because of cost, measurement of serum fT_4 is often reserved for cats with suspected hyperthyroidism in which T_4 values are nondiagnostic. Concurrent illness may increase the serum fT_4 concentration in cats—an increase that can exceed the reference range (see Fig. 48.18). For this reason, serum fT_4 concentration should always be interpreted in conjunction with a T_4 concentration measured from the same blood sample. An increased serum fT_4 concentration in conjunction with a serum T_4 concentration in the upper half of the reference range or higher is supportive of hyperthyroidism if the clinical presentation is consistent with the disease. An increased serum fT_4 concentration in conjunction with a serum T_4 concentration in the lower half of the reference range or lower is suggestive of nonthyroidal illness in a euthyroid cat rather than hyperthyroidism.

Serum TSH Concentration

Although a commercial feline-specific TSH assay is not currently available, a canine TSH assay (Immulite Canine TSH, DPC) has been validated for use in cats (Wakeling et al., 2008). Although sensitivity of the assay is suboptimal, in my experience measurement of baseline serum TSH concentration has provided additional information when thyroid gland function is assessed in cats with suspected early-onset or occult hyperthyroidism. The reference interval in senior cats (>8 years) is < 0.03 to 0.15 ng/mL (Wakeling et al., 2007). Reference ranges will vary depending on the laboratory and the assay used to measure TSH. Serum TSH should not be detectable (i.e., <0.03 ng/mL) in cats with hyperthyroidism. In theory, the finding of a measurable serum TSH concentration is inconsistent with hyperthyroidism and would be a negative indicator for occult hyperthyroidism. In a recent study, serum TSH concentrations were suppressed (i.e., nondetectable) in 98% of 917 hyperthyroid cats, but concentrations were measurable in a few cats with mild to moderate hyperthyroidism (Peterson et al., 2015). In comparison, 70% of 163 euthyroid cats had detectable TSH concentrations. Measurement of serum TSH concentration cannot, by itself, be used to diagnose hyperthyroidism because the reference range extends to nondetectable; a nondetectable TSH result occurs in hyperthyroid and euthyroid cats. Serum TSH concentrations should always be measured in combination with serum T_4 or fT_4.

T_3 Suppression Test

The T_3 suppression test is used to distinguish euthyroid from mildly hyperthyroid cats in cases in which T_4 and fT_4 test results are nebulous and serum TSH is not detectable. The T_3 suppression test is based on the theory that oral administration of liothyronine (T_3) will suppress pituitary TSH secretion in euthyroid cats, resulting in a decrease in circulating T_4 (Fig. 48.19). In contrast, pituitary TSH secretion is already suppressed in cats with hyperthyroidism, oral administration of T_3 will not cause further suppression, and serum T_4 will not decrease following T_3 administration. In this test, 25 µg of T_3 (e.g., Cytomel, King Pharmaceuticals) is administered orally three times per day for seven treatments, and serum T_4 and T_3 concentrations are determined before the first T_3 and 8 hours after the last T_3 administration. Normal cats consistently have postdosing serum T_4 concentrations less than 1.5 µg/dL (20 nmol/L), whereas hyperthyroid cats have postdosing T_4 concentrations greater than 2.0 µg/dL (26 nmol/L). Values of 1.5 to 2.0 µg/dL are nondiagnostic. The percentage decrease in serum T_4 concentration is not as reliable a gauge as the absolute value,

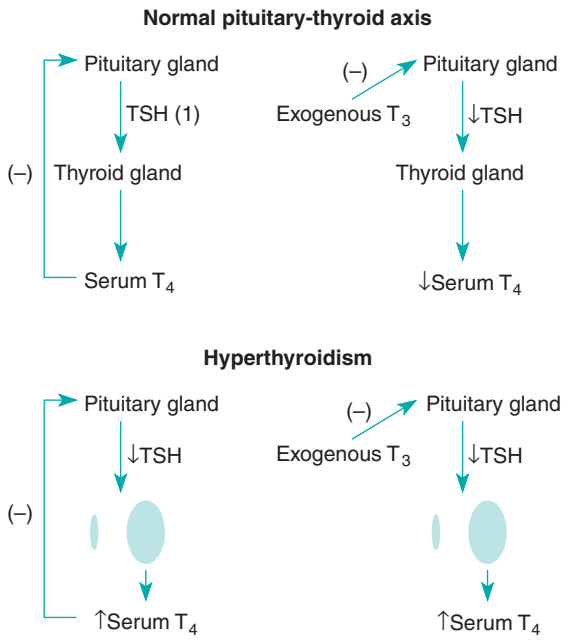

FIG 48.19
Effect of T_3 supplementation on the pituitary-thyroid axis in healthy cats and cats with hyperthyroidism. Suppression of pituitary TSH secretion by the T_3 supplement decreases serum T_4 concentration in healthy cats. In hyperthyroid cats the serum TSH concentration is already suppressed; the T_3 supplementation has no effect. The serum T_4 concentration remains increased.

although suppression of more than 50% below the baseline value occurs in normal but not hyperthyroid cats. Serum T_3 concentrations are used to determine whether the client has successfully administered the thyroid medication to the cat. Serum T_3 concentration measured in the postpill blood sample should be increased compared with results obtained before the test is initiated in all cats properly tested, regardless of the status of thyroid gland function.

Thyroid Scintigraphy

Thyroid scintigraphy identifies functional thyroid tissue and is used as a diagnostic test in cats with suspected occult hyperthyroidism; to identify ectopic thyroid tissue in cats with appropriate signs of hyperthyroidism and increased serum T_4 concentrations but no palpable thyroid nodule in the neck; to identify sites of metastasis in cats with thyroid carcinoma; and to provide guidance for developing the best treatment plan, especially if thyroidectomy is being considered. Radioactive technetium-99m (pertechnetate) is used for routine imaging of the thyroid gland in cats. It has a short physical half-life (6 hours), is concentrated within functioning thyroid follicular cells, and reflects the trapping mechanism of the gland. Because antithyroid drugs do not affect the trapping mechanism of the thyroid pump, thyroid scintigraphy can be done in cats being treated with antithyroid drugs. Salivary glands and the gastric mucosa also concentrate pertechnetate; it is excreted by the kidneys.

Scanning of the thyroid provides a picture of all functioning thyroid tissue and permits the delineation and localization of functioning as opposed to nonfunctioning areas of the thyroid but does not differentiate between adenomatous hyperplasia, adenoma, and carcinoma. Fig. 48.14 shows the similarity between the size and shape of the thyroid lobes and the similarity of radionuclide uptake by the thyroid and salivary glands in a normal cat. This 1:1 ratio of salivary gland to thyroid lobe uptake is the standard by which the status of the thyroid should be judged. Findings in most hyperthyroid cats are markedly abnormal and usually easy to interpret (see Figs. 48.14 to 48.16).

Cervical Ultrasound

Ultrasonographic evaluation of the thyroid gland can be used to confirm the origin of the palpable cervical mass, differentiate unilateral versus bilateral thyroid lobe involvement, assess the size of the thyroid mass(es), and provide guidance for developing the best treatment plan (Fig. 48.20). Ultrasound does not provide information on the functional status of the thyroid mass and should not be used in establishing the diagnosis of hyperthyroidism. Rather, cervical ultrasound should be used as an adjunctive tool for locating cervical thyroid tissue.

Treatment

Hyperthyroidism in cats can be managed by oral antithyroid medications, thyroidectomy, radioactive iodine, or an iodine-restricted diet (Table 48.6). All four modes of therapy are effective. Surgery and radioactive iodine treatments are used in the hope of providing a permanent cure for the disease; oral antithyroid drugs and an iodine-restricted diet only control the hyperthyroidism and must be given daily to achieve and maintain their effects.

Initial Treatment Recommendation

Hyperthyroid cats should be treated initially with an oral antithyroid drug (i.e., methimazole, carbimazole) to reverse hyperthyroid-induced metabolic and cardiac derangements, decrease the anesthetic risk associated with thyroidectomy, and assess the impact of treatment on kidney function. Feeding an iodine-restricted diet (Prescription Diet y/d, Hill's Pet Products) should be considered in situations where owners are unable to administer methimazole to their cat. Hyperthyroidism may mask CKD in some cats (see p. 790); azotemia may develop or worsen and clinical signs of CKD may develop after treatment of the hyperthyroid state. Because it is not easy to determine what impact the hyperthyroid state is having on kidney function, it is preferable to treat cats with reversible therapy (i.e., methimazole) until the impact of hyperthyroidism on kidney function can be determined. If the serum creatinine concentration remains static or improves after resolution of hyperthyroidism with methimazole, a more permanent treatment can be recommended. Idiopathic hypothyroidism can decrease GFR or increase serum creatinine concentration, and must be avoided during methimazole treatment. If the serum creatinine concentration increases significantly (i.e., to IRIS stage 3 or higher) during methimazole therapy, the treatment protocol for methimazole should be modified to attain the best possible control of both disorders, and treatment for CKD should be instituted.

Oral Antithyroid Drugs

Oral antithyroid drugs include methimazole, propylthiouracil, and carbimazole. Oral antithyroid drugs are inexpensive, readily available, relatively safe, and effective in the treatment of hyperthyroidism in cats. They inhibit the synthesis of thyroid hormone by blocking the incorporation of iodine into the tyrosyl groups in thyroglobulin and by preventing the coupling of these iodotyrosyl groups to form T_3 and T_4. Antithyroid drugs do not block the release of stored thyroid hormone into the circulation and do not have antitumor actions. In our experience, oral antithyroid drugs do not interfere with results of pertechnetate scans or radioactive iodine therapy; however, many treatment centers request that methimazole be withdrawn 1 to 2 weeks before pertechnetate scan or radioactive iodine treatment. Indications for oral antithyroid drugs include (1) test treatment to normalize serum T_4 concentrations and assess the effect of resolving hyperthyroidism on kidney function; (2) initial treatment to alleviate or eliminate any medical problems associated with the syndrome before thyroidectomy is performed or before the hospitalization required for radioactive iodine treatment; and (3) long-term treatment of hyperthyroidism.

Methimazole (Felimazole, Dechra Veterinary Products) is currently the antithyroid drug of choice because the

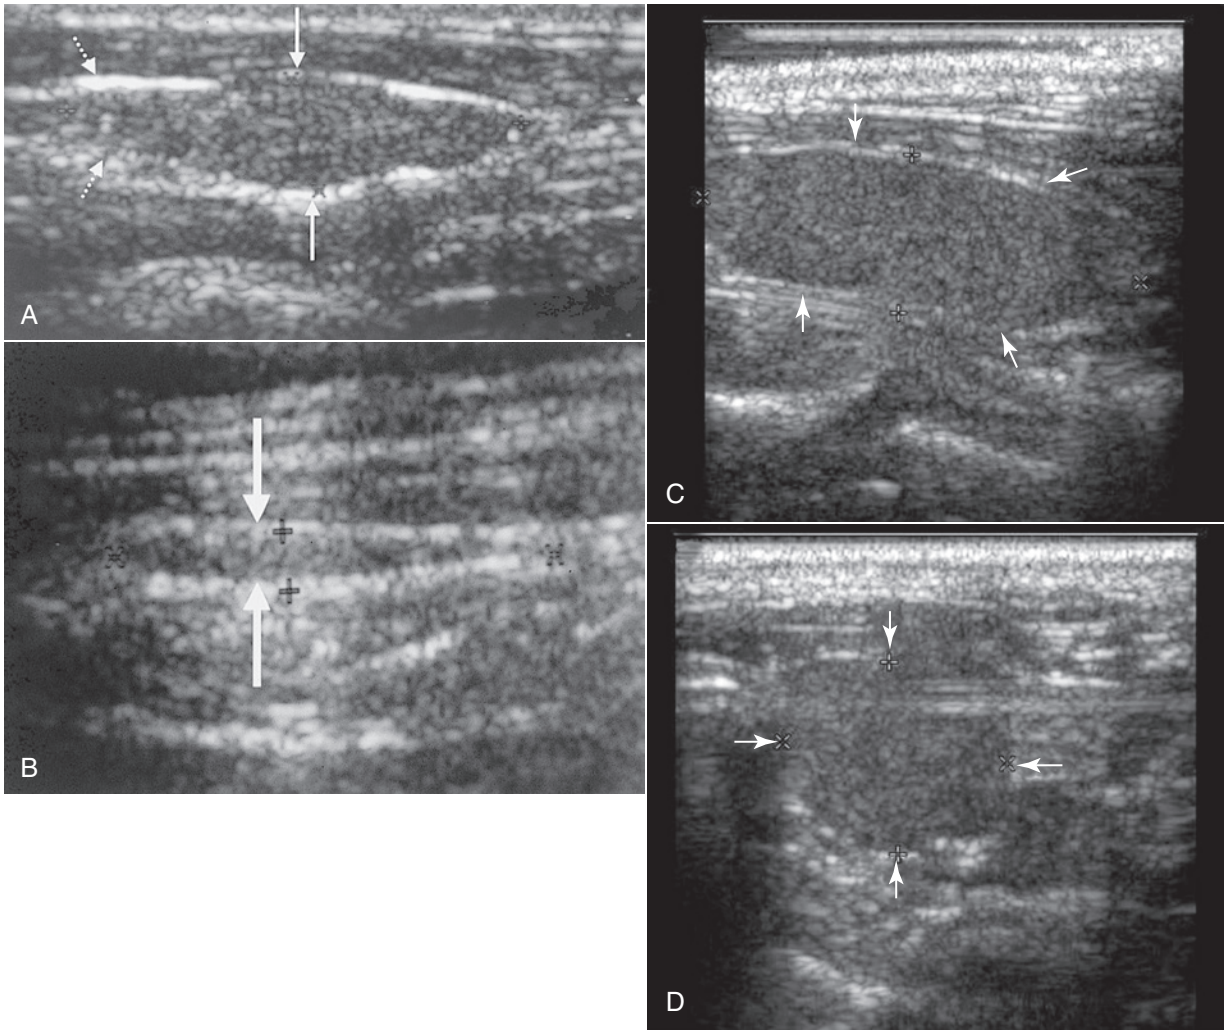

FIG 48.20

Normal-appearing portion of thyroid lobe *(broken arrows)*. **(B)** Ultrasound image of the small (atrophied) normal left thyroid lobe *(solid arrows)*. Left thyroid lobe *(small arrows)*. Results of the ultrasound examination supported unilateral disease affecting the right thyroid lobe, which was confirmed with a sodium pertechnetate scan. Longitudinal **(C)** and transverse **(D)** ultrasound images of a markedly enlarged left thyroid lobe (measuring approximately 1.1 × 2.2 cm) in a 14-year-old domestic short-haired cat with hyperthyroidism. The right thyroid lobe was similar in size. Results of the ultrasound examination support bilateral disease with symmetric enlargement of both thyroid lobes, which was confirmed with a sodium pertechnetate scan.

incidence of adverse reactions associated with its use is lower than that associated with the use of propylthiouracil (Table 48.7). Adverse reactions are less likely to occur when the dosage of methimazole is started low and gradually increased to effect. The recommended initial dose of methimazole is 2.5 mg administered orally twice a day for 2 weeks. If adverse reactions are not observed by the client, if the physical examination reveals no new problems, if results of a CBC and platelet count are within reference limits, if the serum creatinine concentration has not increased, and if serum T_4 concentration is in the upper half of the reference range or higher after 2 weeks of therapy, the dose is increased by 2.5 mg per day (i.e., 5 mg in the morning and 2.5 mg in the evening) twice daily, and the same parameters are evaluated 2 weeks later. The dosage should continue to be increased every 2 weeks by 2.5-mg/day increments until the serum T_4 concentration is in the lower half of the reference range without creating hypothyroidism or until adverse reactions develop. Timing of blood sampling after oral methimazole administration does not appear to be a significant factor in assessing response to methimazole treatment. Serum T_4 concentrations decline into the reference range within 2 weeks once the cat is receiving an effective dose of methimazole; clinical improvement is usually noted by clients within 2 to

TABLE 48.6

Indications, Contraindications, and Disadvantages of the Four Modes of Therapy for Hyperthyroidism in Cats

THERAPY	INDICATIONS	RELATIVE CONTRAINDICATIONS	DISADVANTAGES
Methimazole, propylthiouracil, carbimazole	Long-term therapy for all forms of hyperthyroidism; initial therapy to stabilize cat's condition and assess kidney function before thyroidectomy or radioactive iodine	None	Daily therapy required; no effect on growth of thyroid; mild adverse reactions common; severe reactions possible
Iodine-restricted diet	Therapy for all forms of hyperthyroidism; initial therapy to stabilize cat's condition and assess kidney function before thyroidectomy or radioactive iodine; reversible treatment option for cats that develop adverse reactions to methimazole or for clients unable to administer methimazole to their cat	Concurrent administration of antithyroid medications not recommended by manufacturer of the diet	Rigid requirements to ensure absolutely no access to any other source of dietary iodine; cat must be kept strictly indoors; problematic in multicat households; long term consequences of iodine restriction are unknown
Thyroidectomy	Unilateral lobe involvement; bilateral lobe involvement, asymmetric sizes	Ectopic thyroid lobe; metastatic carcinoma; bilateral, symmetric, large lobes (high risk of hypocalcemia); severe systemic signs; cardiac arrhythmias or failure; renal insufficiency	Anesthetic risks; relapse of disease; postoperative complications, especially hypocalcemia
Radioactive iodine (^{131}I)	Therapy for all forms of hyperthyroidism; treatment of choice for ectopic thyroid lobe and thyroid carcinoma	Renal insufficiency	Limited availability; hospitalization time; potential for retreatment; hazardous to humans

TABLE 48.7

Abnormalities Associated With Methimazole Therapy in 262 Cats With Hyperthyroidism

CLINICAL SIGNS AND PATHOLOGY	PERCENTAGE OF CATS	TIME TO DEVELOP (DAYS)	
		MEAN	RANGE
Clinical Signs			
Anorexia	11	24	1-78
Vomiting	11	22	7-60
Lethargy	9	24	1-60
Excoriations	2	21	6-40
Bleeding	2	31	15-50
Clinical Pathology			
Positive antinuclear antibody titer	22	91	10-870
Eosinophilia	11	57	12-490
Lymphocytosis	7	25	14-90
Leukopenia	5	23	10-41
Thrombocytopenia	3	37	14-90
Agranulocytosis	2	62	26-95
Hepatopathy	2	39	15-60

Adapted from Peterson ME, Kintzer PP, Hurvitz AI: Methimazole treatment of 262 cats with hyperthyroidism, *J Vet Intern Med* 2:150, 1988.

4 weeks once control of serum T_4 concentration is achieved. Most cats respond to 5 to 7.5 mg of methimazole per day, and the drug is most effective when given twice a day. Attempts at decreasing the daily dosage, the frequency of administration, or both can take place once clinical signs have resolved and a euthyroid state is attained, especially for cats receiving long-term methimazole treatment.

Rarely, cats are encountered that seem particularly resistant to methimazole, requiring as much as 20 mg/day. The most common causes for apparent resistance to methimazole are the inability of some clients to administer the drug to their cats and the presence of thyroid carcinoma as the etiology. One alternative for inability to administer methimazole is to have a compounding pharmacy incorporate methimazole into tasty kitty treats. Another alternative is the topical application of methimazole to the nonhaired pinna of the ear. Compounding veterinary pharmacies offer transdermal methimazole in a pluronic lecithin organogel (PLO) formulation. PLO is a permeation enhancer that disrupts the stratum corneum and allows absorption into the skin. There is a slightly slower onset of control of the hyperthyroidism and slightly lower efficacy, compared with oral methimazole, and some cats develop erythema and inflammation of the pinna, necessitating switching to oral methimazole. Creams can be made with methimazole at any concentration and are usually provided in tuberculin syringes that allow the client to place the appropriate dose on the fingertip and rub the cream into the pinna of the inner ear. The client must wear gloves to avoid absorption of methimazole, should alternate ears, and should wipe away any residual cream 30 to 60 minutes after each administration. The dosage and frequency of administration are the same as discussed with oral methimazole treatment. The bioavailability of transdermal methimazole is more variable, the overall effectiveness is not as good, and the prevalence of gastrointestinal adverse effects but not other adverse effects is lower, compared with oral methimazole. Higher doses may be required after prolonged treatment. One important concern in using transdermal methimazole is the lack of regulation of compounding pharmacies; consistency between products created can vary considerably.

Adverse reactions to methimazole typically occur within the first 4 to 8 weeks of therapy (see Table 48.7). The cat should be examined every 2 weeks during the initial 3 months of methimazole treatment and a CBC, platelet count, assessment of kidney function, and serum T_4 concentration evaluated at each visit. After the initial 3 months of therapy, CBC, platelet count, serum biochemistry panel, and serum T_4 concentration should be evaluated every 3 to 6 months. When the dosing protocol described previously is used, lethargy, vomiting, and anorexia occur in less than 10% of cats; these mild adverse reactions are usually transient and often resolve despite continued administration of the drug. Mild methimazole-induced hematologic changes are seen in less than 10% of cats and include eosinophilia, lymphocytosis, and transient leukopenia. More worrisome but less common (less than 5% of cats) alterations include facial excoriations, thrombocytopenia (platelet counts < 75,000/mm^3), leukopenia (total white blood cell counts < 2000/mm^3), and immune-mediated hemolytic anemia. Apparent hepatic toxicity or injury occurs in less than 2% of cats receiving methimazole and is characterized by clinical signs of liver disease (i.e., lethargy, anorexia, vomiting), icterus, and increased serum alanine transaminase and alkaline phosphatase activities. Some cats test positive for antinuclear antibodies, but the importance of this finding is not known. Development of myasthenia gravis has also been reported with methimazole treatment. If any of these serious complications are noted, methimazole treatment should be discontinued and supportive care given. Adverse reactions typically resolve within 1 week after methimazole treatment is discontinued. It is common for these potentially life-threatening adverse reactions to recur, regardless of the dose or type of antithyroid drug used; thus alternative therapy (e.g., surgery, radioactive iodine, iodine-restricted diet) is recommended.

Carbimazole (Neo-Mercazole) is an antithyroid drug that is converted to methimazole in vivo; it is an effective alternative treatment if methimazole is not available. The dosage and frequency of administration are the same as those in oral methimazole treatment. Adverse reactions are similar to those seen in cats receiving methimazole, but they occur less frequently. Cats treated with carbimazole should be monitored in the same manner suggested for cats receiving methimazole.

Long-term, twice-daily schedules for methimazole are effective in controlling hyperthyroidism. However, feline hyperthyroidism is a progressive disease which cannot be arrested with methimazole or an iodine restricted diet. Only radioactive iodine or thyroidectomy remove or destroy the hyperfunctioning tissue. In a recent study evaluating cats treated with methimazole for 1 to 6 years, the prevalence of multifocal disease (3 or more masses), large and huge masses, intrathoracic thyroid tissue, and suspected thyroid carcinoma increased with increasing disease duration (Peterson et al., 2016). Median thyroid mass volume and serum T_4 concentrations also increased with increasing disease duration; a finding which supports periodic evaluation of serum T_4 concentrations in cats on long-term methimazole treatment.

Iodine-Restricted Diet

A commercially available iodine restricted diet (Prescription Diet, y/d, Hill's Pet Products) provides another option for the treatment of hyperthyroidism in cats. Feeding an iodine-restricted diet limits production of thyroid hormone by the thyroid gland, thereby decreasing serum T_4 concentrations. Clinical trials have documented a reduction in serum T_4 concentrations when hyperthyroid cats are fed only Prescription Diet y/d and do not have access to any other source of dietary iodine. Serum T_4 concentrations returned to the reference range within 4 to 8 to weeks of initiation of the diet and remained there for longer than a year of feeding the diet. It is critical that the hyperthyroid cat does not have access to any other source of iodine. Iodine is present in a wide array

of foods, supplements, and even some water sources. Examples include all other pet foods, dairy products, egg yolks, seafood, dried fruit, canned vegetables, cured meats, fresh chicken or turkey, soy products, seaweed products, flavored or artificially colored medications or supplements, and liquids used by some compounding pharmacies. Cats must be kept strictly indoors. Healthy cats in the household can be fed Prescription Diet y/d but must have an additional source of food as an iodine supplement. Concurrent administration of antithyroid medications is not recommended, and these medications should be tapered and stopped over a 1- to 2-week period before the iodine-restricted diet is initiated. Initial recheck of serum T_4 concentration is recommended 4 and 8 weeks after Prescription Diet y/d is initiated. Serum T_4 concentration should be within the reference range by 8 weeks. The most common reason for failure of the diet to control hyperthyroidism is access of the cat to iodine-containing food, water, treats, or medications. The long-term consequences of dietary iodine restriction are unknown. For now, long-term monitoring should include a complete physical examination and evaluation of CBC, serum biochemistry panel, urinalysis, and serum T_4 concentration every 4 to 6 months once the serum T_4 concentration is in the reference range.

Surgery

Thyroidectomy is an effective treatment but should always be considered an elective procedure. Surgery is not indicated if the risk of anesthesia in the cat is unacceptable, its kidney function is questionable, the likelihood of postoperative hypocalcemia is great, ectopic thyroid tissue is present in the thorax, or thyroid carcinoma with metastasis is suspected. Treatment with methimazole for 1 to 2 months before thyroidectomy is recommended for reasons previously discussed. If possible, an ultrasound examination of the ventral neck or thyroid scintigraphy should be performed before surgery to identify the location of the abnormal thyroid tissue, differentiate unilateral from bilateral lobe involvement, and gain some insight into the probability of hypocalcemia developing postoperatively (see Fig. 48.15). Similar information can be gained by direct visualization at the time of surgery although ectopic tissue and early stages of the disease with minimal gross changes of the thyroid lobe may be missed.

Postoperative complications are listed in Box 48.8. The most worrisome is hypocalcemia. A direct correlation has been noted between the size of the thyroid lobes, the inability to visualize the external parathyroid glands, and the risk of hypocalcemia. Care must be taken to preserve at least one (preferably two) parathyroid glands. If all four parathyroid glands are inadvertently removed, the two external parathyroid glands should be removed from their respective thyroid lobes, minced, and placed within the muscle belly of one of the sternohyoideus muscles by blunt dissection parallel to the muscle fibers. Hypoparathyroidism usually resolves within a month of surgery if revascularization of the parathyroid autotransplant occurs.

BOX 48.8

Complications of Thyroidectomy in Cats With Hyperthyroidism

- Transient or permanent hypoparathyroidism causing hypocalcemia:
  - Restlessness
  - Irritability
  - Abnormal behavior
  - Muscle cramping, pain
  - Muscle tremors, especially of ears and face
  - Tetany
  - Convulsions
- Laryngeal paralysis
- Horner syndrome
- Hypothyroidism
- Exacerbation of concurrent renal insufficiency
- No amelioration of hyperthyroidism

Serum calcium concentration should be assessed at least once daily for 5 to 7 days if a bilateral thyroidectomy has been performed. Clinical signs of hypocalcemia typically develop within 72 hours of surgery, although signs may not develop for 7 to 10 days. These signs include lethargy, anorexia, reluctance to move, facial twitching (especially the ears), muscle tremors and cramping, tetany, and convulsions. If all four parathyroid glands are removed at surgery, appropriate calcium and vitamin D supplementation should be initiated once the cat has recovered from anesthesia (see Chapter 47). If at least one parathyroid gland has been spared, transient hypocalcemia may still develop and last for several days to weeks, probably as a result of disruption of blood flow to the parathyroid gland after surgical manipulation. In these cats oral vitamin D and calcium therapy should be initiated only if clinical signs develop or if hypocalcemia becomes severe (i.e., serum total or ionized calcium concentration < 8 mg/dL or < 0.8 mmol/L, respectively). A decline in the blood calcium concentration is not an absolute indication to begin therapy because the remaining parathyroid glands may respond before clinical signs or severe hypocalcemia develop.

The persistence of hypoparathyroidism is unpredictable. Parathyroid function may recover after days, weeks, or months of vitamin D and calcium supplementation. Whenever resolution of hypoparathyroidism is observed, it is assumed that reversible parathyroid damage occurred, accessory parathyroid tissue may be starting to compensate for glands damaged or removed at surgery, or the parathyroid autotransplant (if performed at surgery) has revascularized and become functional. It is also possible that calcium-regulating mechanisms are functioning in the absence of parathyroid hormone. Because it is difficult to predict the long-term requirement for vitamin D therapy in any cat, an attempt should be made to gradually wean all treated cats off medication while the serum calcium concentration is monitored. The tapering process should extend over a period of 3

to 4 months. The goal is to maintain the serum calcium concentration between 8 and 10 mg/dL. If hypocalcemia recurs, therapy with vitamin D and calcium should be reinstituted.

Hypothyroidism may develop in some cats after bilateral thyroidectomy. The clinical signs, diagnosis, and treatment are discussed on page 790. The decision to initiate levothyroxine treatment should be based on the presence or absence of clinical signs and changes in the serum creatinine concentration—not on the serum T_4 concentration, per se. Serum T_4 concentrations commonly decrease after surgery, often to less than 0.5 µg/dL (6 nmol/L), but thyroid function returns in most cats before clinical signs become apparent. Thyroid hormone supplementation should be initiated in cats that develop clinical signs in conjunction with a low serum T_4 concentration and in cats that develop azotemia as a result of decreased GFR induced by the low serum T_4 concentration. Because thyroid hormone replacement therapy may not be needed long term in some of these cats, it should be tapered slowly and then discontinued after 2 to 3 months while monitoring serum T_4 and creatinine concentrations so the continued need for treatment can be determined.

If clinical signs of hyperthyroidism persist despite thyroidectomy, the serum T_4 concentration should be measured. If the serum T_4 concentration is in the lower half of the reference range or lower, another disorder should be suspected. If the serum T_4 concentration is in the upper half of the reference range or higher, ectopic abnormal thyroid tissue, metastatic thyroid carcinoma, or, if unilateral thyroidectomy was performed, abnormal tissue in the remaining thyroid lobe should be suspected. Ectopic thyroid tissue would most likely be found in the mediastinum, cranial to the heart (see Fig. 48.16). Thyroid scintigraphy is recommended to identify ectopic or metastatic thyroid tissue. Alternatively, oral methimazole, radioactive iodine treatment, or an iodine-restricted diet can be considered. Clinical signs of hyperthyroidism may recur months to years after thyroidectomy. The serum T_4 concentration should be monitored two or three times a year in all cats successfully treated with surgery.

Radioactive Iodine

If available, radioactive iodine (^{131}I) is the treatment of choice for hyperthyroidism because of the very low morbidity and mortality and the very high success rate associated with treatment (Fig. 48.21). Hypoparathyroidism is not a concern with radioactive iodine treatment. Radioactive iodine treatment is effective in cats with hyperfunctioning ectopic thyroid tissue and is the only option offering the potential for cure in cats with metastatic or nonresectable thyroid carcinoma. Treatment with methimazole for 1 to 2 months before radioactive iodine treatment is provided is recommended for reasons previously discussed. Prior or current treatment with methimazole does not alter the efficacy of radioactive iodine treatment; however, most treatment centers recommend methimazole treatment be stopped 1 to 2 weeks before treatment with radioactive iodine. Iodine 131 (^{131}I) has a half-life of 8 days. ^{131}I administered intravenously

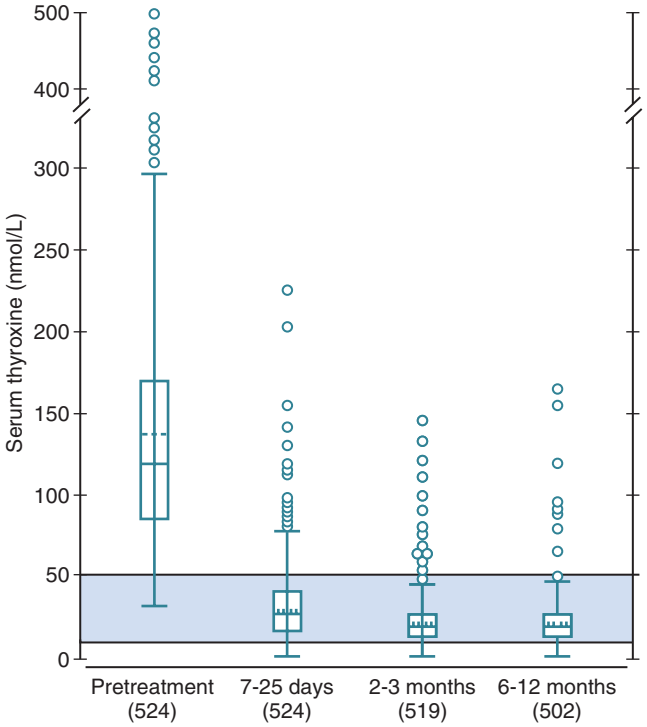

FIG 48.21
Box plots of serum thyroxine (T_4) concentrations in 524 cats before and at various times after administration of radioiodine for treatment of hyperthyroidism. The shaded area indicates the reference range for serum T_4 concentration. Please see Fig. 48.9 for the key. (From Peterson ME et al: Radioiodine treatment of 524 cats with hyperthyroidism, *J Am Vet Med Assoc* 207:1422, 1995.)

or subcutaneously is concentrated within the thyroid, and the emitted radiation destroys surrounding functioning follicular cells while causing minimal radiation damage to contiguous structures. For cats with typical hyperthyroidism (i.e., adenomatous hyperplasia, adenoma), doses of 2 to 5 mCi of ^{131}I kill only the thyroid cells that are functioning. Atrophied normal thyroid cells receive a relatively small dose of radiation and are usually able to return to function, thereby preventing permanent hypothyroidism in most cats. Depending on the dose administered, more than 80% of treated cats become euthyroid within 3 months—most within 1 week—and more than 95% of treated cats are euthyroid at 6 months. The most common complication following radioactive iodine treatment is hypothyroidism, which typically develops in cats with bilateral large, diffusely affected thyroid lobes and cats treated with high doses of radioactive iodine. Initially, serum T_4 and creatinine concentration should be monitored monthly. Thyroid hormone supplementation should be initiated if serum T_4 concentration declines below the reference range and clinical signs of hypothyroidism develop or the cat develops azotemia as a result of decreased GFR induced by the low serum T_4 concentration. If initiated, periodic slow tapering of the dose and frequency of administration should be attempted to determine the need for thyroid hormone treatment.

Approximately 5% of cats require a second ^{131}I treatment. Factors such as dose of radioactive iodine administered, extent of abnormal thyroid tissue, iodine excretion rate, and thyroid pathology may explain treatment failure. Most worrisome is the possibility of thyroid carcinoma. Cats with thyroid carcinoma require higher doses of radioactive iodine than is typically administered to attain a successful outcome. The duration of hospitalization and home care of the cat following ^{131}I administration varies depending on state regulations and the dosage of ^{131}I administered. Hyperthyroidism may recur 1 year or longer after successful treatment.

Prognosis

The prognosis is excellent for most cats with hyperthyroidism, as long as concurrent disease can be managed and thyroid carcinoma is not the cause. Surgery and ^{131}I therapy have the potential for cure, although hyperthyroidism may recur months to years (or not at all) after thyroidectomy or ^{131}I treatment. Hyperthyroid cats with adenomatous hyperplasia or adenoma can potentially be treated with methimazole for years, as long as adverse reactions related to the medication are avoided. In one retrospective study, cats with concurrent CKD had significantly shorter survival times than cats with normal kidney function, and the survival time in cats treated with methimazole alone (median, 2 years; interquartile range, 1-3.9 years) was significantly shorter than in cats treated with ^{131}I alone (4.0 years; 3.0-4.8 years) or methimazole followed by ^{131}I (5.3 years; 2.2-6.5 years; Milner et al., 2006). Age also has an impact on survival data; hyperthyroidism is a geriatric cat disease with an average age at the time of diagnosis of 13 years.

Complications and efficacy of feeding an iodine-deficient diet for a prolonged period (i.e., greater than a year) have yet to be reported.

CANINE THYROID NEOPLASIA

Etiology

Thyroid tumors are relatively common in dogs, where they represent approximately 1% to 3% of all tumors in the dog (Broome et al., 2014). Thyroid adenomas are usually small, nonfunctional masses that do not cause clinical signs and are usually found incidentally at necropsy. Exceptions are thyroid adenomas that are functional and cause hyperthyroidism or are unexpectedly identified during ultrasound examination of the ventral neck. Thyroid carcinomas are more commonly identified antemortem because of their large size, presence of clinical signs that can be recognized by clients, and ease of palpation by veterinarians. One or both thyroid lobes may be involved, and ectopic thyroid tissue located sublingual, in the mediastinum and at the base of the heart occasionally become neoplastic. Thyroid carcinomas are highly vascular, locally invasive, and frequently infiltrate surrounding structures such as the esophagus, trachea, and cervical musculature. Regional and distant metastasis to the retropharyngeal, mandibular, and superficial cervical lymph nodes and lungs are common. Metastasis to other locations such as the liver, kidney, bone, and brain is also possible. Most dogs with thyroid tumor are euthyroid or hypothyroid; less than 15% of dogs have functional thyroid tumors that secrete excess thyroid hormone, causing hyperthyroidism. Clinical signs of hyperthyroidism may predominate in these dogs. Hyperthyroidism may be caused by functional thyroid adenomas and carcinomas. Adenomatous hyperplasia is the most common cause of hyperthyroidism in cats but has not been described in dogs.

Clinical Features

Thyroid tumors occur in middle-aged to older dogs, typically 10 years of age and older. No sex-related predilection has been noted. Although any breed can be affected, Boxers, Beagles, Golden Retrievers, and Siberian Huskies may be at increased risk.

Dogs with nonfunctional thyroid tumors are usually brought to veterinarians because the owner has seen or felt a mass in the ventral cervical region of the dog's neck (Fig. 48.22). Clinical signs may develop as a result of the mass compressing on adjacent structures (e.g., dyspnea, dysphagia) or as a result of metastasis (e.g., exercise intolerance, weight loss; Box 48.9). Clinical signs of hypothyroidism may be noted with large invasive tumors that destroy

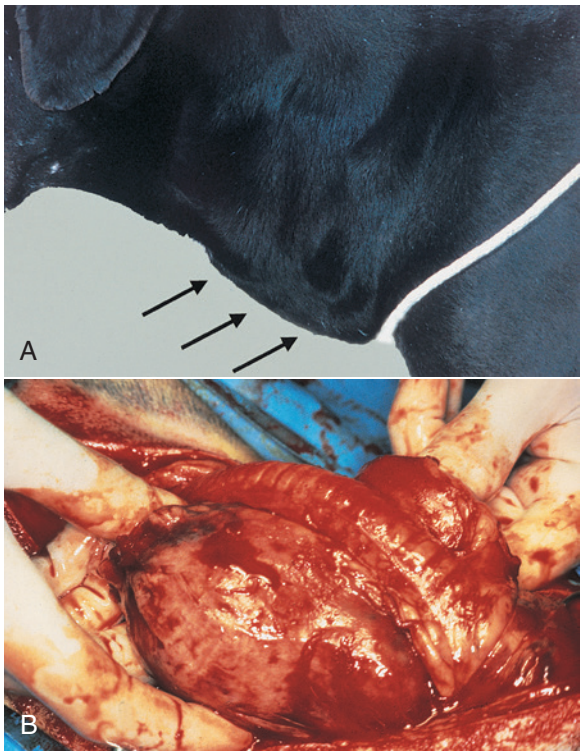

FIG 48.22
(A) A 13-year-old male Labrador Retriever was presented to the veterinarian because the client noticed a mass in the neck *(arrows)*. The mass was a thyroid adenocarcinoma. **(B)** Thyroid adenocarcinoma in an 11-year-old mixed-breed dog. Clinical signs included dysphagia, coughing, and a visible mass in the ventral region of the neck.

BOX 48.9

Clinical Signs Caused by Thyroid Neoplasia in Dogs

Nonfunctional

Swelling or mass in neck
Dyspnea
Cough
Lethargy
Dysphagia
Regurgitation
Anorexia
Weight loss
Horner syndrome
Change in bark
Facial edema

Functional (Hyperthyroid)

Swelling or mass in neck
Polyphagia and weight loss
Hyperactivity
Polyuria and polydipsia
Panting
Change in behavior
Aggression

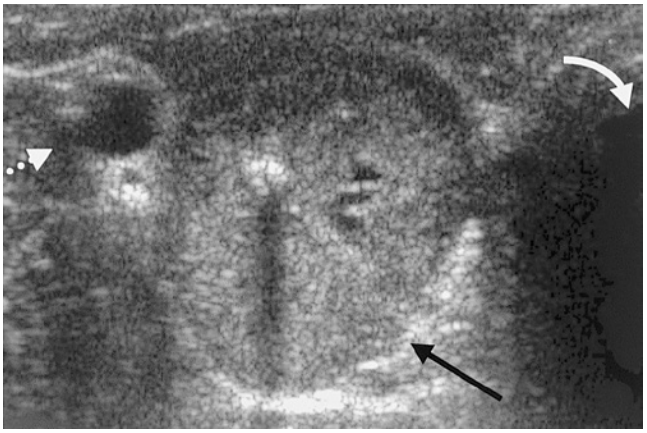

FIG 48.23
Ultrasound image of a mass in the region of the right thyroid lobe *(straight arrow)*, the carotid artery *(broken arrow)*, and the trachea *(curved arrow)* in an 11-year-old female spayed Labrador mix. A small region of mineralization causing a shadowing effect is evident within the mass. The mass was an unexpected finding during a routine physical examination. Thyroid adenocarcinoma was the histopathologic diagnosis after surgical removal of the mass.

both thyroid lobes. Clinical signs of hyperthyroidism occur in dogs with functional thyroid tumors and are similar to those seen in hyperthyroid cats. Most thyroid tumors are firm, asymmetric, lobulated, and nonpainful masses located close to the typical thyroid region in the neck, although larger tumors may extend to the thoracic inlet. The mass usually is well embedded in surrounding tissue and not freely movable; the latter finding suggestive of invasive carcinoma. In some tumors, a bruit, due to the presence of an arteriovenous fistula, can be palpated or auscultated. Additional physical examination findings may include dyspnea, stridor, cough, cachexia, lethargy, Horner syndrome, and a dry, lusterless haircoat. Mandibular or superficial cervical lymph nodes (or both) may be enlarged as a result of tumor spread or lymphatic obstruction. Dogs with functional thyroid tumors may be restless, thin, and panting, and auscultation of the heart frequently reveals tachycardia. Many dogs are found to be remarkably healthy on physical examination.

Findings of CBC, serum biochemistry panel, and urinalysis usually do not help establish the diagnosis. A mild normocytic, normochromic, nonregenerative anemia, hypercholesterolemia, and hypertriglyceridemia causing lipemia may be present in dogs with concurrent hypothyroidism. A mild increase in the blood urea nitrogen concentration and liver enzyme activities may be identified; however, the latter changes are not necessarily indicative of hepatic metastasis. Hypercalcemia has also been noted in a few dogs, and is attributed to a paraneoplastic condition. Systemic hypertension may be present in dogs with functional thyroid tumors causing hyperthyroidism.

Baseline serum T_4 and fT_4 concentrations are increased and serum TSH is undetectable in dogs with a functional thyroid tumor causing hyperthyroidism. However, most canine thyroid tumors are nonfunctional, and most of these dogs are found to be euthyroid when serum thyroid hormone concentrations are evaluated. Approximately 30% of dogs with a thyroid tumor have serum T_4 and fT_4 concentrations below the reference range and an increased serum TSH concentration, suggestive of hypothyroidism resulting from destruction of normal thyroid tissue by the tumor. However, low serum thyroid hormone concentrations must be interpreted with caution and the suppressive effects of nonthyroidal illness on thyroid function considered (see p. 779).

Cervical ultrasonography will confirm the presence of a mass, regardless of its size and location; can distinguish among cavitary, cystic, and solid tumors; can identify the presence and severity of local tumor invasion; can identify the presence and location of metastatic sites in the cervical region; and improve the likelihood that representative tissue for cytologic or histologic evaluation is obtained during fine-needle aspiration or percutaneous biopsy of the mass (Fig. 48.23). Because metastasis to the lungs and to the base of the heart is common with thyroid carcinoma, thoracic radiographs should always be included in the diagnostic evaluation of dogs with a suspected thyroid mass. Cervical radiographs may identify a small mass that was suspected but not definitively identified on physical examination, may show the severity of displacement of adjacent structures, and may identify local invasion of the mass into the larynx and trachea. Abdominal ultrasonography can be used to identify abdominal (most notably hepatic) metastatic lesions.

Computed tomographic (CT) and magnetic resonance imaging (MRI) can define the extent of tumor invasion into surrounding structures, identify distant metastasis to the lymph nodes and lung, and identify ectopic thyroid tissue in the mediastinum (Fig. 48.24)—information that is valuable if surgery or radiation therapy is being considered. Both CT and MRI are superior to ultrasound for establishing extent of invasion of thyroid tumors.

Thyroid scans using sodium pertechnetate can be used to confirm that a cervical mass is thyroid in origin; to assess the degree of regional tissue invasion; and to identify unusual areas of uptake in the head, neck, and thorax suggestive of metastatic sites. Most thyroid carcinomas demonstrate heterogeneous uptake of pertechnetate, irregular gland shape, and evidence of regional tissue invasion. Tumors with a more homogenous diffuse uptake of pertechnetate are more likely to be functional tumors that cause hyperthyroidism. If the malignancy, especially a distant site of metastasis, does not trap iodine effectively, the scintigraphic study will fail to identify the site. Failure to identify distant metastatic sites with scintigraphy does not mean that distant metastasis does not exist. The amount of radionuclide uptake by the thyroid tumor is not a reliable indicator of its functional status (i.e., euthyroid, hypothyroid, or hyperthyroid) or of the benign versus malignant nature of the tumor. Thoracic radiographs are more sensitive than a thyroid scan in identifying pulmonary metastasis.

Diagnosis

Definitive diagnosis can be obtained either by doing a fine needle aspirate for cytology or a biopsy. Unfortunately, canine thyroid tumors are highly vascular, and it is common for hemorrhage to occur after biopsy. Fine-needle aspiration using a 21- or 23-gauge needle and cytologic examination of the mass are recommended initially to confirm that the mass is of thyroid origin. Contamination of the aspirate with blood is common, and differentiation between adenoma and carcinoma is difficult. Large-bore needle biopsy, surgical exploration, or ultrasound-guided biopsy is often required to confirm the diagnosis. Ultrasonography identifies solid areas of the mass to biopsy and large blood vessels to be avoided. This procedure is preferred if the findings yielded by needle aspiration are inconclusive.

Treatment

Treatment options for thyroid tumor in dogs include surgery, chemotherapy, radiation therapy, radioactive iodine treatment, and antithyroid drugs. In many cases more than one treatment option (e.g., surgery and chemotherapy) is used either concurrently or sequentially.

The therapeutic approach is based, in part, on the size and invasiveness of the tumor and the presence of regional and distant metastasis. Approximately 30% to 40% of dogs with thyroid tumors have detectable distant metastasis at the time of diagnosis. Tumor size appears to be predictive of metastatic behavior, with thyroid tumor volume less than 21 cm^3 having a significantly lower risk of metastasis and thyroid tumor volume approaching 100 cm^3 having essentially a 100% probability of metastasis. The functional status of the thyroid tumor does not dramatically alter the treatment approach. All thyroid tumors in dogs should be considered malignant until proven otherwise, regardless of size (Fig. 48.25). Treatment is warranted even for large, locally invasive tumors. Many dogs with large invasive tumors appear more

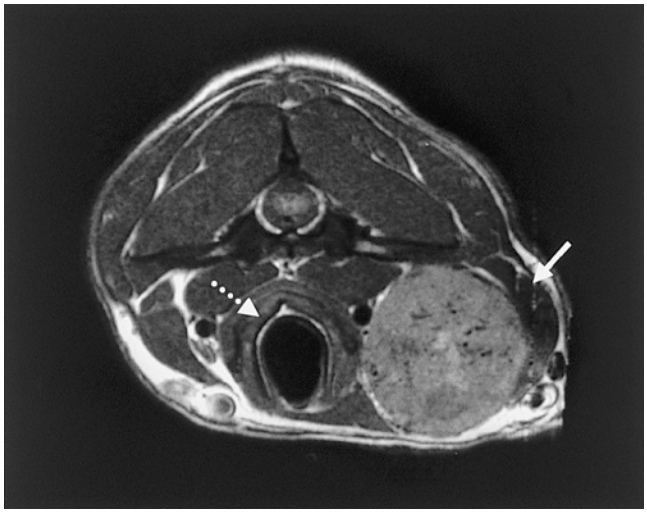

FIG 48.24
Magnetic resonance image of a right-sided thyroid mass *(solid arrow)* adjacent to the trachea *(broken arrow)* in a 10-year-old male castrated Golden Retriever that was presented for a swelling in the neck. The histopathologic diagnosis was thyroid C-cell carcinoma with vascular invasion. The affected region of the neck was treated with radiation after thyroidectomy.

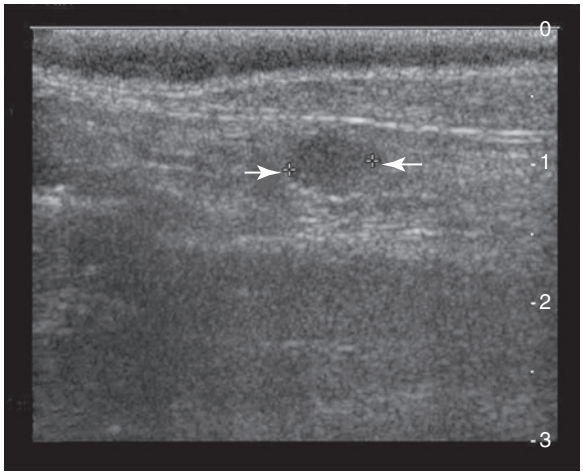

FIG 48.25
Ultrasound image of a 0.61-cm-diameter mass in the right thyroid lobe *(arrows)* in an 11-year-old male castrated Pug. The thyroid mass was an unexpected finding during cervical ultrasound to assess the parathyroid glands during a diagnostic evaluation for hypercalcemia. Thyroid carcinoma was the histopathologic diagnosis after surgical removal of the mass.

comfortable and have the potential for increased longevity after treatment. In addition, local control of the tumor may halt or reduce metastatic dissemination, and the presence of metastases may not ultimately affect outcome. Local control of the thyroid carcinoma is of primary importance in managing this disease.

SURGERY

Surgical excision of thyroid adenomas and small, well-encapsulated, freely movable thyroid carcinomas is likely to be curative. Surgical removal of a fixed, locally invasive thyroid carcinoma, regardless of size, carries a guarded to poor prognosis for complete excision of the tumor. Radiation is the treatment of choice for these tumors. Chemotherapy is indicated if distant metastases are identified, or in some cases, postoperatively in dogs with vascular or lymphatic invasion, or "aggressive" histologic appearance. Surgical debulking of fixed, locally invasive tumors may be indicated to relieve tumor-induced problems such as dysphagia or dyspnea and to allow more time for other therapies to work. Surgical cytoreduction may also be considered after radiation or chemotherapy has caused large invasive tumors to decrease in size. Aggressive attempts at surgical removal, especially of bilateral tumors, threaten the integrity of recurrent laryngeal nerves, parathyroid glands, and normal thyroid tissue. It is important to monitor serum calcium concentrations before and for 2 to 3 weeks after surgery if there is any chance that the parathyroid glands have been excised or damaged. Vitamin D and calcium therapy should be initiated if hypocalcemia develops postoperative (see Chapter 47). Serum T_4 and TSH concentrations should be assessed 4 and 8 weeks after surgery and treatment initiated if clinical signs and blood test results suggest hypothyroidism. (See Tobias and Johnston, 2018, for information on surgical techniques for the thyroparathyroid complex.)

EXTERNAL BEAM RADIATION THERAPY

Radiation therapy is the treatment of choice for locally advanced thyroid carcinoma. External beam radiation can be used alone or in conjunction with surgery or chemotherapy. A slow regression rate of thyroid carcinoma has been noted after radiation therapy in dogs. In one study involving 25 dogs with unresectable differentiated thyroid carcinoma and no evidence of metastasis, the time to attain maximum reduction in tumor size ranged from 8 to 22 months after megavoltage irradiation (Theon et al., 2000). Progression-free survival rates (defined as the time between completion of irradiation and detection of measurable local tumor recurrence or death from causes unrelated to tumor progression) were 80% at 1 year and 72% at 3 years, with a mean progression-free survival time of 55 months in the 25 dogs. Acute adverse reactions to radiation include esophageal, tracheal, or laryngeal mucositis causing dysphagia, cough, hoarseness, and transient neutropenia. These reactions tend to be mild and self-limiting. Chronic radiation reactions include skin fibrosis, permanent alopecia, chronic tracheitis causing a dry cough, and hypothyroidism.

RADIOACTIVE IODINE (^{131}I)

Studies suggest that radioactive iodine therapy will prolong survival time when used as sole therapy or in combination with surgery for the treatment of thyroid tumors in dogs. Worth et al. (2005) reported a median survival time of 30 months for dogs treated with radioiodine alone, 34 months when radioiodine was combined with surgery, and 3 months for dogs that did not receive treatment. Turrel et al. (2006) reported median survival times of 839 days for dogs with local or regional tumors (i.e., stage II and III disease) and 366 days for dogs with metastasis. Tumor site (cervical versus ectopic), age, body weight, treatment protocol (^{131}I alone or with surgery), and serum T_4 concentration were not significantly associated with survival time. Radioactive iodine therapy is useful for any thyroid tumor tissue that retains the ability to trap iodine, including metastatic sites. A technetium scan can be used to determine whether the tumor can trap iodine. Large doses of ^{131}I (i.e., 30-100 mCi or more) are typically administered intravenously to treat canine thyroid carcinoma. Advantages of radioactive iodine treatment include the low risk of adverse effects and the potential to treat both the primary tumor and metastatic lesions. One disadvantage is the need for prolonged isolation of the dog after treatment. Potential adverse reactions include esophagitis, tracheitis, and bone marrow suppression.

CHEMOTHERAPY

Chemotherapy is indicated when total surgical removal or destruction with radiation therapy is not successful, when distant metastatic lesions have been identified, and when the size of the primary tumor is such that local invasion or metastases are likely, even though it cannot be identified with diagnostic tests. A number of different chemotherapeutic drugs have been used to treat thyroid tumors in dogs, including doxorubicin, cisplatin, carboplatin, mitoxantrone, toceranib phosphate, and chlorambucil. Doxorubicin and carboplatin are the two most commonly used to treat thyroid carcinoma in dogs and may be administered on an alternating schedule at 3-week intervals for a combined total of 6 doses. The response of canine thyroid tumors to doxorubicin and carboplatin is variable and unpredictable. In most dogs doxorubicin and carboplatin prevent further growth of the tumor and may cause the tumor to shrink, but total remission is uncommon. One should always consult with an oncologist whenever chemotherapy is being considered. (See Chapters 76 and 77 for discussion of the use of these chemotherapeutic agents.)

ORAL ANTITHYROID DRUGS

Oral antithyroid drugs are used as palliative therapy to control the clinical signs of hyperthyroidism in dogs with functional thyroid tumor; they are not used as primary treatment because they are not cytotoxic. The therapeutic approach is similar to that used in hyperthyroid cats (see p. 794), beginning with 2.5 to 5 mg of methimazole administered twice a day, with subsequent increases in the dosage and frequency of administration as needed to control clinical

signs and maintain the serum T_4 concentration within the reference range.

Prognosis

The prognosis for thyroid adenoma is excellent after surgical removal. The prognosis is guarded to good for dogs that undergo surgical resection of a small, well-encapsulated carcinoma. Unfortunately, most dogs have relatively large thyroid masses, which frequently have invaded surrounding tissues or metastasized at the time of diagnosis. In these dogs aggressive therapy using multiple treatments can alleviate the clinical signs and in some cases dramatically reduce the tumor burden. The long-term prognosis, however, remains guarded to poor, with survival times typically ranging from 6 to 24 months, depending on the aggressiveness of treatment.

CHAPTER 49

Disorders of the Endocrine Pancreas

HYPERGLYCEMIA

Etiology

Hyperglycemia is present if the blood glucose concentration is greater than 125 mg/dL, although clinical signs of hyperglycemia do not develop until the renal tubular threshold for the resorption of glucose is exceeded. In dogs this typically occurs whenever the blood glucose concentration exceeds 180 to 220 mg/dL. The threshold for glucose resorption appears to be more variable in cats, ranging from 200 to 280 mg/dL. Glycosuria causes an osmotic diuresis, which in turn causes polyuria and polydipsia, the hallmark clinical signs of severe hyperglycemia. The most common cause of hyperglycemia and glycosuria is diabetes mellitus. Severe hyperglycemia without glycosuria also occurs commonly in cats with stress-induced hyperglycemia, presumably resulting from the secretion of catecholamines. Transient glycosuria (typically < 1% on urine glucose test strips) may occur in some cats with severe or prolonged stress-induced hyperglycemia.

Clinical Features

Hyperglycemia of between 125 and 180 mg/dL (often as high as 250 mg/dL in cats) is clinically silent and is an unsuspected finding encountered during blood testing for another reason. If a dog or cat with mild hyperglycemia (<180 mg/dL) and no glycosuria is seen because of polyuria and polydipsia, a disorder other than overt diabetes mellitus should be suspected. Mild hyperglycemia can occur in some dogs and cats up to 2 hours after consumption of diets containing increased quantities of monosaccharides and disaccharides, corn syrup, or propylene glycol; during intravenous (IV) administration of total parenteral nutrition fluids; in stressed, agitated, or excitable cats and dogs; in animals in the early stages of diabetes mellitus (i.e., subclinical diabetes); and in animals with disorders and drugs causing insulin resistance (Box 49.1). A diagnostic evaluation for disorders causing insulin resistance is indicated if mild hyperglycemia is found to persist in a fasted, unstressed dog or cat, especially if the blood glucose concentration is increasing over time (see p. 828).

HYPOGLYCEMIA

Etiology

Hypoglycemia is present if the blood glucose concentration is less than 60 mg/dL. It typically results from excessive uptake of glucose by normal cells (e.g., during periods of hyperinsulinism as with a β-cell tumor or xylitol ingestion) or neoplastic cells, impaired hepatic gluconeogenesis and glycogenolysis (e.g., portal shunt, hepatic cirrhosis), a deficiency in diabetogenic hormones (e.g., hypocortisolism), an inadequate dietary intake of glucose and other substrates required for hepatic gluconeogenesis (e.g., anorexia in the neonate or in toy breeds), or a combination of these mechanisms (e.g., sepsis; Box 49.2). Iatrogenic hypoglycemia is a common problem resulting from overzealous insulin administration in diabetic dogs and cats.

Prolonged storage of blood before separation of serum or plasma causes the glucose concentration to decrease at a rate of approximately 7 mg/dL/h. Glycolysis by red and white blood cells becomes even more apparent in dogs and cats with erythrocytosis, leukocytosis, or sepsis. Therefore whole blood obtained for the measurement of glucose concentration should be separated soon after collection (within 30 minutes), and the serum or plasma should be refrigerated or frozen until the assay is performed to minimize artifactual lowering of the blood glucose concentration. Glucose determinations from separated and refrigerated plasma or serum are reliable for as long as 48 hours after separation and refrigeration of the specimen. Alternatively, plasma can be collected in sodium fluoride tubes. Unfortunately, hemolysis is common in blood collected in sodium fluoride–treated tubes, which can result in slight decrements in glucose values related to methodologic problems in laboratory determinations. Blood glucose values as determined by many portable home blood glucose–monitoring devices designed for use by human patients with diabetes are almost

  - Laboratory error

*Common cause.

always lower than actual glucose values as determined by benchtop methods, and this may result in an incorrect diagnosis of hypoglycemia. In contrast, an erroneous reading with the AlphaTRAK glucometer (Abbott Laboratories), designed for use in diabetic dogs and cats, can be high or low compared with actual glucose values. Finally, laboratory error may result in an incorrect value. It is wise to confirm hypoglycemia by determining the blood glucose concentration from a second blood sample and using benchtop methods before embarking on a search for the cause of hypoglycemia.

Clinical Features

Clinical signs of hypoglycemia usually develop when the blood glucose concentration is less than 45 mg/dL, although this can be variable. The development of clinical signs depends on the severity and duration (acute versus chronic) of hypoglycemia and the rate of decline in the blood glucose concentration. Clinical signs are a result of neuroglycopenia- and hypoglycemia-induced stimulation of the sympathoadrenal nervous system. Neuroglycopenic signs include seizures; weakness; collapse; ataxia; and, less commonly, lethargy, blindness, bizarre behavior, and coma. Signs of increased secretion of catecholamines include restlessness, nervousness, and muscle fasciculations.

Depending on the cause, the signs of hypoglycemia may be persistent or intermittent. The hallmark clinical sign of hypoglycemia (i.e., seizures) tends to be intermittent, regardless of the cause. Dogs and cats usually recover from hypoglycemic seizures within a couple of minutes as a result of activation of counterregulatory mechanisms (e.g., secretion of glucagon and catecholamines) that block the effects of insulin, stimulate hepatic glucose secretion, and promote an increase in the blood glucose concentration.

Diagnostic Approach

Hypoglycemia should always be confirmed before diagnostic studies are begun to identify the cause. Careful evaluation of the animal's history, physical examination findings, and results of routine blood and urine tests (i.e., complete blood count [CBC], serum biochemistry panel, urinalysis) usually provides clues to the underlying cause. Hypoglycemia in the

puppy or kitten is usually caused by idiopathic hypoglycemia, starvation, congenital portosystemic shunt, or sepsis. In young adult dogs or cats hypoglycemia is usually caused by hepatobiliary disease, portosystemic shunt, hypoadrenocorticism, or sepsis. In older dogs or cats, hepatobiliary disease, β-cell neoplasia, extrapancreatic neoplasia, hypoadrenocorticism, and sepsis are the most common causes.

Hypoglycemia tends to be mild (>45 mg/dL) and is often an incidental finding in dogs and cats with hypoadrenocorticism or liver insufficiency. Additional clinical pathologic alterations are usually present (e.g., hyponatremia and hyperkalemia in animals with hypoadrenocorticism or increased alanine aminotransferase [ALT] activity, hypocholesterolemia, hypoalbuminemia, low blood urea nitrogen [BUN] concentration in animals with hepatobiliary disease). A baseline serum cortisol concentration, adrenocorticotropic hormone (ACTH) stimulation test or liver function test (i.e., preprandial and postprandial bile acids) may be required to confirm the diagnosis. Severe hypoglycemia (<40 mg/dL) may develop in neonates and juvenile kittens and puppies (especially toy breeds) and in animals with sepsis, β-cell neoplasia, and extrapancreatic neoplasia, most notably hepatic adenocarcinoma and leiomyosarcoma. Sepsis is readily identified on the basis of physical examination findings and abnormal CBC findings, such as a neutrophilic leukocytosis (typically > 30,000/μL), a shift toward immaturity, and signs of toxicity. Extrapancreatic neoplasia can usually be identified on the basis of the physical examination, abdominal or thoracic radiography, and findings on abdominal ultrasonography. Dogs with β-cell neoplasia typically have normal physical examination findings with no abnormalities other than hypoglycemia identified on routine blood and urine tests. Measurement of baseline serum insulin concentration when the blood glucose is less than 60 mg/dL (preferably < 50 mg/dL) is necessary to confirm the diagnosis of a β-cell tumor.

Treatment

Whenever possible, therapy should be directed at eliminating the underlying cause of the hypoglycemia. If the disorder cannot be eliminated and the clinical signs of hypoglycemia persist, long-term symptomatic therapy designed to increase the blood glucose concentration may be necessary to minimize clinical signs (see p. 850). Such therapy is usually required for animals with metastatic β-cell or extrapancreatic neoplasia.

Symptomatic therapy for animals with severe hypoglycemia of acute onset relies on the administration of glucose (Box 49.3). If the dog or cat is having a hypoglycemic seizure at home, the client should rub a sugar solution on the pet's buccal mucosa. Most animals respond within 1 to 2 minutes. Clients should be instructed never to place fingers into, or pour the sugar solution down, the pet's mouth. Once the dog or cat is sternal and cognizant of its surroundings, it should be fed a small meal and brought to the veterinarian. Although clinical trials are needed, at-home glucagon emergency kits used to treat severe hypoglycemia in human patients with diabetes may become a viable option for treating severe hypoglycemia in diabetic dogs and cats (Zeugswetter et al., 2012). If collapse, seizures, or coma develops in the hospital, a blood sample should be obtained to measure the glucose concentration before reversing the signs with IV administration of 50% dextrose, diluted, followed by continuous IV infusion of 5% dextrose. Dextrose should be administered in small amounts slowly (1-5 mL aliquots) rather than in large boluses rapidly. This is especially important in dogs with suspected β-cell neoplasia, in which aggressive glucose administration can result in severe hypoglycemia after excessive insulin secretion by the tumor in response to glucose. Dogs and cats with hypoglycemia usually respond to glucose administration within 2 minutes. Recurrence of hypoglycemia is dependent on the ability to correct the underlying cause.

Occasionally, a dog or cat with severe central nervous system signs (e.g., blindness, coma) does not respond to initial glucose therapy. Irreversible cerebral lesions may result from prolonged severe hypoglycemia and the resultant cerebral hypoxia. The prognosis in these animals is guarded to poor. Therapy is directed at providing a continuous supply of glucose by administering a 2.5% to 5% solution intravenously or by increasing hepatic gluconeogenesis with a

BOX 49.3

Medical Therapy for Acute Hypoglycemic Seizures

Seizures at Home

Step 1. Apply sugar solution to pet's gums.
Step 2. Once pet is sternal, feed a small meal.
Step 3. Call the veterinarian.

Seizures in Hospital

Step 1. Administer 1 to 5 mL (depending on dog size) of 50% dextrose (diluted) IV *slowly* over 1 to 2 minutes followed by continuous infusion of 5% dextrose in water (i.e., D5W).
Step 2. Once animal is sternal, feed a small meal.
Step 3. Initiate long-term medical therapy if necessary (see Box 49.14).

Intractable Seizures in Hospital

Step 1. Administer 2.5% to 5% dextrose in water intravenously at 1.5 to 2 times maintenance fluid rate.
Step 2. Add 0.5 to 1 mg of dexamethasone/kg to IV fluids and administer over 6 hours; repeat every 12 to 24 hours, as necessary.
Step 3. If previous step fails, administer IV glucagon USP (Eli Lilly) by constant-rate infusion at an initial dosage of 5 to 10 ng/kg/min.
Step 4. If preceding steps fail, control seizure activity with diazepam or phenobarbital until medical treatment becomes effective in controlling hypoglycemia.

IV, Intravenous.

constant-rate infusion of glucagon (see p. 851). Seizure activity is controlled with diazepam or a stronger anticonvulsant medication. Glucocorticoids and mannitol may be necessary to combat cerebral edema.

DIABETES MELLITUS IN DOGS

Etiology and Classification

The reported prevalence of diabetes mellitus in dogs varies between countries, ranging from 1.2% in Sweden (Fall et al., 2007) to 0.32% in the United Kingdom (Davison et al., 2005). Guptill et al. (2003) reported a hospital prevalence of 0.64% in the United States. Virtually all dogs with diabetes have type 1 insulin-dependent diabetes mellitus (IDDM) at the time of diagnosis. Type 1 diabetes is characterized by permanent hypoinsulinemia, essentially no increase in the endogenous serum insulin concentration after administration of an insulin secretagogue (e.g., glucose, glucagon) at any time after diagnosis of the disease, failure to establish glycemic control in response to diet or treatment with oral hypoglycemic drugs (or both), and an absolute need for exogenous insulin to maintain glycemic control. The cause of diabetes mellitus in dogs is undoubtedly multifactorial. A genetic predisposition, infection, insulin-antagonistic diseases and drugs, obesity, immune-mediated mechanisms, and pancreatitis have been identified as inciting factors. The end result consists of loss of β cells, hypoinsulinemia, impaired transport of circulating glucose into most cells, and accelerated hepatic gluconeogenesis and glycogenolysis. The subsequent development of hyperglycemia and glycosuria causes polyuria, polydipsia, polyphagia, and weight loss. Ketoacidosis develops as the production of ketone bodies increases to compensate for the underutilization of blood glucose (see p. 840). Loss of β-cell function is irreversible in dogs with IDDM, and lifelong insulin therapy is mandatory to maintain glycemic control of the diabetic state.

Unlike cats, dogs very rarely have a transient or reversible form of diabetes mellitus. The most common scenario for diabetic remission in dogs is correction of insulin antagonism after ovariohysterectomy in a bitch in diestrus. Progesterone stimulates secretion of growth hormone in the bitch. Ovariohysterectomy removes the source of progesterone, plasma growth hormone concentration declines, and insulin antagonism resolves. If an adequate population of functional β cells is still present in the pancreas, hyperglycemia may resolve without the need for insulin treatment after ovariohysterectomy or more commonly within a month of initiation of insulin therapy after ovariohysterectomy. These dogs have a significant reduction in β-cell numbers (i.e., subclinical diabetes), compared with healthy dogs, before the development of hyperglycemia during diestrus and are prone to redevelopment of hyperglycemia and diabetes mellitus if insulin antagonism recurs for any reason after ovariohysterectomy. Although uncommon, a similar situation can occur in dogs with subclinical diabetes treated with insulin-antagonistic drugs (e.g., glucocorticoids) or in the very early stages of an insulin-antagonistic disorder (e.g., hyperadrenocorticism). Failure to quickly correct the insulin antagonism will result in IDDM and the lifelong requirement for insulin treatment to control hyperglycemia.

A honeymoon period occurs in some dogs with newly diagnosed IDDM. It is characterized by excellent glycemic control in response to small doses of insulin (<0.2 U/kg/injection), presumably because of the presence of residual β-cell function. However, glycemic control becomes more difficult and insulin doses usually increase within 3 to 6 months of the start of treatment as residual functioning β cells are destroyed and endogenous insulin secretion declines.

Type 2 non–insulin-dependent diabetes mellitus (NIDDM) is not recognized clinically in dogs. Obesity-induced insulin resistance has been documented in dogs but progression to type 2 diabetes does not occur (Verkest et al., 2012). Studies suggest that at least some of the etiopathogenic mechanisms responsible for development of obesity-associated type 2 diabetes in humans and cats do not occur in dogs.

Clinical Features

SIGNALMENT

Most dogs are 5 to 15 years old at the time diabetes mellitus is diagnosed. Juvenile-onset diabetes occurs in dogs younger than 1 year of age and is uncommon. One large epidemiologic study involving 6807 diabetic dogs and 6807 matched controls in the United States and Canada identified the following: female dogs were at increased risk for diabetes compared with male dogs, neutered male dogs were at increased risk compared with intact male dogs, and mixed-breed dogs were at increased risk compared with pure breeds (Guptill et al., 2003). A seasonal pattern in prevalence of diabetes was not identified. Breeds with a significantly increased or decreased risk for developing diabetes are listed in Table 49.1. Breed popularity and regions of the world may also impact breed predispositions. For example, breeds with the highest risk for diabetes in Italy include the Irish Setter, Poodle, Yorkshire Terrier, and English Setter (Fracassi et al., 2004). In Sweden, high risk breeds included Spitz-type breeds (Samoyed, Swedish Elkhound, and Swedish Lapphund) and Scandinavian hound dogs (Finnish Hound, Hamilton Hound, and Drever) (Fall et al., 2007).

HISTORY

The history in virtually all diabetic dogs includes polyuria, polydipsia, polyphagia, and weight loss. Polyuria and polydipsia do not develop until hyperglycemia results in glycosuria. Occasionally, a client brings in a dog because of blindness caused by cataract formation (Fig. 49.1). If clinical signs associated with uncomplicated diabetes are not observed or are considered irrelevant by the client a diabetic dog is at risk for the development of systemic signs of illness as progressive ketonemia and metabolic acidosis develop. The time sequence from the onset of initial clinical signs to

the development of diabetic ketoacidosis (DKA) is unpredictable, ranging from days to weeks.

PHYSICAL EXAMINATION

Physical examination findings depend on the presence and severity of DKA, the duration of diabetes before its diagnosis, and the nature of any other concurrent disorder. The nonketotic diabetic dog has no classic physical examination findings. Many diabetic dogs are obese but are otherwise in good physical condition. Dogs with prolonged untreated diabetes may have lost weight but are rarely emaciated unless concurrent disease (e.g., pancreatic exocrine insufficiency) is present. The haircoat may be sparse; the hairs may be dry, brittle, and lusterless; and scales from hyperkeratosis may be present. Diabetes-induced hepatic lipidosis may cause hepatomegaly. Lenticular changes consistent with cataract formation are common. Anterior uveitis and keratoconjunctivitis sicca may also be present. In contrast to diabetic cats, clinical signs suggestive of diabetic neuropathy (e.g., rear limb weakness, ataxia) are uncommon in newly diagnosed diabetic dogs. Additional abnormalities may be identified if DKA is present (see p. 840).

Diagnosis

The diagnosis of diabetes mellitus is based on three findings: appropriate clinical signs, persistent fasting hyperglycemia, and glycosuria. Measurement of the blood glucose concentration using a portable blood glucose–monitoring device and testing for the presence of glycosuria using urine reagent test strips (e.g., KetoDiastix) provide rapid confirmation of diabetes mellitus. Concurrent documentation of ketonuria establishes a diagnosis of diabetic ketosis (DK), and documentation of metabolic acidosis establishes a diagnosis of DKA.

It is important to document both persistent hyperglycemia and glycosuria to establish a diagnosis of diabetes mellitus because hyperglycemia differentiates diabetes mellitus from primary renal glycosuria, and glycosuria differentiates diabetes mellitus from other causes of hyperglycemia (see Box 49.1), most notably epinephrine-induced stress hyperglycemia that may develop around the time of blood sampling. Stress-induced hyperglycemia is a common problem in cats and occasionally occurs in dogs, especially those that are very excited, hyperactive, or aggressive. The reader is referred to page 837 for more information on stress-induced hyperglycemia.

Documenting an increase in the serum fructosamine concentration supports the presence of sustained hyperglycemia; however, a serum fructosamine concentration in the upper end of the reference range can occur in symptomatic diabetic dogs if the diabetes developed shortly before presentation of the dog to the veterinarian. The reader is referred to page 818 for more information on serum fructosamine.

A thorough evaluation of the dog's overall health is recommended once the diagnosis of diabetes mellitus has been established to identify any disease that may be causing or contributing to the carbohydrate intolerance (e.g., hyperadrenocorticism), that may result from the carbohydrate intolerance (e.g., bacterial cystitis), or that may mandate a modification of therapy (e.g., pancreatitis). The minimum laboratory evaluation should include a CBC, a serum biochemistry panel, measurement of serum pancreatic lipase immunoreactivity, and urinalysis with bacterial culture. Serum progesterone concentration should be determined if diabetes mellitus is diagnosed in an intact bitch, regardless of her cycling history. If available, abdominal ultrasound is indicated to assess for pancreatitis, adrenomegaly, pyometritis in an intact bitch, and abnormalities affecting the liver and urinary tract (e.g., changes consistent with pyelonephritis or cystitis). Measurement of baseline serum insulin concentration or an insulin response test is not routinely done. Additional tests may be warranted after the history is obtained, the physical examination is performed, or ketoacidosis is identified. Potential clinical pathologic abnormalities are listed in Box 49.4.

BOX 49.4

Clinicopathologic Abnormalities Commonly Found in Dogs and Cats With Uncomplicated Diabetes Mellitus

Complete Blood Count

Typically normal
Neutrophilic leukocytosis, toxic neutrophils if pancreatitis or infection present

Biochemistry Panel

Hyperglycemia
Hypercholesterolemia
Hypertriglyceridemia (lipemia)
Increased alanine aminotransferase activity (typically <500 IU/L)
Increased alkaline phosphatase activity (typically <500 IU/L)

Urinalysis

Urine specific gravity typically > 1.025
Glycosuria
Variable ketonuria
Proteinuria
Bacteriuria

Ancillary Tests

Serum Spec cPL or fPL normal or increased if pancreatitis present
Serum lipase normal or increased if pancreatitis present
Serum trypsin-like immunoreactivity (TLI)
  Low if pancreatic exocrine insufficiency present
  Normal or increased if pancreatitis present
Baseline serum insulin concentration
  IDDM: low, normal
  NIDDM: low, normal, increased
  Insulin resistance induced: low, normal, increased

IDDM, Insulin-dependent diabetes mellitus; *NIDDM,* non–insulin-dependent diabetes mellitus; *Spec cPL,* canine pancreatic-specific lipase; *Spec fPL,* feline pancreatic-specific lipase.

Treatment

The primary goal of therapy is elimination of client-observed clinical signs of diabetes. Persistence of clinical signs and development of chronic complications (Box 49.5) are directly correlated with the severity and duration of hyperglycemia. In the diabetic dog, control of hyperglycemia can be established with insulin, diet, exercise, prevention or control of concurrent insulin antagonistic diseases, and discontinuation of medications that cause insulin resistance. The veterinarian should also guard against the dog developing hypoglycemia, which is most apt to occur as the result of overzealous insulin therapy. The veterinarian should balance the benefits of tight glucose control obtainable with aggressive insulin therapy against the risk of hypoglycemia.

The second goal is to minimize the impact of therapy on the owner's lifestyle. A recent study evaluated the psychological and social impact of diabetes and its treatment on the quality of life of owners of diabetic dogs (Niessen et al., 2012). The top 10 negative impact items were associated mostly with the owner's quality of life rather than the pet's quality of life (Table 49.2). Awareness of the impact of the

treatment regimen, home monitoring and frequency of evaluations by the veterinarian on the client, and simplifying the overall management of the diabetic dog as much as possible without negatively impacting control of glycemia is important for the long-term success of treating diabetes.

OVERVIEW OF INSULIN PREPARATIONS

Types of insulin typically used for home treatment of diabetes in dogs and cats include intermediate-acting insulin (NPH, lente) and long-acting basal insulin (protamine zinc insulin [PZI], insulin glargine, insulin detemir; Table 49.3). NPH (Humulin N, Novolin N) is a recombinant human insulin; lente (Vetsulin, Caninsulin) is a purified pork-source insulin that is a mixture of three parts short-acting amorphous insulin and seven parts long-acting microcrystalline insulin; and PZI (Pro-Zinc, IDEXX) is a recombinant human insulin. Porcine-source lente and protamine zinc insulin are approved by the FDA for treatment of diabetes in dogs and cats, respectively.

NPH insulin, insulin glargine, and insulin detemir are U100 insulin preparations (i.e., 100 units of insulin per mL of solution), and porcine-source lente and protamine zinc insulin and are U40 insulin preparations (i.e., 40 units of insulin per mL of solution). The appropriate insulin syringe should be used for the insulin preparation being administered (i.e., U40 or U100 insulin syringe for a U40 or U100 insulin preparation). Insulin pens are also available for NPH insulin, porcine-source lente insulin, insulin glargine, and insulin detemir. The manufacturer of porcine lente insulin recommends vigorous shaking of the insulin vial until a homogeneous milky suspension is obtained before withdrawal of the insulin into the syringe.

Recombinant DNA technology has been applied for the production of insulin analogs with faster and slower absorption characteristics than are seen with native human insulin preparations. Rapid-acting insulin analogs, including insulin lispro (Humalog), insulin aspart (Novolog), and insulin glulisine (Apidra®) and are typically administered to human patients with diabetes three times a day before each of the three main meals (breakfast, lunch, and dinner), are used to control postprandial hyperglycemia, and are referred to as *prandial insulin preparations*. The role, if any, of these extremely short-acting insulins for the home treatment of diabetic dogs remains to be determined. A recent study documented similar effectiveness of insulin lispro and regular crystalline insulin for the treatment of DKA in dogs (Sears et al., 2012).

Insulin glargine (Lantus) and insulin detemir (Levemir) are long-acting basal insulin analogs that have a slow, sustained absorption from the subcutaneous site of insulin deposition, are designed to inhibit hepatic glucose secretion, are administered once a day at bedtime, and are used

TABLE 49.3

Commonly Used Insulin Preparations for Treating Diabetes in Dogs and Cats

		ADMINISTRATION		TYPICAL DURATION OF EFFECT (h)			
INSULIN	**ORIGIN**	**INDICATIONS**	**ROUTE**	**FREQUENCY**	**DOG**	**CAT**	**COMMON PROBLEMS**
Regular crystalline	Recombinant human	Treat DKA	IV	Continuous infusion	—	—	Rapid decrease in blood glucose concentration
			IM	Hourly initially	4-6	4-6	
			SC	q6-8h	6-8	6-8	May cause hypokalemia
		Treat diabetes at home	SC	q8h	6-8	6-8	
Lispro	Recombinant human analog	Treat DKA	IV	Continuous infusion	—	—	Rapid decrease in blood glucose concentration; may cause hypokalemia
NPH	Recombinant human	Treat diabetes at home	SC	q12h	6-12	6-10	Short duration of effect in dogs and cats
Lente	100% pork	Treat diabetes at home	SC	q12h	8-14	6-12	Short duration of effect in cats
		Good initial insulin for dogs					
PZI	Recombinant human	Treat diabetes at home Good initial insulin for cats	SC	q12h	10-16	10-14	Duration of effect too long for q12h therapy in some dogs Unpredictable timing of glucose nadir in some dogs
Glargine	Recombinant human analog	Treat diabetes at home Good initial insulin for cats	SC	q12-24h	8-24	8-24	Duration of effect too long for q12h therapy in some cats and dogs; weak glucose-lowering effect and unpredictable timing of glucose nadir in some dogs
Detemir	Recombinant human analog	Treat diabetes at home	SC	q12-24h	8-24	8-24	Duration of effect too long for q12h therapy in some cats and dogs; insulin dosage requirements considerably lower than those seen with other insulin preparations

DKA, Diabetic ketoacidosis; *IM,* intramuscular; *IV,* intravenous; *SC,* subcutaneous.

in conjunction with rapid-acting prandial insulin analogs in diabetic humans. Insulin glargine has been modified by replacing the amino acid asparagine with glycine at position A21 of the A chain, and two arginines have been added to the C-terminus of the B chain of insulin—modifications that shift the isoelectric point from a pH of 5.4 toward a neutral pH. This shift makes insulin glargine more soluble at a slightly acidic pH and less soluble at a physiologic pH than native human insulin. The solution in the bottle of glargine is acidic, which keeps glargine soluble and suspended in the solution (i.e., the solution is clear, and the bottle does not need to be rolled before insulin is drawn up into the syringe). Because of this dependency on pH, glargine should not be diluted or mixed with anything that may change the pH of the solution. Glargine forms microprecipitates in the subcutaneous tissue at the site of injection from which small amounts of insulin glargine are slowly released and absorbed into the circulation. Insulin detemir is also a long-acting basal insulin analog in which the amino acid threonine has been removed at B30 and a 14-carbon fatty acid (myristic acid) has been bound to the lysine amino acid at position B29 of the B chain of the insulin molecule. Prolonged action results from a combination of strong self-association at the injection site and binding to albumin, which reduces free insulin detemir concentrations in the circulation. Insulin detemir is a clear, colorless, aqueous neutral solution that does not need to be shaken before drawing up the insulin into the syringe. The manufacturer recommends tht insulin detemir not be mixed or diluted with other insulin preparations. Insulin detemir can be diluted using the Insulin Diluting Medium for NovoRapid® (insulin aspart) and Levemir®(detemir) supplied by Novo Nordisk.

STORAGE AND DILUTION OF INSULIN

Freezing and heating the insulin bottle will inactivate insulin in the bottle. Historically, shaking the bottle of NPH, lente, or PZI insulin was believed to inactivate the insulin, but recent studies performed by the pharmaceutical company have shown that shaking the bottle of lente insulin does not impact insulin action, provides more uniform dispersal of insulin throughout the solution than rolling the bottle, and is currently recommended. Similar recommendations have not yet been reported for NPH and PZI insulins. Although keeping the bottle of insulin at "room temperature" does not inactivate insulin, we routinely instruct clients to store the insulin bottle in the door of the refrigerator to maintain a consistent environment. Some veterinarians advocate replacing insulin with a new bottle every 1 to 2 months to prevent problems caused by loss of activity or sterility. This practice can create financial hardship for some clients and may not be necessary. The shelf life of a bottle of insulin that has been stored appropriately is longer than manufacturer recommendations. We have not appreciated a clinically significant loss of insulin action with time when insulin preparations, including glargine and detemir, are maintained in a constant environment (i.e., refrigerator) and handled appropriately. Routinely purchasing a new bottle of insulin every month may not be necessary, especially if the diabetic dog is doing well. However, development of cloudiness or discoloration suggest contamination, change in pH of the solution (glargine), and/or loss of insulin activity. The bottle of insulin should be discarded and replaced with a new bottle of insulin. Similarly, loss of insulin activity in the bottle should always be considered whenever clinical signs recur, regardless of the quantity of insulin remaining in the bottle.

Dilution of insulin is a common practice, especially in very small dogs and cats. Only diluting solutions provided by the respective company should be used. Although studies evaluating the shelf-life of diluted insulin have not been published, we recommend replacing diluted insulin preparations every 4 to 8 weeks. Even when these guidelines are observed, insufficient amounts of insulin are administered when diluted insulin is used in some dogs and cats, despite appropriate dilution and insulin administration techniques—inadequacies that are corrected when full-strength insulin is used. It is important to remember that insulin glargine is pH-dependent and should not be diluted with solutions that may change the pH of the solution.

INITIAL INSULIN RECOMMENDATIONS FOR DIABETIC DOGS

Once the diagnosis of diabetes is established, dogs should be considered insulin-dependent and treatment with insulin should be initiated. In our opinion, porcine-source lente insulin (Vetsulin, Caninsulin) is the initial insulin of choice for treating newly diagnosed diabetic dogs (see Table 49.3). Recombinant human NPH insulin is also effective, but problems with the short duration of effect are more common with NPH insulin than lente insulin. Studies to date suggest that the median dosage of lente and NPH insulin required to attain glucose control in most diabetic dogs is approximately 0.5 U/kg/injection, with a range of 0.2 to 1 U/kg. One important goal in the initial regulation of the diabetic dog is avoidance of symptomatic hypoglycemia, especially in the home environment. For this reason, our starting insulin dosage is always on the low end of the range (i.e., approximately 0.25 U/kg), and we prefer to start with twice-a-day insulin administration because an overwhelming majority of diabetic dogs require lente and NPH insulin twice a day.

Published experiences with insulin glargine in diabetic dogs is limited. In a study by Fracassi et al. (2012), insulin glargine administered twice a day was effective in improving or maintaining control of glycemia in the majority of diabetic dogs enrolled in the study. By week 24 of the study, 58% and 33% of dogs had attained good or moderate glycemic control, respectively. Insulin dosages required to attain glycemic control were similar to insulin dosages reported with NPH, lente, and PZI insulin (Table 49.4). The timing of the glucose nadir was variable, suggesting that short and especially prolonged duration of action of insulin glargine occurs in diabetic dogs (Fig. 49.2). The authors speculated that the published success rate of other types of insulins (i.e., NPH and lente) was somewhat better than insulin glargine. Our experiences with insulin glargine in dogs have been mixed

TABLE 49.4

Comparison of Insulin Preparation Dosages Required to Attain Control of Glycemia in Diabetic Dogs

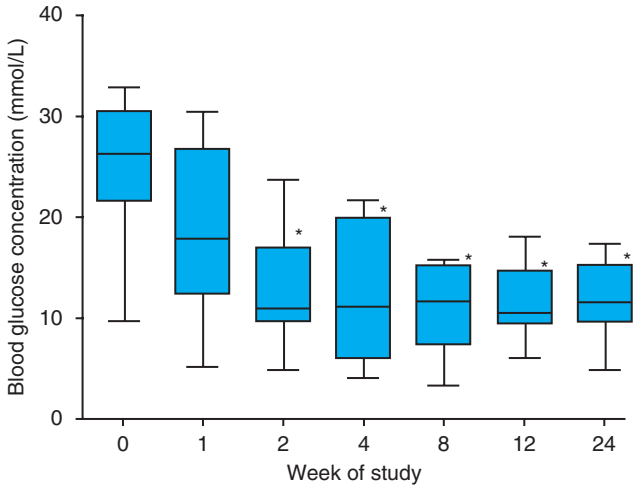

FIG 49.2
Box plots of 12-hour mean blood glucose concentrations in the blood glucose curves for 12 dogs with diabetes mellitus treated by various doses of insulin glargine administration twice daily for 24 weeks. Twelve-hour mean blood glucose concentration is the mean of the seven blood glucose concentrations measured during a 12-hour period. The horizontal line represents the median, the box represents the interquartile range (i.e., 25%-75%), the T-bars represent the main body of data. *=P <0.05. (From Fracassi F et al: Use of insulin glargine in dogs with diabetes mellitus, *Vet Rec* 170:52, 2012.).

and somewhat disappointing. We have been unable to attain good glycemic control in the majority of diabetic dogs treated with insulin glargine. We do not consider insulin glargine a first choice insulin for the treatment of diabetes in dogs but do consider using insulin glargine in diabetic dogs with problems of short duration of effect of NPH and lente insulin and problems with prolonged duration of effect of insulin detemir (see page 826).

Published experiences with insulin detemir in diabetic dogs are also limited. Insulin detemir is currently the longest acting insulin preparation for use in diabetic dogs, with a potential for duration of effect to be 16 hours or longer. The prolonged duration of effect combined with twice a day administration is responsible for lower dosage requirements and a greater likelihood for hypoglyemia with insulin detemir, compared with NPH or lente insulin (see Table 49.4). In an unpublished study, insulin detemir was effective in improving control of glycemia in 13 diabetic dogs managed with home blood glucose monitoring during a 4 to 24 month (median, 10 month) period (Ford et al., 2010). Ten of 13 dogs were previously treated with NPH or lente insulin with poor results. The mean and median insulin dosage on the last week of evaluation was 0.45 and 0.22 U/kg/injection, respectively. Biochemical hypoglycemia (blood glucose < 60 mg/dL; 3.4 mmol/L) was identified in approximately 2% of all blood glucose measurements and occurred on average 7.5 times per dog during the study. Our experiences with insulin detemir in dogs have been mixed but better than our experiences with insulin glargine. The absorption of insulin detemir from the subcutaneous site of injection is variable. In some diabetic dogs the absorption is slow and sustained, resulting in relatively flat blood glucose curves. In other dogs the absorption is similar to that seen with intermediate-acting insulin preparations like lente, resulting in "U"-shaped blood glucose curves. The most common problem with insulin detemir has been hypoglycemia when insulin detemir is given twice a day. We do not consider insulin detemir a first choice insulin for the treatment of diabetes in dogs but consider it the insulin of choice in diabetic dogs with problems of short duration of effect of NPH and lente insulin. Our starting dosage for insulin detemir is 0.1 U/kg twice a day.

Although recombinant human PZI, insulin glargine, and insulin detemir are effective in controlling glycemia in some

diabetic dogs, problems with consistency of effect, variable and unpredictable timing of the glucose nadir, and prolonged duration of effect preclude recommending these insulin preparations for use in the newly diagnosed diabetic dog. However, these insulin preparations should be considered when problems caused by short duration of insulin effect develop with lente or NPH insulin.

DIET

Diet plays an important role in management of the diabetic dog. What diet is ultimately fed is dictated, in part, by the weight of the dog, concurrent disease, and owner and dog preferences. Correction of obesity is the most beneficial step that can be taken to improve control of glycemia. Obesity causes insulin resistance in dogs and is an important factor accounting for variations in response to insulin therapy in diabetic dogs. Weight loss improves insulin resistance in obese diabetic dogs. Weight loss usually requires a combination of the following: restricting caloric intake, feeding low-calorie-dense diets, and increasing caloric expenditure through exercise. The reader is referred to Chapter 51 for more information on treating obesity.

Increasing the fiber content of the diet is beneficial for treating obesity and improving control of glycemia in diabetic dogs. Most major pet food companies offer diets designed for diabetic dogs that contain a mixture of soluble and insoluble fiber sources that slow glucose absorption from the gut and help minimize postprandial hyperglycemia (Box 49.6). Many diets designed for weight loss contain higher levels of insoluble fiber than diabetic diets and lower fat content to decrease the caloric density of the food. These diets may be fed to obese diabetic dogs to promote weight loss. High-fiber diets should not be fed to thin or emaciated diabetic dogs until control of glycemia is established and a normal body weight is attained with a higher-calorie-dense, lower-fiber diet designed for maintenance. Complications of feeding diabetic diets containing high fiber content are listed in Box 49.7. Most of these problems will resolve by changing the type or quantity of fiber consumed (i.e., a change in the diet).

Concurrent disease in which diet is an important aspect of therapy also dictates the type of diet to be fed. For example, diabetic dogs with concurrent chronic pancreatitis or exocrine pancreatic insufficiency (pancreatic acinar atrophy) should be fed a low-fat, low-fiber, highly digestible diet. Diabetic dogs with chronic kidney disease should be fed a lower-protein diet designed for kidney failure. Diabetic dogs with concurrent inflammatory bowel disease may need a hypoallergenic diet to help control inflammation and clinical signs. Whenever possible, dietary therapy for all disorders should be "blended," but if this is not possible, dietary therapy for the most serious disorder should take priority.

EXERCISE

Exercise plays an important role in maintaining glycemic control in the diabetic dog by helping to promote weight loss and by eliminating the insulin resistance induced by obesity.

BOX 49.6

Recommendations for Dietary Treatment of Diabetes Mellitus in Dogs and Cats

- Correct obesity and maintain body weight in an acceptable range (see Chapter 51).
  - Control daily caloric intake.
  - Increase daily exercise.
  - Avoid excessive amounts of insulin.
- Maintain consistency in the timing and caloric content of meals.
  - Feed within the time frame of insulin action.
  - Feed one half the daily caloric intake at the time of each insulin injection with q12h insulin therapy or at the time of the insulin injection and 6 to 10 hours later with q24h insulin therapy.
- Minimize the impact of food on postprandial blood glucose concentrations.
  - Avoid monosaccharides and disaccharides, propylene glycol, and corn syrup.
  - Let "nibbler" cats and dogs nibble throughout the day and night; ensure that other pets do not have access to the food.
  - Increase the fiber content of the diet (dogs).
  - Feed high-protein, low-carbohydrate diets (cats).

Examples of Veterinary Diets for Diabetic Dogs	Examples of Veterinary Diets for Diabetic Cats
Hill's Prescription Diet w/d	High-protein, low-carbohydrate diets:
Hill's Prescription Diet r/d (obese diabetic dog)	Purina DM
Purina DCO	Hill's Prescription Diet MD
Purina OM (obese diabetic dog)	Royal Canin Diabetic
Royal Canin Diabetic	Fiber-containing diets:
Royal Canin Calorie Control CC High Fiber (obese diabetic dog)	Hill's Prescription Diet w/d
Iams Glucose and Weight Control Plus	Hill's Prescription Diet r/d (obese diabetic cat)
	Purina OM (obese diabetic cat)
	Royal Canin Calorie Control (obese diabetic cat)

BOX 49.7

Common Complications Associated With Feeding Diets Containing Increased Quantities of Fiber

- Inapetence caused by poor palatability or boredom with food
- Increased frequency of defecation
- Constipation and obstipation (insoluble fiber)
- Soft stools and diarrhea (soluble fiber)
- Increased flatulence (soluble fiber)
- Weight loss
- Hypoglycemia

Exercise also has a glucose-lowering effect by increasing the mobilization of insulin from its injection site, presumably resulting from increased blood and lymph flow, by increasing blood flow (and therefore insulin delivery) to exercising muscles, and by stimulating glucose transporters in muscle

cells. The daily routine for diabetic dogs should include exercise, preferably at the same time each day and not around the time of peak insulin effect. Strenuous and sporadic exercise can cause severe hypoglycemia and should be avoided. If it is unavoidable, the insulin dose should be decreased in dogs subjected to sporadic strenuous exercise on those days of anticipated increased exercise. The reduction in insulin dose required to prevent hypoglycemia is variable and determined by trial and error. Reducing the insulin dose by 50% initially is recommended, with further adjustments based on the occurrence of symptomatic hypoglycemia and the severity of polyuria and polydipsia that develop during the ensuing 24 to 48 hours, or based on results of blood glucose testing by clients who monitor blood glucose concentrations in their diabetic dog using a portable blood glucose monitor (PBGM). Regardless, clients must be aware of the signs of hypoglycemia and must have a source of glucose readily available to give to their dog should any of these signs develop.

IDENTIFICATION AND CONTROL OF CONCURRENT PROBLEMS

Concurrent disease and insulin-antagonistic drugs can interfere with tissue responsiveness to insulin, resulting in insulin resistance and poor control of diabetes. Concurrent disease and insulin-antagonistic drugs typically cause insulin resistance by altering insulin metabolism (prereceptor problem), by decreasing the concentration or binding affinity of insulin receptors on the cell membrane (receptor problem), by interfering with the insulin receptor signaling cascade (postreceptor problem), or through a combination of these. Depending on the cause, insulin resistance may be mild and easily overcome by increasing the dose of insulin (e.g., obesity); may be severe, causing sustained and marked hyperglycemia regardless of the type and dose of insulin administered (e.g., hyperadrenocorticism); or may fluctuate in severity over time (e.g., chronic pancreatitis; Box 49.8). Some causes of insulin resistance, such as obesity and the administration of insulin-antagonistic drugs (e.g., glucocorticoids), are readily apparent at the time diabetes is diagnosed. Other causes of insulin resistance are not readily apparent and require an extensive diagnostic evaluation to be identified. In general, any concurrent inflammatory, infectious, hormonal, or neoplastic disorder can cause insulin resistance and can interfere with the effectiveness of insulin therapy. Identification and treatment of concurrent disease play integral roles in the successful management of the diabetic dog. A thorough history and physical examination and a complete diagnostic evaluation are imperative for the newly diagnosed diabetic dog (see the section on diagnosis).

PROTOCOL FOR IDENTIFYING INITIAL INSULIN REQUIREMENTS

Diabetic dogs require several days to equilibrate to changes in insulin dose or preparation. Therefore newly diagnosed diabetic dogs are typically hospitalized for no longer than 48 hours to finish the diagnostic evaluation of the dog, begin insulin therapy, and evaluate the initial glycemic response to the insulin. The intent is to identify low blood glucose concentrations (i.e., blood glucose < 80 mg/dL) in those dogs that are unusually sensitive to the actions of insulin and to modify the insulin dose in those dogs that remain hyperglycemic during the first few days of insulin therapy. The objective during this first visit is *not* to establish perfect glycemic control before sending the dog home. Rather, the objectives are to begin to reverse the metabolic derangements induced by the disease, to allow the dog to equilibrate to the insulin and the change in diet, to teach the client how to administer insulin, and to give the client a few days to become accustomed to treating the diabetic dog at home. Additional adjustments in insulin therapy are made on subsequent evaluations once the client and the pet have become accustomed to the treatment regimen. Glycemic control is attained when clinical signs of diabetes have resolved; the pet is healthy and interactive in the home; its body weight is stable (unless the dog is undergoing weight loss to correct obesity); the client is satisfied with the progress of therapy; and, if possible, blood glucose concentrations range between 100 and 250 mg/dL throughout the day. The goals of therapy are explained to the client; changes in insulin dose and possibly in insulin type are common and should be anticipated by the client. If the dog remains poorly controlled, the dose of insulin is gradually increased by 1 to 5 U/injection (depending on the size of the dog) each week until control is attained. This gradual increase in dose helps prevent hypoglycemia. Control of glycemia can be established in most dogs using insulin doses in the range of 1 U of insulin/kg or less (median, 0.5 U/kg) administered twice each day. If the insulin dose exceeds 1 U/kg/injection without adequate glycemic control, further investigations are indicated to determine the reason

BOX 49.8

Recognized Causes of Insulin Resistance in Diabetic Dogs and Cats

Disorders Typically Causing Severe Insulin Resistance	Disorders Typically Causing Mild or Fluctuating Insulin Resistance
Hyperadrenocorticism	Obesity
Acromegaly (cat)	Infection
Diestrus in intact female dog (causes increase in serum progesterone and growth hormone)	Chronic inflammation
	Chronic pancreatitis
	Chronic inflammatory bowel disease
Progesterone-secreting adrenocortical carcinoma	Disease of the oral cavity
	Chronic kidney disease
Diabetogenic drugs (most notably glucocorticoids and progestins)	Hepatobiliary disease
	Cardiac disease
	Hypothyroidism
	Hyperthyroidism
	Pancreatic exocrine insufficiency
	Hyperlipidemia
	Neoplasia
	Glucagonoma
	Pheochromocytoma

for treatment failure (see the section on complications of insulin therapy). If hypoglycemia is noted clinically or biochemically at any time, the insulin dosage should be decreased and further adjustments in the insulin dose made as needed to attain glycemic control.

Many factors affect the dog's glycemic control from day to day, including variations in insulin administration and absorption, dietary indiscretions and caloric intake, amount of exercise, and variables that affect insulin responsiveness (e.g., stress, concurrent inflammation, infection). As a consequence, the insulin dosage required to maintain glycemic control typically changes with time. Initially, a fixed dose of insulin is administered at home and changes are made only after the client consults with the veterinarian. As the insulin dose range required to maintain glycemic control becomes apparent, and as confidence is gained in the client's ability to recognize signs of hypoglycemia and hyperglycemia, the client is eventually allowed to make *slight* adjustments in the insulin dose at home on the basis of clinical observations of the pet's well-being and ideally results of home blood glucose monitoring.

Techniques for Monitoring Diabetic Control

The basic objective of insulin therapy is to eliminate the clinical signs of diabetes mellitus while avoiding or delaying the onset of common complications associated with the disease (see Box 49.5). Blindness caused by cataract formation is inevitable for most diabetic dogs but can be delayed if good glycemic control can be established and wide fluctuations in the blood glucose concentration avoided (see page 828). Complications to avoid include poor haircoat and unthrifty appearance, weight loss, hypoglycemia, recurring ketosis, and recurrence of polyuria and polydipsia. The devastating chronic complications of human diabetes (e.g., diabetic nephropathy, atherosclerosis) require years to develop and become clinically relevant and are uncommon in diabetic dogs, in part, because diabetes is diagnosed in older dogs. As such, the need to establish nearly normal blood glucose concentrations is not necessary in diabetic dogs. Most clients are happy and most dogs are healthy and relatively asymptomatic if most blood glucose concentrations are kept between 100 mg/dL and 250 mg/dL.

HISTORY AND PHYSICAL EXAMINATION

The most important initial parameters for assessing control of glycemia are the client's subjective opinion of severity of clinical signs and overall health of the pet, findings on physical examination, and stability of body weight. If the client is happy with the results of treatment, the physical examination is supportive of good glycemic control, and the body weight is stable, the diabetic dog is usually adequately controlled. Measurement of serum fructosamine concentrations can add further objective evidence for the status of glycemic control (discussed in greater detail later). Poor control of glycemia should be suspected and additional diagnostics (e.g., serial blood glucose curve) or a change in insulin therapy considered if the client reports clinical signs suggestive of hyperglycemia or hypoglycemia, if the physical examination identifies problems consistent with poor control of glycemia (e.g., thin appearance, poor haircoat), or if the dog is losing weight.

SINGLE BLOOD GLUCOSE DETERMINATION

Measuring a single blood glucose concentration is helpful only if hypoglycemia is identified. Documenting hypoglycemia supports insulin overdosage and the need to decrease the insulin dose, especially if glycemic control is poor. In contrast, documenting an increased blood glucose concentration does not, *by itself,* confirm poor control of glycemia. Stress or excitement can cause marked hyperglycemia, which does not reflect the dog's responsiveness to insulin and can lead to the erroneous belief that the diabetic dog is poorly controlled. If a discrepancy exists between the history, physical examination findings, and blood glucose concentration, or if the dog is fractious, aggressive, excited, or scared and the blood glucose concentration is known to be unreliable, serum fructosamine concentration should be measured for further evaluation of the status of glycemic control. In addition, a single blood glucose concentration is not reliable for evaluating the effects of a given type and dose of insulin in a poorly controlled diabetic dog (see the section on serial blood glucose curve).

SERUM FRUCTOSAMINE CONCENTRATION

Fructosamines are glycated proteins that result from an irreversible, nonenzymatic, insulin-independent binding of glucose to serum proteins. The extent of glycosylation of serum proteins is directly related to the blood glucose concentration; the higher the average blood glucose concentration during the preceding 2 to 3 weeks, the higher the serum fructosamine concentration and vice versa. Serum fructosamine concentration is not affected by acute increases in the blood glucose concentration, as occurs with stress- or excitement-induced hyperglycemia, but can be affected by concurrent hypoalbuminemia, hypoproteinemia, hypertriglyceridemia, hyperthyroidism (cats), hypothyroidism, azotemia, prolonged storage at room temperature, and interfering substances such as hemolysis (Table 49.5). Serum fructosamine concentrations can be measured during the routine evaluation of glycemic control in a diabetic dog; to clarify the effect of stress or excitement on blood glucose concentrations; to clarify discrepancies between the history, physical examination findings, and serial blood glucose concentrations; and to assess the effectiveness of changes in insulin therapy.

Fructosamine is measured in serum, which should be frozen and shipped on cold packs overnight to the laboratory. Although freezing does not cause a significant change in results, prolonged storage of serum at room temperature or in the refrigerator can decrease serum fructosamine results. Each laboratory should furnish its own reference

TABLE 49.5

Sample Handling, Methodology, and Normal Values for Serum Fructosamine Concentrations Measured in Our Laboratory

	FRUCTOSAMINE
Blood sample	1-2 mL; allow to clot, obtain serum
Sample handling	Freeze until assayed
Methodology	Automated colorimetric assay using nitroblue tetrazolium chloride
Factors affecting results	Hypoalbuminemia (decreased), hyperlipidemia (mild decrease—dogs), hemolysis-decrease, zotemia (mild decrease—dogs), hyperthyroidism (decreased—cats), hypothyroidism (increased—dogs), obesity (mild increase—cats), storage at room temperature (decreased)
Normal range	225-365 µmol/L (dogs) 190-365 µmol/L (cats)
Interpretation in Diabetic Dogs and Cats	
Excellent control	350-400 µmol/L
Good control	400-450 µmol/L
Fair control	450-500 µmol/L
Poor control	>500 µmol/L
Prolonged hypoglycemia	<300 µmol/L
DDiabetic remission (cats)	<300 µmol/L

range. In our laboratory the reference range for serum fructosamine in dogs is 225 to 365 µmol/L—a range determined in healthy dogs with persistently normal blood glucose concentrations. Interpretation of serum fructosamine in a diabetic dog must take into consideration the fact that hyperglycemia is common, even in well-controlled diabetic dogs. Most clients are happy with the pet's response to insulin treatment if serum fructosamine concentrations can be kept between 350 and 450 µmol/L. Values greater than 500 µmol/L suggest inadequate control of the diabetic state, and values greater than 600 µmol/L indicate serious lack of glycemic control. Serum fructosamine concentrations in the lower half of the reference range (i.e., <300 µmol/L) or below the reference range should raise concern about significant periods of hypoglycemia in the diabetic dog or concurrent problems that decrease the serum fructosamine concentration. Increased serum fructosamine concentrations (i.e., >500 µmol/L) suggest poor control of glycemia and a need for insulin adjustments but do not identify the underlying problem.

Serum fructosamine concentrations should not be used as the sole indicator of status of glycemic control but rather should be interpreted in conjunction with the history, findings on physical examination, and stability of body weight. A disconnect between interpretation of the serum fructosamine concentration and the clinical picture or, more commonly, results of blood glucose concentrations may occur in some diabetic dogs. When a low serum fructosamine concentration is identified in a dog with suspected poor control of the diabetic state, reasons for a low fructosamine test result (see Table 49.5) or an increase in serum glucose concentrations should be considered, and vice versa when a high serum fructosamine concentration is identified in a dog with suspected good control of the diabetic state. Whenever information used to assess glycemic control conflicts, we rely most heavily on history, physical examination findings, and stability of body weight when deciding whether a change in insulin therapy is indicated.

URINE GLUCOSE MONITORING

Occasional monitoring of urine for glycosuria and ketonuria is helpful in diabetic dogs that have problems with recurring ketosis or hypoglycemia to identify ketonuria or persistent negative glycosuria, respectively. The client is instructed not to adjust daily insulin doses on the basis of morning urine glucose measurements, except to decrease the insulin dose in dogs with recurring hypoglycemia and persistent negative glycosuria. Many diabetic dogs develop complications because clients were misled by morning urine glucose concentrations and increase the insulin dose, which eventually results in insulin overdosing, hypoglycemia, and glucose counter regulation (see page 825). Persistent glycosuria throughout the day and night suggests inadequate control of the diabetic state and the need for a more complete evaluation of diabetic control using other techniques discussed in this section.

SERIAL BLOOD GLUCOSE CURVES

If an adjustment in insulin therapy is deemed necessary after a review of the history, physical examination findings, and changes in body weight, a serial blood glucose curve should be generated to provide guidance in making the adjustment, unless blood glucose measurements are unreliable because of stress, aggression, or excitement. The serial blood glucose curve provides guidelines for making adjustments in insulin therapy. Evaluation of a serial blood glucose curve is mandatory during the initial regulation of the diabetic dog and is necessary in the dog in which clinical manifestations of hyperglycemia or hypoglycemia have developed. Reliance on history, physical examination findings, and body weight to determine when a blood glucose curve is needed helps reduce the frequency of performing glucose curves, thereby minimizing the animal's aversion to these evaluations and improving the chances of obtaining meaningful results when a blood glucose curve is needed. Insulin therapy is adjusted

according to interpretation of a single serial blood glucose curve, and the impact of the change is initially assessed by client perceptions of clinical response. If problems persist, the blood glucose curve can be repeated. If possible, performing blood glucose curves on multiple, consecutive days should be avoided because it promotes stress-induced hyperglycemia. Information gained from a prior serial blood glucose curve should never be assumed to be reproducible on subsequent curves. Lack of consistency in the results of serial blood glucose curves is a source of frustration for many veterinarians and is a direct reflection of all the variables that affect the blood glucose concentration in diabetic dogs. Daily self-monitoring of blood glucose concentrations and adjustments in insulin dose are used in human patients with diabetes to minimize the effects of these variables on control of glycemia. A similar approach for diabetic dogs and cats is becoming more common with the advent of home blood glucose monitoring of diabetic dogs and cats by their owners (see next section).

When a blood glucose curve is generated, the insulin and feeding schedule used by the client should be maintained and the dog dropped off at the hospital early in the morning. Owners of diabetic dogs who are finicky eaters should feed their pet at their home, not at the hospital. Inappetence can profoundly alter the results of a serial blood glucose curve (Fig. 49.3). The first blood sample for blood glucose measurement is obtained when the dog enters the hospital, and subsequent blood samples are typically obtained every 2 hours throughout the day for glucose determination. Glucose measurements should be done more frequently than every 2 hours if the blood glucose is dropping quickly or hypoglycemia is identified. If there are concerns regarding the client's technique for administering insulin, the client can administer insulin (using his or her own insulin and syringe) in the hospital *after* the initial blood glucose is obtained or can demonstrate his or her technique using sterile saline after arriving to pick up the pet at the end of the day. The veterinarian or a veterinary technician should closely evaluate the entire insulin administration procedure. By measuring blood glucose concentration every 2 hours throughout the day, the clinician will be able to determine if the insulin is effective and identify the glucose nadir, time of peak insulin effect, approximate duration of insulin effect, and range of blood glucose concentrations in that particular dog. Identifying the glucose nadir and the time of the glucose nadir in relation to the time of insulin administration is critical for assessing the duration of insulin effect. If the glucose nadir has not been identified by the time of the next insulin injection, the glucose curve should be continued, the scheduled insulin injection aborted, and the dog fed its evening meal (see the discussion of the prolonged duration of insulin effect, p. 826). Obtaining only one or two blood glucose concentrations during the day has not been reliable for evaluating the effect of a given insulin dose (Fig. 49.4). Persistent poor control of the diabetic state often stems from misinterpretation of the effects of insulin based on assessment of only one or two blood glucose concentrations.

Changes in blood glucose concentrations are typically assumed to be comparable following the morning and evening administration of insulin so most dogs receive the same dose of insulin morning and evening (Mori et al., 2013). This assumption is fine as long as the dog is doing

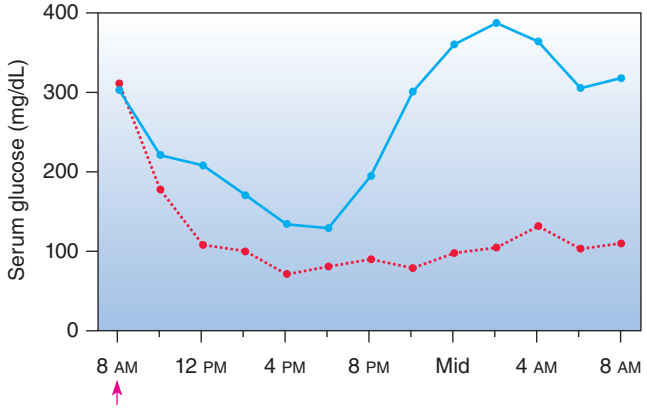

FIG 49.3
Mean blood glucose concentrations in eight diabetic dogs after administration of NPH insulin (↑) and the feeding of equally sized meals at 8 AM and 6 PM *(blue line)* or feeding of nothing *(red line)* during the 24 hours of blood sampling.

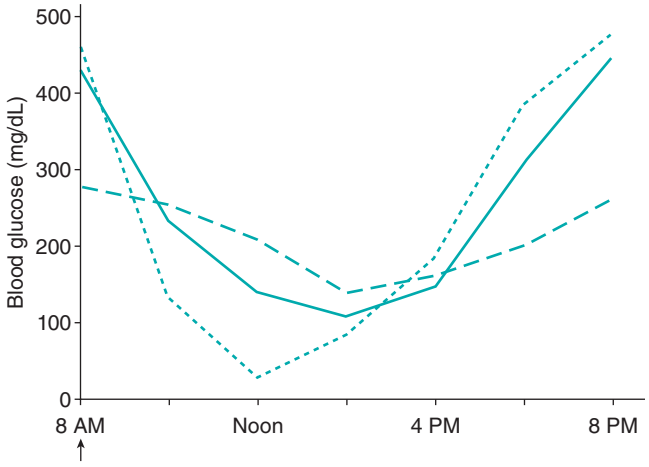

FIG 49.4
Blood glucose concentration curve in a Dachshund receiving 0.8 U of recombinant human lente insulin per kilogram of body weight twice a day *(solid line)*, a Miniature Poodle receiving 0.6 U of recombinant human lente insulin per kilogram of body weight twice a day *(dashed line)*, and a Terrier-mix receiving 1.1 U of recombinant human lente insulin per kilogram of body weight twice a day *(dotted line)*. Insulin and food were given to each dog at 8 AM. Interpretation of the blood glucose curves suggests a short duration of insulin effect in the Dachshund, insulin underdosing in the Miniature Poodle, and the Somogyi response in the Terrier-mix. Blood glucose concentrations were similar in all dogs at 2 PM and 4 PM; glucose results at these times do not establish the diagnosis in any of the dogs.

well. However, different blood glucose results during the day versus the night should be suspected if polyuria and polydipsia persist despite blood glucose concentrations that are close to acceptable during the day, especially if polyuria and polydipsia are worse at night. For these cases, obtaining a 24-hour blood glucose curve or use of a continuous glucose monitoring device should be considered.

Blood glucose concentrations are typically determined by either a point-of-care glucose analyzer or handheld PBGM device. The accuracy of commercially available PBGM devices designed for use in human diabetics varies considerably when used in diabetic dogs, compared with results using standard reference methods (i.e., glucose oxidase and hexokinase methods) (Cohn et al., 2000; Cohen et al., 2009; Wess and Reusch., 2000). Blood glucose values determined by most PBGM devices designed for use in human diabetics are typically lower than actual glucose values determined by reference methods and the difference between the actual glucose value and value obtained from the PBGM increases as hyperglycemia worsens. This bias may result in an incorrect diagnosis of hypoglycemia or the misperception that glycemic control is better than it actually is. Failure to consider this rror could result in insulin underdosage and the potential for persistence of clinical signs despite apparently acceptable blood glucose results. One exception is the AlphaTRAK® by Abbott Laboratories, a PBGM device designed for use in diabetic dogs and cats. Accuracy of this PBGM device is very good, but glucose values may be higher or lower than glucose values measured by reference methodologies on the same blood sample, forcing the veterinarian to accept the blood glucose concentration at face value (Cohen et al., 2009). Haematocrit may also affect the results of PBGMs. In one study, results of the AlphaTRAK® were less accurate compared with a laboratory reference method in blood samples with a lower haematocrit (<30%) but not an increased haematocrit (>50%), whereas results from a PBGM for use in humans was less accurate with increased haematocrit but not a decreased haematocrit (Paul et al., 2011).

Home Blood Glucose Monitoring

Hyperglycemia induced by stress, aggression, or excitement is the single biggest problem affecting accuracy of the serial blood glucose curves (Fig. 49.5). The biggest factors causing stress-induced hyperglycemia are frequent hospitalizations and multiple venipunctures. An alternative to hospital-generated blood glucose curves is to have the client generate the blood glucose curve at home using the ear or metacarpal, metatarsal or foot pad prick technique and a PBGM device that allows the client to touch the drop of blood on the ear or foot pad with the end of the glucose test strip. There are several excellent online sites that demonstrate home blood glucose monitoring techniques for the owner of a diabetic dog (e.g., Abbott Laboratories website for the AlphaTRAK2®). This technique should be considered for diabetic dogs in which the reliability of blood glucose results generated in the veterinary hospital is questionable. Home blood glucose monitoring is also becoming a routine monitoring technique

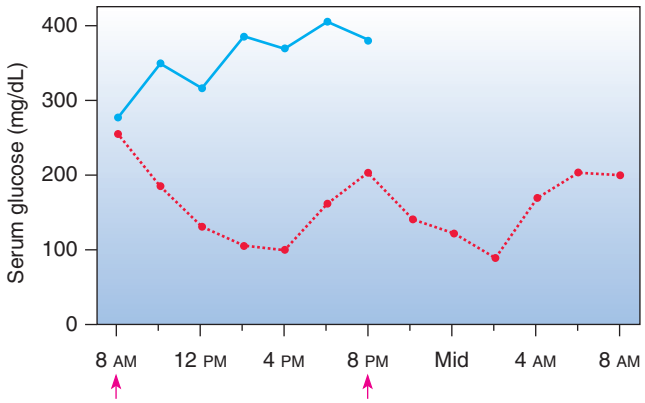

FIG 49.5
Blood glucose concentration curves in a fractious Terrier-mix. The same dose of NPH insulin was given for each curve. One glucose curve *(blue line)* was obtained with the dog in an agitated state, requiring physical restraint each time a blood specimen was obtained; blood for the other glucose curve *(red line)* was obtained through a jugular catheter with minimal to no restraint and with the dog in a quiet state. ↑, Insulin administration and food.

used by clients. The biggest problem has been overzealous owners who monitor blood glucose concentrations too frequently and begin to interpret results and adjust the insulin dose without consulting their veterinarian, a practice that ultimately leads to insulin overdosage. The reader is referred to page 835 for more information on home blood glucose monitoring.

Continuous Glucose-Monitoring Systems

Continuous glucose-monitoring (CGM) systems are frequently used to monitor glucose concentrations in diabetic humans and are beginning to be used in diabetic dogs and cats. CGM systems measure interstitial fluid glucose concentrations rather than blood glucose concentrations. The correlation between interstitial and blood glucose concentrations is good. A frequently used CGM system (Guardian REAL-time, Medtronic, Northridge, Calif) measures interstitial glucose with a small, flexible sensor inserted through the skin into the subcutaneous space and secured to the skin. Interstitial glucose is detected via the glucose oxidase reaction, and detection occurs entirely at the electrode within the sensor component. Glucose results are transmitted by a wireless transmitter to a pager-sized monitor. The interstitial fluid glucose concentration is recorded and stored every 5 minutes, and the data can be downloaded to a computer for analysis (Fig. 49.6). Calibration of the CGM system is required at initiation and once every 12 hours. The working glucose range for the CGM system is 40 to 400 mg/dL. Studies to date suggest that the primary advantage of continuous glucose monitoring is detection of hypoglycemic periods that are not detected with serial blood glucose curves and a PBGM device. (See Suggested Readings for more information on continuous glucose monitoring.)

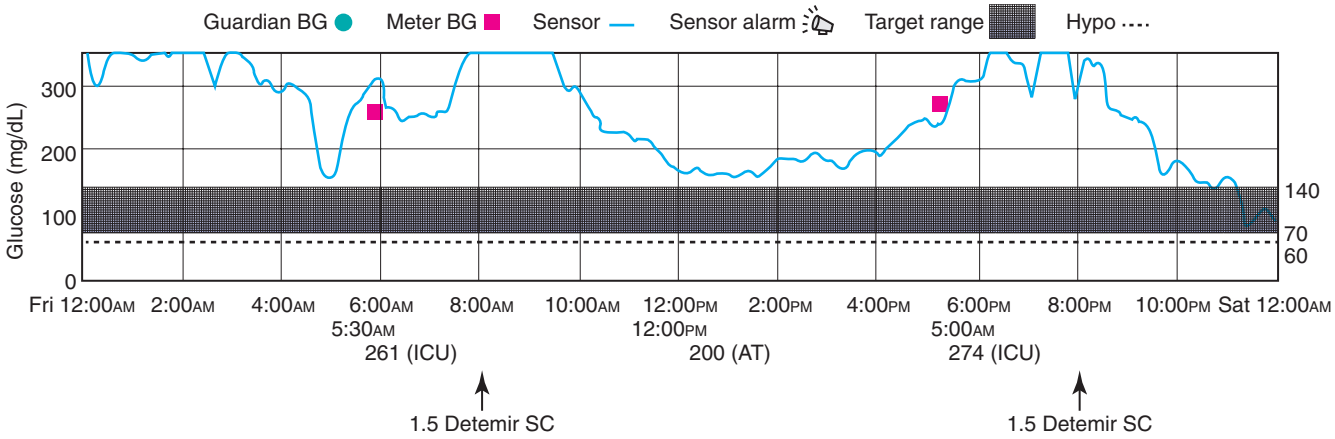

FIG 49.6
Example of results of continuous glucose monitoring using the Guardian EAL-Time monitor in a female-spayed Miniature Schnauzer with persistent polyuria, polydipsia and weight loss despite various doses of insulin detemir twice daily. Hypoglycemia and possible glucose counter-regulation was suspected but blood glucose concentrations obtained by venipuncture were always increased. Stress-induced hyperglycemia was believed to be interfering with glucose results. Results of continuous glucose monitoring with minimal blood sampling documented efficacy of insulin detemir and the occurrence of hypoglycemia in the dog. (From Feldman EC et al: *Canine and feline endocrinology,* ed 4, St Louis, 2015, Elsevier Saunders.)

Interpreting the Serial Blood Glucose Curve

An overview of how to interpret results of a serial blood glucose curve is provided in Fig. 49.7. The *ideal* goal is to maintain the blood glucose concentration between 80 mg/dL and 250 mg/dL during the time period between insulin injections, although many diabetic dogs do well despite blood glucose concentrations consistently in the high 100s to low 300s. The goal of insulin therapy is to have the highest blood glucose concentration less than 300 mg/dL, the glucose nadir between 80 and 130 mg/dL, and the mean of all blood glucose values measured that day at less than 250 mg/dL. Typically, the highest blood glucose concentrations occur at the time of each insulin injection, but this is not always so. If the blood glucose nadir is greater than 130 mg/dL, the insulin dose may need to be increased, and if the nadir is less than 60 mg/dL, the insulin dose should be decreased.

Duration of insulin effect can be assessed if the glucose nadir is greater than 80 mg/dL and no rapid decrease in blood glucose concentration is noted after insulin administration. Assessment of duration of insulin effect may not be valid when blood glucose decreases to less than 60 mg/dL or decreases rapidly because of the potential induction of glucose counterregulation (i.e., secretion of glucagon, epinephrine, and cortisol), which can falsely decrease the apparent duration of insulin effect (see p. 825). A rough approximation of the duration of effect of insulin can be gained by examining the time of the glucose nadir. For most well-controlled diabetic dogs, the initial blood glucose concentration near the time of insulin administration is less than 300 mg/dL, and the glucose nadir occurs approximately 8 hours after injection of insulin. An initial blood glucose concentration greater than 300 mg/dL, combined with a glucose nadir occurring less than 8 hours after insulin administration and subsequent blood glucose concentrations increasing to greater than 300 mg/dL, is supportive of a short duration of insulin effect. A glucose nadir that occurs 12 hours or longer after insulin administration is supportive of a prolonged duration of insulin effect. Dogs may develop hypoglycemia (blood glucose < 60 mg/dL) and initiate glucose counterregulation if the duration of insulin effect is greater than 14 hours and insulin is administered twice a day (Fig. 49.8).

Role of Serum Fructosamine in Aggressive, Excitable, or Stressed Dogs

Blood glucose curves are unreliable in aggressive, excitable, or stressed dogs because of problems related to stress-induced hyperglycemia. Hyperglycemia presumably develops as a result of increased catecholamine and glucocorticoid secretion and can significantly increase the blood glucose concentration despite insulin administration. In these dogs home blood glucose monitoring by the client may provide accurate blood glucose results. If home blood glucose monitoring is not available, the clinician must make an educated guess as to where the problem lies (e.g., wrong type of insulin, low dose), make an adjustment in therapy, and rely on changes in serum fructosamine to assess the benefit of the change in treatment. The reader is referred to page 818 for more information on the use of serum fructosamine in diabetic dogs and cats with stress-induced hyperglycemia.

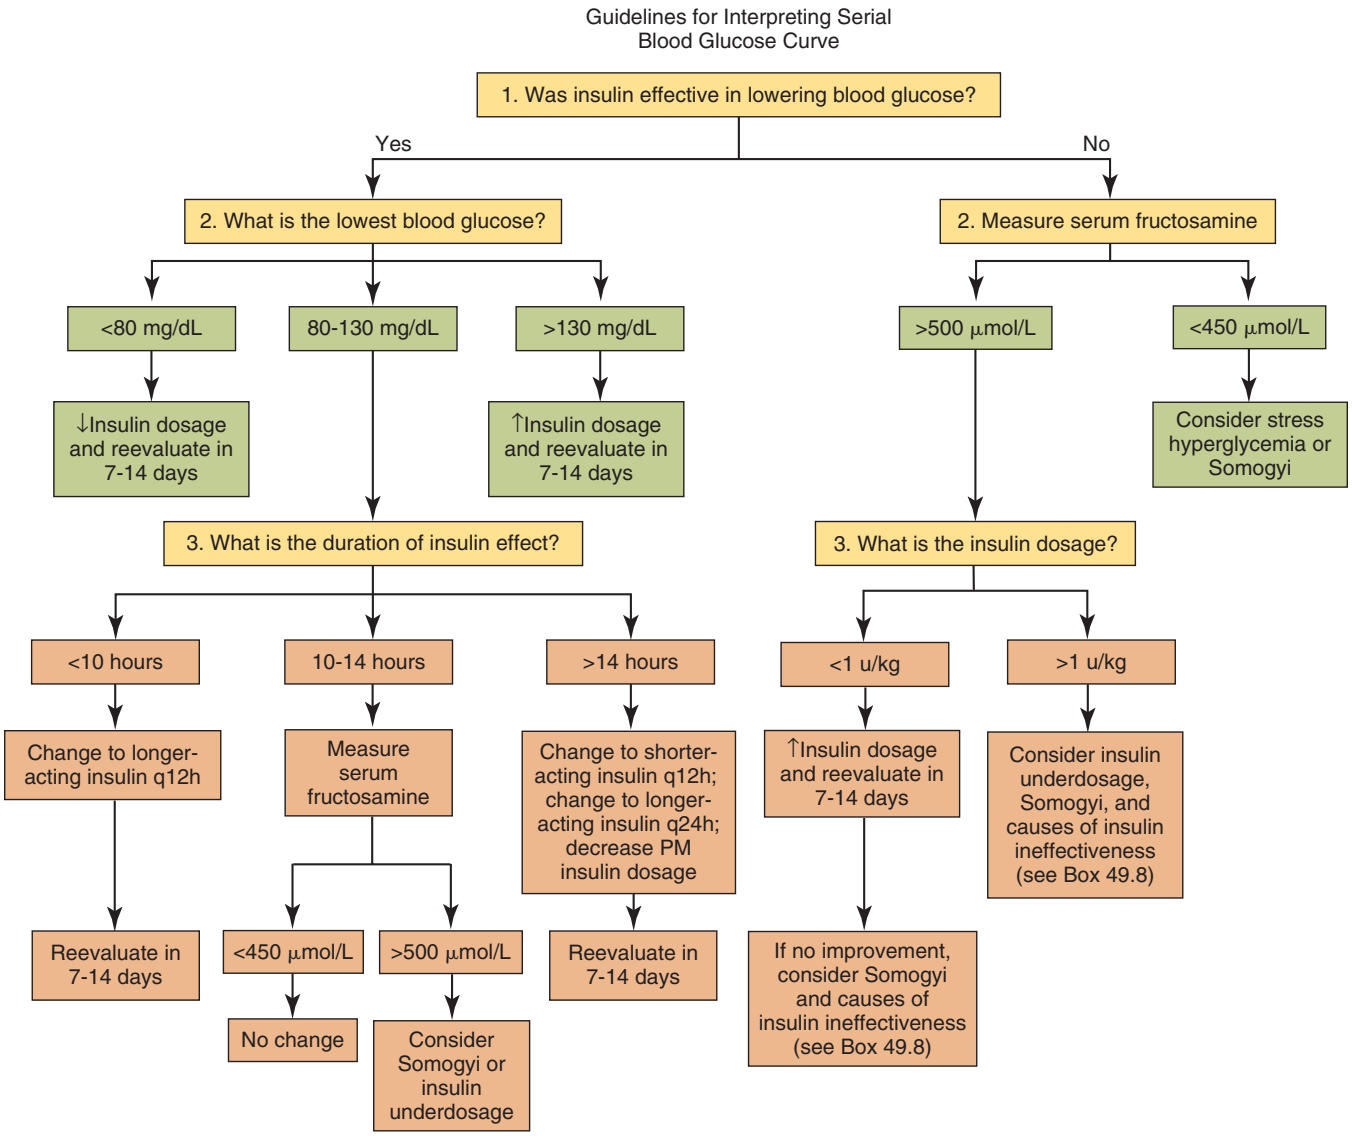

FIG 49.7
Algorithm for interpreting results of a blood glucose concentration curve.

INSULIN THERAPY DURING SURGERY

Generally, elective surgery should be delayed in diabetic dogs until the animal's clinical condition is stable and the diabetic state is controlled with insulin. Exceptions are those situations in which surgery is required to eliminate insulin resistance (e.g., ovariohysterectomy in a diestrus bitch) or to save the animal's life. The surgery itself does not pose a greater risk in a stable diabetic dog than in a nondiabetic dog. The concern is the interplay between insulin therapy and the lack of food intake during the perioperative period. The stress of anesthesia and surgery also causes the release of diabetogenic hormones, which promote ketogenesis. Insulin must be administered during the perioperative period to prevent severe hyperglycemia and to minimize ketone formation. To compensate for the lack of food intake and prevent hypoglycemia, the amount of insulin administered during the perioperative period is decreased and IV dextrose is administered when needed.

We use the following protocol during the perioperative period in dogs and cats undergoing surgery. The day before surgery the dog or cat is given its normal dose of insulin and fed as usual. Food is withheld after 10 PM. On the morning of the procedure, the blood glucose concentration is measured before the dog or cat is given insulin. If the blood glucose concentration is less than 100 mg/dL, insulin is not given and an IV infusion of 5% dextrose is initiated. If the blood glucose concentration is between 100 and 200 mg/dL, one quarter of the animal's usual morning dose of insulin is given and an IV infusion of dextrose is initiated. If the blood glucose concentration is greater than 200 mg/dL, one half of the usual morning dose of insulin is given, but the IV dextrose infusion is withheld until the blood glucose

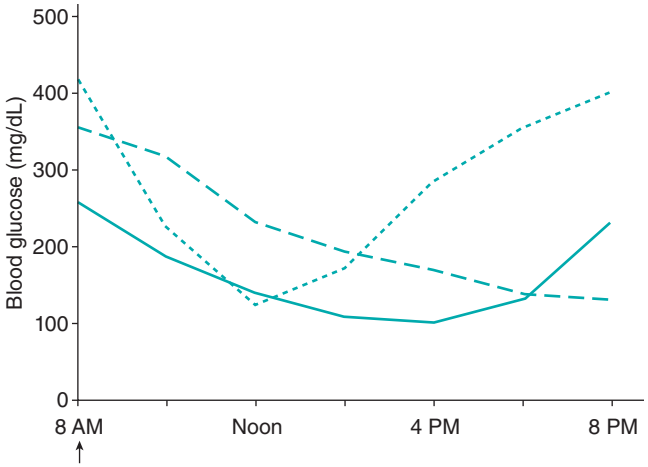

FIG 49.8
Blood glucose concentration curves obtained from three diabetic dogs treated with recombinant human lente insulin twice a day, illustrating a difference between dogs in the duration of insulin effect. The insulin is effective in lowering the blood glucose concentration in all dogs, and the blood glucose nadir is between 100 and 175 mg/dL for the dogs. However, the duration of insulin effect is approximately 12 hours *(solid line)* in one dog with good control of glycemia (ideal duration of effect), approximately 8 hours *(dotted line)* in one dog with persistently poor control of glycemia (short duration of effect), and longer than 12 hours *(dashed line)* in one dog with a history of good days and bad days of glycemic control (prolonged duration of effect)—a history suggestive of the Somogyi response (see Fig. 49.9).

concentration is less than 150 mg/dL. In all three situations the blood glucose concentration is measured every 30 to 60 minutes during the surgical procedure. The goal is to maintain the blood glucose concentration at between 150 and 250 mg/dL during the perioperative period. A 5% dextrose infusion is administered intravenously as needed to correct or prevent hypoglycemia. When the blood glucose concentration exceeds 300 mg/dL, the dextrose infusion should be discontinued and the blood glucose concentration evaluated 30 and 60 minutes later. If the blood glucose concentration remains greater than 300 mg/dL, regular crystalline insulin is administered intramuscularly at approximately 20% of the dose of the long-acting insulin used at home. Subsequent doses of regular crystalline insulin should be given no more frequently than every 4 hours (every 6 hours if administered subcutaneously), and the dose should be adjusted on the basis of the effect of the first insulin injection on the blood glucose concentration.

On the day after surgery the diabetic dog or cat can usually be returned to the routine schedule of insulin administration and feeding. An animal that is not eating can be maintained with IV dextrose infusions and regular crystalline insulin injections given subcutaneously every 6 to 8 hours. Once the animal is eating regularly, it can be returned to its normal insulin and feeding schedule.

COMPLICATIONS OF INSULIN THERAPY

Hypoglycemia

Hypoglycemia is a common complication of insulin therapy. Signs of hypoglycemia are most apt to occur after sudden large increases in the insulin dose, with excessive overlap of insulin action in dogs receiving insulin twice a day, after prolonged inappetence, during unusually strenuous exercise, following sudden improvement in concurrent insulin resistance, and in insulin-treated cats that have undergone diabetic remission. In these situations severe hypoglycemia may occur before glucose counterregulation (i.e., secretion of glucagon, epinephrine, and cortisol) is able to compensate for and reverse hypoglycemia. The occurrence and severity of clinical signs are dependent on the rate of blood glucose decline and the severity of hypoglycemia. In many diabetic dogs, signs of hypoglycemia are not apparent to clients, and hypoglycemia is identified during evaluation of a serial blood glucose curve or is suspected when a low serum fructosamine concentration is identified. Clinical signs and treatment of hypoglycemia are discussed on page 806. If clinical signs of hypoglycemia have occurred, insulin therapy should be stopped until hyperglycemia and glycosuria recur. Urine glucose testing by the owner with the dog in the home environment is useful for identifying when glycosuria recurs. The adjustment in the insulin dose is somewhat arbitrary; as a general rule of thumb, the insulin dose initially should be decreased by 25% to 50% and subsequent adjustments in the dose based on clinical response and results of blood glucose measurements. Failure of glycosuria to recur after a hypoglycemic episode suggests diabetic remission or impaired glucose counterregulation.

Recurrence of Clinical Signs

Recurrence or persistence of clinical signs is perhaps the most common complication of insulin therapy in diabetic dogs. This is usually caused by problems with client technique in administering insulin; problems with insulin therapy related to the insulin type, dose, or frequency of administration; or problems with responsiveness to insulin caused by concurrent inflammatory, infectious, neoplastic, or hormonal disorders (i.e., insulin resistance).

Problems with client administration and insulin activity

Failure to administer an appropriate dose of biologically active insulin will result in recurrence or persistence of clinical signs. Common reasons include administration of biologically inactive (e.g., outdated, previously heated or frozen) insulin, administration of diluted insulin, use of inappropriate insulin syringes for the concentration of insulin (e.g., U100 syringe with U40 insulin), and problems with the insulin administration technique (e.g., failure to correctly read the insulin syringe, inappropriate injection technique). These problems are identified by evaluating the client's insulin administration technique and by administering new undiluted insulin and measuring several blood glucose concentrations throughout the day.

Problems with the insulin treatment regimen

The most common problems with the insulin treatment regimen in the dog include insulin underdosage, insulin overdosage causing hypoglycemia and glucose counterregulation, short duration of effect of lente or NPH insulin, prolonged duration of effect of insulin glargine and insulin detemir, and once-daily insulin administration. Discrepancies in the parameters used to assess glycemic control, resulting in an erroneous belief that the diabetic dog is poorly controlled, should also be considered. This is usually caused by erroneously high blood glucose concentrations induced by stress that suggest insulin ineffectiveness or presence of a concurrent unrecognized disorder that also causes polyuria and polydipsia such as early renal insufficiency. When evaluating a diabetic dog for suspected insulin ineffectiveness, it is important that all parameters used to assess glycemic control be critically analyzed, most notably the owner's perceptions of how their dog is doing in the home environment, findings on physical examination, and changes in body weight. If the history, physical examination, change in body weight, and serum fructosamine concentration suggest poor control of the diabetic state, a diagnostic evaluation to identify the cause is warranted, beginning with evaluation of the owner's insulin administration technique and the biologic activity of the insulin preparation. The insulin treatment regimen should be critically evaluated for possible problems and appropriate changes made in an attempt to improve insulin effectiveness, especially if the history and physical examination do not suggest a concurrent disorder causing insulin resistance.

Insulin underdosing

Control of glycemia can be established in most dogs with less than 1 U of insulin/kg of body weight (median, 0.5 U/kg) administered twice daily. An inadequate dose of insulin in conjunction with once-daily insulin therapy is a common cause for persistence of clinical signs. In general, insulin underdosing should be considered if the insulin dose is less than 1 U/kg and the dog is receiving insulin twice a day. If insulin underdosing is suspected, the dose of insulin should be gradually increased by 1 to 5 U/injection (depending on the size of the dog) per week. The effectiveness of the change in therapy should be evaluated by client perception of clinical response and measurement of serial blood glucose concentrations or serum fructosamine concentration. Although some dogs require insulin dosages as high as 1.5 U/kg to attain control of glycemia, other causes of insulin ineffectiveness, most notably occult hypoglycemia inducing glucose counterregulation and concurrent insulin resistance, should be considered once the insulin dose exceeds 1 U/kg/injection, the insulin is being administered every 12 hours, and control of glycemia remains poor.

Insulin overdosing and glucose counterregulation (Somogyi response). The Somogyi response results from a normal physiologic response to impending hypoglycemia induced by excessive insulin. When the blood glucose concentration declines to less than 60 mg/dL, or when the blood glucose concentration decreases rapidly regardless of the glucose nadir, direct hypoglycemia-induced stimulation of hepatic glycogenolysis and secretion of diabetogenic hormones, most notably epinephrine and glucagon, increase the blood glucose concentration, minimize signs of hypoglycemia, and may cause marked hyperglycemia within 12 hours of glucose counterregulation. The hyperglycemia that occurs after hypoglycemia is due, in part, to an inability of the diabetic dog to secrete sufficient endogenous insulin to dampen the rising blood glucose concentration in conjunction with insufficient concentrations of circulating insulin derived from the injected insulin. By the next morning the blood glucose concentration can be extremely elevated (>400 mg/dL), and the morning urine glucose concentration is consistently 1 to 2 g/dL as measured with urine glucose test strips. Unrecognized short duration of insulin effect, combined with insulin dose adjustments based on morning urine glucose concentrations, is historically the most common cause for the Somogyi response in dogs. Currently, the most common event seen with the Somogyi response involves clients who monitor their pet's blood glucose concentration at home and adjust the insulin dose (i.e., increase the dose) without consulting their veterinarian. The increasing use of longer-acting insulin preparations (i.e., insulin glargine, insulin detemir) that have the potential to last longer than 12 hours may dampen the severity of the post-hypoglycemic hyperglycemia historically affiliated with the Somogyi response, presumably because insulin derived from the injected insulin is still present in the circulation. The diabetogenic hormonal response to hypoglycemia is still intact, and persistently increased concentrations of these hormones will still negatively impact control of glycemia, especially if hypoglycemia and the diabetogenic hormonal response reoccur frequently.

Clinical signs of hypoglycemia typically are mild or not recognized by the client; clinical signs caused by hyperglycemia tend to dominate the clinical picture. The insulin dose that induces the Somogyi response is variable and unpredictable. The Somogyi response should be suspected in poorly controlled diabetic dogs in which insulin dosage exceeds 1 U/kg body weight/injection but can also occur at insulin dosages less than 0.5 U/kg/injection. Toy and miniature breeds of dogs are especially susceptible to development of the Somogyi response with lower than expected doses of insulin.

Diagnosis of the Somogyi response requires demonstration of hypoglycemia (<60 mg/dL) followed by hyperglycemia (>300 mg/dL) after insulin administration (Fig. 49.9). The Somogyi response should also be suspected when the blood glucose concentration decreases rapidly regardless of the glucose nadir (e.g., a drop from 400 to 100 mg/dL in 2-3 hours). If the duration of insulin effect is greater than 12 hours, hypoglycemia often occurs at night after the evening dose of insulin, and the serum glucose concentration is typically greater than 300 mg/dL the next morning. Unfortunately, the diagnosis of the Somogyi response can be elusive, in part, because the glucose-lowering effects of the insulin vary from day to day, and on any given day hypoglycemia is

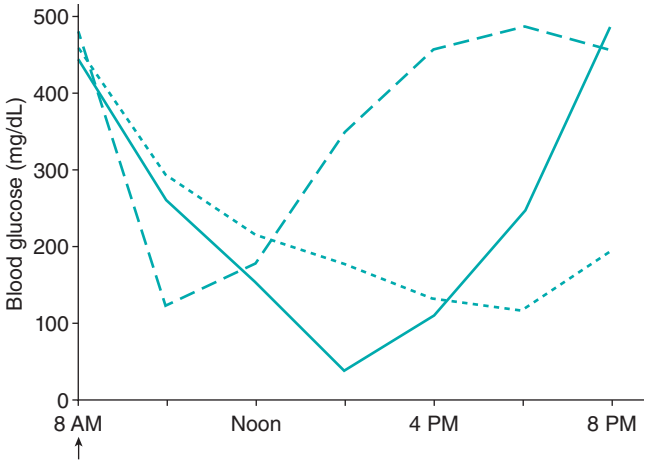

FIG 49.9
Blood glucose concentration curves obtained from three poorly controlled diabetic dogs treated with recombinant human lente insulin twice a day, illustrating the typical blood glucose curves suggestive of the Somogyi response. In one dog *(solid line)* the glucose nadir is less than 80 mg/dL and is followed by a rapid increase in blood glucose concentration. In another dog *(dashed line)* a rapid decrease in blood glucose concentration occurs within 2 hours of insulin administration and is followed by a rapid increase in blood glucose concentration; the rapid decrease in blood glucose stimulates glucose counterregulation, despite maintaining the blood glucose nadir above 80 mg/dL. In one dog *(dotted line)* the blood glucose curve is not suggestive of the Somogyi response, per se. However, the insulin injection causes blood glucose to decrease by approximately 300 mg/dL during the day, and the blood glucose concentration at the time of the evening insulin injection is considerably lower than the 8 am blood glucose concentration. If a similar decrease in blood glucose occurs with the evening insulin injection, hypoglycemia and the Somogyi response would occur at night and would explain the high blood glucose concentration in the morning and the poor control of the diabetic state.

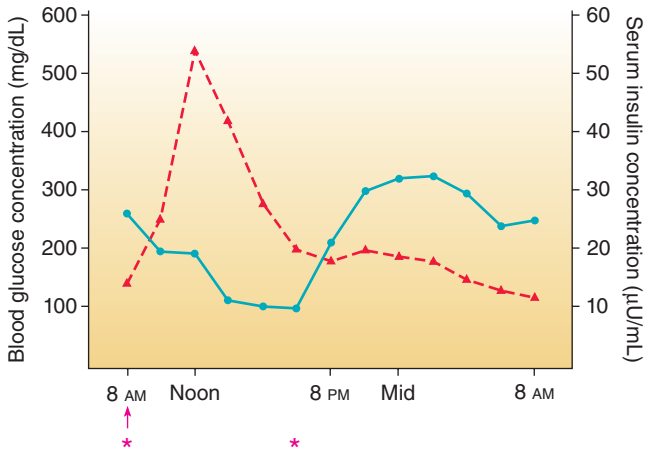

FIG 49.10
Mean blood glucose *(blue line)* and serum insulin *(red line)* concentrations in eight dogs with diabetes mellitus treated with beef/pork-source NPH insulin subcutaneously once daily. The duration of NPH effect is too short, resulting in prolonged periods of hyperglycemia beginning shortly after the evening meal. ↑, Insulin injection; *, equally sized meals consumed.

not always identified. Serum fructosamine concentrations are unpredictable but are usually increased (>500 μmol/L); these results confirm poor glycemic control but do not identify the underlying cause.

Establishing the diagnosis may require several days of hospitalization and serial blood glucose curves—an approach that eventually leads to problems with stress-induced hyperglycemia. An alternative, preferable approach consists of arbitrarily gradually reducing the insulin dose by 1 to 3 U (depending on the size of the dog and the dose of insulin) and having the client evaluate the dog's clinical response over the ensuing 2 to 5 days, specifically as it relates to changes in polyuria and polydipsia. If the severity of polyuria and polydipsia worsens after an initial reduction in the insulin dose, another cause for the insulin ineffectiveness should be pursued. However, if the client reports no change or improvement in polyuria and polydipsia, continued gradual reduction of the insulin dose should be pursued until polyuria and polydipsia worsen again, which identifies an inadequate dose of insulin for the dog. Alternatively, glycemic regulation of the diabetic dog could be started over with an insulin dose of 0.25 U/kg given twice daily.

Short duration of insulin effect

For most dogs the duration of effect of lente and NPH insulin is 10 to 14 hours, and twice-daily insulin administration is effective in controlling blood glucose concentrations. However, in some diabetic dogs the duration of effect of lente and NPH insulin is less than 10 hours—a duration that is too short to prevent periods of hyperglycemia and persistence of clinical signs (Fig. 49.10). Serum fructosamine concentrations are variable but usually greater than 500 μmol/L. A diagnosis of short duration of insulin effect is made by demonstrating an initial blood glucose concentration greater than 300 mg/dL combined with a glucose nadir above 80 mg/dL that occurs less than 8 hours after insulin administration and recurrence of hyperglycemia (>300 mg/dL) within 12 hours of the insulin injection (see Fig. 49.8). Treatment involves a change to longer-acting insulin (Fig. 49.11). Although PZI, insulin glargine, and insulin detemir all have the potential to be effective in diabetic dogs, our preference is to start with insulin detemir at an initial dosage of 0.1 U/kg administered twice a day. The most common problem with insulin detemir is a prolonged duration of effect (>14 hours), which can create issues with hypoglycemia and glucose counterregulation when insulin detemir is given twice a day. Regardless, most diabetic dogs require insulin detemir twice a day to attain diabetic control, and the insulin dosage can be quite small to compensate for prolonged duration of effect in dogs with this problem.

Prolonged duration of insulin effect

In some diabetic dogs the duration of effect of lente or NPH insulin is greater than 12 hours, and twice-daily insulin

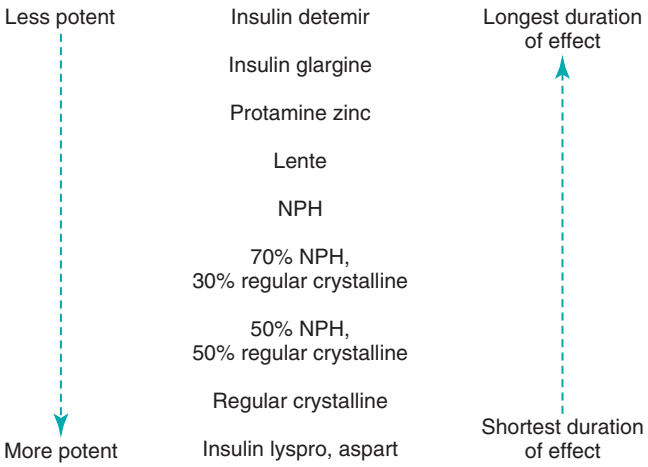

FIG 49.11
Categorization of types of commercial insulin based on potency and duration of effect. An inverse relationship exists between potency and duration of effect.

administration creates problems with hypoglycemia and glucose counterregulation. In these dogs the glucose nadir after the morning administration of insulin typically occurs near or after the time of the evening insulin administration, and the morning blood glucose concentration is usually greater than 300 mg/dL (see Fig. 49.8). Gradually decreasing blood glucose concentrations measured at the time of sequential insulin injections is another indication of prolonged insulin effect. The effectiveness of insulin in lowering the blood glucose concentration is variable from day to day, presumably because of varying concentrations of diabetogenic hormones, the secretion of which was induced by prior hypoglycemia. Serum fructosamine concentrations are variable but usually greater than 500 µmol/L. An effective treatment depends, in part, on the duration of effect of the insulin. An extended blood glucose curve should be generated after administration of insulin once in the morning and feeding of the dog at normal times of the day. This will allow the clinician to evaluate the effect of the evening meal on postprandial blood glucose concentrations and to estimate whether insulin from the morning injection is still present in the blood and capable of preventing a postprandial increase in blood glucose. If postprandial blood glucose increases (typically ≥ 75 mg/dL) within 2 hours of feeding, the duration of effect is close to 12 hours, and manipulation of the insulin dose, timing of the meals in relation to the timing of insulin injections, or both should be tried before a switch is made to longer-acting insulin. Failure of the blood glucose to increase 2 hours or longer after the evening meal is eaten suggests a prolonged duration of effect (i.e., 14 hours or longer). Switching to a longer-acting insulin (e.g., insulin detemir) administered once a day can be tried initially (see Fig. 49.11).

Inadequate insulin absorption

Slow or inadequate absorption of insulin from the subcutaneous site is uncommon in diabetic dogs treated with NPH or lente insulin. Impaired absorption of insulin may occur as a result of thickening of the skin and inflammation of the subcutaneous tissues caused by chronic injection of insulin in the same area of the body. Rotation of the injection site will help prevent this problem.

Allergic reactions to insulin

Allergic reactions to insulin have been poorly documented in diabetic dogs. Pain on injection of insulin is usually caused by inappropriate injection technique, inappropriate site of injection, a reaction to the cold temperature of insulin stored in the refrigerator, the acidic pH of insulin glargine, or issues with behavior and not an adverse reaction to insulin, per se. Chronic injection of insulin in the same area of the body may cause inflammation and thickening of the skin and subcutaneous tissues, and may be caused by an immune reaction to insulin or some other protein (e.g., protamine) in the insulin bottle. Inflammation and thickening of the skin and subcutaneous tissues may impair insulin absorption, resulting in recurrence of clinical signs of diabetes. Rarely, diabetic dogs will develop acute focal subcutaneous edema and swelling at the site of an insulin injection. Insulin allergy is suspected in these animals. Treatment includes switching to a less antigenic insulin and to a more purified insulin preparation. Systemic allergic reactions to insulin in dogs have yet to be identified.

Concurrent disorders causing insulin resistance

Insulin resistance is a condition in which a normal amount of insulin produces a subnormal biologic response. Insulin resistance may result from problems occurring before the interaction of insulin with its receptor, at the receptor, or at steps distal to the interaction of insulin and its receptor. In dogs, receptor and postreceptor abnormalities are usually attributable to obesity, circulating acute phase proteins and inflammatory cytokines (e.g., tumor necrosis factor [TNF]-α, interleukin-1, interleukin-6) that interfere with insulin signal transduction or a disorder causing excessive or deficient secretion of an insulin-antagonistic hormone, such as cortisol, growth hormone, progesterone, or thyroid hormone. No insulin dose clearly defines insulin resistance. For most diabetic dogs control of glycemia can usually be attained using 1.0 U or less of lente or NPH insulin per kilogram of body weight given twice daily (see Table 49.4). Insulin resistance should be suspected if control of glycemia is poor despite an insulin dosage in excess of 1.5 U/kg, when excessive amounts of insulin (i.e., insulin dosage >1.5 U/kg) are necessary to maintain the blood glucose concentration below 300 mg/dL), and when control of glycemia is erratic and insulin requirements are constantly changing in an attempt to maintain control of glycemia. Failure of the blood glucose concentration to decrease below 300 mg/dL during a serial blood glucose curve is suggestive of, but not definitive for, the presence of insulin resistance. An insulin resistance–type blood glucose curve can also result from other problems with insulin therapy (see Box 49.8), and a decrease in the blood glucose concentration below 300 mg/dL can occur with disorders causing relatively mild insulin resistance (e.g., obesity, inflammation). Serum fructosamine

concentrations are typically greater than 500 µmol/L in dogs with insulin resistance and can exceed 700 µmol/L if resistance is severe. Unfortunately, an increased serum fructosamine concentration is merely indicative of poor glycemic control not insulin resistance, per se.

The severity of insulin resistance is dependent, in part, on the underlying etiology. Insulin resistance may be mild and easily overcome by increasing the dosage of insulin or may be severe, causing marked hyperglycemia regardless of the type and dosage of insulin administered. Some causes of insulin resistance are readily apparent at the time diabetes is diagnosed, such as obesity and the administration of insulin-antagonistic drugs (e.g., glucocorticoids). Other causes of insulin resistance are not readily apparent and require an extensive diagnostic evaluation to be identified. In general, any concurrent inflammatory, infectious, hormonal, neoplastic, or organ system disorder can cause insulin resistance and interfere with the effectiveness of insulin therapy. In our experience, the most common concurrent disorders interfering with insulin effectiveness in diabetic dogs include diabetogenic drugs (glucocorticoids), severe obesity, hyperadrenocorticism, diestrus, chronic pancreatitis, chronic kidney disease, inflammatory bowel disease, oral cavity disease, infections of the urinary tract, hyperlipidemia, and insulin-binding antibodies in dogs receiving beef insulin. Obtaining a complete history and performing a thorough physical examination is the most important initial step in identifying these concurrent disorders. If the history and physical examination are unremarkable, a CBC, serum biochemical analysis, serum canine pancreatic-specific lipase (cPL), serum progesterone concentration (intact female dog), abdominal ultrasound, and urinalysis with bacterial culture should be obtained to further screen for concurrent illness. Additional tests will be dependent on results of the initial screening tests (Box 49.9).

Treatment and reversibility of insulin resistance is dependent on the etiology. Insulin resistance is reversible with treatable disorders, for example, sodium levothyroxine treatment in a diabetic dog with concurrent hypothyroidism or ovariohysterectomy in an intact female diabetic dog in diestrus. In contrast, insulin resistance often persists with disorders that are difficult to treat such as chronic recurring pancreatitis. In some situations, measures can be taken to prevent insulin resistance, such as avoidance of glucocorticoids in diabetic dogs and an ovariohysterectomy at the time diabetes mellitus is diagnosed in an intact female dog.

BOX 49.9

Diagnostic Tests to Consider for Evaluation of Insulin Resistance in Diabetic Dogs and Cats

- Complete blood count, serum biochemistry panel, urinalysis
- Bacterial culture of the urine
- Serum canine/feline pancreatic-specific lipase (Spec cP/fPL) (pancreatitis)
- Serum trypsin-like immunoreactivity (TLI) (exocrine pancreatic insufficiency)
- Adrenocortical function tests
  - Urine cortisol/creatinine ratio (spontaneous hyperadrenocorticism)
  - Low-dose dexamethasone suppression test (spontaneous hyperadrenocorticism)
  - Adrenocorticotropic hormone (ACTH)–stimulation test (iatrogenic hyperadrenocorticism)
- Thyroid function tests
  - Baseline serum total and free thyroxine (hypothyroidism and hyperthyroidism)
  - Serum thyroid-stimulating hormone (TSH; hypothyroidism)
- Serum progesterone concentration (diestrus in intact female dog)
- Fasting serum triglyceride concentration (hyperlipidemia)
- Plasma growth hormone or serum insulin-like growth factor 1 concentration (acromegaly)
- Serum insulin concentration 24 hours after discontinuation of insulin therapy (insulin antibodies)
- Abdominal ultrasonography (adrenomegaly, adrenal mass, pancreatitis, pancreatic mass)
- Thoracic radiography (cardiomegaly, neoplasia)
- Computed tomography or magnetic resonance imaging (pituitary mass)

CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Complications resulting from diabetes or its treatment are common in diabetic dogs and include blindness and anterior uveitis resulting from cataract formation, hypoglycemia, chronic pancreatitis, recurring infection, poor glycemic control, and ketoacidosis (see Box 49.5). Many clients are hesitant to treat their newly diagnosed diabetic dog because of knowledge regarding chronic complications experienced in humans with diabetes and concern that a similar fate awaits their pet. However, clients should be assured that the devastating effects of human diabetes (e.g., nephropathy, vasculopathy, coronary artery disease) require 10 to 20 years or longer to occur and therefore are uncommon in diabetic dogs.

Cataracts

Cataract formation is the most common and one of the most important long-term complications of diabetes mellitus in the dog. A retrospective cohort study on the development of cataracts in 132 diabetic dogs referred to a university referral hospital that found cataract formation in 14% of dogs at the time diabetes was diagnosed, and a time interval for 25%, 50%, 75%, and 80% of the study population to develop cataracts at 60, 170, 370, and 470 days, respectively (Beam et al., 1999). The pathogenesis of diabetic cataract formation is thought to be related to altered osmotic relationships in the lens induced by the accumulation of sorbitol and galactitol—sugar alcohols produced following reduction of glucose and galactose by the enzyme aldose reductase in the lens are potent hydrophilic agents, which cause an influx of water

into the lens, leading to swelling and rupture of lens fibers and the development of cataracts. Cataract formation is an irreversible process once it begins, and it can occur rapidly. Diabetic dogs that are poorly controlled and have problems with wide fluctuations in blood glucose concentrations seem especially at risk for rapid development of cataracts. Good glycemic control and minimal fluctuation in the blood glucose concentration prolongs the onset of cataract formation. Once blindness occurs as a result of cataract formation, the need for stringent blood glucose control is reduced.

Blindness may be eliminated by removing the abnormal lens. Vision is restored in approximately 80% of diabetic dogs that undergo cataract removal. Factors that affect the success of surgery include the degree of glycemic control preceding surgery, the presence of retinal disease, and the presence of lens-induced uveitis. Acquired retinal degeneration affecting vision is more of a concern in older diabetic dogs than diabetic retinopathy. Fortunately, acquired retinal degeneration is unlikely in an older diabetic dog with vision immediately before cataract formation. If available, electroretinography should be performed before surgery to evaluate retinal function.

Lens-Induced Uveitis

During embryogenesis the lens is formed within its own capsule, and its structural proteins are not exposed to the immune system. Therefore immune tolerance to the crystalline proteins does not develop. During cataract formation and reabsorption, lens proteins are exposed to the local immune system, resulting in inflammation and uveitis. Uveitis that occurs in association with a reabsorbing, hypermature cataract may decrease the success of cataract surgery and must be controlled before surgery. Treatment of lens-induced uveitis focuses on decreasing inflammation and preventing further intraocular damage. Topical ophthalmic glucocorticoids (e.g., prednisone acetate) are the most commonly used drug for the control of ocular inflammation. However, systemic absorption of topically applied glucocorticoids may cause insulin resistance and interfere with glycemic control of the diabetic state, especially in toy and miniature breeds. An alternative is the topical administration of nonsteroidal antiinflammatory agents such as diclofenac (Voltaren) or flurbiprofen ophthalmic (Ocufen). Although not as potent an antiinflammatory agent as glucocorticoids, nonsteroidal antiinflammatory drugs should not interfere with glycemic control.

Diabetic Neuropathy

Although a common complication in the diabetic cat (see p. 833), diabetic neuropathy is infrequently recognized in the diabetic dog. Subclinical neuropathy is probably more common than is severe neuropathy resulting in clinical signs. Clinical signs consistent with diabetic neuropathy are most commonly recognized in dogs that have been diabetic for a long time (i.e., 5 years or longer), although diabetic neuropathy has been diagnosed in dogs shortly after the diagnosis of diabetes has been established. Clinical signs and physical examination findings include pelvic limb paresis, abnormal gait, knuckling, decreased muscle tone, muscle atrophy, depressed limb reflexes, and deficits in postural reaction testing. Diabetic neuropathy in the dog is primarily a distal polyneuropathy, characterized by segmental demyelination and axonal degeneration. Electrodiagnostic abnormalities include spontaneous sharp waves and fibrillation potentials and decreased M-wave amplitude on electromyogram and decreased motor and sensory nerve conduction velocities. No specific treatment for diabetic neuropathy is known besides meticulous metabolic control of the diabetic state.

Diabetic Nephropathy

Diabetic nephropathy has occasionally been reported in the dog. Diabetic nephropathy is a microvascular disease involving the capillary and precapillary arterioles, and is manifested mainly by thickening of the capillary basement membrane. Histopathologic findings include membranous glomerulonephropathy, glomerular and tubular basement membrane thickening, an increase in the mesangial matrix material, and the presence of subendothelial deposits, glomerular fibrosis, and glomerulosclerosis. Glucose plays a central role in the development of microvascular damage. Clinical signs depend on the severity of glomerulosclerosis and the functional ability of the kidney to excrete metabolic wastes. Initially, diabetic nephropathy is manifested as proteinuria, primarily albuminuria. As glomerular changes progress, glomerular filtration becomes progressively impaired, resulting in the development of azotemia and eventually uremia. With severe fibrosis of the glomeruli, oliguric and anuric kidney failure may develop.

Monitoring urine for the presence of microalbuminuria is used as an early marker for development of diabetic nephropathy in diabetic humans. Microalbuminuria occurs in diabetic dogs, and increased urine albumin:creatine ratios precede increased urine protein:creatinine ratios. In one study, 11 (55%) of 20 diabetic dogs had an increase in the urine albumin:creatinine ratio, and only 6 of these 11 dogs also had an increase in urine protein:creatinine ratio, suggesting that monitoring urine albumin:creatinine ratio may be of value as an early marker for kidney disease in diabetic dogs (Mazzi et al., 2008). However, the predictive value of microalbuminuria for diabetic nephropathy and the clinical relevance of microalbuminuria in diabetic dogs remains to be clarified. Diabetic nephropathy is a significant chronic complication in diabetic humans that takes years to progress to chronic end-stage kidney disease; a time line that may explain why clinically relevant diabetic nephropathy is uncommon in diabetic dogs. Regardless, proteinuria, kidney function, and systemic blood pressure should be monitored in diabetic dogs that have developed microalbuminuria. No specific treatment for diabetic nephropathy is known, apart from meticulous metabolic control of the diabetic state, conservative medical management of kidney disease, administration of angiotensin-converting enzyme (ACE) inhibitors to minimize proteinuria, and control of systemic hypertension.

Systemic Hypertension

Diabetes mellitus and hypertension commonly coexist in dogs. Struble et al. (1998) found the prevalence of hypertension to be 46% in 50 insulin-treated diabetic dogs in which hypertension was defined as systolic, diastolic, or mean blood pressure greater than 160, 100, or 120 mm Hg, respectively. The development of hypertension was associated with the duration of diabetes and an increased albumin/creatinine ratio in the urine. Diastolic and mean blood pressure values were higher in dogs with longer duration of disease. A correlation between control of glycemia and blood pressure was not identified. Systemic hypertension may result from existing subclinical kidney disease or develop secondary to the effects of diabetes on vascular compliance, glomerular function, or some other mechanism. Treatment for hypertension should be initiated if the systolic blood pressure is consistently greater than 160 mm Hg.

Prognosis

The prognosis for dogs diagnosed with diabetes mellitus depends, in part, on owner commitment to treating the disorder, ease of glycemic regulation, presence and reversibility of concurrent disorders, avoidance of chronic complications associated with the diabetic state, and minimizing the impact of treatment on the quality of life of the owner (see Table 49.2). In a large study involving insured dogs in Sweden, the median survival time after the first diabetes mellitus claim (686 dogs) was 57 days and for dogs surviving at least one day (463 dogs) was 2.0 years (Fall et al., 2007). For dogs surviving at least 30 days after the first diabetes mellitus claim (347 dogs), the proportion of dogs surviving 1, 2, and 3 years was 40%, 36%, and 33%, respectively. However, survival times will vary between countries and between socioeconomic regions within a country, and survival time is somewhat skewed because dogs are often 8 to 12 years old at the time of diagnosis, and a relatively high mortality rate exists during the first 6 months because of concurrent life-threatening or uncontrollable disease (e.g., ketoacidosis, acute pancreatitis, kidney failure). In our experience, diabetic dogs that survive the first 6 months can easily maintain a good quality of life for longer than 5 years with proper care by the owners, timely evaluations by the veterinarian, and good client-veterinarian communication.

DIABETES MELLITUS IN CATS

Etiology, Classification, and Diabetic Remission

Type 1 diabetes mellitus with an underlying immune-mediated etiology appears to be rare in cats. Although lymphocytic infiltration of islets has been described in diabetic cats, this histologic finding is not common, and β-cell and insulin autoantibodies have not been identified in newly diagnosed diabetic cats.

Type 2 diabetes predominates in cats and is characterized by insulin resistance and dysfunctional β cells. Common histologic findings in the pancreatic islets include islet-specific amyloidosis, β-cell vacuolar degeneration, and a reduction in the number of pancreatic islets, insulin-containing β cells in the islet, or both. Genetics undoubtedly plays a role in Burmese cats in Australia, New Zealand, and the United Kingdom, but the role of genetics in other breeds remains to be determined. Additional risk factors for type 2 diabetes mellitus include male neutered cat, inactivity (indoor cat), increasing age, insulin-resistant medications (e.g., glucorticoids) and disease (e.g., hypersomatotropism), and perhaps most important – obesity.

Adipose tissue produces two important adipokines: adiponectin, an adipokine that enhances insulin sensitivity and has antiinflammatory properties, and leptin, an adipokine involved in appetite suppression, energy expenditure, and modulation of insulin sensitivity (Hoenig, 2012). Obesity results in a decrease in circulating adiponectin and causes leptin resistance. Adipose tissue also secretes a number of proinflammatory cytokines (e.g., TNF-α, IL-6) that negatively influence insulin signaling and cause insulin resistance (Hoenig et al., 2006). All of these actions promote the development of diabetes, and all of these actions are potentially reversible with weight loss.

Islet amyloidosis also plays an important role in the development of type 2 diabetes in cats. Islet-amyloid polypeptide (IAPP), or amylin, is the principal constituent of amyloid in adult cats with diabetes, is stored in β-cell secretory granules, and is co-secreted with insulin by the β cell. Stimulants of insulin secretion also stimulate the secretion of amylin. Chronic increased secretion of insulin and amylin, as occurs with obesity and other insulin-resistant states, results in aggregation and deposition of amylin in the islets as amyloid (Fig. 49.12). IAPP-derived amyloid fibrils are cytotoxic and may lead to a decline in β-cell function and β-cell apoptosis (Costes et al., 2013). Loss of β-cell function may be present before amyloid depositions are visible in the islets.

If deposition of amyloid is progressive, as occurs with a sustained demand for insulin secretion in response to persistent insulin resistance, islet cell destruction progresses and eventually leads to diabetes mellitus. The severity of islet amyloidosis and β-cell destruction determines, in part, whether the diabetic cat is insulin-dependent or not and whether diabetic remission is possible. Total destruction of the islets results in insulin-dependent diabetes mellitus (IDDM) and the need for insulin treatment for the rest of the cat's life. Partial destruction of the islets may or may not result in clinically evident diabetes, insulin treatment may or may not be required to control glycemia, and diabetic remission may or may not occur once treatment is initiated. If amyloid deposition is progressive, the cat will progress from subclinical diabetes to noninsulin dependent diabetes (NIDDM; i.e., glycemia can be controlled with correction of insulin resistance and diet) and ultimately to IDDM. The difference between IDDM and NIDDM is primarily a difference in severity of loss of β cells and severity and reversibility of concurrent insulin resistance.

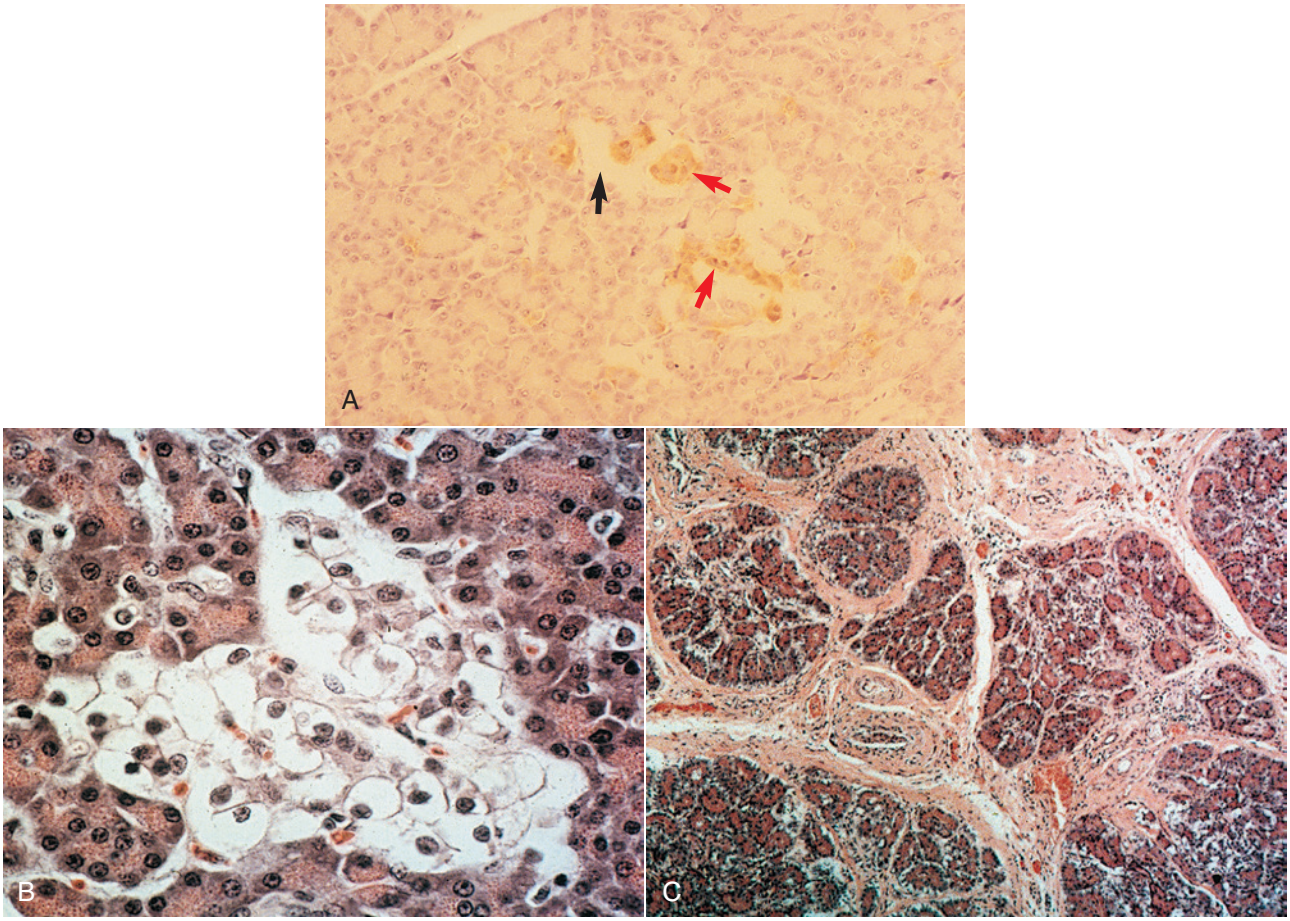

FIG 49.12
(A) Severe islet amyloidosis *(black arrow)* in a cat with initial non–insulin-dependent diabetes mellitus (NIDDM) that progressed to insulin-dependent diabetes mellitus (IDDM). A pancreatic biopsy specimen was obtained while the animal was in the IDDM state. Residual β cells containing insulin *(red arrows)* are also present. (Immunoperoxidase stain, ×100.) **(B)** Severe vacuolar degeneration of islet cells. Pancreatic tissue was evaluated at necropsy 28 months after diabetes was diagnosed and 20 months after the cat progressed from NIDDM to IDDM, requiring insulin to control blood glucose concentrations. The cat died from metastatic exocrine pancreatic adenocarcinoma. (Hematoxylin and eosin stain; ×500.) **(C)** Severe chronic pancreatitis with fibrosis in a diabetic cat with IDDM. The cat was euthanized because of persistent problems with lethargy, inappetence, and poorly controlled diabetes mellitus. (Hematoxylin and eosin stain; ×100.) (**A** from Feldman EC et al: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

Glucose toxicity also plays an important role in diabetic cats, especially as it relates to diabetic remission. Diabetic remission is defined as a scenario in which diabetes mellitus is correctly diagnosed in a cat, insulin treatment is initiated in conjunction with adjustments in diet and discontinuation of insulin antagonistic medications (most notably glucocorticoids) and, weeks to months later, hyperglycemia resolves and insulin is discontinued without recurrence of hyperglycemia. Blood glucose concentrations should remain in the reference range for at least 4 weeks before diabetes is considered to be in remission.

Cats that experience diabetic remission are in a subclinical diabetic state that becomes clinical when the cat is exposed to a concurrent insulin-antagonistic drug or disease, most notably glucocorticoids and chronic inflammation (Fig. 49.13). Unlike healthy cats, those that experience diabetic remission have a reduced population of β cells, dysfunctional β cells, or both, and this impairs the ability of the pancreas to compensate for concurrent insulin resistance. An inadequate insulin response results in hyperglycemia. Persistent hyperglycemia can, in turn, cause hypoinsulinemia by suppressing the function of remaining β cells and can induce insulin resistance by promoting downregulation of glucose transport systems, causing a defect in posttransport insulin action. This phenomenon is referred to as *glucose toxicity*. β cells have an impaired response to stimulation by

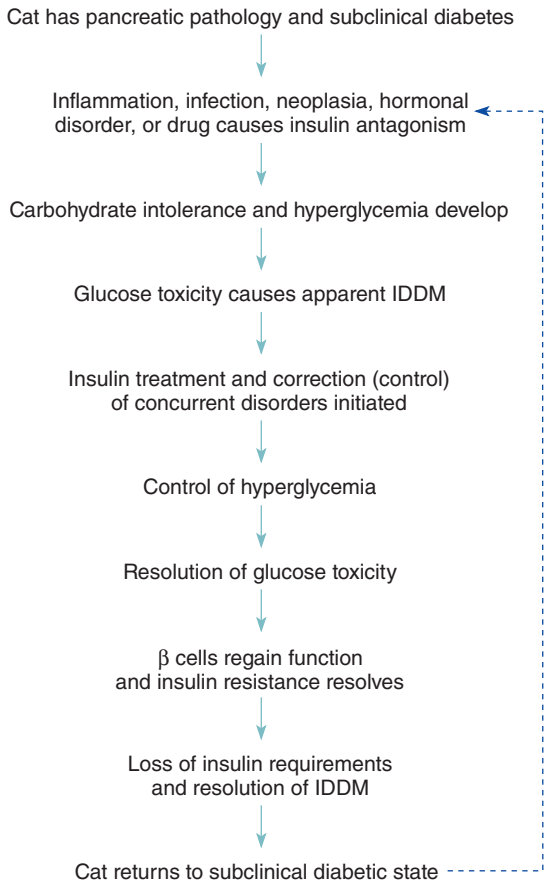

FIG 49.13
Sequence of events in the development and resolution of an insulin-requiring diabetic episode in cats with transient diabetes. (From Feldman EC et al: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

insulin secretagogues, thereby mimicking type 1 IDDM. The effects of glucose toxicity are potentially reversible upon correction of the hyperglycemic state. The clinician makes a correct diagnosis of diabetes mellitus; insulin therapy, discontinuation of insulin antagonistic drugs, and treatment of insulin-antagonistic disorders improve hyperglycemia and insulin resistance; glucose toxicity resolves; β-cell function improves; insulin secretion returns; and an apparent IDDM state resolves (Nelson et al., 1999). Diabetic remission usually occurs during the first 2 to 3 months of treatment, but we have seen cats undergo remission up to a year or longer after initiating insulin treatment. Cats that experience diabetic remission have impaired glucose tolerance. Approximately 30% of cats relapse, usually within 5 to 6 months of discontinuing insulin. The future requirement for insulin treatment depends on the underlying abnormality in the islets. If the abnormality is progressive (e.g., amyloidosis), eventually enough β cells will be destroyed and IDDM will develop.

Glucose toxicity is a secondary event that only becomes apparent after hyperglycemia has occurred. The cellular mechanisms by which chronic hyperglycemia affects insulin secretion and insulin sensitivity are poorly understood, although oxidative stress and inflammatory cytokines are believed to play a role (Zini et al., 2009a). Reversal of glucose toxicity is an important mechanism to explain diabetic remission. The key to diabetic remission lies in the ability to correct insulin resistance and attain and maintain good glycemic control of the diabetic state. Factors involved in diabetic remission are listed in Box 49.10. Published remission rates vary, but most veterinary internists report rates between 25% and 50%. A recent study among primary care veterinarians in the southern United States under "everyday conditions" reported an approximate remission rate of 26% (Smith et al., 2012).

BOX 49.10

Factors Involved in Diabetic Remission in Cats

Recently diagnosed diabetic cat
Correction of glucose toxicity
Maintaining good glycemic control
Using long-acting insulin preparations twice daily
Feeding low carbohydrate diets
Avoiding insulin resistant medications (e.g., glucocorticoids)
Nature and reversibility of concurrent disorders
Frequent evaluations
  Intensity of home blood glucose monitoring
  Ability to attain blood glucose targets

Clinical Features

SIGNALMENT AND RISK FACTORS

Although diabetes mellitus may be diagnosed in cats of any age, most diabetic cats are 7 to 15 years of age at the time of diagnosis. Diabetes mellitus occurs predominantly in neutered male cats. Studies with a large cohort of cats performed in in Sweden and the United Kingdom identified Burmese, Russian Blue, Norwegian Forest, and Abyssinian cats at increased risk for diabetes mellitus. Additional risk factors included age, increasing body weight, indoor confinement, and possibly dry cat food in normal weight cats.

HISTORY

The history in virtually all diabetic cats includes polydipsia, polyuria, polyphagia, and weight loss. A common complaint of cat owners is the constant need to change the litter and an increase in the size of the litter clumps. Additional clinical signs include lethargy; decreased interaction with family members; lack of grooming behavior and development of a dry, lusterless, unkempt, or matted haircoat; and decreased jumping ability, rear limb weakness, or development of a plantigrade posture (Fig. 49.14; Video 49.1). If the client does not notice clinical signs associated with uncomplicated diabetes, a diabetic cat may be at risk for developing DKA. The time sequence from the onset of initial clinical signs to the development of DKA is unpredictable.

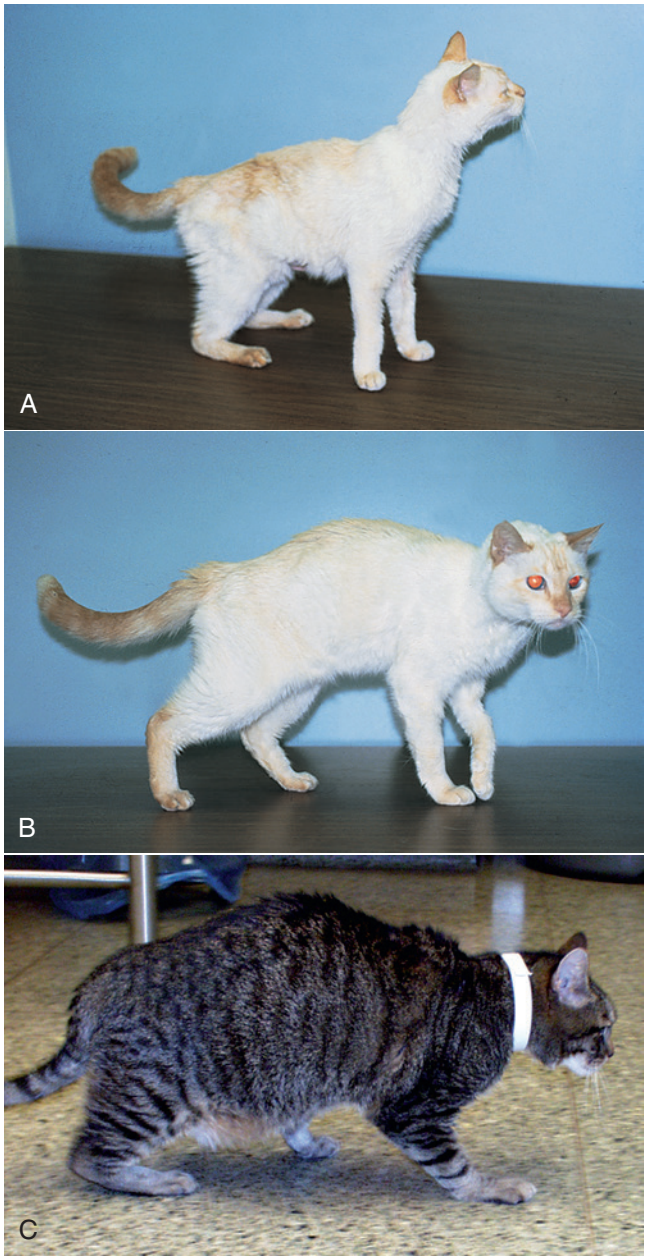

FIG 49.14
(A) Plantigrade posture in a cat with diabetes mellitus and exocrine pancreatic insufficiency. **(B)** Resolution of hindlimb weakness and plantigrade posture after glycemic control is improved by adjustment of insulin therapy and initiation of pancreatic enzyme replacement therapy. **(C)** Severe diabetic neuropathy in a cat with diabetes mellitus. Note the palmigrade and plantigrade posture. The more severe and the more chronic the neuropathy, the less likely the neuropathy will improve after diabetic control is improved.

PHYSICAL EXAMINATION

Physical examination findings depend on the presence and severity of DKA and the nature of other concurrent disorders. The nonketotic diabetic cat has no classic physical examination findings. Many diabetic cats are obese but otherwise in good physical condition. Cats with prolonged untreated diabetes may have lost weight but are rarely emaciated unless concurrent disease (e.g., hyperthyroidism) is present. Newly diagnosed and poorly controlled diabetic cats often stop grooming and develop a dry, lusterless haircoat. Diabetes-induced hepatic lipidosis may cause hepatomegaly. Impaired ability to jump, weakness in the rear limbs, ataxia, or a plantigrade posture (i.e., the hocks touch the ground when the cat walks) may be evident if the cat has developed diabetic neuropathy (see Video 49.1). Distal muscles of the rear limbs may feel hard on digital palpation, and cats may object to palpation or manipulation of the rear limbs, presumably because of pain associated with the neuropathy. Additional abnormalities may be identified in the ketoacidotic diabetic cat.

Diagnosis

Establishing the diagnosis of diabetes mellitus is similar for cats and dogs and is based on identification of appropriate clinical signs, persistent hyperglycemia, and glycosuria (see p. 811). Transient, stress-induced hyperglycemia is a common problem in cats and can cause the blood glucose concentration to increase to above 300 mg/dL. Unfortunately, stress is a subjective state that cannot be accurately measured, is not always easily recognized, and may evoke inconsistent responses among individual cats. Glycosuria usually does not develop in cats with transient stress-induced hyperglycemia but can be present if stress is prolonged (i.e., hours). For this reason, the presence of appropriate clinical signs, persistent hyperglycemia, and glycosuria should always be documented when a diagnosis of diabetes mellitus is established in cats. If the clinician is in doubt, the stressed cat can be sent home with instructions for the client to monitor the urine for the presence of glucose in the nonstressed home environment. Alternatively, a serum fructosamine concentration can be measured. A documented increase in the serum fructosamine concentration supports the presence of sustained hyperglycemia; however, a serum fructosamine concentration in the upper end of the reference range can occur in symptomatic diabetic cats if diabetes developed shortly before presentation of the cat to the veterinarian.

Clinical signs develop when hyperglycemia causes glycosuria and are the same regardless of the functional status of pancreatic islets. Information used to establish the diagnosis of diabetes mellitus does not provide information on the status of pancreatic islet health, the presence of glucose toxicity, the ability of the cat to secrete insulin, or the severity and reversibility of concurrent insulin resistance. Unfortunately, measurements of baseline serum insulin concentration or serum insulin concentrations after administration of an insulin secretagogue have not been consistent aids in assessing the function of the islets. Identification of a baseline serum insulin concentration greater than 15 μU/mL (reference range, 5-20 μU/mL [40-145 pmol/L]) in a newly diagnosed, untreated diabetic cat supports the presence of functional β cells and partial destruction of the islets; however, low or undetectable serum insulin concentrations do not rule out partial β-cell loss and the potential for

diabetic remission because of the suppressive effects of glucose toxicity on circulating insulin concentrations. An insulin assay validated for the cat should be used when measuring serum insulin concentrations in cats.

A thorough evaluation of the cat's overall health is recommended once the diagnosis of diabetes mellitus has been established. The minimal laboratory evaluation in any diabetic cat should include a CBC, a serum biochemical panel, a serum thyroxine concentration, and urinalysis with bacterial culture. If available, abdominal ultrasound should also be a routine part of the diagnostic evaluation to assess the liver, kidneys, adrenal glands, and especially the pancreas for chronic pancreatitis. Measurement of baseline serum insulin concentration or performance of an insulin secretory response test is not routinely done in cats because of problems encountered with glucose toxicity. Additional tests may be warranted after the history is obtained, the physical examination is performed, or ketoacidosis is identified. See Box 49.4 for a list of potential clinical pathologic abnormalities.

Treatment

The significant incidence of type 2 diabetes in cats raises interesting questions regarding the need for insulin treatment. Glycemic control can be maintained in some diabetic cats with dietary changes, correction of obesity, control of concurrent diseases, discontinuation of insulin-antagonistic drugs, or a combination of these. The ultimate differentiation between insulin-dependent and non–insulin-dependent diabetes is usually made retrospectively, after the clinician has had several weeks to assess the response of the cat to therapy and to determine the cat's need for insulin. The initial treatment strategy is based on the severity of clinical signs and physical abnormalities, the presence or absence of ketonuria and ketoacidosis, the general health of the cat, and client wishes. For most newly diagnosed diabetic cats, treatment includes insulin, adjustments in diet, and correction or control of concurrent insulin resistance.

INITIAL INSULIN RECOMMENDATIONS FOR DIABETIC CATS

Diabetic cats are notoriously unpredictable in their response to exogenous insulin, and all insulin preparations have the potential for short duration of effect in cats. No insulin preparation is consistently effective in maintaining control of glycemia, even with twice-daily administration. Insulin preparations used for the long-term management of diabetic cats include porcine lente insulin, recombinant human PZI, insulin glargine, and insulin detemir (see p. 812 and Fig. 49.11). Because short duration of insulin effect is common in cats, we prefer to start insulin therapy using insulin glargine (Lantus) or recombinant human PZI (ProZinc). Both insulin preparations are effective in controlling glycemia and inducing diabetic remission in diabetic cats. Studies to date suggest that the median dosage of insulin glargine and PZI required to attain glucose control in most diabetic cats is approximately 0.5 U/kg/injection, with a range of 0.2 to 0.8 U/kg. One important goal in the initial regulation of the diabetic cat is avoidance of symptomatic hypoglycemia, especially in the home environment. Considerable overlap in the insulin dosage range that causes hypoglycemia, establishes control of glycemia, and does not establish control of glycemia exists with all insulin preparations. Predicting an effective dosage of any insulin product that does not cause hypoglycemia in some diabetic cats is difficult, in part because of variability between cats in their response to insulin. For this reason, our starting insulin dosage is always on the low end of the range, typically 0.25 U/kg per injection (½ to 2 U/injection), and we prefer to start with twice-a-day insulin administration because the overwhelming majority of diabetic cats require insulin glargine and PZI twice a day. The most common problem with insulin glargine and PZI is a prolonged duration of effect (>12 hours). This can create problems with hypoglycemia when these insulin preparations are administered twice a day, problems that can be minimized by starting with an insulin dose at the lower end of the effective range.

DIET

The general principles for dietary therapy are listed in Box 49.6. Obesity, feeding practices, and content of the diet warrant discussion in diabetic cats. Obesity is common in diabetic cats and results from excessive caloric intake typically caused by free-choice feeding of dry cat food. Obesity causes reversible insulin resistance that resolves as obesity is corrected. Control of glycemia often improves, and some diabetic cats experience diabetic remission after weight reduction. Correction of obesity is difficult in cats because it requires restriction of daily caloric intake without a corresponding increase in caloric expenditure (i.e., exercise). Typical weight-reducing diets recommended for obese diabetic cats include diets with increased protein and decreased carbohydrate content, and low-calorie-dense diets with decreased fat and increased fiber content. The reader is referred to Chapter 51 for more information on correction of obesity in cats.

The eating habits of cats vary considerably, from eating everything at the time food is offered to grazing throughout the day and night. The primary goal of dietary therapy is to minimize the impact of a meal on postprandial blood glucose concentrations. Consuming the same number of calories in multiple small amounts throughout a 12-hour period should have less impact than consuming the calories at a single large meal. Half of the cat's total daily caloric intake should be offered at the time of each insulin injection and should remain available to the cat to consume when it wishes. Attempts to force a grazing cat to eat the entire meal at one time usually fail and are not warranted as long as the cat has access to the food during the ensuing 12 hours.

Cats are carnivores and, as such, have higher dietary protein requirements than omnivores such as humans and dogs. Hepatic glucokinase and hexokinase activity is lower in cats, compared with that in carnivores with omnivorous eating habits. This suggests that diabetic cats may be predisposed to developing higher postprandial blood glucose

concentrations after consumption of diets containing a high carbohydrate load and vice versa. Dietary studies in diabetic cats have documented improved control of glycemia with diets containing increased protein and decreased carbohydrate content, and low-calorie-dense fiber-containing diets. The central theme in these dietary studies has been restriction of carbohydrate absorption by the gastrointestinal tract, either by delaying intestinal glucose absorption (fiber) or decreasing carbohydrate ingestion (low-carbohydrate-containing diets). Intuitively, the most effective means to minimize gastrointestinal absorption of carbohydrates in the diabetic cat is to feed diets that contain minimal amounts of carbohydrate. Currently, we initially use diets with high protein and low carbohydrate content. If problems with palatability, satiation, azotemia, or chronic pancreatitis become an issue, or if poor control of glycemia persists despite adjustments in insulin therapy, a switch to one of the low-calorie-dense fiber-containing diets designed for diabetic cats, or a switch to a more appropriate diet that addresses concurrent problems (e.g., a kidney diet in an azotemic cat or a moderate-protein, highly digestible diet for chronic pancreatitis) should be considered. Diets with high fat and low carbohydrate content (e.g., growth diets) are not recommended because of concerns related to the impact of high dietary fat content on obesity, hepatic lipidosis, chronic pancreatitis, and insulin resistance—the latter induced by increased circulating concentrations of nonesterified fatty acids, β-hydroxybutyric acid, and triglycerides.

IDENTIFICATION AND CONTROL OF CONCURRENT PROBLEMS

Identification and correction of concurrent disorders that cause insulin resistance and interfere with the success of insulin therapy is critical to the successful treatment of diabetes in cats. Examples include obesity; chronic pancreatitis and other chronic inflammatory diseases; infection; and insulin-resistant disease such as hyperthyroidism, hyperadrenocorticism, and acromegaly. In diabetic cats with partial loss of β cells, correction of insulin resistance may result in diabetic remission. An evaluation of the diabetic cat for concurrent problems is indicated at the time diabetes is diagnosed and whenever control of glycemia deteriorates in a previously well-controlled cat. The initial evaluation should include a thorough history, physical examination, CBC, serum biochemistry panel, serum thyroxine concentration, urinalysis with culture, and (if available) abdominal ultrasound.

ORAL HYPOGLYCEMIC DRUGS

Oral hypoglycemic drugs work by stimulating pancreatic insulin secretion (e.g., sulfonylureas), enhancing tissue sensitivity to insulin (e.g., metformin, thiazolidinediones), or slowing postprandial intestinal glucose absorption (α-glucosidase inhibitors). Only the sulfonylurea drug glipizide was marginally effective in diabetic cats and was used as an alternative treatment for owners who initially refused to administer insulin. The current recommendation in this situation is to feed diets containing increased protein and decreased carbohydrate content to the cat rather than administer glipizide.

Newer antidiabetic medications for the treatment of type 2 diabetes in humans have focused on incretins. Incretins such as glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) are gastrointestinal hormones released in response to food intake that increase glucose-dependent insulin secretion, inhibit glucagon secretion, slow gastric emptying, induce satiation, and promote weight loss in humans. A recent pilot study evaluating the effect of a GLP-1 analogue (Exenatide Extended) in newly diagnosed diabetic cats concurrently treated with insulin glargine and a low-carbohydrate diet achieved diabetic remission or good metabolic control in 40% and 89% of the diabetic cats compared with 20% and 58% in control diabetic cats, respectively (Riederer et al., 2016). Exenatide Extended was safe in cats, did not result in weight gain, and stimulated insulin secretion. What role, if any, incretin medications may have for the treatment of diabetic cats remains to be determined. These medications are presumably not indicated in dogs because dogs do not develop type 2 diabetes.

Adjusting Insulin Treatment and Blood Glucose Monitoring

Stress hyperglycemia and diabetic remission are two important considerations when monitoring and adjusting insulin in the diabetic cat. Cats have the propensity to develop stress-induced hyperglycemia caused by frequent visits to the veterinary hospital for blood samplings. Once stress-induced hyperglycemia develops, it is a perpetual problem and blood glucose measurements can no longer be considered accurate. Veterinarians must remain wary of stress hyperglycemia in diabetic cats and should take steps to prevent its development. Micromanaging diabetic cats is not recommended, and blood glucose curves should be done only when the clinician perceives a need to change insulin therapy.

In a newly diagnosed diabetic cat, we will initially do an abbreviated blood glucose curve, measuring blood glucose at the time of the insulin injection and 3 or 4 more measurements during the day, making sure hypoglycemia has not occurred, and then send the cat home to be treated by the client. During this time period, we also talk to the client about diabetic remission and home blood glucose monitoring. We initially rely on the client's perception of response one week after initiating insulin treatment to determine if an increase in the insulin dose is indicated. If the client believes the cat is doing well, we will not adjust the insulin dose and evaluate a blood glucose curve a week later. If the client has seen minimal to no improvement in clinical signs, we will increase the insulin dose one half to one unit per injection (depending on the size of the cat) and evaluate a blood glucose curve one week later. The subsequent frequency of monitoring and obtaining blood glucose curves depends on

the response of the cat to insulin. Most clients of diabetic cats are happy with the response to insulin treatment if blood glucose concentrations range between 80 and 280 mg/dL throughout the day, and the average blood glucose concentration is less than 250 mg/dL.

The frequency of glucose monitoring is at the discretion of the client. If home blood glucose monitoring is not an option, a more conservative, hands-off approach to monitoring and adjusting insulin is taken. In this scenario, micromanaging the diabetic cat is not recommended, and blood glucose curves are usually done when the clinician perceives a need to change insulin therapy. Determination of good versus poor control of glycemia should be based on the client's subjective opinion of the presence and severity of clinical signs and the overall health of the pet, the ability of the cat to jump, grooming behavior, findings on physical examination, and stability of body weight. Generation of a blood glucose curve is reserved for when problems with control are perceived.

Home Blood Glucose Monitoring and Diabetic Remission

A more intensive approach to treating diabetic cats involves frequent home blood glucose monitoring by the client and adjusting the insulin dose based on glucose results, an approach that has the potential to be more aggressive in maintaining control of blood glucose concentrations, increasing the chance for diabetic remission, and potentially delaying the onset of diabetic neuropathy. The key to diabetic remission lies in the ability to correct insulin resistance and attain and maintain good glycemic control of the diabetic state. Home blood glucose monitoring relies on obtaining capillary blood samples by pricking the inner aspect of the pinna or the metacarpal or metatarsal pads using a lancet or needle and a PBGM device that allows the client to touch the drop of blood to with the end of the glucose test strip (Fig. 49.15). The ear and pad prick technique decreases the need for physical restraint during sample collection, thereby minimizing the cat's discomfort and stress. Accuracy of blood

FIG 49.15
Ear prick technique for measuring blood glucose concentration. **(A)** A hot washcloth is applied to the pinna for 2 to 3 minutes to increase circulation to the ear. **(B)** A spot is identified on the periphery of the outer side of the pinna, a small coating of petrolatum jelly is applied, and the spot is pricked with the lancet device supplied with the portable blood glucose meter. Gauze should be placed between the pinna and the digit holding the pinna to prevent pricking of the finger if the blade of the lancet accidentally passes through the pinna. Petrolatum jelly is applied to help the blood form into a ball on the pinna as it seeps from the site that is lanced. **(C)** Digital pressure is applied in the area of the lanced skin to promote bleeding. The glucose test strip is touched to the drop of capillary blood that forms and is removed once enough blood has been drawn into the test strip to activate the meter.

glucose results are similar when blood for glucose determination is obtained by the ear and pad prick technique and venipuncture. However, blood glucose results obtained by PBGM devices designed for use in humans with diabetes may overestimate but more commonly underestimate the actual blood glucose values obtained with reference methods. This inherent error must be considered when blood glucose results obtained by these PBGM devices are interpreted. One exception is the AlphaTRAK2®(Abbott Laboratories). Accuracy of this portable glucometer is very good in cats, but glucose values may be higher or lower than glucose values measured by benchtop methods on the same blood sample, forcing the veterinarian and client to accept the blood glucose concentration at face value. There are several excellent online sites that demonstrate home blood glucose monitoring techniques for the owner of a diabetic cat (e.g., Abbott Laboratories website for the AlphaTRAK2®). The clinician or technician should allow ample time to teach the technique to clients willing to give it a try and provide advice regarding how often to measure blood glucose concentration and when to monitor blood glucose concentration in relation to the time of insulin injection. Use of the ear and pad prick technique in cats has produced excellent results. Stress is often significantly reduced, and the accuracy of blood glucose measurements is improved. Problems with at-home monitoring of blood glucose concentrations include overzealous clients who start monitoring blood glucose concentrations too frequently, insulin overdosing and hypoglycemia caused by clients who interpret blood glucose results and adjust the insulin dose independent of input from the veterinarian, difficulty obtaining blood from the ear or pads, and cats who do not tolerate manipulation and pricking of the ear or pads.

Role of Serum Fructosamine in Stressed Diabetic Cats

The use of serum fructosamine concentrations for assessing control of glycemia is discussed on page 818. Serum fructosamine concentrations are not affected by acute transient increases in blood glucose concentration. Unlike blood glucose measurements, evaluation of serum fructosamine concentrations in fractious or stressed diabetic cats provides reliable objective information on the status of glycemic control during the previous 2 to 3 weeks. In fractious or stressed cats, the clinician must make an educated guess as to where the problem lies (e.g., wrong type of insulin, low insulin dose), make an adjustment in therapy, and rely on owner perception and changes in serum fructosamine to assess the benefit of the change in treatment. Serum fructosamine concentrations can be measured before and 2 to 3 weeks after insulin therapy is changed to assess the effectiveness of the change. If changes in insulin therapy are appropriate, the client should observe improvement in the severity of polyuria and polydipsia, and serum fructosamine concentration should decrease by more than 50 µmol/L. If the serum fructosamine concentration is the same or has increased, then the change was ineffective in improving glycemic control, another change in therapy based on an educated guess should be performed, and serum fructosamine should be measured again 2 to 3 weeks later.

INSULIN THERAPY DURING SURGERY

Approaches to managing the diabetic cat and dog during surgery are similar and are discussed on page 813.

COMPLICATIONS OF INSULIN THERAPY

Complications of insulin therapy are similar for diabetic dogs and cats and are discussed on page 824. The most common complications of insulin therapy in the diabetic cat are recurring hypoglycemia and diabetic remission; incorrect assessment of glycemic control caused by stress-induced hyperglycemia; insulin overdose; short duration of effect of NPH, lente, and, less commonly, PZI, insulin glargine, and insulin detemir; prolonged duration of effect of PZI, insulin glargine, and insulin detemir; and insulin resistance caused by concurrent inflammatory and hormonal disorders, most notably chronic pancreatitis. Evaluation of a serial blood glucose curve is usually required to identify the underlying problem. A common mistake when insulin glargine or insulin detemir is evaluated in a poorly controlled diabetic cat is that only one or two blood glucose concentrations are measured during the day under the assumption that insulin glargine and insulin detemir have a slow, sustained absorption that results in a relatively flat blood glucose curve (Fig. 49.16, *A*). Unfortunately, the absorption pattern and the duration of effect of insulin glargine and insulin detemir are unpredictable in diabetic cats (see Fig. 49.16, *B*), and interpretation of only one or two blood glucose concentrations can be misleading. A complete serial blood glucose curve as discussed on page 819 should always be done in a diabetic cat with persistence of clinical signs and poor diabetic control, regardless of the type of insulin being administered.

Stress Hyperglycemia

Transient hyperglycemia is a well-recognized problem in fractious, scared, and otherwise stressed cats. Hyperglycemia develops as a result of increased catecholamine concentrations. Blood glucose concentrations typically exceed 200 mg/dL in affected cats, and values in excess of 300 mg/dL are common. Stress hyperglycemia can significantly increase blood glucose concentrations in diabetic cats despite the administration of insulin—an effect that compromises the clinician's ability to accurately judge the effectiveness of the insulin injection. Frequent hospitalizations and venipunctures for monitoring blood glucose concentrations are the most common cause of stress hyperglycemia. Blood glucose concentrations can remain greater than 400 mg/dL throughout the day despite administration of insulin. Failure to recognize the effect of stress on blood glucose results may lead to the erroneous perception that the diabetic cat is poorly controlled. Insulin therapy is invariably adjusted, often by increasing the insulin dose, and another blood glucose curve is obtained 1 to 2 weeks later with essentially the same results. A vicious cycle ensues, which eventually

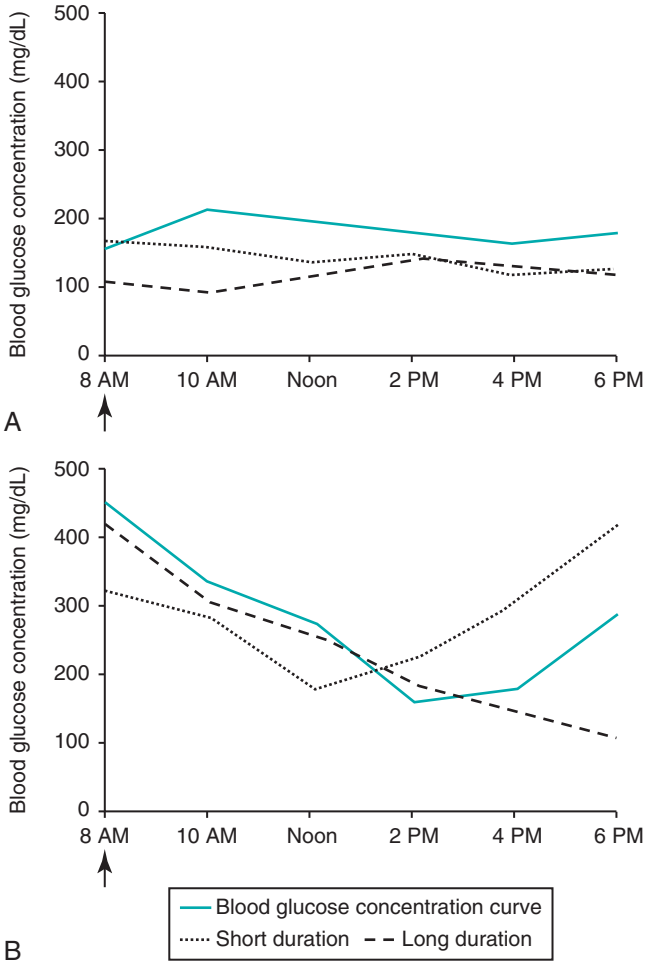

FIG 49.16
Blood glucose concentration curves in six diabetic cats weighing approximately 4 to 5 kg and receiving 1 or 2 units of insulin glargine twice a day, illustrating differences in the effect of insulin glargine on blood glucose results. The three cats in Fig. 49.16, *A* are well regulated and have relatively flat blood glucose curves, with most blood glucose concentrations remaining between 100 and 200 mg/dL, suggesting a slow sustained absorption of insulin glargine. The cats in Fig. 49.16, *B* are not well regulated, and the glycemic effect of insulin glargine is variable, ranging from short duration *(dotted line)* to prolonged duration *(dashed line)* of effect.

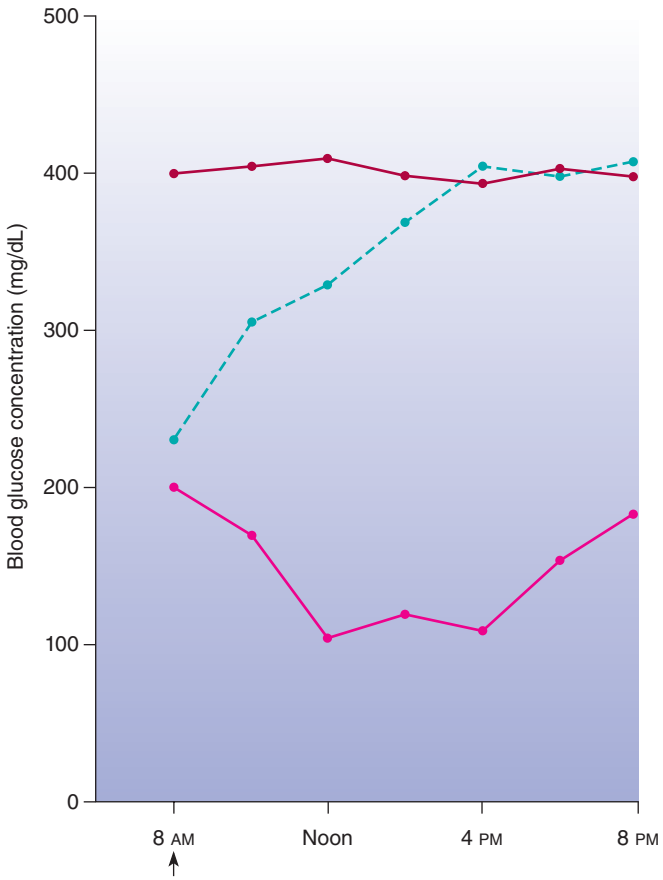

FIG 49.17
Blood glucose concentration curves in a 5.3-kg male cat receiving 2 U of recombinant human ultralente insulin *(pink line)* 2 weeks after initiation of insulin therapy, 2 U of recombinant human ultralente insulin *(blue line)* 2 months later, and 6 U of recombinant human ultralente insulin *(red line)* 4 months later. The insulin dose had been gradually increased on the basis of the blood glucose concentration curves. The client reported minimal clinical signs regardless of the insulin dose; at the 4-month recheck the cat had maintained its body weight, and results of the physical examination were normal. The cat became progressively more fractious during each hospitalization, supporting the existence of stress-induced hyperglycemia as the reason for the discrepancy between blood glucose values and other parameters used to evaluate glycemic control. Subcutaneous insulin injection and food. (From Feldman EC et al: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

culminates in symptomatic hypoglycemia, glucose counter-regulatory response, and referral for evaluation of insulin ineffectiveness.

Failure to identify the presence of stress hyperglycemia and its impact on the interpretation of blood glucose measurements is one of the most important reasons that the status of glycemic control in diabetic cats is misinterpreted. Stress hyperglycemia should be suspected if the cat is visibly upset or aggressive, or struggles during restraint and the venipuncture process. However, stress hyperglycemia can also be present in diabetic cats that are easily removed from the cage and do not resist the blood-sampling procedure. These cats are scared, but rather than becoming aggressive, they remain crouched in the back of the cage, often have dilated pupils, and usually are flaccid when handled. Stress hyperglycemia should also be suspected if a disparity exists between assessment of glycemic control based on results of the history, physical examination, and stability of body weight versus assessment of glycemic control based on results of blood glucose measurements; or when the initial blood glucose concentration measured in the morning is in an acceptable range (i.e., 150-250 mg/dL), but subsequent blood glucose concentrations increase steadily throughout the day (Fig. 49.17). Once stress hyperglycemia develops, it

is a perpetual problem, and blood glucose measurements can no longer be considered accurate. If stress hyperglycemia is suspected, reliance on home monitoring of blood glucose or evaluation of sequential serum fructosamine concentrations in conjunction with the history, physical examination, and stability of body weight should be used to assess control of glycemia.

Hypoglycemia and Diabetic Remission

Hypoglycemia is a common complication of insulin therapy and is discussed on page 806. In diabetic cats symptomatic hypoglycemia is most apt to occur after sudden large increases in the insulin dose, after sudden improvement in concurrent insulin resistance, with excessive duration of insulin action in cats receiving long-acting basal insulin preparations twice a day, after prolonged inappetence, and in insulin-treated cats that have undergone diabetic remission. In these situations severe hypoglycemia may occur before glucose counterregulation (i.e., secretion of glucagon and catecholamines) is able to compensate for and reverse low blood glucose concentrations. The initial treatment approach for symptomatic hypoglycemia is to discontinue insulin until hyperglycemia recurs and then reduce the ensuing insulin dose by 25% to 50%. If hypoglycemia remains a recurring problem despite reductions in the insulin dose, prolonged duration of insulin effect or diabetic remission should be considered. Diabetic remission should be suspected if hypoglycemia remains a persistent problem despite administration of small doses of insulin (i.e., 1 U or less per injection) and administration of insulin once a day; if blood glucose concentrations are consistently below 200 mg/dL before insulin administration; if serum fructosamine concentration is less than 300 µmol/L (reference interval in cats, 190-365 µmol/L); or if urine glucose test strips are consistently negative. Insulin therapy should be discontinued and periodic urine or blood glucose testing at any time of the day or night should be performed in the home environment to identify recurrence of glycosuria or hyperglycemia.

Insulin Underdosing

Insulin underdosing is discussed on page 825. Control of glycemia can be established in most diabetic cats by using less than 1 U of a long-acting insulin/kg of body weight/injection (median, 0.5 U/kg) administered twice daily. In general, insulin underdosing should be considered if the insulin dose is less than 1 U/kg/injection and the cat is receiving insulin twice a day. If insulin underdosing is suspected, the dose of insulin should be gradually increased by 0.5 to 1 U/injection per week. The effectiveness of the change in therapy should be evaluated by client perception of clinical response and measurement of blood glucose concentrations, preferably obtained in the home environment. Other causes of poor glycemic control should be ruled out before an increase in the insulin dose greater than 1 U/kg/injection is considered.

Short Duration of Insulin Effect

Short duration of insulin effect is discussed on page 826. Short duration of insulin effect is a common problem in diabetic cats despite twice-daily insulin administration. Short duration of effect is common with NPH and lente insulin but occurs with all insulins used to treat diabetic cats, including PZI, insulin glargine, and insulin detemir (see Table 49.3). A diagnosis of short duration of insulin effect is made by demonstrating an initial blood glucose concentration greater than 300 mg/dL combined with a glucose nadir above 80 mg/dL that occurs less than 8 hours after insulin administration and recurrence of hyperglycemia (>300 mg/dL) within 10 hours of the insulin injection (see Fig. 49.8). Treatment involves changing to a longer-acting insulin preparation (see Fig. 49.11).

Prolonged Duration of Insulin Effect

Prolonged duration of insulin effect is discussed on page 826. In diabetic cats problems with prolonged duration of insulin effect are most common with twice-daily administration of PZI, insulin glargine, and insulin detemir.

Inadequate Insulin Absorption

See page 827.

Concurrent Disorders Causing Insulin Resistance

Concurrent disorders causing insulin resistance are discussed on page 827. The most common concurrent disorders interfering with insulin effectiveness in cats include severe obesity, chronic inflammation such as chronic pancreatitis and gingivitis, chronic kidney disease, hyperthyroidism, acromegaly, and hyperadrenocorticism (see Box 49.8). Obtaining a complete history and performing a thorough physical examination are the most important steps in identifying these concurrent disorders. If the history and physical examination are unremarkable, a CBC, serum biochemical analysis, serum thyroxine concentration, urinalysis with bacterial culture, and (if available) abdominal ultrasound should be obtained to further screen for concurrent illness. Additional tests will depend on results of the initial screening tests (see Box 49.9).

CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Chronic complications of diabetes mellitus are discussed on page 828. The most common complications in the diabetic cat are hypoglycemia; chronic pancreatitis; weight loss; poor grooming behavior causing a dry, lusterless, and unkempt haircoat; and peripheral neuropathy of the hindlimbs, causing weakness, inability to jump, a plantigrade stance, and ataxia (see Box 49.5). Diabetic cats are also at risk for ketoacidosis.

Diabetic Neuropathy

Diabetic neuropathy is the most important chronic complication of diabetes in cats. Clinical signs of a coexistent

neuropathy in the diabetic cat include weakness, impaired ability to jump, knuckling, a plantigrade posture with the cat's hocks touching the ground when it walks (see Fig. 49.14, Video 49.1), muscle atrophy, depressed limb reflexes, and deficits in postural reaction testing. Clinical signs may progress to include the thoracic limbs (palmigrade posture). Abnormalities on electrophysiologic testing are consistent with demyelination at all levels of the motor and sensory peripheral nerves and include decreased motor and sensory nerve conduction velocities in pelvic and thoracic limbs and decreased muscle action potential amplitudes. Electromyographic abnormalities are usually absent and, when identified, are consistent with denervation. Histologic examination of nerve biopsies from affected cats reveals endoneurial microvascular pathology, segmental demyelination, and axonal degeneration in myelinated nerve fibers that culminate in loss of myelinated fibers. The pathogenesis of diabetic peripheral neuropathy is considered multifactorial, with contributions from both metabolic and vascular factors. Currently, no specific therapy is available. Aggressive glucoregulation with insulin may improve nerve conduction and reverse posterior weakness and plantigrade posture (see Fig. 49.14). However, the response to therapy is unpredictable, and the risks of hypoglycemia increase with aggressive insulin treatment. Generally, the longer the neuropathy has been present and the more severe the neuropathy, the less likely it is that improving glycemic control will reverse the clinical signs of neuropathy. (See Suggested Readings for more information on diabetic neuropathy in cats.)

Prognosis

Variables that impact the prognosis are similar for diabetic cats and dogs and include owner commitment to treating the disorder, ease of glycemic regulation, presence and reversibility of concurrent disorders, avoidance of chronic complications associated with the diabetic state, and minimizing the impact of treatment on the quality of life of the owner (see p. 830). Median survival time from the time of diagnosis was 516 days (range, 1-3468 days) in 114 diabetic cats in Zurich, Switzerland (Callegari et al., 2013). In our experience, the mean survival time in diabetic cats is approximately 3 years from the time of diagnosis. However, survival times are somewhat skewed because cats are usually 8 to 15 years old at the time of diagnosis, and a high mortality rate exists during the first 6 months because of concurrent life-threatening or uncontrollable disease (e.g., pancreatitis, chronic kidney disease, acromegaly). In general, "younger" diabetic cats that survive the first 6 months can easily live longer than 5 years with the disease if properly treated.

DIABETIC KETOACIDOSIS

Etiology

Ketone bodies (i.e., acetoacetic acid, β-hydroxybutyric acid, acetone) are derived from oxidation of nonesterified or free fatty acids (FFAs) by the liver and are used as an energy source by many tissues during periods of glucose deficiency. Excessive production of ketone bodies as occurs in uncontrolled diabetes results in their accumulation in the circulation and development of the ketosis and acidosis of ketoacidosis.

The etiopathogenesis of DKA is complex and usually affected by concurrent clinical disorders. Virtually all dogs and cats with DKA have a relative or absolute deficiency of insulin. DKA develops in some diabetic dogs and cats even though they receive daily injections of insulin, and their circulating insulin concentrations may even be increased. The "relative" insulin deficiency in these animals is created by concurrent insulin resistance, which in turn is created by concurrent disorders such as pancreatitis, infection, or insulin-resistant hormonal disorder. Increased circulating concentrations of diabetogenic hormones, most notably glucagon, accentuate insulin deficiency by promoting insulin resistance; stimulate lipolysis, leading to ketogenesis; and stimulate hepatic gluconeogenesis, which worsens hyperglycemia.

Insulin deficiency and insulin resistance, together with increased circulating concentrations of diabetogenic hormones, play a critical role in the stimulation of ketogenesis. For the synthesis of ketone bodies to be enhanced, two major alterations in intermediary metabolism must occur: (1) enhanced mobilization of FFAs from triglycerides stored in adipose tissue, and (2) a shift in hepatic metabolism from fat synthesis to fat oxidation and ketogenesis. Insulin is a powerful inhibitor of lipolysis and FFA oxidation. A relative or absolute deficiency of insulin allows lipolysis to increase, thus increasing the availability of FFAs to the liver and in turn promoting ketogenesis. As ketones continue to accumulate in the blood, the body's buffering system becomes overwhelmed, and metabolic acidosis develops. As ketones accumulate in the extracellular space, the quantity eventually surpasses the renal tubular threshold for complete resorption, and they spill into the urine, contributing to the osmotic diuresis caused by glycosuria and enhancing the excretion of solutes (e.g., sodium, potassium, calcium, magnesium). Insulin deficiency per se also contributes to excessive renal losses of water and electrolytes. The result is excessive loss of electrolytes and water, leading to volume contraction, underperfusion of tissues, and the development of prerenal azotemia. The rise in blood glucose concentration raises plasma osmolality, and the resulting osmotic diuresis further aggravates the rise in plasma osmolality by causing water losses in excess of salt loss. The increase in plasma osmolality causes water to shift out of cells, leading to cellular dehydration. The metabolic consequences of DKA, which include severe acidosis, hyperosmolality, obligatory osmotic diuresis, dehydration, and electrolyte derangements, eventually become life-threatening.

Clinical Features

DKA is a serious complication of diabetes mellitus that occurs most commonly in dogs and cats with diabetes that has gone undiagnosed. Less commonly, DKA develops in an insulin-treated diabetic dog or cat receiving an inadequate

dose of insulin, often occurring in conjunction with an infectious, inflammatory, or insulin-resistant hormonal disorder. Because of the close association between DKA and newly diagnosed diabetes mellitus, the signalment of DKA in dogs and cats is similar to that of nonketotic diabetics.

The history and physical examination findings are variable, in part because of the progressive nature of the disorder and the variable time between the onset of DKA and client recognition of a problem. Polyuria, polydipsia, polyphagia, and weight loss develop initially but may be unnoticed or considered insignificant by the client. Systemic signs of illness (e.g., lethargy, anorexia, vomiting) ensue as ketonemia and metabolic acidosis develop and worsen, with the severity of these signs directly related to the severity of the metabolic acidosis and the nature of concurrent disorders that are often present. The time interval from onset of the clinical signs of diabetes to development of systemic signs of DKA is unpredictable and ranges from a few days to several months. Once ketoacidosis begins to develop, however, severe illness usually becomes evident within a week.

Common physical examination findings include dehydration, lethargy, weakness, tachypnea, tachycardia, and sometimes a strong odor of acetone on the breath. Slow, deep breathing may be observed in animals with severe metabolic acidosis. Gastrointestinal tract signs such as vomiting and abdominal pain are common in animals with DKA, in part because of the common concurrent occurrence of pancreatitis. Other intraabdominal disorders should be considered and diagnostic tests (e.g., abdominal ultrasound) performed to help identify the cause of the gastrointestinal signs. Additional physical examination findings associated with uncomplicated diabetes mellitus (e.g., hepatomegaly, cataracts, diabetic neuropathy) may be identified.

Diagnosis

The diagnosis of diabetes mellitus is based on appropriate clinical signs, persistent fasting hyperglycemia, and glycosuria. The concurrent documentation of ketonuria establishes a diagnosis of DK and documenting metabolic acidosis establishes the diagnosis of DKA. Commonly used nitroprusside reagent test strips for ketonuria (e.g., KetoDiastix) measure only acetoacetate and its byproduct acetone. β-hydroxybutyrate is not detected by conventional nitroprusside tests. If ketonuria is not present but DKA is suspected, serum or urine can be tested for acetone using Acetest tablets, blood can be tested for the presence of β-hydroxybutyrate using a quantitative enzymatic assay or a portable blood glucose and ketone analyzer (e.g., Precision Xtra, Abbott Diagnostics), or plasma from heparinized hematocrit tubes can be used to test for the presence of acetoacetate using urine reagent test strips used to document ketonuria.

Treatment of "Healthy" Dogs or Cats With Diabetic Ketosis or Diabetic Ketoacidosis

If systemic signs of illness are absent or mild, inappetence is not present, serious abnormalities are not readily identifiable on physical examination, and metabolic acidosis is mild (i.e., with total venous carbon dioxide [CO_2] or arterial bicarbonate concentration > 16 mEq/L), short-acting regular crystalline insulin can be administered subcutaneously three times daily at 8-hour intervals until the ketonuria resolves. Fluid therapy and intensive care usually are not needed. Because regular crystalline insulin is a potent insulin, the initial dosage (0.1-0.2 U/kg/injection) is lower than that recommended for longer-acting insulin preparations. To minimize hypoglycemia, the dog or cat should be fed one third of its daily caloric intake at the time of each insulin injection. Subsequent adjustments in the insulin dose are based on clinical response and results of blood glucose measurements. Urine ketone concentrations should be monitored and, if available, blood β-hydroxybutyrate concentrations should be monitored using a portable glucose and ketone meter (e.g., Precision Xtra®, Abbott). A decrease in the blood glucose concentration implies a decrease in ketone production. This, in combination with metabolism of ketones and loss of ketones in urine, will usually correct ketosis within 48 to 96 hours of initiating insulin therapy. Prolonged ketonemia and ketonuria is suggestive of a significant concurrent illness (e.g., chronic pancreatitis) or inadequate blood insulin concentrations to suppress lipolysis and ketogenesis. Once the ketosis has resolved, insulin therapy may be initiated using longer-acting insulin preparations. As a general rule of thumb, the initial dosage of the longer-acting insulin preparation is approximately the same as the dosage of regular crystalline insulin administered at the time the switch in insulin is made, with subsequent adjustments in the dosage based on the animal's response to the insulin.

Treatment of Sick Dogs or Cats With Diabetic Ketoacidosis

Aggressive therapy is called for if the dog or cat has systemic signs of illness (e.g., lethargy, anorexia, vomiting); physical examination reveals dehydration, depression, weakness, or a combination of these; or metabolic acidosis is severe (i.e., total venous CO_2 or arterial bicarbonate concentration < 12 mEq/L). The five goals of treatment of a severely ill, ketoacidotic, diabetic pet are (1) to provide adequate amounts of insulin to suppress lipolysis, ketogenesis, and hepatic gluconeogenesis; (2) to restore water and electrolyte losses; (3) to correct acidosis; (4) to identify the factors precipitating the present illness; and (5) to provide a carbohydrate substrate (i.e., dextrose) when necessary to allow continued administration of insulin without causing hypoglycemia (Box 49.11). Proper therapy does not mean forcing a return to a normal state as rapidly as possible. Because osmotic and biochemical problems can arise as a result of overly aggressive therapy as well as from the disease itself, rapid changes in various vital parameters can be as harmful as, or more harmful than, no change. If all abnormal parameters can be slowly returned toward normal over a period of 24 to 48 hours, therapy is more likely to be successful.

Critically important information for formulating the initial treatment protocol includes hematocrit and total

BOX 49.11

Initial Management of Dogs or Cats With Severe Diabetic Ketoacidosis

Fluid Therapy

Type: 0.9% saline if hyponatremia is severe (<130 mEq/L); isotonic crystalloid solution such as Ringer's, Ringer's lactate, Plasma-Lyte 148, or Normosol-R if serum sodium concentration ≥ 130 mEq/L

Rate: 60 to 100 mL/kg/24 h initially; adjust based on hydration status, urine output, persistence of fluid losses

Potassium supplement: Based on serum K^+ concentration (see Table 53.1); if unknown, initially add 40 mEq of KCl to each liter of fluids

Phosphate supplement: Administer if serum phosphorus concentration < 1.5 mg/dL; initial IV infusion rate is 0.01 to 0.03 mmol phosphate/kg/h in calcium-free intravenous fluids

Dextrose supplement: Not indicated until blood glucose concentration is less than 250 mg/dL, then begin 5% dextrose infusion

Bicarbonate Therapy

Indication: Administer if plasma bicarbonate concentration is less than 12 mEq/L or if total venous CO_2 concentration is less than12 mmol/L; if not known, do not administer unless animal is severely ill and then only once.

Amount: mEq HCO_3– = body weight (kg) × 0.4 × (12 – animal's HCO_3^-) × 0.5; if animal's HCO_3^- or total CO_2 concentration is unknown, use 10 in place of (12 – animal's HCO_3^-)

Administration: Add to intravenous fluids and give over 6 hours; do not give as bolus infusion

Retreatment: Only if plasma bicarbonate concentration remains less than 12 mEq/L after 6 hours of therapy

Insulin Therapy

Type: Regular crystalline insulin

Administration Technique

Intermittent intramuscular technique: Initial dose, 0.1 to 0.2 U/kg intramuscularly; then 0.1 U/kg intramuscularly hourly until blood glucose concentration is less than 250 mg/dL; then switch to regular insulin administered IM q4-6h or SC q6-8h

Low-dose intravenous infusion technique: To prepare infusion, add 2.2 U/kg (dogs) or 1.1 U/kg (cats) of regular insulin to 250 mL of 0.9% saline; run 50 mL through the drip set and discard; then administer via infusion or syringe pump through a line separate from that used for fluid therapy at an initial rate of 10 mL/h; adjust infusion rate according to hourly blood glucose measurements; switch to subcutaneous regular insulin q6-8h once blood glucose is less than 250 mg/dL, or continue insulin infusion at a decreased rate to prevent hypoglycemia until the insulin preparation is exchanged for a longer-acting product.

Goal: Gradual decline in blood glucose concentration, preferably around 50 mg/dL/h until concentration is less than 250 mg/dL

Ancillary Therapy

Concurrent pancreatitis is common in diabetic ketoacidosis; nothing by mouth and aggressive fluid therapy are usually indicated

Concurrent infections are common in diabetic ketoacidosis; use of broad-spectrum, parenteral antibiotics is usually indicated

Additional therapy may be needed, depending on the nature of concurrent disorders

Patient Monitoring

Blood glucose measurement q1-2h initially; adjust insulin therapy and begin dextrose infusion when decreases to below 250 mg/dL

Hydration status, respiration, pulse q2-4h; adjust fluids accordingly

Serum electrolyte and total venous CO_2 concentrations q6-12h; adjust fluid and bicarbonate therapy accordingly

Urine output, glycosuria, ketonuria q2-4h; adjust fluid therapy accordingly

Body weight, packed cell volume, temperature, and blood pressure q6-8h

Additional monitoring, depending on concurrent disease

plasma protein concentration; serum glucose, albumin, creatinine, and urea nitrogen concentrations; serum electrolytes; venous total CO_2 or arterial acid-base evaluation; and urine specific gravity. Abnormalities frequently associated with DKA are listed in Box 49.12. Once treatment for DKA is initiated, additional studies, such as CBC, serum biochemistry panel, urinalysis, urine culture, thoracic radiographs, and abdominal ultrasound, or diagnostic tests for pancreatitis, diestrus in the female dog, and hyperthyroidism in the cat are usually warranted to identify underlying concurrent disorders (see Box 49.8).

FLUID THERAPY

Initiation of appropriate fluid therapy should be the first step in the treatment of DKA, and in most cases it should precede the initiation of insulin therapy by 2 hours or longer to minimize the development of complications affiliated with insulin administration. Replacement of fluid deficiencies and maintenance of normal fluid balance are important to ensure adequate cardiac output, blood pressure, and blood flow to all tissues. Improvement in renal blood flow is especially critical. In addition to the general beneficial aspects of fluid therapy in any dehydrated animal, fluid therapy can correct

BOX 49.12

Common Clinicopathologic Abnormalities Identified in Dogs and Cats With Diabetic Ketoacidosis

Neutrophilic leukocytosis, signs of toxicity if septic
Hemoconcentration
Hyperglycemia
Hypercholesterolemia, lipemia
Increased alkaline phosphatase activity
Increased alanine aminotransferase activity
Increased blood urea nitrogen and serum creatinine concentrations
Hyponatremia
Hypochloremia
Hypokalemia
Metabolic acidosis (decreased total carbon dioxide concentration)
Hyperosmolality
Glycosuria
Ketonuria
Urinary tract infection

deficiencies in total body sodium and potassium, dampen the potassium-lowering effect of insulin treatment, and lower the blood glucose concentration in diabetic individuals, even in the absence of insulin administration. Unfortunately, fluid therapy alone does not suppress ketogenesis. For this reason, insulin is always required.

The type of parenteral fluid used initially will depend on the animal's electrolyte status, blood glucose concentration, and osmolality. Most sick dogs and cats with DKA have severe deficits in total body sodium, regardless of the measured serum concentration. Ringer's solution or Plasma-Lyte 148 (Baxter Healthcare Corp.) can be used for mild hyponatremia (serum sodium concentration of more than 130 mEq/L) and 0.9% (physiologic) saline for more severe hyponatremia (serum sodium concentration of less than 130 mEq/L) with appropriate potassium supplementation. Alternative isotonic crystalloid solutions that could be used include Ringer's lactated solution and Normosol-R® (Abbott Laboratories). Each of these solutions has a slightly different electrolyte composition; none contain as much sodium as 0.9% saline (see Tables 53.1 and 53.2). Most dogs and cats with severe DKA are sodium depleted and therefore not suffering from dramatic hyperosmolality. Hypotonic fluids (e.g., 0.45% saline) are rarely indicated in dogs and cats with DKA, even when severe hyperosmolality is present. Hypotonic fluids do not provide adequate amounts of sodium to correct the sodium deficiency, restore normal fluid balance, or stabilize blood pressure. Rapid administration of hypotonic fluids can cause a rapid decrease in the osmolality of extracellular fluid (ECF), which may result in cerebral edema, deterioration in mentation, and eventually coma. Hyperosmolality is best treated with isotonic fluids and the judicious administration of insulin. Fluid administration should be directed at gradually replacing hydration deficits over 24 hours while supplying maintenance fluid needs and matching ongoing losses. Rapid replacement of fluids is rarely indicated unless the dog or cat is in shock. Once the animal is out of this critical phase, fluid replacement should be decreased in an effort to correct the fluid imbalance in a slow but steady manner. As a general rule of thumb, a fluid rate of 1.5 to 2 times maintenance (i.e., 60-100 mL/kg q24h) is typically chosen initially, with subsequent adjustments based on frequent assessment of hydration status, urine output, severity of azotemia, and persistence of vomiting and diarrhea.

Potassium Supplementation

Most dogs and cats with DKA initially have normal or decreased serum potassium concentrations. During therapy for DKA the serum potassium concentration decreases because of rehydration (dilution), insulin-mediated cellular uptake of potassium (with glucose), continued urinary losses, and correction of acidemia (translocation of potassium into the intracellular fluid compartment; Fig. 49.18). Severe hypokalemia is the most common complication that develops during the initial 24 hours of treatment of DKA. Dogs and cats with hypokalemia require aggressive potassium replacement therapy to replace deficits and to prevent worsening, life-threatening hypokalemia after initiation of insulin therapy. The exception to potassium supplementation of fluids is hyperkalemia associated with oliguric kidney failure. Potassium supplementation should initially be withheld in these dogs and cats until glomerular filtration is restored, urine production increases, and hyperkalemia is resolving.

Ideally, the amount of potassium required should be based on actual measurement of the serum potassium concentration. If an accurate measurement of serum potassium is not available, potassium should be added to the liter of fluids to bring the potassium concentration to 40 mEq/L. For example, 0.9% saline solution does not contain potassium, and Ringer's solution contains 4 mEq of potassium per liter, thus these fluids should be supplemented with 40 mEq and 36 mEq of potassium, respectively. Subsequent adjustments in potassium supplementation should be based on measurement of serum potassium, preferably every 4 to 8 hours until the dog or cat is stable and serum electrolytes are in the reference range.

Phosphate Supplementation

Most dogs and cats with DKA have normal or decreased serum phosphorus concentrations on pretreatment testing. Within 24 hours of initiation of treatment for DKA, serum phosphorus concentration can decline to severe levels (i.e., <1 mg/dL) as a result of the dilutional effects of fluid therapy, the intracellular shift of phosphorus following the initiation of insulin therapy, and continuing renal and gastrointestinal loss (see Fig. 49.18). Hypophosphatemia primarily affects the hematologic and neuromuscular systems in dogs and cats. Hemolytic anemia is the most common problem and can be life-threatening if not recognized and treated. Weakness,

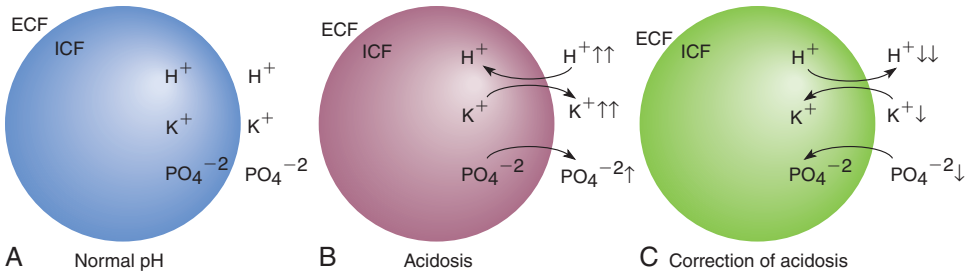

FIG 49.18
Redistribution of extracellular fluid *(ECF)* and intracellular fluid *(ICF)* hydrogen, potassium, and phosphate ions in response to a decrease in ECF pH (i.e., acidosis), an increase in ECF glucose and osmolality, and translocation of water from the ICF to the ECF compartment and subsequent correction of acidosis and the intracellular shift of glucose and electrolytes with insulin treatment. **(A)** Normal ECF pH. **(B)** ECF H^+ concentration increases during acidosis, causing H^+ to move into cells and down its concentration gradient. Increases in ECF glucose and osmolality cause extracellular shifts of water, K^+, and PO_4^{+2}. **(C)** ECF H^+ concentration decreases during correction of acidosis, causing H^+ to move out of the cells. Insulin administration and correction of acidemia cause an intracellular shift of glucose, K^+, and PO_4^{+2}, decreasing ECF K^+ and PO_4^{+2} concentrations. (From Feldman EC et al: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

ataxia, and seizures may be observed. Severe hypophosphatemia may be clinically silent in many animals.

Phosphate therapy is indicated if clinical signs or hemolysis is identified or if the serum phosphorus concentration decreases to less than 1.5 mg/dL. Phosphate is supplemented by IV infusion. Potassium and sodium phosphate solutions contain 3 mmol of phosphate and 4.4 mEq of potassium or 4 mEq of sodium per milliliter. The recommended dosage for phosphate supplementation is 0.01 to 0.03 mmol of phosphate per kilogram of body weight per hour, preferably administered in calcium-free IV fluids (e.g., 0.9% sodium chloride). In dogs and cats with severe hypophosphatemia, it may be necessary to increase the dosage to 0.03 to 0.12 mmol/kg/h. Because the dose of phosphate necessary to replete an animal and the animal's response to therapy cannot be predicted, it is important to initially monitor the serum phosphorus concentration every 8 to 12 hours and adjust the phosphate infusion accordingly. Adverse effects from overzealous phosphate administration include iatrogenic hypocalcemia and its associated neuromuscular signs, hypernatremia, hypotension, and calcification of soft tissues. Serum ionized calcium concentration should be measured at the same time as serum phosphorus concentration and the rate of phosphate infusion decreased if hypocalcemia is identified. Phosphorus supplementation is not indicated in dogs and cats with hypercalcemia, hyperphosphatemia, oliguria, or suspected tissue necrosis. If kidney function is in question, phosphorus supplementation should not be done until the status of kidney function and serum phosphorus concentration are known.

Magnesium Supplementation

Plasma total and ionized magnesium concentrations may be within or below the reference range at the time DKA is diagnosed in the dog or cat, often decrease during initial treatment of DKA, and typically normalize without treatment as DKA resolves. Clinical signs of hypomagnesemia do not usually occur until serum total and ionized magnesium concentrations are less than 1.0 and 0.4 mg/dL, respectively, and even at these low levels many dogs and cats remain asymptomatic. We do not routinely treat hypomagnesemia in dogs or cats with DKA unless problems with persistent lethargy, anorexia, weakness, or refractory hypokalemia or hypocalcemia are encountered after 24 to 48 hours of fluid and insulin therapy, and another cause for the problem cannot be identified. See Chapter 53 for information on the treatment of hypomagnesemia.

Bicarbonate Therapy

The clinical presentation of the dog or cat, in conjunction with the plasma bicarbonate or total venous CO_2 concentration, should be used to determine the need for bicarbonate therapy. Bicarbonate supplementation is not recommended when plasma bicarbonate (or total venous CO_2) is 12 mEq/L or greater, especially if the animal is alert. An alert dog or cat probably has a normal or near-normal pH in the cerebrospinal fluid (CSF). Acidosis in these animals is corrected through insulin and fluid therapy. Improvement in renal perfusion enhances urinary loss of ketoacids, and insulin therapy markedly diminishes the production of ketoacids. Acetoacetate and β-hydroxybutyrate are metabolically usable anions, and 1 mEq of bicarbonate is generated from each 1 mEq of ketoacid metabolized.

When the plasma bicarbonate concentration is 11 mEq/L or less (total venous $CO_2 < 12$ mEq/L), bicarbonate therapy should be initiated. Many of these animals have severe depression that may be a result of concurrent severe central nervous system acidosis. Metabolic acidosis should be corrected slowly, thereby avoiding major alterations in the pH of the CSF. Only a portion of the bicarbonate deficit is given

initially over a 6-hour period. The bicarbonate deficit (i.e., the milliequivalents of bicarbonate initially needed to correct acidosis to the critical level of 12 mEq/L over a period of 6 hours) is calculated by the following formula:

$$\text{mEq bicarbonate} = \text{body weight (kg)} \times 0.4 \times (12 - \text{animal's bicarbonate}) \times 0.5$$

If the serum bicarbonate concentration is not known, the following formula should be used:

$$\text{mEq bicarbonate} = \text{body weight (kg)} \times 2$$

The difference between the animal's serum bicarbonate concentration and the critical value of 12 mEq/L represents the treatable base deficit in DKA. If the animal's serum bicarbonate concentration is not known, the number 10 should be used for the treatable base deficit. The factor 0.4 corrects for the ECF space in which bicarbonate is distributed (40% of body weight). The factor 0.5 provides one half of the required dose of bicarbonate in the IV infusion. This technique allows a conservative dose to be given over a 6-hour period. Bicarbonate should not be given by bolus infusion. After 6 hours of therapy, the acid-base status should be reevaluated and a new dose calculated. Once the plasma bicarbonate level is greater than 12 mEq/L, further bicarbonate supplementation is not indicated.

INSULIN THERAPY

Insulin therapy is critical for the resolution of ketoacidosis. However, overzealous insulin treatment can cause severe hypokalemia, hypophosphatemia, and hypoglycemia during the first 24 hours of treatment—problems that can be minimized by appropriate fluid therapy, frequent monitoring of serum electrolytes and blood glucose concentrations, and modification of the initial insulin treatment protocol as indicated. Initiating appropriate fluid therapy should always be the first step in the treatment of DKA. Delaying insulin therapy for a minimum of 2 hours is recommended to allow the benefits of fluid therapy to begin to be realized before the glucose-, potassium-, and phosphorus-lowering effects of insulin therapy commence. Additional delays and decisions on the initial dosage of insulin administered are based on serum electrolyte results. If the serum potassium concentration is within the normal range after 2 hours of fluid therapy, insulin treatment should commence as described in the subsequent paragraphs. If hypokalemia persists, insulin therapy can be delayed an additional 2 hours to allow fluid therapy to replenish potassium, the initial insulin dose can be reduced to dampen the intracellular shift of potassium and phosphorus, or both can be done. However, in our opinion, insulin therapy should be started within 4 hours of initiation of fluid therapy.

The amount of insulin needed by an individual animal is difficult to predict. Therefore an insulin preparation with a rapid onset of action and a brief duration of effect is ideal for making rapid adjustments in the dose and frequency of administration to meet the needs of that particular dog or cat. Rapid-acting regular crystalline insulin meets these criteria and is recommended for the treatment of DKA. Rapid-acting insulin analogs (e.g., insulin lispro and insulin aspart) are also effective for treating DKA in, dogs and cats. The rapid-acting insulin analog lispro insulin (Humalog) is also effective when administered as a constant-rate infusion, as described later.

Insulin protocols for the treatment of DKA include the hourly intramuscular technique, the continuous low-dose IV infusion technique, and the intermittent intramuscular then subcutaneous technique. All three routes (IV, intramuscular, and subcutaneous) of insulin administration are effective in decreasing blood glucose and ketone concentrations. Successful management of DKA is *not* dependent on the route of insulin administration. Rather, it is dependent on proper treatment of each disorder associated with DKA.

Hourly Intramuscular Insulin Technique

Dogs and cats with severe DKA should receive an initial regular crystalline insulin loading dose of 0.1 to 0.2 U/kg followed by 0.1 U/kg every1 to 2 hours thereafter. The insulin dose can be reduced by 25% to 50% for the first 2 to 3 injections if hypokalemia is a concern. Insulin should be administered into the muscles of the rear legs to ensure that the injections are penetrating muscle rather than fat or subcutaneous tissue where insulin absorption may be impaired in the dehydrated dog or cat. Diluting regular insulin 1:10 with sterile saline or special diluents available from the insulin manufacturer and using 0.3 mL U100 insulin syringes are helpful when small doses of insulin are required. The blood glucose concentration should be measured every hour using a point-of-care chemistry analyzer or PBGM device, and the insulin dosage adjusted accordingly. The goal of initial insulin therapy is to *slowly* lower the blood glucose concentration to the range of 200 to 250 mg/dL, preferably over a 6- to 10-hour time period. An hourly decline of 50 mg/dL in the blood glucose concentration is ideal. This provides a steady moderate decline, with no major shifts in osmolality. A declining blood glucose concentration also ensures that lipolysis and the supply of FFAs for ketone production have been effectively turned off. Glucose concentrations, however, decrease much more rapidly than do ketone concentrations. In general, hyperglycemia is corrected within 12 hours, but ketosis may take 48 to 72 hours to resolve.

Once initial hourly insulin therapy brings the blood glucose concentration near 250 mg/dL, hourly administration of regular insulin should be discontinued and regular insulin given every 4 to 6 hours intramuscularly or, if hydration status is good, every 6 to 8 hours subcutaneously. The initial dose is usually 0.1 to 0.3 U/kg, with subsequent adjustments based on blood glucose concentrations. In addition, at this point the IV infusion solution should have enough 50% dextrose added to create a 5% dextrose solution (100 mL of 50% dextrose added to each liter of fluids). The blood glucose concentration should be maintained between 150 and 300 mg/dL until the dog or cat is stable and eating.

Usually, a 5% dextrose solution is adequate in maintaining the desired blood glucose concentration. If the blood glucose concentration dips below 150 mg/dL or rises above 300 mg/dL, the insulin dose can be lowered or raised accordingly. Dextrose helps minimize problems with hypoglycemia and allows insulin to be administered on schedule. Delaying the administration of insulin delays correction of the ketoacidotic state.

Constant Low-Dose Intravenous Insulin Infusion Technique

Constant IV infusion of regular crystalline insulin is also effective in decreasing blood glucose concentrations. To prepare the infusion, regular crystalline insulin (2.2 U/kg for dogs; 1.1 U/kg for cats) is added to 250 mL of 0.9% saline and is initially administered at a rate of 10 mL/h in a line separate from that used for fluid therapy. This provides an insulin infusion of 0.05 (cat) and 0.1 (dog) U/kg/h—an infusion rate that has been shown to produce plasma insulin concentrations between 100 and 200 μU/mL (700-1400 pmol/L) in dogs. Because insulin adheres to glass and plastic surfaces, approximately 50 mL of the insulin-containing fluid should be run through the drip set before it is administered to the animal. The rate of insulin infusion can be reduced for the initial 2 to 4 hours if hypokalemia is a concern. Two separate catheters are recommended for treatment: a peripheral catheter for insulin administration and a central catheter for fluid administration and blood sampling. An infusion or syringe pump should be used to ensure a constant rate of insulin infusion.

Adjustments in the infusion rate are based on hourly measurements of blood glucose concentration; an hourly decline of 50 mg/dL in the blood glucose concentration is ideal. Once the blood glucose concentration approaches 250 mg/dL, the insulin infusion can be discontinued and regular insulin given every 4 to 6 hours intramuscularly or every 6 to 8 hours subcutaneously, as discussed for the hourly intramuscular protocol. Alternatively, the insulin infusion can be continued (at a decreased rate to prevent hypoglycemia) until the insulin preparation is exchanged for a longer-acting product. Dextrose should be added to the IV fluids once the blood glucose concentration approaches 250 mg/dL, as discussed in the section on hourly intramuscular insulin technique.

Sears et al. (2012) evaluated the efficacy of the short-acting insulin analog lispro (Humalog®, Eli Lilly) for the treatment of DKA using an IV constant rate infusion technique. Treatment with IV constant rate infusion of lispro was safe and as effective as treatment with regular crystalline insulin. Use of lispro insulin is a viable option for treating DKA, especially if production of regular crystalline insulin is discontinued in the future.

Intermittent Intramuscular/Subcutaneous Insulin Technique

The intermittent intramuscular followed by intermittent subcutaneous insulin technique is less labor intensive than the other techniques for insulin administration, but the decrease in blood glucose can be rapid and the risk of hypoglycemia greater. The initial regular crystalline insulin dose is 0.2 U/kg, administered intramuscularly. Subsequent intramuscular injections are repeated every 4 hours. Usually, insulin is administered intramuscularly only once or twice. Once the animal is rehydrated, the insulin is administered subcutaneously rather than intramuscularly every 6 to 8 hours. Subcutaneous administration is not recommended initially because of potential problems with insulin absorption from subcutaneous sites of deposition in a dehydrated dog or cat. The dosage of intramuscular or subcutaneous insulin is adjusted according to blood glucose concentrations, which initially should be measured hourly beginning with the first intramuscular injection. An hourly decline of 50 mg/dL in blood glucose concentration is ideal. Subsequent insulin dosages should be decreased by 25% to 50% if this goal is exceeded. Dextrose should be added to the IV fluids once the blood glucose concentration approaches 250 mg/dL, as discussed in the section on hourly intramuscular insulin technique.

Initiating Longer-Acting Insulin

Longer-acting insulin (e.g., Lente, PZI, glargine) should not be administered until the dog or cat is stable, eating, and maintaining fluid balance without any IV infusions, and is no longer acidotic, azotemic, or electrolyte-deficient. The initial dose of the longer-acting insulin is similar to the regular insulin dose that is being used just before the switch to a longer-acting insulin. Subsequent adjustments in the longer-acting insulin dose should be based on clinical response and measurement of blood glucose concentrations, as described on page 817.

CONCURRENT ILLNESS

Therapy for DKA frequently involves the management of concurrent, often serious, illness. Common concurrent illnesses in dogs and cats with DKA include bacterial infection; pancreatitis; congestive heart failure; chronic kidney disease; hepatobiliary disease; and insulin-antagonistic disorders, most notably hyperadrenocorticism (dog), hyperthyroidism (cat), and diestrus (intact female dog). It may be necessary in such animals to modify the therapy for DKA (e.g., fluid therapy in animals with concurrent heart failure) or to implement additional therapy (e.g., antibiotics), depending on the nature of the concurrent illness. Insulin therapy, however, should not be delayed or discontinued because of concurrent illness. Resolution of ketoacidosis can be achieved only through insulin therapy. If nothing is to be given per os, insulin therapy should be continued and the blood glucose concentration maintained with IV dextrose infusions. If a concurrent insulin-antagonistic disease is present, it may be necessary to eliminate the disease while the animal is still ill to improve insulin effectiveness and resolve the ketoacidosis (e.g., ovariohysterectomy in diestrual bitch).

Prognosis

DKA remains one of the most difficult metabolic therapeutic challenges in veterinary medicine. One must remain aware of all the complicating factors in treatment and remember that fluid therapy, insulin, and potassium supplementation are the cornerstones of successful management. Added to these factors are close supervision and monitoring of the animal and identification and treatment of concurrent disease that is invariably present. Reported in-hospital mortality rates for DKA range from 20% to 30%, primarily as a result of severe concurrent illness. During the past decade in our hospital, the mortality rate has decreased to approximately 5% and death has usually been attributed to underlying medical disorders (e.g., pancreatitis) that precipitated the DKA, client financial constraints, or both rather than to the metabolic complications of ketoacidosis. It is worth reiterating that a careful search should always be made, both at the time of initial history and physical examination and during therapy, for underlying problems that might have precipitated the episode of DKA or developed during treatment of DKA. In particular, pneumonia, sepsis, pancreatitis, and hormonal diseases causing insulin resistance are often silent at the time of presentation. Despite all precautions and diligent therapy, a fatal outcome cannot be avoided in some cases. Nevertheless, with logical therapy and careful monitoring, the goal of therapy for DKA (i.e., achieving a healthy diabetic dog or cat) is attainable. Diabetic remission is also possible in cats following resolution of DKA, especially in cats with concurrent pancreatic disease or cats being treated with glucocorticoids at the time DKA is diagnosed.

Diabetic Hyperosmolar Hyperglycemic State

Diabetic hyperosmolar hypyerglycemic state (HHS) is an uncommon complication of diabetes mellitus in the dog and cat. This syndrome is characterized by severe hyperglycemia (blood glucose concentration >600 mg/dL), hyperosmolality (>350 mOsm/kg), and dehydration in the absence of significant ketosis. Progressively worsening lethargy ultimately leads to obtundation and coma as hyperosmolality becomes more severe. Concurrent disorders such as kidney failure, congestive heart failure, infection, and pancreatitis are common. The onset of HHS may be insidious and preceded for days or weeks by the classic signs of diabetes mellitus. Progressive weakness, anorexia, and lethargy develop, usually in conjunction with a reduction in water intake. Physical examination often reveals the presence of profound dehydration. These pets are typically lethargic, extremely depressed, or actually comatose. There is a direct relationship between the severity of the hyperosmolality and the severity of neurologic signs. Hyperosmolality is a consistent finding in HHS and can exceed 400 mOsm/kg. Ketosis is usually absent in dogs and cats with HHS, although trace ketonuria may occur. Ketoacidosis is not a part of HHS but metabolic acidosis may be identified, usually in the form of lactic acidosis. The goals of therapy for HHS are similar to DKA (see page 841). Restoring intravascular volume and lost electrolytes using isotonic fluids has the highest priority. Osmolality is returned to normal by lowering the blood glucose concentration and by replacing water deficits. Initially, fluid therapy is used to lower the blood glucose concentration; insulin should not be administered until intravascular volume is restored, electrolyte derangements improved, and blood pressure stabilized. Careful and frequent monitoring of the dog's or cat's clinical and laboratory response to therapy is essential. The need for insulin treatment is not as critical with HHS as with DKA, in part because ketone production and its metabolic consequences are minimal to nonexistent with HHS. In addition, insulin can cause a rapid decrease in the blood glucose concentration and ECF osmolality, changes which promote cerebral edema. The techniques for insulin administration are similar to those discussed for DKA. However, the insulin dosage used for the hourly IM technique or the insulin infusion rate used for the constant low-dose insulin infusion technique should be decreased by 50% initially to dampen the decrease in the blood glucose concentration and avoid a rapid decrease in ECF osmolality. These animals are critically ill and require close supervision. The prognosis for recovery is guarded to poor.

INSULIN-SECRETING β-CELL NEOPLASIA

Etiology

Functional tumors arising from the β cells of the pancreatic islets are malignant tumors that secrete insulin independent of the typically suppressive effects of hypoglycemia. β-Cell tumors, however, are not completely autonomous and respond to provocative stimuli such as an increase in blood glucose by secreting insulin, often in excessive amounts. Immunohistochemical analysis of β-cell tumors has revealed a high incidence of multihormonal production, including pancreatic polypeptide, somatostatin, glucagon, serotonin, and gastrin. However, insulin has been identified as the most common product demonstrated within the neoplastic cells, and clinical signs are primarily those that result from insulin-induced hypoglycemia.

Insulin-secreting β-cell tumors are uncommon in dogs and rare in cats. Virtually all β-cell tumors in dogs are malignant, and most dogs have microscopic or grossly visible metastatic lesions at the time the disease is diagnosed. The most common metastatic sites are the regional lymphatics and lymph nodes, liver, and peripancreatic omentum. Pulmonary metastasis is uncommon and occurs late in the disease. In most dogs hypoglycemia recurs days to weeks after surgical excision of the tumor. The high prevalence of metastatic lesions at the time afflicted dogs are initially examined results, in part, from the typically protracted time it takes for clinical signs to develop and the interval between the time a client initially observes signs (e.g., collapsing episodes, seizures) and seeks assistance from a veterinarian. Most dogs are symptomatic for 1 to 3 months before they are brought to a veterinarian.

Clinical Features

SIGNALMENT

β-Cell tumors typically occur in middle-aged or older dogs (median age, 10 years) but can occur in dogs as young as 3 to 4 years of age. No sex-related predilection is seen. β-Cell tumors are most commonly diagnosed in large breeds of dogs such as the German Shepherd dog, Labrador Retriever, Golden Retriever, and mixed breed dogs but also occur in dogs as small as Pomeranians. β-Cell tumors have also been reported in Siamese and mixed-breed cats older than 10 years of age.

CLINICAL SIGNS

Clinical signs are caused by hypoglycemia and an increase in circulating catecholamine concentrations and include, weakness, seizures, collapsing episodes, tremors, ataxia and disorientation (Box 49.13). The severity of clinical signs depends on the duration and severity of hypoglycemia. Dogs with chronic hypoglycemia or with recurring episodes appear to tolerate low blood glucose concentrations (20-30 mg/dL) for prolonged periods without clinical signs, and only small additional changes in the blood glucose concentration are then required to produce symptomatic episodes. Fasting, excitement, exercise, and eating may trigger the development of clinical signs. Because of the compensatory counterregulatory mechanisms that are designed to increase blood glucose concentrations when hypoglycemia develops, clinical signs tend to be episodic and are generally observed for only a few seconds to minutes. If these counterregulatory mechanisms are inadequate, seizures occur as the blood glucose concentration continues to decrease. Seizures are often self-limiting, lasting from 30 seconds to a few minutes, and may stimulate further catecholamine secretion and the activation of other counterregulatory mechanisms that increase blood glucose concentrations above critical levels.

BOX 49.13

Clinical Signs Associated With Insulin-Secreting Tumors in Dogs

Seizures*
Weakness*
Collapse
Ataxia
Tremors, shaking
Muscle fasciculations
Nervousness
Abnormal behavior
Disorientation
Polyphagia
Weight gain
Posterior weakness (neuropathy)
Lethargy

*Common clinical signs.

PHYSICAL EXAMINATION

Physical examination findings in dogs with β-cell tumors are surprisingly unremarkable; dogs are usually free of visible or palpable abnormalities. Weakness and lethargy are the most common findings and are identified in approximately 30% and 20% of our cases, respectively. Collapsing episodes and seizures may occur during the examination but are uncommon. Weight gain is evident in some dogs and is a result of the anabolic effects of excess insulin in dogs with a normal or increased appetite.

Peripheral Neuropathy

Peripheral neuropathies have been observed in dogs with β-cell tumors and may cause paraparesis to tetraparesis; facial paresis to paralysis; hyporeflexia to areflexia; hypotonia; and muscle atrophy of the appendicular, masticatory, and/or facial muscles. Sensory nerves may also be affected. Onset of clinical signs may be acute (i.e., days) or insidious (i.e., weeks to months). Histopathologic findings in motor and sensory nerves include moderate to severe axonal necrosis, nerve fiber loss, and variable demyelination-remyelination. The pathogenesis of the polyneuropathy is not known. Proposed theories include metabolic derangements of the nerves induced by chronic and severe hypoglycemia or some other tumor-induced metabolic deficiency, an immune-mediated paraneoplastic syndrome resulting from shared antigens between tumor and nerves, or toxic factors produced by the tumor that deleteriously affect the nerves. Treatment is aimed at surgical removal of the β-cell tumor. Prednisone therapy (initially 0.5 mg/kg q12h) may also improve clinical signs. Prognosis for improvement in clinical signs is guarded to poor, although the occasional dog shows remarkable improvement in ambulation after removal of the tumor and reestablishment of a normal blood glucose concentration.

CLINICAL PATHOLOGY

Results of CBC and urinalysis are usually normal. The only abnormality consistently identified in serum biochemistry profiles is hypoglycemia. The remainder of the serum biochemistry profile is usually normal. Hypoalbuminemia, hypophosphatemia, hypokalemia, and increased alkaline phosphatase and ALT activities may occur, but these findings are considered nonspecific and not helpful in arriving at a definitive diagnosis. A correlation between increased liver enzyme activities and metastasis of β-cell tumors to the liver has not been established.

Serum fructosamine concentration is a marker of the average blood glucose concentration during the lifespan of the circulating protein. Serum fructosamine concentrations below the reference range support the existence of significant hypoglycemia and an insulin secreting tumor, assuming the history, physical examination and findings on routine bloodwork are consistent with the diagnosis of a β-cell tumor. A serum fructosamine concentration below the reference range may also occur with other disorders that cause prolonged periods of hypoglycemia or that interfere with the assay (see page 818).

Ninety percent of dogs seen at our hospital had a random blood glucose concentration less than 60 mg/dL (median, 38 mg/dL). Dogs with β-cell tumors occasionally have a blood glucose concentration of 60 to 75 mg/dL. Such a finding does not rule out hypoglycemia as a cause of episodic weakness or seizure activity. Fasting with hourly evaluations of the blood glucose concentration should be carried out to induce hypoglycemia in dogs with suspected β-cell tumor. The time required to induce hypoglycemia with fasting depends in part on the extent of disease at the time the dog is examined and ranges from a few hours to longer than 24 hours. Hypoglycemia (blood glucose < 60 mg/dL) usually occurs within 12 hours of withholding food. We have had a few dogs require longer than 24 hours of fasting before hypoglycemia became apparent and a couple of dogs that did not develop hypoglycemia after 30 hours of fasting, and the diagnosis of β-cell tumor was not established until 2 to 3 months after initial presentation.

Diagnosis

Diagnosis of a β-cell tumor requires initial confirmation of hypoglycemia, followed by documentation of inappropriate insulin secretion and identification of a pancreatic mass using ultrasonography, computed tomography (CT), or exploratory celiotomy. Given the potential differential diagnoses for hypoglycemia (see Box 49.2), a tentative diagnosis of a β-cell tumor can often be made on the basis of the history, physical examination findings, and an absence of abnormalities other than hypoglycemia shown by routine blood tests. Abdominal ultrasonography can be used to identify a mass in the region of the pancreas and to look for evidence of potential metastatic disease in the liver and surrounding structures (Fig. 49.19). Because of the small size of most β-cell tumors and similar echogenicity of the tumor and the adjacent normal pancreas, abdominal ultrasonographic findings are often interpreted as normal, although a pancreatic mass or a metastatic lesion can be found at surgery. A normal abdominal ultrasonographic finding does not rule out the diagnosis of a β-cell tumor. Because β-cell tumors are highly vascular compared with the pancreas, evaluation of the arterial phase of a contrast study during dual-phase CT angiography, if available, is recommended to identify the tumor and its metastatic sites before surgery is performed. Thoracic radiographs are of minimal value in documenting metastatic disease, primarily because identifiable metastatic nodules in the lung occur late in the disease.

The diagnosis of a β-cell tumor is established by evaluating the serum insulin concentration at a time when hypoglycemia is present. Hypoglycemia suppresses insulin secretion in normal animals, with the degree of suppression directly related to its severity. Hypoglycemia fails to have this same suppressive effect on insulin secretion if the insulin is synthesized and secreted from autonomous neoplastic cells because tumor cells that produce and secrete insulin are less responsive to hypoglycemia than are normal β cells. Invariably, the dog with a β-cell tumor will have an inappropriate excess of insulin relative to that needed for a particular blood glucose concentration. Confidence in identifying an inappropriate excess of insulin depends on the severity of the hypoglycemia; the lower the blood glucose concentration, the more confident the clinician can be in identifying inappropriate hyperinsulinemia, especially when the serum insulin concentration falls in the reference range. If the blood glucose concentration is low (preferably < 50 mg/dL) and the insulin concentration is in the upper half of the reference range or is increased, the animal has a relative or absolute excess of insulin that can best be explained by the presence of an insulin-secreting β-cell tumor.

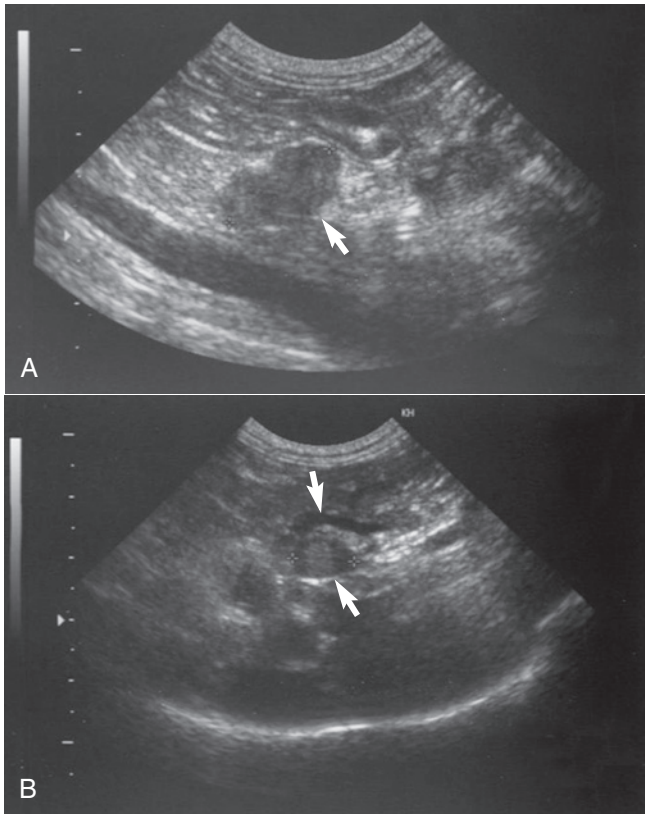

FIG 49.19
Ultrasonogram of the pancreas showing an islet β-cell tumor *(arrow)* **(A)** and an enlarged hepatic lymph node *(arrows)* **(B)** resulting from metastasis of the β-cell tumor to the liver in a 9-year-old Cocker Spaniel.

Most dogs with β-cell neoplasia are persistently hypoglycemic. If the blood glucose concentration is less than 60 mg/dL (preferably < 50 mg/dL), serum should be submitted to a commercial veterinary endocrine laboratory for determination of glucose and insulin concentration. The insulin assay must be validated for use in dogs (and cats), and interpretation of insulin results should be based on the reference interval established by the laboratory utilized. If the blood glucose concentration is greater than 60 mg/dL, fasting may be necessary to induce hypoglycemia. Blood glucose concentrations should be evaluated hourly during the fast, and blood obtained for glucose and insulin determination when the blood glucose concentration decreases

to less than 50 mg/dL. It is important to remember that blood glucose results obtained from PBGM devices are often lower than results obtained using benchtop methods. A blood sample for submission to a commercial laboratory for glucose and insulin determinations should not be obtained until the blood glucose measured on these devices is less than 50 mg/dL. Once hypoglycemia has been induced, the dog can be fed several small meals over the next 2 to 3 hours to minimize overstimulation of the tumor and rebound hypoglycemia.

Serum insulin concentrations must be evaluated simultaneously in relation to the blood glucose concentration. Finding a serum insulin concentration that exceeds the upper limit of the reference range in a dog with a corresponding blood glucose concentration less than 50 mg/dL in combination with appropriate clinical signs and clinicopathologic findings strongly supports the diagnosis of a β-cell tumor. A β-cell tumor is also possible if the serum insulin concentration is in the upper half of the reference range. Insulin values near the lower end of the reference range may be found in dogs with other causes of hypoglycemia as well as a β-cell tumor. Carefully reviewing the history, physical examination findings, and diagnostic test results in relation to the differentials for hypoglycemia (see Box 49.2) and, if necessary, repeating serum glucose and insulin measurements when hypoglycemia is more severe will usually reveal the cause of the hypoglycemia. Any serum insulin concentration that is below the reference range is consistent with insulinopenia and does not indicate the presence of a β-cell tumor. Similar guidelines are used for cats with a suspected β-cell tumor.

Treatment

OVERVIEW OF TREATMENT

Treatment options for a β-cell tumor include surgical exploration, medical treatment for chronic hypoglycemia, and both of these treatments combined. Surgery offers a chance to cure dogs with a resectable solitary mass. In dogs with nonresectable tumors or with obvious metastatic lesions, removal of as much abnormal tissue as possible frequently results in remission, or at least alleviation, of clinical signs and an improved response to medical therapy. Survival time is longer in dogs undergoing surgical exploration and tumor debulking followed by medical therapy compared with dogs that receive only medical treatment. Despite these benefits, surgery remains a relatively aggressive mode of treatment, in part because of the high prevalence of metastatic disease, the older age of many dogs at the time β-cell neoplasia is diagnosed, the potential for postoperative pancreatitis, and the unpredictable response to surgery as it relates to improvement in hypoglycemia and clinical signs. As a general rule, we are less inclined to recommend surgery in aged dogs (i.e., older than 12 years), dogs with extensive metastatic disease identified by diagnostic imaging, and dogs with significant concurrent disease. (See Suggested Readings for detailed information on surgical techniques.)

PERIOPERATIVE MANAGEMENT OF DOGS UNDERGOING SURGERY

The success of surgery depends in part on providing appropriate fluid therapy, dextrose, and supportive care during the perioperative period to avoid severe hypoglycemia and postoperative pancreatitis and to improve the likelihood of an uneventful recovery. This can usually be accomplished through frequent feeding of small meals and administration of glucocorticoids (Box 49.14). A continuous IV infusion of a balanced electrolyte solution containing 2.5% to 5% dextrose is important during the perioperative period. The goal of the dextrose infusion is to provide substrate for CNS function thereby minimizing signs of hypoglycemia while maintaining blood glucose concentrations greater than 40 mg/dL—not to reestablish a normal blood glucose concentration.

BOX 49.14

Long-Term Medical Therapy for Dogs With β-Cell Neoplasia

Standard Treatments

1. Dietary therapy
   a. Feed canned or dry food in three to six small meals daily.
   b. Dietary fat, complex carbohydrates, and fiber help prolong postprandial glucose absorption.
   c. Avoid foods containing monosaccharides, disaccharides, propylene glycol, and corn syrup.
2. Limit exercise to walks; avoid strenuous exercise.
3. Glucocorticoid therapy
   a. Prednisone, 0.5 mg/kg divided into two doses initially
   b. Gradually increase dose and frequency of administration, as needed.
   c. Goal is to control clinical signs, not to reestablish euglycemia.
   d. Consider alternative treatments if signs of iatrogenic hypercortisolism become severe or if glucocorticoids become ineffective.

Additional Treatments

1. Diazoxide therapy
   a. Continue standard treatment; reduce glucocorticoid dose if polyuria-polydipsia (PU-PD) is unacceptable.
   b. May initiate diazoxide early when glucocorticoid dose is low or later when glucocorticoids become ineffective or PU-PD becomes unacceptable
   c. Diazoxide, 5 mg/kg q12h initially
   d. Gradually increase dose as needed, not to exceed 60 mg/kg/day.
   e. Goal is to control clinical signs, not to reestablish euglycemia.
2. Somatostatin therapy
   a. Continue standard treatment; reduce glucocorticoid dose if PU-PD is unacceptable.
   b. Octreotide (Sandostatin), 10 to 40 µg/dog administered subcutaneously q12h to q8h

The IV dextrose infusion can be initiated the evening before surgery, at the time food and water are withheld and continued throughout the perioperative period. Initiating fluid therapy before surgery helps ensure adequate circulation to the pancreas thereby minimizing the risk of postoperative pancreatitis.

Concentrations of dextrose in excess of 5% should be avoided to prevent overstimulation of the pancreatic tumor and rebound hypoglycemia. If the dextrose infusion is ineffective in preventing severe hypoglycemia, a constant-rate infusion of glucagon should be considered. Glucagon is a potent stimulant of hepatic glycogenolysis and gluconeogenesis and is effective in maintaining normal blood glucose concentrations in dogs with β-cell neoplasia when administered by constant rate infusion (Fig. 49.20). Lyophilized glucagon USP (1 mg) is reconstituted with the diluent provided by the manufacturer (Eli Lilly), and the solution is added to 1 L of 0.9% saline, making a 1-μg/mL solution that can be administered by syringe pump. The initial dose is 5 to 10 ng/kg of body weight/min. The dose is adjusted, as needed, to maintain blood glucose concentration between 60 and 100 mg/dL. When glucagon is discontinued, the dose should be gradually decreased over 1 to 2 days and the blood glucose concentration monitored for recurrence of hypoglycemia.

POSTOPERATIVE COMPLICATIONS

The most common postoperative complications are pancreatitis, hyperglycemia, and hypoglycemia. The development of these complications is directly related to the expertise of the surgeon in handling pancreas and excising these tumors, the location of the tumor in the pancreas (i.e., peripheral limb versus body of the pancreas; Fig. 49.21), the presence or absence of functional metastatic lesions, and the adequacy of fluid therapy during the perioperative period. Severe pancreatitis occurs most commonly with attempts to remove tumors located in the body of the pancreas, where the blood supply and the pancreatic ducts are located. Tumors located in the body of the pancreas should be considered inoperable because of the high prevalence of postoperative life-threatening pancreatitis despite appropriate perioperative treatment aimed at preventing its development. The reader is referred to Chapter 37 for information on the treatment of pancreatitis.

The development of transient diabetes mellitus after surgical removal of a β-cell tumor is not an indication of cure. It is believed to result from inadequate insulin secretion by "atrophied" normal β cells. Removal of all, or most, of the neoplastic cells acutely deprives the dog of insulin. Until the atrophied normal cells regain their secretory abilities, the dog will be hypoinsulinemic and may require exogenous insulin injections to maintain euglycemia. Insulin therapy is initiated postoperatively only if hyperglycemia and glycosuria persist for longer than 1 to 2 days beyond the time that all dextrose-containing IV fluids have been discontinued. Initial insulin therapy should be conservative, that is, 0.25 U of lente or NPH insulin per kilogram of body weight should be given once daily. Subsequent adjustments in insulin dosage or frequency of administration should be made according to clinical response and blood glucose determinations. The need for insulin treatment is usually transient, lasting from a few days to a few months. Rarely will a dog remain diabetic for longer than 6 months. Client evaluation

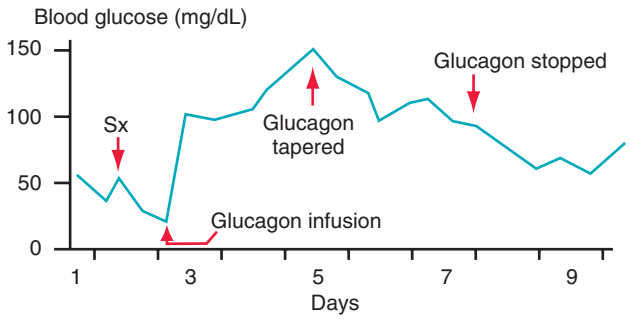

FIG 49.20
Blood glucose concentrations in a 13-year-old female spayed Pomeranian before and after surgical removal of an insulin-secreting β-cell tumor. Pancreatitis and severe hypoglycemia developed postoperatively. The hypoglycemia resolved and euglycemia was maintained after the initiation of a constant-rate intravenous (IV) infusion of glucagon. The dosage of glucagon was gradually tapered beginning on day 5, feeding of small amounts of food was begun on day 7, and the IV infusion of glucagon was stopped on day 8. Severe hypoglycemia did not recur. *Sx,* surgery (From Feldman EC et al: *Canine and feline endocrinology,* ed 4, St Louis, 2015, Elsevier Saunders.)

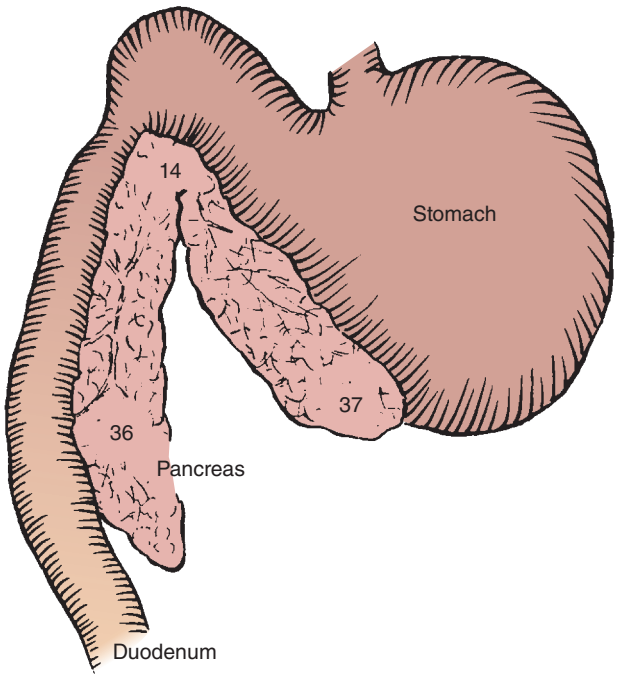

FIG 49.21
Tumor location in 87 dogs with islet β-cell tumors. (Adapted from Feldman EC et al: *Canine and feline endocrinology and reproduction,* ed 3, St Louis, 2004, WB Saunders.)

of the pet's urine glucose is helpful in identifying when insulin therapy is no longer needed. Failure to identify glucose in the urine in conjunction with the disappearance of polyuria and polydipsia is an indication that insulin therapy should be discontinued. If hyperglycemia and glycosuria recur, insulin therapy can be reinstituted but at a lower dose.

Dogs that remain hypoglycemic after surgical removal of a β-cell tumor have functional metastatic lesions. The dextrose and/or glucagon infusion should be continued postoperatively until pancreatitis has resolved (if present); the dog is stable, eating, and drinking; and medical treatment for chronic hypoglycemia can be initiated.

MEDICAL TREATMENT FOR CHRONIC HYPOGLYCEMIA

Medical treatment for chronic hypoglycemia should be initiated if surgery is not performed, or when metastatic or inoperable neoplasia results in the recurrence of hypoglycemia following surgery. The goals of medical treatment are to reduce the frequency and severity of clinical signs of hypoglycemia and to prevent an acute hypoglycemic crisis—not to establish euglycemia, per se. Medical treatment is palliative and minimizes hypoglycemia by providing a continuous source of glucose from the gastrointestinal tract (frequent feedings); increasing hepatic gluconeogenesis and glycogenolysis (glucocorticoids); or inhibiting the synthesis, secretion, or peripheral cellular actions of insulin (glucocorticoids, diazoxide, somatostatin; see Box 49.14). Surgical debulking of functional masses may enhance the effectiveness of medical therapy. The best results are obtained when surgical debulking is performed shortly after the diagnosis of an insulin-secreting tumor has been established.

Frequent Feedings

Frequent feedings provide a constant source of calories as a substrate for the excess insulin secreted by β-cell tumors. Diets that are high in fat, complex carbohydrates, and fiber will delay gastric emptying and slow intestinal glucose absorption, helping to minimize the postprandial increase in portal blood glucose concentration and the stimulation of insulin secretion by the tumor. Simple sugars are rapidly absorbed, have a potent stimulatory effect on insulin secretion by neoplastic β cells, and should be avoided. A combination of canned and dry dog food, fed in three to six small meals daily, is recommended. Daily caloric intake should be controlled because hyperinsulinemia promotes obesity. Exercise should be limited to short walks on a leash.

Glucocorticoid Therapy

Glucocorticoid therapy should be initiated when dietary manipulations are no longer effective in preventing clinical signs of hypoglycemia. Glucocorticoids antagonize the effects of insulin at the cellular level, stimulate hepatic glycogenolysis, and indirectly provide the necessary substrates for hepatic gluconeogenesis. Prednisone (dog) or prednisolone (cat) are most often used at an initial dose of 0.25 mg/kg every 12 hours. Adjustments in the dose are based on clinical response. The dose of prednisone required to control clinical signs increases with time in response to growth of the tumor and its metastatic sites. Eventually, the adverse effects of prednisone, specifically polyuria and polydipsia, become unacceptable to clients. When this occurs, the dose of prednisone should be reduced by 25% to 50% but not stopped and additional therapy considered.

Diazoxide Therapy

Diazoxide (Proglycem) is a benzothiadiazide diuretic that inhibits insulin secretion, stimulates hepatic gluconeogenesis and glycogenolysis, and inhibits tissue use of glucose. The net effect is hyperglycemia. Diazoxide therapy can be initiated early in the medical treatment of a β-cell tumor when the glucocorticoid dose is low and polyuria and polydipsia are acceptable to the client, or it can be initiated later when glucocorticoids are no longer effective in controlling clinical signs of hypoglycemia or when the severity of polyuria and polydipsia has become unacceptable to the client. In the latter situation, glucocorticoids should be continued but at a lower dose. The initial dose of diazoxide is 5 mg/kg every 12 hours. The dose may be gradually increased as needed to control clinical signs but should not exceed 60 mg/kg/day. The most common adverse reactions to diazoxide are anorexia and vomiting. Administering the drug with a meal or decreasing the dose, at least temporarily, is usually effective in controlling adverse gastrointestinal signs. Other potential complications include diarrhea, bone marrow suppression, pancreatitis and diabetes mellitus.

Somatostatin Therapy

Octreotide (Sandostatin) is an analog of somatostatin that inhibits the synthesis and secretion of insulin by normal and neoplastic β cells. The responsiveness of β-cell tumors to the suppressive effects of octreotide is unpredictable and depends on the presence of somatostatin-binding membrane receptors on the tumor cells. Octreotide at a dose of 10 to 40 μg/dog, administered subcutaneously two to three times a day, has alleviated hypoglycemia in approximately 40% of treated dogs, but the suppressive effect on serum insulin concentration is short (<6 hours). Adverse reactions have not been seen at these doses. Octreotide is not a viable option for most clients because of cost.

Streptozotocin Therapy

Streptozotocin is a naturally occurring nitrosourea that selectively destroys pancreatic β cells and has been used to treat β-cell tumors in dogs. Unfortunately, the effectiveness of streptozotocin in improving hypoglycemia, controlling clinical signs, and prolonging survival time has been variable, and adverse reactions to streptozotocin (severe vomiting, acute pancreatitis, kidney failure) can be severe and life-threatening. In one study, diabetes mellitus developed in 8 of 19 dogs and, in 6 dogs, resulted in euthanasia or death (Northrup et al., 2013). (See Suggested Readings for more information on streptozotocin.)

Prognosis

The long-term prognosis for β-cell neoplasia is guarded to poor. Studies suggest that survival is longer in dogs that undergo surgical exploration and tumor debulking followed by medical therapy, compared with dogs that receive only medical treatment. Tobin et al. (1999) and Polton et al. (2007) reported median survival times after diagnosis of 74 and 196 days for dogs treated medically compared with 381 and 785 days for dogs that initially underwent surgery followed by medical therapy, respectively. The extent to which surgery can alter the prognosis depends on the clinical stage of the disease, most notably the extent of metastatic lesions. In our hospital, approximately 10% to 15% of dogs undergoing surgery for a β-cell tumor die or are euthanized at the time of or within 1 month of surgery because metastatic disease causes postoperative hypoglycemia that is refractory to medical management, or because complications related to pancreatitis develop. An additional 20% to 25% of dogs die or are euthanized within 6 months of surgery because of recurrence of clinical hypoglycemia that becomes refractory to medical management. The remaining 60% to 70% live beyond 6 months postoperatively, many beyond 1 year after surgery, before uncontrollable hypoglycemia develops, resulting in death or necessitating euthanasia. Additional surgery to debulk metastatic lesions may improve the dog's responsiveness to medical therapy and prolong survival time in some dogs that become nonresponsive to medical treatment after the initial surgery.

GASTRIN-SECRETING NEOPLASIA

Gastrin-secreting tumors (gastrinomas) are functional malignant tumors that are usually located in the pancreas of dogs and cats. Sites of metastasis include the liver, regional lymph nodes, spleen, and mesentery. Clinical signs result from the consequences of excess gastric hydrochloric acid secretion in response to excess secretion of gastrin by the tumor.

Clinical Features

The most consistent clinical signs are chronic vomiting, weight loss, anorexia, and diarrhea in an older animal (Box 49.15). Gastric and duodenal ulcers and esophagitis are common and may cause hematemesis, hematochezia, melena, and regurgitation. Acidification of intestinal contents may inactivate pancreatic digestive enzymes, precipitate bile salts, interfere with formation of chylomicrons, and damage intestinal mucosal cells. Diarrhea with malabsorption and steatorrhea may develop as a consequence. Findings on physical examination include lethargy, fever, dehydration, abdominal pain, and shock if blood loss is severe or ulcers have perforated. Potential abnormalities identified on a CBC include regenerative anemia, hypoproteinemia, and neutrophilic leukocytosis. Abnormalities in the serum biochemistry panel include hypoproteinemia, hypoalbuminemia, hypocalcemia, and mild increases in serum ALT and alkaline phosphatase activities. Hyponatremia, hypochloremia, hypokalemia, and metabolic alkalosis may develop in dogs and cats that vomit frequently. Hyperglycemia and hypoglycemia have been noted in a few cases. The urinalysis is usually unremarkable.

BOX 49.15

Clinical Signs of Gastrinoma in Dogs and Cats

Vomiting*
Anorexia*
Lethargy, depression*
Diarrhea*
Weight loss*
Melena
Hematemesis
Fever
Polydipsia
Abdominal pain
Hematochezia

*Common clinical signs.

Abdominal radiographs are usually normal. If an ulcer has perforated through the serosal surface, radiographic signs consistent with peritonitis may be present. Contrast-enhanced radiographic studies may show gastric or duodenal ulcers; thickening of the gastric rugal folds, pyloric antrum, or intestine; and the rapid intestinal transit of barium. In an animal with concurrent severe esophagitis, secondary megaesophagus or aberrant, nonperistaltic esophageal motility may be identified fluoroscopically. Ultrasonographic evaluation of the abdomen may identify a pancreatic mass or its metastasis. However, gastrinomas vary tremendously in size and may not be detected with ultrasound.

Gastroduodenoscopy may reveal severe esophagitis and ulceration, especially near the cardia. Gastric rugal folds may be thickened. Gastric and duodenal hyperemia, erosions, or ulcerations are often visible. Histologic evaluation of esophageal, gastric, and duodenal biopsy specimens may be normal or may reveal variable degrees of inflammation consisting of infiltrates of lymphocytes, plasma cells, and neutrophils; gastric mucosal hypertrophy; fibrosis; and loss of the mucosal barrier.

Diagnosis

Gastrinoma should be included among the differential diagnoses for any dog or cat with melena or hematemesis or in which severe gastric and duodenal ulceration is identified. Unless a pancreatic mass is identified by ultrasonography, most dogs and cats with gastrinoma will inadvertently be diagnosed with severe inflammatory bowel disease, gastroduodenal erosions, and ulcers, and they will be treated with inhibitors of gastric acid secretion, mucosal protectants, antibiotics, and changes in diet. The probability of a gastrinoma increases if ultrasonography reveals a pancreatic mass, the dog or cat does not respond to medical therapy directed at nonspecific inflammation and ulceration of the gastrointestinal tract, or clinical signs and gastrointestinal tract

ulceration recur after antiulcer therapy is discontinued. A definitive diagnosis of gastrinoma requires histologic and immunocytochemical evaluation of a pancreatic mass excised at surgery. A finding of increased baseline serum gastrin concentrations from blood obtained after an overnight fast increases the suspicion of gastrinoma. Additional differential diagnoses for increased serum gastrin concentrations include gastric outflow tract obstruction, kidney failure, short-bowel syndrome, chronic gastritis, hepatic disease, and animals receiving antacid therapy (e.g., H_2-receptor antagonists, proton pump inhibitors). Baseline serum gastrin concentrations may vary, with occasional values in the reference range in animals with gastrinoma. Provocative testing (e.g., secretin stimulation test, calcium challenge test) or exploratory laparotomy should be considered in dogs strongly suspected of having gastrinoma but with normal baseline serum gastrin concentrations. (See Suggested Readings for more information on provocative testing.)

Treatment

Treatment should be directed at surgical excision of the tumor and control of gastric acid hypersecretion. Gastrointestinal tract ulceration can usually be managed by reducing gastric hyperacidity through administration of H_2-receptor antagonists (e.g., ranitidine, famotidine), proton pump inhibitors (e.g., omeprazole), gastrointestinal tract protectants (e.g., sucralfate), or prostaglandin E_1 analogs (e.g., misoprostol). (See Chapter 28 for more information on these gastrointestinal tract drugs.) Surgical resection of an ulcer may be required, especially if the ulcer has perforated the bowel. Surgical resection of the tumor is necessary to obtain a cure, although metastasis to the liver, regional lymph nodes, and mesentery is common. Even if metastatic disease is present, tumor debulking may enhance the success of medical therapy.

Prognosis

The long-term prognosis for gastrinoma is guarded to poor. Evidence of metastasis was present in 76% of reported dogs and cats at the time a gastrinoma was diagnosed. Reported survival time in dogs and cats treated surgically, medically, or both ranged from 1 week to 18 months (mean, 4.8 months). However, the short-term prognosis has improved with the advent of drugs that can reduce gastric hyperacidity and protect and promote healing of the ulcers.

CHAPTER 50

Disorders of the Adrenal Gland

HYPERADRENOCORTICISM IN DOGS

Etiology

Hyperadrenocorticism (Cushing's disease) is classified as pituitary dependent, adrenocortical dependent, or iatrogenic (i.e., resulting from excessive administration of glucocorticoids by the veterinarian or client).

PITUITARY-DEPENDENT HYPERADRENOCORTICISM

Pituitary-dependent hyperadrenocorticism (PDH) is the most common cause of spontaneous hyperadrenocorticism, accounting for approximately 80% to 85% of cases. A functional adrenocorticotropic hormone (ACTH)–secreting pituitary tumor is found at necropsy in approximately 85% of dogs with PDH. Adenoma of the pars distalis is the most common histologic finding, with a smaller percentage of dogs diagnosed with adenoma of the pars intermedia and a few dogs diagnosed with functional pituitary carcinoma. Approximately 50% of dogs with PDH have pituitary tumors measuring less than 3 mm in diameter, and most of the remaining dogs, specifically those without central nervous system (CNS) signs, have tumors 3 to 10 mm in diameter at the time PDH is diagnosed. Approximately 10% to 20% of dogs have pituitary tumors (i.e., macrotumors) exceeding 10 mm in diameter at the time PDH is diagnosed. These tumors have the potential to compress or invade adjacent structures and cause neurologic signs as they expand dorsally into the hypothalamus and thalamus (i.e., pituitary macrotumor syndrome) (Fig. 50.1).

Excessive secretion of ACTH causes bilateral adrenocortical hyperplasia and excess cortisol secretion from the zona fasciculata of the adrenal cortex (Fig. 50.2). Because normal feedback inhibition of ACTH secretion by cortisol is missing, excessive ACTH secretion persists despite increased adrenocortical secretion of cortisol. Episodic secretion of ACTH and cortisol is common and results in fluctuating plasma concentrations that, at times, may be within the reference range.

ADRENOCORTICAL TUMORS

Adrenocortical tumors causing hyperadrenocorticism (adrenal-dependent hyperadrenocorticism [ADH]) account for the remaining 15% to 20% of dogs with spontaneous hyperadrenocorticism. Adrenocortical adenoma and carcinoma occur with approximately equal frequency. No consistent clinical or biochemical features can help distinguish dogs with functional adrenal adenomas from those with adrenal carcinomas, although large adrenocortical masses (maximum width >4 cm) are more likely to be carcinomas. Adrenocortical carcinomas may invade adjacent structures (e.g., phrenicoabdominal vein, caudal vena cava, kidney, body wall) or may metastasize to the liver and lung—findings that are not consistent with adrenocortical adenomas.

Bilateral adrenocortical tumors can occur in dogs, but this is uncommon. A nonfunctional adrenocortical tumor or ADH with a pheochromocytoma in the contralateral gland is a more common cause of bilateral adrenal masses in dogs. Macronodular hyperplasia of the adrenals has also been identified in dogs. The adrenals in such animals are usually grossly enlarged, with multiple nodules of varying sizes within the adrenal cortex. The exact pathogenesis of this latter syndrome is unclear, although most cases in dogs are presumed to represent an anatomic variant of PDH. Adrenocortical tumors can also secrete one of the precursor hormones involved in adrenal steroid synthesis (e.g., progesterone and 17-OH-progesterone; see the section on occult [atypical] hyperadrenocorticism, p. 878).

Adrenal tumors causing ADH are autonomous and functional, and randomly secrete excessive amounts of cortisol independent of pituitary control. The cortisol produced by these tumors suppresses circulating plasma ACTH concentrations, causing cortical atrophy of the uninvolved adrenal and atrophy of all normal cells in the involved adrenal (see Fig. 50.2). This atrophy creates asymmetry in the size of the adrenal glands, which can be identified on abdominal ultrasonography. Most, if not all, of these tumors appear to retain ACTH receptors and respond to administration of exogenous ACTH. Adrenocortical tumors causing ADH are

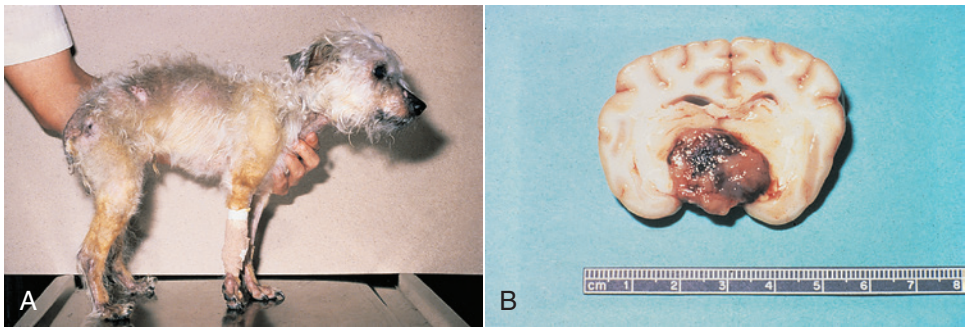

FIG 50.1
(A) A 10-year-old male castrated mixed-breed dog with pituitary-dependent hyperadrenocorticism. Initial clinical signs of polyuria, polydipsia, and endocrine alopecia progressed to severe stupor, anorexia, adipsia, weight loss, and loss of body temperature regulation. **(B)** Cross-section of the brain from the dog in **A,** showing a pituitary macroadenoma severely compressing surrounding brain structures.

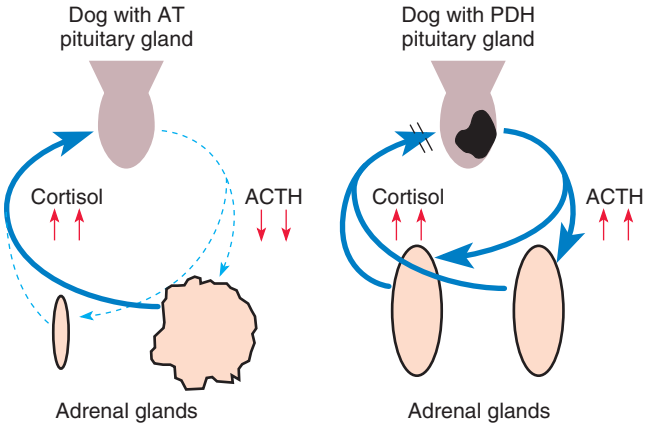

FIG 50.2
The pituitary-adrenocortical axis in dogs with a functioning adrenocortical tumor *(AT; left)* and in dogs with pituitary-dependent hyperadrenocorticism *(PDH; right)*. Excessive cortisol secretion from an AT causes pituitary suppression, decreased plasma adrenocorticotropic hormone *(ACTH)* concentration, and atrophy of the contralateral adrenal gland. Dogs with PDH have excessive ACTH secretion, usually from a functional pituitary adenoma, which causes bilateral adrenomegaly and excessive plasma cortisol concentrations.

typically unresponsive to manipulation of the hypothalamic-pituitary axis with glucocorticoids such as dexamethasone.

IATROGENIC HYPERADRENOCORTICISM

Iatrogenic hyperadrenocorticism typically results from excessive administration of glucocorticoids to control allergic or immune-mediated disorders. It can also develop as a result of the administration of eye, ear, or skin medications containing glucocorticoids, especially in small dogs receiving them long term. Because the hypothalamic-pituitary-adrenocortical axis is normal, the prolonged excessive administration of glucocorticoids suppresses circulating plasma ACTH concentrations, causing bilateral adrenocortical atrophy. In these dogs ACTH stimulation test results are consistent with spontaneous hypoadrenocorticism despite clinical signs of hyperadrenocorticism.

Clinical Features

SIGNALMENT

Hyperadrenocorticism typically develops in dogs 6 years of age and older (median age, 10 years) but has been documented in dogs younger than 5 years of age. There is no apparent sex-related predisposition, although ADH appears to be diagnosed more commonly in female dogs. PDH and ATH have been diagnosed in numerous breeds. All Poodle breeds, Dachshunds, various Terrier breeds, German Shepherd dogs, Beagles, Labrador Retrievers, and Australian Shepherds are commonly represented, and Boxers and Boston Terriers appear to be at increased risk for PDH. PDH tends to occur more frequently in smaller dogs; 75% of dogs with PDH weigh less than 20 kg. Approximately 50% of dogs with ADH weigh more than 20 kg.

CLINICAL SIGNS

The most common clinical signs are polyuria, polydipsia, polyphagia, panting, abdominal enlargement, endocrine alopecia, and mild muscle weakness (Fig. 50.3 and Table 50.1). Most dogs exhibit several, but not all, of these clinical signs. Cutaneous changes such as nonpruritic truncal alopecia, thin skin, and failure to regrow shaved hair may be the only clinical signs. A history that includes a greater number of signs leads to a greater index of suspicion for hyperadrenocorticism. Additional findings on physical examination (see Table 50.1) provide further support for hyperadrenocorticism and strengthen the indication to pursue diagnostic testing.

Additional uncommon clinical manifestations of hyperadrenocorticism may develop as a consequence of chronic hypercortisolism. Suppression of pituitary function can result in persistent anestrus, testicular atrophy, and secondary hypothyroidism. Laxity of ligaments may lead to tearing of a ligament and lameness. Severe polyuria may

FIG 50.3
(A) A 1-year-old male Miniature Poodle with pituitary-dependent hyperadrenocorticism (PDH). Note the truncal distribution of the endocrine alopecia with the pot-bellied appearance. **(B)** A 9-year-old male castrated mixed-breed dog with PDH. Note the severe laxity of the ligaments, resulting in hyperextension of the carpal ligaments and ambulation on the hocks. A "rat tail" has also developed and is a finding associated with hypothyroidism. **(C)** An 8-year-old male castrated Chihuahua with PDH. Note the pot-bellied appearance and the severe calcinosis cutis. **(D)** A 7-year-old Standard Poodle with PDH. Complaints of the primary owner at presentation included polyuria, polydipsia, and progressively worsening symmetric endocrine alopecia. **(E)** An adult mixed-breed dog with PDH. Complaints of the primary owner included polyuria, polydipsia, excessive panting, and severe weakness of the rear limbs. Note the absence of hair growth on the ventral abdomen, which had been shaved for an abdominal ultrasound 2 months before presentation.

lead to dribbling of urine, especially when the dog is asleep, and owner-perceived urinary incontinence in the home. Hypercoagulability may result in formation of spontaneous thrombi, typically involving pulmonary vessels and resulting in acute onset of respiratory distress. Cortisol-induced insulin resistance may play a role in the development of diabetes mellitus in dogs and definitely interferes with the effectiveness of insulin treatment. Hyperadrenocorticism is a differential for persistent systemic hypertension. Cholestatic disease and gall bladder mucocele formation may develop possibly as a consequence of hypercholesterolemia. Clinical manifestations of hyperadrenocorticism may also develop as a consequence of growth of the pituitary or adrenal tumor independent of cortisol secretion. For all of these less common clinical presentations of hyperadrenocorticism, a thorough review of the history, findings on physical examination, and results of routine blood and urine tests usually provide evidence of the disease and the need for additional tests.

PITUITARY MACROTUMOR SYNDROME

Neurologic signs may develop in dogs with PDH as a result of expansion of the pituitary tumor into the hypothalamus and thalamus (see Fig. 50.1; Video 50.1). Neurologic signs may be present at the time PDH is diagnosed but more commonly develop 12 months or longer after PDH is identified. The most common neurologic sign is a dull, listless attitude (i.e., stupor). Additional signs of pituitary macroadenoma include inappetence, aimless wandering, pacing, ataxia, head pressing, circling, and behavioral alterations. In the

TABLE 50.1

Clinical Signs and Physical Examination Findings in Dogs With Hyperadrenocorticism

CLINICAL SIGNS	PHYSICAL EXAMINATION FINDINGS
Polyuria, polydipsia*	Endocrine alopecia*
Polyphagia*	Epidermal atrophy (thin skin)*
Panting*	Failure of hair regrowth*
Abdominal distention*	Abdominal distention*
Endocrine alopecia*	Hepatomegaly*
Weakness*	Muscle wasting*
Lethargy	Cutaneous hyperpigmentation
Calcinosis cutis	Comedones
Cutaneous hyperpigmentation	Calcinosis cutis
Urine dribbling	Bruising
Persistent anestrus (female)	Testicular atrophy
Decreased libido (male)	Neurologic signs (PMA)
Neurologic signs (PMA)	Facial nerve paralysis
Stupor	Respiratory distress—tachypnea (PTE)
Ataxia	Myotonia
Circling	Lameness (ligament laxity, torn)
Aimless wandering	
Pacing	
Behavioral alterations	
Respiratory distress—tachypnea (PTE)	
Lameness (ligament problems)	
Stiff gait (myotonia)	

PMA, Pituitary macroadenoma; *PTE,* pulmonary thromboemboli.
*Common findings.

event of severe compression of the hypothalamus, abnormalities related to dysfunction of the autonomic nervous system, including adipsia, loss of temperature regulation, erratic heart rate, and inability to be roused from a sleep-like state, may develop. Identification of a pituitary macrotumor requires computed tomography (CT) or magnetic resonance imaging (MRI; Fig. 50.4). No biochemical or endocrine test results reliably correlate with the size of the pituitary tumor.

MEDICAL COMPLICATIONS: THROMBOEMBOLISM

Several medical complications can develop secondary to prolonged cortisol excess (Box 50.1). The most worrisome is
